5. Danazol is an androgenic drug that has been used for the treatment of endometriosis-associated pain. It should be used for 4–6 months in the lowest dose necessary to suppress menstruation, usually 200–400 mg orally twice daily. However, danazol has a high incidence of androgenic side effects that are more severe than other drugs available, including decreased breast size, weight gain, acne, and hirsutism.
6. Intrauterine progestin use with the levonorgestrel intrauterine system also has been shown to be effective in reducing endometriosis-associated pelvic pain.
7. The use of aromatase inhibitors (such as anastrozole or letrozole) have been evaluated in women with chronic pain resistant to other forms of medical management or surgical management. Although promising, there are insufficient data to recommend their routine use.

B. Surgical Measures

Surgical treatment of endometriosis—particularly extensive disease—is effective both in reducing pain and in promoting fertility. Laparoscopic ablation of endometrial implants along with uterine nerve ablation significantly reduces pain. Ablation of implants and, if necessary, removal of ovarian endometriomas enhance fertility, although subsequent pregnancy rates are inversely related to the severity of disease. Women with disabling pain who no longer desire childbearing can be treated definitively with total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO). Hormone replacement may be used in premenopausal women to relieve vasomotor symptoms. However, there may be recurrence of disease and associated pain.

▶ Prognosis

There is little systematic research regarding either the progression of the disease or the prediction of clinical outcomes. The prognosis for reproductive function in early or moderately advanced endometriosis appears to be good with conservative therapy. Hysterectomy, with bilateral salpingo-oophorectomy, often is regarded as definitive therapy for the treatment of endometriosis associated with intractable pelvic pain, adnexal masses, or multiple previous conservative surgical procedures. However, symptoms may recur in women even after hysterectomy and oophorectomy.

▶ When to Refer

Refer to a gynecologist for laparoscopic diagnosis or treatment.

▶ When to Admit

Rarely necessary except for acute abdomen associated with ruptured or bleeding endometrioma.

American College of Obstetricians and Gynecologists. ACOG Practice Bulletin No. 114: Management of endometriosis. *Obstet Gynecol.* 2010 July;116(1): 223–36. [PMID: 20567196]

PELVIC ORGAN PROLAPSE

▶ General Considerations

Cystocele, rectocele, and enterocele are vaginal hernias commonly seen in multiparous women. Cystocele is a hernia of the bladder wall into the vagina, causing a soft anterior fullness. Cystocele may be accompanied by urethrocele, which is not a hernia but a sagging of the urethra following its detachment from the pubic symphysis during childbirth. Rectocele is a herniation of the terminal rectum into the posterior vagina, causing a collapsible pouch-like fullness. Enterocele is a vaginal vault hernia containing small intestine, usually in the posterior vagina and resulting from a deepening of the pouch of Douglas. Two or all three types of hernia may occur in combination. Risk factors may include vaginal birth, genetic predisposition, advancing age, prior pelvic surgery, connective tissue disorders, and increased intra-abdominal pressure associated with obesity or straining associated with chronic constipation or coughing.

▶ Classification

A simple classification system, the Baden-Walker System, standardizes the degree of descent of the anterior vaginal wall, cervix or vaginal apex, and the posterior vaginal wall. The degree of prolapse can be evaluated by having the woman perform the Valsalva maneuver while in the lithotomy position. In stage I prolapse, the presenting anatomy descends halfway to the hymen; in stage II prolapse, to the hymen; in stage III prolapse, halfway past the hymen; and in stage IV prolapse, there is the maximum possible descent. Evaluation of the ability to empty the bladder should be evaluated by measuring postvoid residual. If stress incontinence is not present on Valsalva, the prolapse should be reduced to evaluate the possibility of potential post-repair incontinence.

▶ Clinical Findings

Symptoms of pelvic organ prolapse may include sensation of a bulge or protrusion in the vagina, urinary or fecal incontinence, a sense of incomplete bladder emptying, and dyspareunia. The cause of pelvic organ prolapse, including prolapse of the uterus, vaginal apex, and anterior or posterior vaginal walls, is likely multifactorial.

▶ Treatment

The type of therapy depends on the extent of prolapse and the patient's age and her desire for menstruation, pregnancy, and coitus.

A. General Measures

Supportive measures include a high-fiber diet and laxatives to improve constipation. Weight reduction in obese patients and limitation of straining and lifting are helpful. Pelvic muscle training (Kegel exercises) is a simple, noninvasive intervention that may improve pelvic function that has clearly demonstrated benefit for women with urinary or fecal symptoms, especially incontinence. Pessaries may reduce cystocele, rectocele, or enterocele and are helpful in women who do not wish to undergo surgery or who are chronically ill.

B. Surgical Measures

The only cure for symptomatic cystocele, rectocele, enterocele, or associated stress urinary incontinence is corrective surgery. The most common surgical procedure is vaginal or abdominal hysterectomy with vaginal vault suspension by either uterosacral or sacrospinous fixation vaginally or abdominal sacral colpopexy. Since stress incontinence is common after vault suspension procedures, an anti-incontinence procedure should be considered. If the patient desires pregnancy, a partial resection of the cervix with plication of the cardinal ligaments can be attempted. For elderly women who do not desire coitus, colpocleisis, the partial obliteration of the vagina, is surgically simple and effective. Uterine suspension with sacrospinous cervicocolpopexy may be an effective approach in older women who wish to avoid hysterectomy but preserve coital function.

▶ When to Refer

- Refer to urogynecologist or gynecologist for stress urinary incontinence or stage III prolapse.
- Refer if nonsurgical therapy is ineffective.

PELVIC INFLAMMATORY DISEASE (Salpingitis, Endometritis)

ESSENTIALS OF DIAGNOSIS

- ▶ Uterine, adnexal, or cervical motion tenderness.
- ▶ Abnormal discharge from the vagina or cervix.
- ▶ Absence of a competing diagnosis.

► General Considerations

Pelvic inflammatory disease (PID) is a polymicrobial infection of the upper genital tract associated with the sexually transmitted organisms *N gonorrhoeae* and *Chlamydia trachomatis* as well as endogenous organisms, including anaerobes, *Haemophilus influenzae*, enteric gram-negative rods, and streptococci. It is most common in young, nulliparous, sexually active women with multiple partners. Other risk markers include nonwhite race, douching, and smoking. The use of oral contraceptives or barrier methods of contraception may provide significant protection.

Tuberculous salpingitis is rare in the United States but more common in developing countries; it is characterized by pelvic pain and irregular pelvic masses not responsive to antibiotic therapy. It is not sexually transmitted.

► Clinical Findings

A. Symptoms and Signs

Patients with PID may have lower abdominal pain, chills and fever, menstrual disturbances, purulent cervical discharge, and cervical and adnexal tenderness. Right upper quadrant pain (Fitz-Hugh and Curtis syndrome) may indicate an associated perihepatitis. However, diagnosis of PID is complicated by the fact that many women may have subtle or mild symptoms that are not readily recognized as PID, such as postcoital bleeding, urinary frequency, or low back pain.

B. Minimum Diagnostic Criteria

Women with uterine, adnexal, or cervical motion tenderness should be considered to have PID and be treated with antibiotics unless there is a competing diagnosis such as ectopic pregnancy or appendicitis.

C. Additional Criteria

The following criteria may be used to enhance the specificity of the diagnosis: (1) oral temperature $> 38.3^{\circ}\text{C}$, (2) abnormal cervical or vaginal discharge with white cells on saline microscopy (> 1 leukocyte per epithelial cell), (3) elevated erythrocyte sedimentation rate, (4) elevated C-reactive protein, and (5) laboratory documentation of cervical infection with *N gonorrhoeae* or *C trachomatis*. Endocervical culture should be performed routinely, but treatment should not be delayed while awaiting results.

D. Definitive Criteria

In selected cases where the diagnosis based on clinical or laboratory evidence is uncertain, the following criteria may be used: (1) histopathologic evidence of endometritis on endometrial biopsy, (2) transvaginal sonography or MRI showing thickened fluid-filled tubes with or without free pelvic fluid or tubo-ovarian complex, and (3) laparoscopic abnormalities consistent with PID.

► Differential Diagnosis

Appendicitis, ectopic pregnancy, septic abortion, hemorrhagic or ruptured ovarian cysts or tumors, twisted ovarian

cyst, degeneration of a myoma, and acute enteritis must be considered. PID is more likely to occur when there is a history of PID, recent sexual contact, recent onset of menses, recent insertion of an IUD, or if the partner has a sexually transmitted disease. Acute PID is highly unlikely when recent intercourse has not taken place. A sensitive serum pregnancy test should be obtained to rule out ectopic pregnancy. Culdocentesis will differentiate hemoperitoneum (ruptured ectopic pregnancy or hemorrhagic cyst) from pelvic sepsis (salpingitis, ruptured pelvic abscess, or ruptured appendix). Pelvic and vaginal ultrasonography is helpful in the differential diagnosis of ectopic pregnancy of over 6 weeks. Laparoscopy is often used to diagnose PID, and it is imperative if the diagnosis is not certain or if the patient has not responded to antibiotic therapy after 48 hours. The appendix should be visualized at laparoscopy to rule out appendicitis. Cultures obtained at the time of laparoscopy are often specific and helpful.

► Treatment

A. Antibiotics

Early treatment with appropriate antibiotics effective against *N gonorrhoeae*, *C trachomatis*, and the endogenous organisms listed above is essential to prevent long-term sequelae. The sexual partner should be examined and treated appropriately. Most women with mild to moderate disease can be treated successfully as an outpatient. The recommended outpatient regimen is a single dose of cefoxitin, 2 g intramuscularly, with probenecid, 1 g orally, or ceftriaxone 250 mg intramuscularly plus doxycycline, 100 mg orally twice daily, for 14 days, with or without metronidazole 500 mg orally twice daily for 14 days. Adding metronidazole will treat bacterial vaginosis that is frequently associated with PID. For patients with severe disease or those who meet the other criteria for hospitalization, there are two recommended regimens. One regimen includes cefotetan, 2 g intravenously every 12 hours, or cefoxitin, 2 g intravenously every 6 hours, plus doxycycline 100 mg orally or intravenously every 12 hours. The other recommended regimen is clindamycin, 900 mg intravenously every 8 hours, plus gentamicin, a loading dose of 2 mg/kg intravenously or intramuscularly followed by a maintenance dose of 1.5 mg/kg every 8 hours (or as a single daily dose, 3–5 mg/kg). These regimens should be continued for a minimum of 24 hours after the patient shows significant clinical improvement. Then, an oral regimen should be continued for 14 days. Tetracycline, 100 mg orally twice daily, is recommended if no tubo-ovarian abscess is present. If a tubo-ovarian abscess is present, clindamycin, 450 mg orally four times a day, should be given for 14 days.

B. Surgical Measures

Tubo-ovarian abscesses may require surgical excision or transcuteaneous or transvaginal aspiration. Unless rupture is suspected, institute high-dose antibiotic therapy in the hospital, and monitor therapy with ultrasound. In 70% of cases, antibiotics are effective; in 30%, there is inadequate response in 48–72 hours, and surgical intervention is

required. Unilateral adnexectomy is acceptable for unilateral abscess. Hysterectomy and bilateral salpingo-oophorectomy may be necessary for overwhelming infection or in cases of chronic disease with intractable pelvic pain.

► Prognosis

In spite of treatment, long-term sequelae, including repeated episodes of infection, chronic pelvic pain, dyspareunia, ectopic pregnancy, or infertility, develop in one-fourth of women with acute disease. The risk of infertility increases with repeated episodes of salpingitis: it is estimated at 10% after the first episode, 25% after a second episode, and 50% after a third episode.

► When to Admit

The following patients with acute PID should be admitted for intravenous antibiotic therapy:

- The patient has a tubo-ovarian abscess (direct inpatient observation for at least 24 hours before switching to outpatient parenteral therapy).
- The patient is pregnant.
- The patient is unable to follow or tolerate an outpatient regimen.
- The patient has not responded clinically to outpatient therapy.
- The patient has severe illness, nausea and vomiting, or high fever.
- Another surgical emergency, such as appendicitis, cannot be ruled out.

OVARIAN CANCER & OVARIAN TUMORS

ESSENTIALS OF DIAGNOSIS

- Vague gastrointestinal discomfort.
- Pelvic pressure and pain.
- Many cases of early-stage cancer are asymptomatic.
- Pelvic examination and ultrasound are mainstays of diagnosis.

► General Considerations

Ovarian tumors are common. Most are benign, but malignant ovarian tumors are the leading cause of death from reproductive tract cancer. The wide range of types and patterns of ovarian tumors is due to the complexity of ovarian embryology and differences in tissues of origin.

In women with no family history of ovarian cancer, the lifetime risk is 1.6%, whereas a woman with one affected first-degree relative has a 5% lifetime risk. Ultrasound or tumor marker screening for women with one or no affected first-degree relatives have not been shown to reduce mortality from ovarian cancer, and the risks associated with unnecessary prophylactic surgical procedures outweigh the benefits in low-risk women. With two or more affected first-degree relatives, the risk is 7%. Approximately 3% of women with two or more affected first-degree relatives will have a hereditary ovarian cancer syndrome with a lifetime risk of 40%. Women with a *BRCA1* gene mutation have a 45% lifetime risk of ovarian cancer and those with a *BRCA2* mutation a 25% risk. Consideration should be given to screening these women every 6 months with transvaginal sonography and serum CA 125 testing, starting at age 35 or 5–10 years earlier than the earliest age that ovarian cancer was first diagnosed in a family member. Because this screening regimen has not been shown to reduce mortality, oophorectomy is recommended by age 35 or whenever childbearing is completed because of the high risk of disease.

► Clinical Findings

A. Symptoms and Signs

Unfortunately, most women with both benign and malignant ovarian neoplasms are either asymptomatic or experience only mild nonspecific gastrointestinal symptoms or pelvic pressure. Women with early disease are typically detected on routine pelvic examination. Women with advanced malignant disease may experience abdominal pain and bloating, and a palpable abdominal mass with ascites is often present.

B. Laboratory Findings

CA 125 is elevated in 80% of women with epithelial ovarian cancer overall but in only 50% of women with early disease. Serum CA 125 may be elevated in premenopausal women with benign disease (such as endometriosis), minimizing its usefulness in ovarian cancer screening. In premenopausal women, other markers (such as human chorionic gonadotropin [hCG], lactate dehydrogenase, or alpha fetoprotein) may be indicators of the type of tumor present.

C. Imaging Studies

Transvaginal sonography is useful for screening high-risk women but has inadequate sensitivity for screening low-risk women. Ultrasound is helpful in differentiating ovarian masses that are benign and likely to resolve spontaneously from those with malignant potential. Color Doppler imaging may further enhance the specificity of ultrasound diagnosis.

► Differential Diagnosis

Once an ovarian mass has been detected, it must be categorized as functional, benign neoplastic, or potentially malignant. Predictive factors include age, size of the mass, ultrasound configuration, CA 125 levels, the presence of

symptoms, and whether the mass is unilateral or bilateral. In a premenopausal woman, an asymptomatic, mobile, unilateral, simple cystic mass < 7.5 cm may be observed for 4–6 weeks. Most will resolve spontaneously. If the mass is larger or unchanged on repeat pelvic examination and transvaginal sonography, surgical evaluation is required.

Most ovarian masses in postmenopausal women require surgical evaluation. However, a postmenopausal woman with an asymptomatic unilateral simple cyst < 5 cm in diameter and a normal CA 125 level may be followed closely with transvaginal sonography. All others require surgical evaluation.

Laparoscopy may be used when an ovarian mass is small enough to be removed with a laparoscopic approach. If malignancy is suspected, because of findings on transvaginal ultrasound with morphologic scoring, color Doppler assessment of vascular quality, and serum CA 125 level, then laparotomy is preferable.

▶ Treatment

If a malignant ovarian mass is suspected, surgical evaluation should be performed by a gynecologic oncologist. For benign neoplasms, tumor removal or unilateral oophorectomy is usually performed. For ovarian cancer in an early stage, the standard therapy is complete surgical staging followed by abdominal hysterectomy and bilateral salpingo-oophorectomy with omentectomy and selective lymphadenectomy. With more advanced disease, aggressive removal of all visible tumor improves survival. Except for women with low-grade ovarian cancer in an early stage, postoperative chemotherapy is indicated (see Table 39–11). Several chemotherapy regimens are effective, such as the combination of cisplatin or carboplatin with paclitaxel, with clinical response rates of up to 60–70% (see Table 39–12).

▶ Prognosis

Unfortunately, approximately 75% of women with ovarian cancer are diagnosed with advanced disease after regional or distant metastases have become established. The overall 5-year survival is approximately 17% with distant metastases, 36% with local spread, and 89% with early disease.

▶ When to Refer

If a malignant mass is suspected, surgical evaluation should be performed by a gynecologic oncologist.

POLYCYSTIC OVARY SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Clinical or biochemical evidence of hyperandrogenism.
- ▶ Oligoovulation or anovulation.
- ▶ Polycystic ovaries on ultrasonography.

▶ General Considerations

Polycystic ovary syndrome (PCOS) is a common endocrine disorder of unknown etiology affecting 5–10% of women of reproductive age. It is characterized by chronic anovulation, polycystic ovaries, and hyperandrogenism. It is associated with hirsutism, obesity, as well as an increased risk of diabetes mellitus, cardiovascular disease, and metabolic syndrome. Unrecognized or untreated PCOS is an important risk factor for cardiovascular disease.

Women with Cushing syndrome, congenital adrenal hyperplasia, and androgen-secreting adrenal tumors also tend to have high circulating androgen levels and anovulation with polycystic ovaries; these disorders must be ruled out in women with presumed PCOS.

▶ Clinical Findings

PCOS is manifested by hirsutism (50% of cases), obesity (80%), and virilization (20%). Fifty percent of patients have amenorrhea, 30% have abnormal uterine bleeding, and 20% have normal menstruation. In addition, they show insulin resistance and hyperinsulinemia, and these women are at increased risk for early-onset type 2 diabetes. The patients are often infertile, although they may ovulate occasionally. Patients who do become pregnant are at increased risk for perinatal complications. In addition, they have an increased long-term risk of cancer of the endometrium because of unopposed estrogen secretion.

▶ Differential Diagnosis

Anovulation in the reproductive years may also be due to: (1) premature ovarian failure (high FSH and LH levels); (2) rapid weight loss, extreme physical exertion (normal FSH and LH levels for age), or obesity; (3) discontinuation of hormonal contraceptives (anovulation for 6 months or more occasionally occurs); (4) pituitary adenoma with elevated prolactin (galactorrhea may or may not be present); and (5) hyperthyroidism or hypothyroidism. To rule out other etiologies in women with suspected PCOS, serum FSH, LH, prolactin, and TSH should be checked. Because of the high risk of insulin resistance and dyslipidemia, all women with suspected PCOS should have a hemoglobin A1C and fasting glucose along with a lipid and lipoprotein profile. Women with clinical evidence of androgen excess should have total testosterone and sex hormone-binding globulin or free (bioavailable) testosterone, and 17-hydroxyprogesterone measured. Women with stigmata of Cushing syndrome should have a 24-hour urinary free cortisol or a low-dose dexamethasone suppression test.

► Treatment

In obese patients with PCOS, weight reduction and exercise are often effective in reversing the metabolic effects and in inducing ovulation. For those women who do not respond to weight loss and exercise, metformin therapy may be helpful and may be offered along with contraceptive counseling to prevent unplanned pregnancy in case of a return of ovulatory cycles. For women who are seeking pregnancy and remain anovulatory, clomiphene or other drugs can be used for ovulatory stimulation (see section on Infertility below). The addition of dexamethasone, 0.5 mg orally at bedtime, to a clomiphene regimen may increase the likelihood of ovulation by suppression of ACTH and any circulating adrenal androgens. For women who are unresponsive to clomiphene, adding the oral hypoglycemic agent, metformin, 500 mg three times daily, may enhance the likelihood of ovulation. These agents reduce the hyperinsulinemia and hyperandrogenemia in PCOS. If induction of ovulation fails with the above regimens, treatment with low-dose gonadotropins or laparoscopic “ovarian drilling” may be considered. Women with PCOS are at greater risk than normal women for twin gestation with ovulation induction.

If the patient does not desire pregnancy, medroxyprogesterone acetate, 10 mg/d orally for the first 10 days of each month, should be given to ensure regular shedding of the endometrium and avoid hyperplasia. If contraception is desired, a low-dose combination oral contraceptive can be used; this is also useful in controlling hirsutism, for which treatment must be continued for 6–12 months before results are seen.

Dexamethasone, 0.5 mg orally each night, is helpful in women with excess adrenal androgen secretion. Spironolactone, an aldosterone antagonist, is also useful for hirsutism in doses of 25 mg three or four times daily. Flutamide, 125–250 mg orally daily, and finasteride, 5 mg orally daily, are also effective for treating hirsutism. Because these three agents are potentially teratogenic, they should be used only in conjunction with secure contraception. Topical eflornithine cream applied to affected facial areas twice daily for 6 months may be helpful in the majority of women. Hirsutism may also be managed with depilatory creams, electrolysis, and laser therapy. The combination of laser therapy and topical eflornithine may be particularly effective.

Weight loss, exercise, and treatment of unresolved metabolic derangements are important in preventing cardiovascular disease. Women with PCOS should be managed aggressively and should have regular monitoring of lipid profiles and glucose.

► When to Refer

- If expertise in diagnosis is needed.
- If patient is infertile.

FEMALE SEXUAL DYSFUNCTION

► General Considerations

Female sexual dysfunction is a common problem. Depending on the questions asked, surveys have shown that from 35% to 98% of women report sexual concerns. Questions related to sexual functioning should be asked as part of the routine medical history. Three helpful questions are: “Are you currently involved in a sexual relationship?”, “With men, women, or both?”, and “Are there any sexual concerns or pain with sex?” If the woman is not involved in a sexual relationship, she should be asked about any concerns that are contributing to a lack of sexual behavior. If a history of sexual dysfunction is elicited, a complete history of factors that may affect sexual function should be taken. These factors include her reproductive history (including pregnancies and mode of delivery) as well as history of infertility, sexually transmitted diseases, rape or sexual abuse, gynecologic or urologic disorders, endocrine abnormalities (such as diabetes mellitus or thyroid disease), neurologic problems, cardiovascular disease, psychiatric disease, and current prescription and over-the-counter medication use. A detailed history of the specific sexual dysfunction should be elicited, and a gynecologic examination should focus on findings that may contribute to her sexual complaints.

► Etiology

A. Disorders of Sexual Desire

Sexual desire in women is a complex and poorly understood phenomenon. Emotion is a key factor in sexual desire. Anger toward a partner, fear or anxiety related to previous sexual encounters, or history of sexual abuse may contribute. Physical factors, such as chronic illness, fatigue, depression, and specific medical disorders (such as diabetes mellitus, thyroid disease, or adrenal insufficiency) may contribute to a lack of desire. Attitudes toward aging and menopause may play a role. In addition, sexual desire may be influenced by other sexual dysfunctions, such as arousal disorders, dyspareunia, or anorgasmia.

B. Sexual Arousal Disorders

Sexual arousal disorders may be both subjective and objective. Sexual stimulation normally leads to genital vasocongestion and lubrication. Some women may have a physiologic response to sexual stimuli but may not subjectively feel aroused because of factors such as distractions; negative expectations; anxiety; fatigue; depression; or medications, such as selective serotonin reuptake inhibitors (SSRIs) or oral contraceptives. Other women may lack both a subjective and physiologic response to sexual stimuli related to vaginal atrophy.

C. Orgasmic Disorders

In spite of subjective and physiologic arousal, women may experience a marked delay in orgasm, diminished sensation of an orgasm, or anorgasmia. The etiology is complex and typically multifactorial, but the disorder is usually amenable to treatment.

D. Sexual Pain Disorders

Dyspareunia and vaginismus are two subcategories of sexual pain disorders. **Dyspareunia** is defined as recurrent or persistent genital pain associated with sexual intercourse that is not caused exclusively by lack of lubrication or by vaginismus and causes marked distress or interpersonal difficulty. **Vaginismus** is defined as recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse, causing marked distress or interpersonal difficulty. Other medical causes of sexual pain may include vulvovaginitis; vulvar disease, including lichen planus, lichen sclerosus, and lichen simplex chronicus; pelvic disease, such as endometriosis or chronic PID; vulvodynia; or vaginal atrophy. Vulvodynia is the most frequent cause of dyspareunia in premenopausal women. It is characterized by a sensation of burning along with other symptoms, including pain, itching, stinging, irritation, and rawness. The discomfort may be constant or intermittent, focal or diffuse, and experienced as either deep or superficial. There are generally no physical findings except minimal erythema that may be associated in a subset of patients with vulvodynia, those with vulvar vestibulitis. Vulvar vestibulitis is normally asymptomatic, but pain is associated with touching or pressure on the vestibule, such as with vaginal entry or insertion of a tampon. Pain occurring with deep thrusting during coitus is usually due to acute or chronic infection of the cervix, uterus, or adnexa; endometriosis; adnexal tumors; or adhesions resulting from prior pelvic disease or operation. Vaginismus is voluntary or involuntary contraction of the muscles around the introitus. It results from fear, pain, sexual trauma, or a negative attitude toward sex, often learned in childhood.

► Treatment

A. Disorders of Sexual Desire

In the absence of specific medical disorders, arousal or orgasmic disorders or dyspareunia, the focus of therapy is psychological. Cognitive behavioral therapy, sexual therapy, and marital therapy may all play a role. Success with pharmacologic therapy, particularly the use of dopamine agonists or testosterone with estrogen has been reported, but data from large long-term clinical trials are lacking.

B. Sexual Arousal Disorders

As with disorders of sexual desire, arousal disorders may respond to psychological therapy. Specific pharmacologic therapy is lacking. The use of the phosphodiesterase inhibitors used in men does not appear to benefit the majority of women with sexual arousal disorders. However, there is some evidence to suggest a role for sildenafil in women with sexual dysfunction due to multiple sclerosis, type 1 diabetes

mellitus, spinal cord injury, and antidepressant medications, if other, better established, approaches fail.

C. Orgasmic Disorders

For many women, brief sexual counseling along with the use of educational books (such as *For Yourself*, by Lonnie Barbach) may be adequate therapy. Also, the FDA has approved a vacuum device, the EROS-CTD, that increases clitoral enlargement and improves the likelihood of orgasm.

D. Sexual Pain Disorders

Specific medical disorders, such as endometriosis, vulvovaginitis, or vaginal atrophy, should be treated as outlined in other sections of this chapter. Lichen planus and lichen simplex chronicus are addressed in Chapter 6. Lichen sclerosus, a thinning and whitening of the vulvar epithelium is treated with clobetasol propionate 0.05% ointment, applied twice daily for 2–3 months.

Vaginismus may be treated initially with sexual counseling and education on anatomy and sexual functioning. The patient can be instructed in self-dilation, using a lubricated finger or test tubes of graduated sizes. Before coitus (with adequate lubrication) is attempted, the patient—and then her partner—should be able to easily and painlessly introduce two fingers into the vagina. Penetration should never be forced, and the woman should always be the one to control the depth of insertion during dilation or intercourse. Injection of botulinum toxin has been used successfully in refractory cases.

Since the cause of vulvodynia is unknown, management is difficult. Few treatment approaches have been subjected to methodologically rigorous trials. A variety of topical agents have been tried, although only topical anesthetics (eg, estrogen cream and a compounded mixture of topical amitriptyline 2% and baclofen 2% in a water washable base) have been useful in relieving vulvodynia. Useful oral medications include tricyclic antidepressants, such as amitriptyline in gradually increasing doses from 10 mg/d to 75–100 mg/d; various SSRIs; and anticonvulsants, such as gabapentin, starting at 300 mg three times daily and increasing to 1200 mg three times daily. Biofeedback and physical therapy, with a physical therapist experienced with the treatment of vulvar pain, have been shown to be helpful. Surgery—usually consisting of vestibulectomy—has been useful for women with introital dyspareunia.

► When to Refer

- When symptoms or concerns persist despite first-line therapy.
- For expertise in surgical procedures.

INFERTILITY

A couple is said to be infertile if pregnancy does not result after 1 year of normal sexual activity without contraceptives. About 25% of couples experience infertility at some point in their reproductive lives; the incidence of infertility increases with age, with a decline in fertility beginning in the early 30s and accelerating in the late 30s. The male partner contributes to about 40% of cases of infertility, and a combination of factors is common.

A. Initial Testing

During the initial interview, the clinician can present an overview of infertility and discuss a plan of study. Separate private consultations are then conducted, allowing appraisal of psychosexual adjustment without embarrassment or criticism. Pertinent details (eg, sexually transmitted disease or prior pregnancies) must be obtained. The ill effects of cigarettes, alcohol, and other recreational drugs on male fertility should be discussed. Prescription medications that impair male potency and factors that may lead to scrotal hyperthermia, such as tight underwear or frequent use of saunas or hot tubs, should be discussed. The gynecologic history should include the menstrual pattern, the use and types of contraceptives, douching, libido, sex techniques, frequency and success of coitus, and correlation of intercourse with time of ovulation. Family history includes repeated spontaneous abortions and maternal DES use.

General physical and genital examinations are performed on the female partner. Basic laboratory studies include complete blood count, urinalysis, cervical culture for *Chlamydia*, rubella antibody determination, and thyroid function tests. If the woman has regular menses, the likelihood of ovulatory cycles is very high. A luteal phase serum progesterone above 3 ng/mL establishes ovulation. Couples should be advised that coitus resulting in conception occurs during the 6-day window around the day of ovulation. Self-performed urine tests for the midcycle LH surge at ovulation can enhance basal temperature charting.

A semen analysis to rule out a male factor for infertility should be completed. Men must abstain from sexual activity for at least 3 days before the semen is obtained. A clean, dry, wide-mouthed bottle for collection is preferred. Semen should be examined within 1–2 hours after collection. Semen is considered normal with the following minimum values: volume, 2.0 mL; concentration, 20 million sperm per milliliter; motility, $\geq 50\%$ forward progression, $\geq 25\%$ rapid progression; and normal forms, 30%. If the sperm count is abnormal, further evaluation includes physical examination of the male partner and a search for exposure to environmental and workplace toxins, alcohol or drug abuse.

B. Further Testing

1. Gross deficiencies of sperm (number, motility, or appearance) require repeat analysis. Zona-free hamster egg penetration tests are available to evaluate the ability of human sperm to fertilize an egg. Intracytoplasmic sperm injection (ICSI) is the treatment option available for sperm deficiencies except for azoospermia (absence of sperm).

2. A screening pelvic ultrasound and hysterosalpingography to identify uterine cavity or tubal anomalies should be performed. Hysterosalpingography using an oil dye is performed within 3 days following the menstrual period if structural abnormalities are suspected. This radiographic study will demonstrate uterine abnormalities (septa, polyps, submucous myomas) and tubal obstruction. This test has been associated with an increased pregnancy rate if an oil-based rather than water-soluble contrast medium is used. Women who have had prior pelvic inflammation should receive doxycycline, 100 mg orally twice daily, beginning immediately before and for 7 days after the radiographic study. Obvious obstruction of the uterine tubes requires assessment for microsurgery, although in vitro fertilization (IVF) is recommended as the primary treatment option for this condition.
3. Absent or infrequent ovulation requires additional laboratory evaluation. Elevated FSH and LH levels indicate ovarian failure causing premature menopause. Elevated LH levels in the presence of normal FSH levels confirm the presence of polycystic ovaries. Elevation of blood prolactin (PRL) levels suggests a pituitary adenoma. In women over age 35, evaluation of ovarian reserve should be assessed. A markedly elevated FSH (>15 – 20 international units/L) on day 3 of the menstrual cycle suggests inadequate ovarian reserve. In addition, a Clomiphene Citrate Challenge Test, with measurement of FSH on day 10 after administration of clomiphene from day 5–9, should be completed to determine if diminished ovarian reserve indicates a need for donor eggs.
4. Ultrasound monitoring of folliculogenesis may reveal the occurrence of unruptured luteinized follicles.
5. If all the above testing is normal, the patient is diagnosed with unexplained infertility. In approximately 25% of women whose basic evaluation is normal, laparoscopy will identify abnormal findings that may explain the couple's infertility (eg, peritubal adhesions, endometriotic implants).

▶ Treatment

A. Medical Measures

Fertility may be restored by treatment of endocrine abnormalities, particularly hypothyroidism or hyperthyroidism. Antibiotic treatment of cervicitis may be of value. Women who engage in vigorous athletic training often have low sex hormone levels; fertility improves with reduced exercise and some weight gain.

B. Surgical Measures

Excision of ovarian tumors or ovarian foci of endometriosis can improve fertility. Microsurgical relief of tubal obstruction due to salpingitis or tubal ligation will reestablish fertility in a significant number of cases, although with severe disease or proximal obstruction, IVF is preferable. Peritubal adhesions or endometriotic implants often can be treated via laparoscopy.

In a male with a varicocele, sperm characteristics are often improved following surgical treatment.

C. Induction of Ovulation

1. Clomiphene citrate—Clomiphene citrate stimulates gonadotropin release, especially LH. Consequently, plasma estrone (E_1) and estradiol (E_2) also rise, reflecting ovarian follicle maturation. If E_2 rises sufficiently, an LH surge occurs to trigger ovulation.

After a normal menstrual period or induction of withdrawal bleeding with progestin, one should give 50 mg of clomiphene orally daily for 5 days. If ovulation does not occur, the dosage is increased to 100 mg daily for 5 days. If ovulation still does not occur, the course is repeated with 150 mg daily and then 200 mg daily for 5 days, with the addition of chorionic gonadotropin, 10,000 units intramuscularly, 7 days after clomiphene.

The rate of ovulation following this treatment is 90% in the absence of other infertility factors. The pregnancy rate is high. Twinning occurs in 5% of these patients, and three or more fetuses are found in rare instances (<0.5% of cases).

In the presence of increased androgen production ($DHEA-S > 200$ mcg/dL), the addition of dexamethasone, 0.5 mg orally, or prednisone, 5 mg orally, at bedtime, improves the response to clomiphene. Dexamethasone should be discontinued after pregnancy is confirmed.

2. Letrozole—The aromatase inhibitor, letrozole, appears to be at least as effective as clomiphene for ovulation induction in women with PCOS. There is a reduced risk of multiple pregnancy, a lack of antiestrogenic effects, and a reduced need for ultrasound monitoring. The dose is 5–7.5 mg daily, starting on day 3 of the menstrual cycle.

3. Bromocriptine—Bromocriptine is used only if PRL levels are elevated and there is no withdrawal bleeding following progesterone administration (otherwise, clomiphene is used). The initial dosage is 2.5 mg orally once daily, increased to two or three times daily in increments of 1.25 mg. The drug is discontinued once pregnancy has occurred.

4. Human menopausal gonadotropins (hMG) or recombinant FSH—hMG or recombinant FSH is indicated in cases of hypogonadotropism and most other types of anovulation resistant to clomiphene treatment. Because of the complexities, laboratory tests, and expense associated with this treatment, these patients should be referred to an infertility specialist.

D. Treatment of Endometriosis

See above.

E. Artificial Insemination in Azoospermia

If azoospermia is present, artificial insemination by a donor usually results in pregnancy, assuming female function is normal. The use of frozen sperm is currently preferable to fresh sperm because the frozen specimen can be held pending cultures and blood test results for sexually transmitted diseases, including HIV infection.

F. Assisted Reproductive Technologies (ART)

Couples who have not responded to traditional infertility treatments, including those with tubal disease, severe endometriosis, oligospermia, and immunologic or unexplained infertility, may benefit from IVF, gamete intrafallopian transfer (GIFT), and zygote intrafallopian transfer (ZIFT). These techniques are complex and require a highly organized team of specialists. All of the procedures involve ovarian stimulation to produce multiple oocytes, oocyte retrieval by transvaginal sonography–guided needle aspiration, and handling of the oocytes outside the body. With IVF, the eggs are fertilized in vitro and the embryos transferred to the uterine fundus. ICSI allows fertilization with a single sperm. While originally intended for couples with male factor infertility, it is now used in more than half of all IVF procedures in the United States.

GIFT involves the placement of sperm and eggs in the uterine tube by laparoscopy or minilaparotomy. With ZIFT, fertilization occurs in vitro, and the early development of the embryo occurs in the uterine tube after transfer by laparoscopy or minilaparotomy. The latter two procedures are used infrequently.

The chance of a multiple gestation pregnancy (ie, twins, triplets) is increased in all assisted reproductive procedures, increasing the risk of preterm delivery and other pregnancy complications. To minimize this risk, most infertility specialists recommend only transferring one to four embryos depending on the woman's age and reproductive history. In the event of a multiple gestation pregnancy, a couple may consider selective reduction to avoid the medical issues generally related to multiple births. This issue should be discussed with the couple before embryo transfer.

► Prognosis

The prognosis for conception and normal pregnancy is good if minor (even multiple) disorders can be identified and treated; it is poor if the causes of infertility are severe, untreatable, or of prolonged duration (over 3 years).

It is important to remember that in the absence of identifiable causes of infertility, 60% of couples will achieve a pregnancy within 3 years. Couples with unexplained infertility who do not achieve pregnancy within 3 years may be offered ovulation induction or assisted reproductive technology. Women over the age of 35 should be offered a more aggressive approach, with consideration of ART within 3–6 months of not achieving pregnancy with more conservative approaches. Also, offering appropriately timed information about adoption is considered part of a complete infertility regimen.

► When to Refer

Refer to reproductive endocrinologist if ART are indicated.

CONTRACEPTION

Voluntary control of childbearing benefits women, men, and their children. Contraception should be available to all women and men of reproductive age. Education about and access to contraception are especially important for sexually active teenagers and for women following childbirth or abortion.

1. Oral Contraceptives

A. Combined Oral Contraceptives

1. Efficacy and methods of use—Combined oral contraceptives have a perfect use failure rate of 0.3% and a typical use failure rate of 8%. Their primary mode of action is suppression of ovulation. The pills can be initially started on the first day of the menstrual cycle, the first Sunday after the onset of the cycle or on any day of the cycle. If started on any day other than the first day of the cycle, a backup method should be used. There are also pills packaged to be taken continuously for 84 days, followed by 7 days of placebos as well as a pill packaged for 365 days, to be taken continuously without a break. If an active pill is missed at any time, and no intercourse occurred in the past 5 days, two pills should be taken immediately and a backup method should be used for 7 days. If intercourse occurred in the previous 5 days, emergency contraception (see below) should be used immediately, and the pills restarted the following day. A backup method should be used for 5 days.

2. Benefits of oral contraceptives—Noncontraceptive benefits of oral contraceptives include lighter menses, reducing the likelihood of anemia. Dysmenorrhea is relieved for most women. Functional ovarian cysts are less likely with oral contraceptive use. The risk of ovarian and endometrial cancer is decreased. The risks of salpingitis and ectopic pregnancy may be diminished. Acne is usually improved. The frequency of developing myomas is lower in long-term users (> 4 years). There is a beneficial effect on bone mass.

3. Selection of an oral contraceptive—Any of the combination oral contraceptives containing 35 mcg or less of ethinyl estradiol or 3 mg of estradiol valerate are suitable for most women. There is some variation in potency of the various progestins in the pills, but there are essentially no clinically significant differences for most women among the progestins in the low-dose pills. Women who have acne or hirsutism may benefit from use of one of the pills containing the third-generation progestins, desogestrel, drospirenone, or norgestimate, as they are the least androgenic. A combination regimen with 84 active and 7 inert pills that results in only four menses per year is available. There is also a combination regimen that is taken

continuously with no regular menses. At the end of one year's use, 58% of the women had amenorrhea, and nearly 80% reported no bleeding requiring sanitary protection. Studies have not shown any significant risk from long-term amenorrhea in patients taking continuous oral contraceptives. The low-dose oral contraceptives commonly used in the United States are listed in Table 18–3.

4. Drug interactions—Several drugs interact with oral contraceptives to decrease their efficacy by causing induction of microsomal enzymes in the liver, or by other mechanisms. Some commonly prescribed drugs in this category are phenytoin, phenobarbital (and other barbiturates), primidone, topiramate, carbamazepine, and rifampin and St. John's Wort. Women taking these drugs should use another means of contraception for maximum safety.

Antiretroviral medications, specifically ritonavir-boosted protease inhibitors, may significantly decrease the efficacy of combined oral contraceptives, and the concomitant use of oral contraceptives may increase the toxicity of these antiretroviral agents. Non-nucleoside reverse transcriptase inhibitors have smaller effects on oral contraceptive efficacy, while nucleoside reverse transcriptase inhibitors appear to have no effect.

5. Contraindications and adverse effects—Oral contraceptives have been associated with many adverse effects; they are contraindicated in some situations and should be used with caution in others (Table 18–4).

A. MYOCARDIAL INFARCTION—The risk of heart attack is higher with use of oral contraceptives, particularly with pills containing 50 mcg of estrogen or more. Cigarette smoking, obesity, hypertension, diabetes, or hypercholesterolemia increases the risk. Young nonsmoking women have minimal increased risk. Smokers over age 35 and women with other cardiovascular risk factors should use other methods of birth control.

B. THROMBOEMBOLIC DISEASE—An increased rate of venous thromboembolism is found in oral contraceptive users, especially if the dose of estrogen is 50 mcg or more. While the overall risk is very low (5–6 per 100,000 woman-years), several studies have reported a twofold increased risk in women using oral contraceptives containing the progestins gestodene (not available in the United States), drospirenone, or desogestrel compared with women using oral contraceptives with levonorgestrel and norethindrone. Women in whom thrombophlebitis develops should stop using this method, as should those at increased risk for thrombophlebitis because of surgery, fracture, serious injury, hypercoagulable condition, or immobilization. Women with a known thrombophilia should not use oral contraceptives.

C. CEREBROVASCULAR DISEASE—Overall, a small increased risk of hemorrhagic stroke and subarachnoid hemorrhage and a somewhat greater increased risk of thrombotic stroke have been found; smoking, hypertension, and age over 35 years are associated with increased risk. Women should stop using contraceptives if such warning symptoms as severe headache, blurred or lost vision, or other transient neurologic disorders develop.

Table 18-3. Commonly used low-dose oral contraceptives.

Name	Progestin	Estrogen (Ethinyl Estradiol)	Cost per Month ¹
COMBINATION			
Alesse ^{2,3}	0.1 mg levonorgestrel	20 mcg	\$35.00

²Generic equivalent available.

³Multiple other brands available.

D. CARCINOMA—A relationship between long-term (3–4 years) oral contraceptive use and occurrence of cervical dysplasia and cancer has been found in various studies. A 2002 study showed that there is no increased risk of breast cancer in women aged 35–64 who are current or former users of oral contraceptives. Women with a family history of breast cancer or women who started oral contraceptive use at a young age are not at increased risk. Combination oral contraceptives reduce the risk of endometrial carcinoma by 40% after 2 years of use and 60% after 4 or more years of use. The risk of ovarian cancer is reduced by 30% with pill use for < 4 years, by 60% with use for 5–11 years, and by 80% after 12 or more years. Rarely, oral contraceptives have been associated with the development of benign

or malignant hepatic tumors; this may lead to rupture of the liver, hemorrhage, and death. The risk increases with higher dosage, longer duration of use, and older age.

E. HYPERTENSION—Oral contraceptives may cause hypertension in some women; the risk is increased with longer duration of use and older age. Women in whom hypertension develops while using oral contraceptives should use other contraceptive methods. However, with regular blood pressure monitoring, nonsmoking women under the age of 40 with well-controlled mild hypertension may use oral contraceptives.

F. HEADACHE—Migraine or other vascular headaches may occur or worsen with pill use. If severe or frequent headaches develop while using this method, it should be discontinued. Women with migraine headaches with an aura should not use oral contraceptives.

G. LACTATION—Combined oral contraceptives can impair the quantity and quality of breast milk. While it is preferable to avoid the use of combination oral contraceptives during lactation, the effects on milk quality are small and are not associated with developmental abnormalities in infants. Combination oral contraceptives should be started no earlier than 6 weeks postpartum to allow for establishment of lactation. Progestin-only pills, levonorgestrel implants, and depot medroxyprogesterone acetate are alternatives with no adverse effects on milk quality.

H. OTHER DISORDERS—Depression may occur or be worsened with oral contraceptive use. Fluid retention may occur. Patients who had cholestatic jaundice during pregnancy may develop it while taking birth control pills.

6. Minor side effects—Nausea and dizziness may occur in the first few months of pill use. A weight gain of 2–5 lb (0.9–2.25 kg) commonly occurs. Spotting or breakthrough bleeding between menstrual periods may occur, especially if a pill is skipped or taken late; this may be helped by switching to a pill of slightly greater potency (see section 3, above) or by switching to a triphasic regimen. Missed menstrual periods may occur, especially with low-dose pills. A pregnancy test should be performed if pills have been skipped or if two or more expected menstrual periods are

Table 18-4. Contraindications to use of oral contraceptives.

Absolute contraindications
Pregnancy
Thrombophlebitis or thromboembolic disorders (past or present)
Stroke or coronary artery disease (past or present)
Cancer of the breast (known or suspected)
Undiagnosed abnormal vaginal bleeding
Estrogen-dependent cancer (known or suspected)
Benign or malignant tumor of the liver (past or present)
Uncontrolled hypertension
Diabetes mellitus with vascular disease
Age over 35 and smoking > 15 cigarettes daily
Known thrombophilia
Migraine with aura
Active hepatitis
Surgery or orthopedic injury requiring prolonged immobilization
Relative contraindications
Migraine without aura
Hypertension
Heart or kidney disease
Diabetes mellitus
Gallbladder disease
Cholestasis during pregnancy
Sickle cell disease (S/S or S/C type)
Lactation

missed. Fatigue and decreased libido can occur. Chloasma may occur, as in pregnancy, and is increased by exposure to sunlight.

B. Progestin Minipill

1. Efficacy and methods of use—A formulation containing 0.35 mg of norethindrone is available in the United States. The efficacy is similar to that of combined oral contraceptives. The minipill is believed to prevent conception by causing thickening of the cervical mucus to make it hostile to sperm, alteration of ovum transport (which may account for the slightly higher rate of ectopic pregnancy with these pills), and inhibition of implantation. Ovulation is inhibited inconsistently with this method. The minipill is begun on the first day of a menstrual cycle and then taken continuously for as long as contraception is desired.

2. Advantages—The low dose and absence of estrogen make the minipill safe during lactation; it may increase the flow of milk. It is often tried by women who want minimal doses of hormones and by patients who are over age 35. They lack the cardiovascular side effects of combination pills. The minipill can be safely used by women with sickle cell disease (S/S or S/C).

3. Complications and contraindications—Minipill users often have bleeding irregularities (eg, prolonged flow, spotting, or amenorrhea); such patients may need regular pregnancy tests. Ectopic pregnancies are more frequent, and complaints of abdominal pain should be investigated with this in mind. Many of the absolute contraindications and relative contraindications listed in Table 18–4 apply to the minipill; however, the contraceptive benefit of the minipill may outweigh the risks for patients who smoke, who are over age 35, or who have such conditions as superficial deep venous thrombosis or known thromboembolic disorders or diabetes with vascular disease. Minor side effects of combination oral contraceptives such as weight gain and mild headache may also occur with the minipill.

Centers for Disease Control and Prevention (CDC). U.S. medical eligibility criteria for contraceptive use, 2010. *MMWR Recomm Rep.* 2010 Jun 18;59(No.RR-4):1–85. [PMID: 20559203]

Cremer M et al. Recent innovations in oral contraception. *Semin Reprod Med.* 2010 Mar;28(2):140–6. [PMID: 20391327]

2. Contraceptive Injections & Implants (Long-Acting Progestins)

The injectable progestin DMPA is approved for contraceptive use in the United States. There is extensive worldwide experience with this method over the past 3 decades. The medication is given as a deep intramuscular injection of 150 mg every 3 months and has a contraceptive efficacy of 99.7%. A subcutaneous preparation, containing 104 mg of DMPA is available in the United States. Common side effects include irregular bleeding, amenorrhea, weight gain, and headache. It is associated with bone mineral loss that is usually reversible after discontinuation of the method. Users commonly have irregular bleeding initially

and subsequently develop amenorrhea. Ovulation may be delayed after the last injection. Contraindications are similar to those for the minipill.

A single-rod, subdermal progestin implant, Implanon, is approved for use in the United States. Implanon is a 40-mm by 2-mm rod containing 68 mg of the progestin etonogestrel that is inserted in the inner aspect of the non-dominant arm. Insertion and removal are much simpler and faster than with the original Norplant subdermal system. Hormone levels drop rapidly after removal, and there is no delay in the return of fertility. In clinical trials, the pregnancy rate was 0.0% with 3 years of use. The side effect profile is similar to minipills, DMPA, and Norplant. Irregular bleeding has been the most common reason for discontinuation.

McDonald-Mosley R et al. Contraceptive implants. *Semin Reprod Med.* 2010 Mar;28(2):110–17. [PMID: 20352560]

Roy G. Injectable contraception. *Semin Reprod Med.* 2010 Mar;28(2):126–32. [PMID: 20352562]

3. Other Hormonal Methods

A transdermal contraceptive patch containing 150 mcg norelgestromin and 20 mcg ethinyl estradiol and measuring 20 cm² is available. The patch is applied to the lower abdomen, upper torso, or buttock once a week for 3 consecutive weeks, followed by 1 week without the patch. It appears that the average steady-state concentration of ethinyl estradiol with the patch is approximately 60% higher than with a 35 mcg pill. However, there is currently no evidence for an increased incidence of estrogen-related side effects. The mechanism of action, side effects, and efficacy are similar to those associated with oral contraceptives, although compliance may be better. However, discontinuation for side effects is more frequent.

A contraceptive vaginal ring that releases 120 mcg of etonogestrel and 15 mcg of ethinyl estradiol daily is available. The ring is soft and flexible and is placed in the upper vagina for 3 weeks, removed, and replaced 1 week later. The efficacy, mechanism of action, and systemic side effects are similar to those associated with oral contraceptives. Ring users may experience an increased incidence of vaginal discharge.

Lopez LM et al. Skin patch and vaginal ring versus combined oral contraceptives for contraception. *Cochrane Database Syst Rev.* 2010 Mar 17;(3):CD003552. [PMID: 20238323]

4. Intrauterine Devices

IUDs available in the United States include the Mirena (which releases levonorgestrel) and the copper-bearing TCu380A. The mechanism of action of IUDs is thought to involve either spermicidal or inhibitory effects on sperm capacitation and transport. IUDs are not abortifacients.

The Mirena is effective for 5 years, and the TCu380A for 10 years. The hormone-containing IUDs have the advantage of reducing cramping and menstrual flow.

The IUD is an excellent contraceptive method for most women. The devices are highly effective, with failure rates

similar to those achieved with surgical sterilization. Nulliparity is not a contraindication to IUD use. Women who are not in mutually monogamous relationships should use condoms for protection from sexually transmitted diseases. The Mirena may have a protective effect against upper tract infection similar to that of the oral contraceptives.

A. Insertion

Insertion can be performed during or after the menses, at midcycle to prevent implantation, or later in the cycle if the patient has not become pregnant. Both types of IUDs may be inserted up to 48 hours after vaginal delivery, or prior to closure of the uterus at the time of cesarean section. Insertion immediately following abortion is acceptable if there is no sepsis and if follow-up insertion a month later will not be possible; otherwise, it is wise to wait until 4 weeks post abortion. Misoprostol (200 mcg the night before) and NSAIDs given as premedications may help insertions in nulliparous patients or when insertion is not performed during menses.

B. Contraindications & Complications

Contraindications to use of IUDs are outlined in Table 18–5.

1. Pregnancy—A copper-containing IUD can be inserted within 5 days following a single episode of unprotected mid-cycle coitus as a postcoital contraceptive. An IUD should not be inserted into a pregnant uterus. If pregnancy occurs as an IUD failure, there is a greater chance of spontaneous abortion if the IUD is left in situ (50%) than if it is removed (25%). Spontaneous abortion with an IUD in place is associated with a high risk of severe sepsis, and death can occur rapidly. Women using an IUD who become pregnant should have the IUD removed if the string is visible. It can be removed at the time of abortion if this is desired. If the string is not visible and the patient wants to continue the pregnancy, she should be informed of the serious risk of sepsis and, occasionally, death with such pregnancies. She should be informed that any flu-like symptoms such as fever, myalgia, headache, or nausea warrant immediate medical attention for possible septic abortion.

Table 18–5. Contraindications to IUD use.

Absolute contraindications

- Pregnancy
- Acute or subacute pelvic inflammatory disease or purulent cervicitis
- Significant anatomic abnormality of uterus
- Unexplained uterine bleeding
- Active liver disease (Mirena only)

Relative contraindications

- History of pelvic inflammatory disease since the last pregnancy
- Lack of available follow-up care
- Menorrhagia or severe dysmenorrhea (copper IUD)
- Cervical or uterine neoplasia

IUD, intrauterine device.

Since the ratio of ectopic to intrauterine pregnancies is increased among IUD wearers, clinicians should search for adnexal masses in early pregnancy and should always check the products of conception for placental tissue following abortion.

2. Pelvic infection—There is an increased risk of pelvic infection during the first month following insertion. The subsequent risk of pelvic infection appears to be primarily related to the risk of acquiring sexually transmitted infections. Infertility rates do not appear to be increased among women who have previously used the currently available IUDs. At the time of insertion, women with an increased risk of sexually transmitted diseases should be screened for gonorrhea and *Chlamydia*. Women with a history of recent or recurrent pelvic infection are not good candidates for IUD use.

3. Menorrhagia or severe dysmenorrhea—The copper IUD can cause heavier menstrual periods, bleeding between periods, and more cramping, so it is generally not suitable for women who already suffer from these problems. Alternatively, the hormone-releasing IUD Mirena has been approved by the FDA to treat heavy menstrual bleeding. NSAIDs are also helpful in decreasing bleeding and pain in IUD users.

4. Complete or partial expulsion—Spontaneous expulsion of the IUD occurs in 10–20% of cases during the first year of use. Any IUD should be removed if the body of the device can be seen or felt in the cervical os.

5. Missing IUD strings—If the transcervical tail cannot be seen, this may signify unnoticed expulsion, perforation of the uterus with abdominal migration of the IUD, or simply retraction of the string into the cervical canal or uterus owing to movement of the IUD or uterine growth with pregnancy. Once pregnancy is ruled out, a cervical speculum may be used to visualize the IUD string in the cervical canal. If not visualized, one should probe for the IUD with a sterile sound or forceps designed for IUD removal after administering a paracervical block. If the IUD cannot be detected, pelvic ultrasound will demonstrate the IUD if it is in the uterus. Alternatively, obtain anteroposterior and lateral radiographs of the pelvis with another IUD or a sound in the uterus as a marker, to confirm an extrauterine IUD. If the IUD is in the abdominal cavity, it should generally be removed by laparoscopy or laparotomy. Perforations of the uterus are less likely if insertion is performed slowly, with meticulous care taken to follow directions applicable to each type of IUD.

Shimoni N. Intrauterine contraceptives: a review of uses, side effects and candidates. *Semin Reprod Med.* 2010 Mar;28(2): 118–25. [PMID: 20352561]

5. Diaphragm & Cervical Cap

The diaphragm (with contraceptive jelly) is a safe and effective contraceptive method with features that make it acceptable to some women and not others. Failure rates range from 6% to 16%, depending on the motivation of the woman and the care with which the diaphragm is used.

The advantages of this method are that it has no systemic side effects and gives significant protection against pelvic infection and cervical dysplasia as well as pregnancy. The disadvantages are that it must be inserted near the time of coitus and that pressure from the rim predisposes some women to cystitis after intercourse.

The cervical cap (with contraceptive jelly) is similar to the diaphragm but fits snugly over the cervix only (the diaphragm stretches from behind the cervix to behind the pubic symphysis). The cervical cap is more difficult to insert and remove than the diaphragm. The main advantages are that it can be used by women who cannot be fitted for a diaphragm because of a relaxed anterior vaginal wall or by women who have discomfort or develop repeated bladder infections with the diaphragm. However, failure rates are 9% (perfect use) and 16% (typical use) in nulliparous women and 26% (perfect use) and 32% (typical use) in parous women.

Because of the small risk of toxic shock syndrome, a cervical cap or diaphragm should not be left in the vagina for over 12–18 hours, nor should these devices be used during the menstrual period.

6. Contraceptive Foam, Cream, Film, Sponge, Jelly, & Suppository

These products are available without prescription, are easy to use, and are fairly effective, with typical failure rates of 10–22%. All contain the spermicide nonoxynol-9, which also has some virucidal and bactericidal activity. Nonoxynol-9 does not appear to adversely affect the vaginal colonization of hydrogen peroxide-producing lactobacilli. A 2002 study suggests that nonoxynol-9 is not protective against HIV infection, particularly in women who have frequent intercourse. The FDA now requires products containing nonoxynol-9 to include a warning that the products do not protect against HIV or other sexually transmitted diseases and that use of these products can irritate the vagina and rectum and may increase the risk of getting the AIDS virus from an infected partner. Recent data suggest that low-risk women using a nonoxynol-9 product, with coital activity two to three times per week, are not at increased risk for epithelial disruption, compared with couples using condoms alone.

7. Condom

The male condom of latex or animal membrane affords good protection against pregnancy—equivalent to that of a diaphragm and spermicidal jelly; latex (but not animal membrane) condoms also offer protection against many sexually transmitted diseases, including HIV. When a spermicide, such as vaginal foam, is used with the condom, the failure rate (approximately 2% with perfect use and 15% with typical use) approaches that of oral contraceptives. The disadvantages of condoms are dulling of sensation and spillage of semen due to tearing, slipping, or leakage with detumescence of the penis.

Two female condoms, one made of polyurethane and the other of synthetic nitrile, are available in the United States. The reported failure rates range from 5% to 21%;

the efficacy is comparable to that of the diaphragm. These are the only female-controlled method that offers significant protection from both pregnancy and sexually transmitted diseases.

8. Contraception Based on Awareness of Fertile Periods

These methods are most effective when the couple restricts intercourse to the post ovular phase of the cycle or uses a barrier method at other times. Well-instructed, motivated couples may be able to achieve low pregnancy rates with fertility awareness methods. However, properly done randomized clinical trials comparing the efficacy of most of these methods with other contraceptive methods do not exist.

A. “Symptothermal” Natural Family Planning

The basis for this approach is patient-observed increase in clear elastic cervical mucus, brief abdominal midcycle discomfort (“mittelschmerz”), and a sustained rise of the basal body temperature about 2 weeks after onset of menstruation. Unprotected intercourse is avoided from shortly after the menstrual period, when fertile mucus is first identified, until 48 hours after ovulation, as identified by a sustained rise in temperature and the disappearance of clear elastic mucus.

B. Calendar Method

After the length of the menstrual cycle has been observed for at least 8 months, the following calculations are made: (1) The first fertile day is determined by subtracting 18 days from the shortest cycle, and (2) the last fertile day is determined by subtracting 11 days from the longest cycle. For example, if the observed cycles run from 24 to 28 days, the fertile period would extend from the sixth day of the cycle (24 minus 18) through the 17th day (28 minus 11). Day 1 of the cycle is the first day of menses.

C. Basal Body Temperature Method

This method indicates the safe time for intercourse after ovulation has passed. The temperature must be taken immediately upon awakening, before any activity. A slight drop in temperature often occurs 12–24 hours before ovulation, and a rise of about 0.4°C occurs 1–2 days after ovulation. The elevated temperature continues throughout the remainder of the cycle. Data suggest that the risk of pregnancy increases starting 5 days prior to the day of ovulation, peaks on the day of ovulation, and then rapidly decreases to zero by the day after ovulation.

D. Standard Days Method

This fertility awareness method requires the use of a set of beads that reminds the couple to avoid intercourse (or use a barrier method of contraception) during days 8 through 19 of the menstrual cycle. The beads are in a circle and color-coded to show the days when a woman is likely to become pregnant and the days that are “safe” during the cycle. A movable ring is repositioned to a new bead each day starting

on the first day of menses. In a small multicenter trial, the perfect use failure rate was 5% and the typical use failure rate was 12%. The method is applicable to women with a history of menstrual cycles between 29 and 32 days.

E. TwoDay Method

The TwoDay method requires that women be able to identify cervical secretions by observation or touching them in underwear or toilet paper, by touching the genitals, or by the sensation of wetness in the genital area or on underwear. The woman then uses a two-question algorithm to determine whether she is fertile. She asks herself: (1) Did I note secretions today? and (2) Did I note secretions yesterday? If the answer to either of these questions is “yes,” she should consider herself fertile. In a multicenter study of 450 women, effectiveness with perfect use was 96.5% and with typical use 76.3%.

Pallone SR et al. Fertility awareness-based methods: another option for family planning. *J Am Board Fam Med.* 2009 Mar-Apr;22(2):147–57. [PMID: 19264938]

9. Emergency Contraception

If unprotected intercourse occurs in midcycle and if the woman is certain she has not inadvertently become pregnant earlier in the cycle, the following regimens are effective in preventing implantation. These methods should be started as soon as possible and within 120 hours after unprotected coitus. (1) Levonorgestrel, 1.5 mg orally as a single dose (available in the United States prepackaged as Plan B and available over-the-counter for women aged 17 years and above), has a 1% failure rate, when taken within 72 hours. It remains efficacious up to 120 hours after intercourse, though less so compared with earlier use. (2) If the levonorgestrel regimen is not available, a combination oral contraceptive containing ethinyl estradiol and levonorgestrel given in a regimen of two to six tablets initially, followed by two to six tablets 12 hours later may be used. At least 20 brands of pills may be used in this way. For specific instructions for each pill brand, consult www.not-2-late.com. Used within 72 hours, the failure rate of these regimens is approximately 3%, but anti-nausea medication is often necessary. (3) Ulipristal, 30 mg orally as a single dose, has been shown to be more effective than levonorgestrel, particularly when used between 72 and 120 hours. It is available by prescription in the United States and Western Europe. (4) IUD insertion within 5 days after one episode of unprotected midcycle coitus will also prevent pregnancy; copper-bearing IUDs have been tested for this purpose.

Information on clinics or individual clinicians providing emergency contraception in the United States may be obtained by calling 1-888-668-2528.

Glasier AF et al. Ulipristal acetate versus levonorgestrel for emergency contraception: a randomized non-inferiority trial and meta-analysis. *Lancet.* 2010 Feb 13;375(9714):555–62. [PMID: 20116841]

10. Abortion

Since the legalization of abortion in the United States in 1973, the related maternal mortality rate has fallen markedly, because illegal and self-induced abortions have been replaced by safer medical procedures. Abortions in the first trimester of pregnancy are performed by vacuum aspiration under local anesthesia or with medical regimens. Dilation and evacuation, a variation of vacuum aspiration is generally used in the second trimester. Techniques utilizing intra-amniotic instillation of hypertonic saline solution or various prostaglandins regimens, along with medical or osmotic dilators are occasionally used after 18 weeks. Several medical abortion regimens utilizing mifepristone and multiple doses of misoprostol have been reported as being effective in the second trimester. Overall, legal abortion in the United States has a mortality rate of < 1:100,000. Rates of morbidity and mortality rise with length of gestation. Currently in the United States, 88% of abortions are performed before 13 weeks' gestation and only 1.3% are performed after 20 weeks. If abortion is chosen, every effort should be made to encourage the patient to seek an early procedure. While numerous state laws limiting access to abortion and a federal law banning a rarely used variation of dilation and evacuation have been enacted, abortion remains legal and available until fetal viability, between 24 and 28 weeks gestation, under *Roe v. Wade*.

Complications resulting from abortion include retained products of conception (often associated with infection and heavy bleeding) and unrecognized ectopic pregnancy. Immediate analysis of the removed tissue for placenta can exclude or corroborate the diagnosis of ectopic pregnancy. Women who have fever, bleeding, or abdominal pain after abortion should be examined; use of broad-spectrum antibiotics and reaspiration of the uterus are frequently necessary. Hospitalization is advisable if acute salpingitis requires intravenous administration of antibiotics. Complications following illegal abortion often need emergency care for hemorrhage, septic shock, or uterine perforation.

Rh immune globulin should be given to all Rh-negative women following abortion. Prophylactic antibiotics are indicated for surgical abortion; for example a one-dose regimen of doxycycline, 200 mg orally 1 hour before the procedure. Many clinics prescribe tetracycline, 500 mg orally four times daily for 5 days after the procedure, as presumptive treatment for *Chlamydia*.

Mifepristone (RU 486) is approved by the FDA as an oral abortifacient at a dose of 600 mg on day 1, followed by 400 mcg orally of misoprostol on day 3. This combination is 95% successful in terminating pregnancies of up to 9 weeks' duration with minimum complications. A more commonly used, evidence-based regimen is mifepristone, 200 mg orally on day 1, followed by misoprostol, 800 mcg vaginally either immediately or within 6–8 hours. Although not approved by the FDA for this indication, a combination of intramuscular methotrexate, 50 mg/m² of body surface area, followed 3–7 days later by vaginal misoprostol, 800 mcg, is 98% successful in terminating pregnancy at 8 weeks or less. Minor side effects, such as nausea, vomiting, and diarrhea, are common with these regimens. There

is a 5–10% incidence of hemorrhage or incomplete abortion requiring curettage. Medical abortion is generally considered as safe as surgical abortion in the first trimester but is associated with more pain and a lower success rate (requiring surgical abortion). Overall, the risk of uterine infection is lower with medical than with surgical abortion. As of 2010, there have been reports of eight deaths occurring within 1 week of medical abortion, associated with endometritis and toxic shock caused by *Clostridium sordellii* or *Clostridium perfringens* for a rate of 0.58 per 100,000 medical abortions in the United States. To improve early diagnosis and treatment of this entity, clinicians should be aware of the constellation of presenting symptoms of tachycardia, hypotension, edema, hemoconcentration, profound leukocytosis, and absence of fever.

Lièvre M et al. Meta-analysis of 200 or 600 mg mifepristone in association with two prostaglandins for termination of early pregnancy. *Contraception*. 2009 Jul;80(1):95–100. [PMID: 19501223]

Zane S et al. Gynecologic clostridial toxic shock in women of reproductive age. *Curr Infect Dis Rep*. 2011 Dec;13(6):561–70. [PMID: 21882086]

11. Sterilization

In the United States, sterilization is the most popular method of birth control for couples who want no more children. Although sterilization is reversible in some instances, reversal surgery in both men and women is costly, complicated, and not always successful. Therefore, patients should be counseled carefully before sterilization and should view the procedure as permanent.

Vasectomy is a safe, simple procedure in which the vas deferens is severed and sealed through a scrotal incision under local anesthesia. Long-term follow-up studies on vasectomized men show no excess risk of cardiovascular disease. Several studies have shown a possible association with prostate cancer, but the evidence is weak and inconsistent.

Female sterilization procedures include laparoscopic bipolar electrocoagulation, or plastic ring application on the uterine tubes, or minilaparotomy with Pomeroy tubal resection. The advantages of laparoscopy are minimal postoperative pain, small incisions, and rapid recovery. The advantages of minilaparotomy are that it can be performed with standard surgical instruments under local or general anesthesia. However, there is more postoperative pain and a longer recovery period. The cumulative 10-year failure rate for all methods combined is 1.85%, varying from 0.75% for postpartum partial salpingectomy and laparoscopic unipolar coagulation to 3.65% for spring clips; this fact should be discussed with women preoperatively. Some studies have found an increased risk of menstrual irregularities as a long-term complication of tubal ligation, but findings in different studies have been inconsistent. Two methods of transcervical sterilization, Essure and Adiana, can be performed as outpatient procedures. Essure involves the placement of an expanding microcoil of titanium into the proximal uterine tube under hysteroscopic guidance. The efficacy rate at 1 year is 99.8%. Adiana involves hysteroscopically guided superficial radiofrequency damage to

the tubal lumen and immediate placement of a nonabsorbable silicone elastomer matrix in the tube to allow tissue in-growth. The efficacy rate at 1 year is 98.9%. Both procedures should have tubal occlusion confirmed at 3 months with a hysterosalpingogram.

▶ When to Refer

Refer to experienced clinicians for Implanon or other subcutaneous insertion, IUD insertion, tubal occlusion or ligation, vasectomy, or therapeutic abortion.

RAPE

ESSENTIALS OF DIAGNOSIS

- ▶ Women neither secretly want to be raped nor do they expect, encourage, or enjoy rape.
- ▶ Rape is always a terrifying experience in which most victims fear for their lives.
- ▶ The rapist is usually a hostile man who uses sexual intercourse to terrorize and humiliate a woman.
- ▶ Knowledge of state laws and collection of evidence requirements are essential for clinicians evaluating possible rape victims.

▶ General Considerations

Rape, or sexual assault, is legally defined in different ways in various jurisdictions. Clinicians and emergency department personnel who deal with rape victims should be familiar with the laws pertaining to sexual assault in their own state. From a medical and psychological viewpoint, it is essential that persons treating rape victims recognize the nonconsensual and violent nature of the crime. About 95% of reported rape victims are women. Penetration may be vaginal, anal, or oral and may be by the penis, hand, or a foreign object. The absence of genital injury does not imply consent by the victim. The assailant may be unknown to the victim or, more frequently, may be an acquaintance or even the spouse.

“Unlawful sexual intercourse,” or statutory rape, is intercourse with a female before the age of majority even with her consent.

Rape represents an expression of anger, power, and sexuality on the part of the rapist. The rapist is usually a hostile man who uses sexual intercourse to terrorize and humiliate a woman. Women neither secretly want to be raped nor do they expect, encourage, or enjoy rape.

Rape involves severe physical injury in 5–10% of cases and is always a terrifying experience in which most victims fear for their lives. Consequently, all victims suffer some psychological aftermath. Moreover, some rape victims may acquire sexually transmissible disease or become pregnant.

Because rape is a personal crisis, each patient will react differently, but anxiety disorders and posttraumatic stress disorder (PTSD) are common sequelae. The rape trauma syndrome comprises two principal phases. (1) Immediate or acute: Shaking, sobbing, and restless activity may last from a few days to a few weeks. The patient may experience anger, guilt, or shame or may repress these emotions. Reactions vary depending on the victim's personality and the circumstances of the attack. (2) Late or chronic: Problems related to the attack may develop weeks or months later. The lifestyle and work patterns of the individual may change. Sleep disorders or phobias often develop. Loss of self-esteem can rarely lead to suicide.

Clinicians and emergency department personnel who deal with rape victims should work with community rape crisis centers or other sources of ongoing psychological support and counseling.

► General Office Procedures

The clinician who first sees the alleged rape victim should be empathetic. Begin with a statement such as, "This is a terrible thing that has happened to you. I want to help."

1. Secure written consent from the patient, guardian, or next of kin for gynecologic examination and for photographs if they are likely to be useful as evidence. If police are to be notified, do so, and obtain advice on the preservation and transfer of evidence.
2. Obtain and record the history in the patient's own words. The sequence of events, ie, the time, place, and circumstances, must be included. Note the date of the LMP, whether or not the woman is pregnant, and the time of the most recent coitus prior to the sexual assault. Note the details of the assault such as body cavities penetrated, use of foreign objects, and number of assailants. Note whether the victim is calm, agitated, or confused (drugs or alcohol may be involved). Record whether the patient came directly to the hospital or whether she bathed or changed her clothing. Record findings but do not issue even a tentative diagnosis lest it be erroneous or incomplete.
3. Have the patient disrobe while standing on a white sheet. Hair, dirt, and leaves, underclothing, and any torn or stained clothing should be kept as evidence. Scrape material from beneath fingernails and comb pubic hair for evidence. Place all evidence in separate clean paper bags or envelopes and label carefully.
4. Examine the patient, noting any traumatized areas that should be photographed. Examine the body and genitals with a Wood light to identify semen, which fluoresces; positive areas should be swabbed with a premoistened swab and air-dried in order to identify acid phosphatase. Colposcopy can be used to identify small areas of trauma from forced entry especially at the posterior fourchette.
5. Perform a pelvic examination, explaining all procedures and obtaining the patient's consent before proceeding gently with the examination. Use a narrow speculum lubricated with water only. Collect material with sterile cotton swabs from the vaginal walls and cervix and

make two air-dried smears on clean glass slides. Wet and dry swabs of vaginal secretions should be collected and refrigerated for subsequent acid phosphatase and DNA evaluation. Swab the mouth (around molars and cheeks) and anus in the same way, if appropriate. Label all slides carefully. Collect secretions from the vagina, anus, or mouth with a premoistened cotton swab, place at once on a slide with a drop of saline, and cover with a coverslip. Look for motile or nonmotile sperm under high, dry magnification, and record the percentage of motile forms.

6. Perform appropriate laboratory tests as follows. Culture the vagina, anus, or mouth (as appropriate) for *N gonorrhoeae* and *Chlamydia*. Perform a Papanicolaou smear of the cervix, a wet mount for *T vaginalis*, a baseline pregnancy test, and VDRL test. A confidential test for HIV viral load or antibody can be obtained if desired by the patient. Antibody testing can be repeated in 2–4 months if initially negative. Repeat the pregnancy test if the next menses is missed, and repeat the VDRL test in 6 weeks. Obtain blood (10 mL without anticoagulant) and urine (100 mL) specimens if there is a history of forced ingestion or injection of drugs or alcohol.
7. Transfer clearly labeled evidence, eg, laboratory specimens, directly to the clinical pathologist in charge or to the responsible laboratory technician, in the presence of witnesses (never via messenger), so that the rules of evidence will not be breached.

► Treatment

Give analgesics or sedatives if indicated. Administer tetanus toxoid if deep lacerations contain soil or dirt particles.

Give ceftriaxone, 125 mg intramuscularly, to prevent gonorrhea. In addition, give metronidazole, 2 g as a single dose, and azithromycin 1 g orally or doxycycline, 100 mg orally twice daily for 7 days to treat chlamydia infection. Incubating syphilis will probably be prevented by these medications, but the VDRL test should be repeated 6 weeks after the assault.

Prevent pregnancy by using one of the methods discussed under Emergency Contraception, if necessary (this chapter).

Vaccinate against hepatitis B. Consider HIV prophylaxis (see Chapter 31).

Because women who are sexually assaulted are at increased risk for long-term psychological sequelae, such as PTSD and anxiety disorders, it is critical that the patient and her family and friends have a source of ongoing counseling and psychological support.

► When to Refer

All women who seek care for sexual assault should be referred to a facility that has expertise in the management of victims of sexual assault and is capable of performing expert forensic examination, if requested.

Vickerman KA et al. Rape treatment outcome research: empirical findings and state of the literature. *Clin Psychol Rev*. 2009 Jul;29(5):431–48. [PMID: 19442425]

MENOPAUSAL SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Cessation of menses due to aging or to bilateral oophorectomy.
- ▶ Elevation of FSH and LH levels.
- ▶ Hot flushes and night sweats (in 80% of women).
- ▶ Decreased vaginal lubrication; thinned vaginal mucosa with or without dyspareunia.

▶ General Considerations

The term “menopause” denotes the final cessation of menstruation, either as a normal part of aging or as the result of surgical removal of both ovaries. In a broader sense, as the term is commonly used, it denotes a 1- to 3-year period during which a woman adjusts to a diminishing and then absent menstrual flow and the physiologic changes that may be associated—hot flushes, night sweats, and vaginal dryness.

The average age at menopause in Western societies today is 51 years. Premature menopause is defined as ovarian failure and menstrual cessation before age 40; this often has a genetic or autoimmune basis. Surgical menopause due to bilateral oophorectomy is common and can cause more severe symptoms owing to the sudden rapid drop in sex hormone levels.

There is no objective evidence that cessation of ovarian function is associated with severe emotional disturbance or personality changes. However, mood changes toward depression and anxiety can occur at this time. Furthermore, the time of menopause often coincides with other major life changes, such as departure of children from the home, a midlife identity crisis, or divorce. These events, coupled with a sense of the loss of youth, may exacerbate the symptoms of menopause and cause psychological distress.

▶ Clinical Findings

A. Symptoms and Signs

1. Cessation of menstruation—Menstrual cycles generally become irregular as menopause approaches. Anovular cycles occur more often, with irregular cycle length and occasional menorrhagia. Menstrual flow usually diminishes in amount owing to decreased estrogen secretion, resulting in less abundant endometrial growth. Finally, cycles become longer, with missed periods or episodes of spotting only. When no bleeding has occurred for 1 year, the menopausal transition can be said to have occurred. Any bleeding after this time warrants investigation by endometrial curettage or aspiration to rule out endometrial cancer.

2. Hot flushes—Hot flushes (feelings of intense heat over the trunk and face, with flushing of the skin and sweating) occur in > 80% of women as a result of the decrease in

ovarian hormones. Hot flushes can begin before the cessation of menses. The etiology of hot flushes is unknown. They typically persist for 2 to 3 years, but up to 16% of women aged 67 may continue to experience symptoms. Hot flushes are more severe in women who undergo surgical menopause. Occurring at night, they often cause sweating and insomnia and result in fatigue on the following day.

3. Vaginal atrophy—With decreased estrogen secretion, thinning of the vaginal mucosa and decreased vaginal lubrication occur and may lead to dyspareunia. The introitus decreases in diameter. Pelvic examination reveals pale, smooth vaginal mucosa and a small cervix and uterus. The ovaries are not normally palpable after the menopause. Continued sexual activity will help prevent tissue shrinkage.

4. Osteoporosis—Osteoporosis may occur as a late sequela of menopause.

B. Laboratory Findings

Serum FSH and LH levels are elevated. Vaginal cytologic examination will show a low estrogen effect with predominantly parabasal cells, indicating lack of epithelial maturation due to hypoestrogenism.

▶ Treatment

A. Natural Menopause

Education and support from health providers, midlife discussion groups, and reading material will help most women having difficulty adjusting to the menopause. Physiologic symptoms can be treated as follows.

1. Vasomotor symptoms—For women with moderate to severe vasomotor symptoms, estrogen or estrogen/progestin regimens are the most effective approach to symptom relief. Conjugated estrogens, 0.3 mg, 0.45 mg, or 0.625 mg; 17-beta-estradiol, 0.5 or 1 mg; or estrone sulfate, 0.625 mg can be given once daily orally; or estradiol can be given transdermally as skin patches that are changed once or twice weekly and secrete 0.05–0.1 mg of hormone daily. Unless the patient has undergone hysterectomy, a combination regimen of an estrogen with a progestin such as medroxyprogesterone, 1.5 or 2.5 mg, or norethindrone, 0.1, 0.25, or 0.5 mg, should be used to prevent endometrial hyperplasia or cancer. There is also a patch available containing estradiol and the progestin levonorgestrel. The oral hormones can be given in several differing regimens. Give estrogen on days 1–25 of each calendar month, with 5–10 mg of oral medroxyprogesterone acetate added on days 14–25. Withhold hormones from day 26 until the end of the month, when the endometrium will be shed, producing a light, generally painless monthly period. Alternatively, give the estrogen along with a progestin daily, without stopping. This regimen causes some initial bleeding or spotting, but within a few months it produces an atrophic endometrium that will not bleed. If the patient has had a hysterectomy, a progestin need not be used.

Data from the Women’s Health Initiative (WHI) study suggest that women should not use combination

progestin-estrogen therapy for more than 3 or 4 years. In this study, the increased risk of cardiovascular disease, cerebrovascular disease, and breast cancer with this regimen outweighed the benefits. Women who cannot find relief with alternative approaches may wish to consider continuing use of combination therapy after a thorough discussion of the risks and benefits. Alternatives to hormone therapy for vasomotor symptoms include SSRIs such as paroxetine, 12.5 mg or 25 mg/d orally, or venlafaxine, 75 mg/d orally. Gabapentin, an antiseizure medication, is also effective at 900 mg/d orally. Clonidine given orally or transdermally, 100–150 mcg daily, may also reduce the frequency of hot flashes, but its use is limited by side effects, including dry mouth, drowsiness, and hypotension. There is some evidence that soy isoflavones may be effective in treating menopausal symptoms. Other compounds including red clover and black cohosh have not been shown to be effective. Because little is known about adverse effects, particularly with long-term use, dietary supplements should be used with caution.

2. Vaginal atrophy—A vaginal ring containing 2 mg of estradiol can be left in place for 3 months and is suitable for long-term use. Short-term use of estrogen vaginal cream will relieve symptoms of atrophy, but because of variable absorption, therapy with either the vaginal ring or systemic hormone replacement is preferable. A low-dose estradiol tablet (10 mcg) is available and is inserted in the vagina daily for 2 weeks and then twice a week for long-term use. Testosterone propionate 1–2%, 0.5–1 g, in a vanishing cream base used in the same manner is also effective if estrogen is contraindicated. A bland lubricant such as unscented cold cream or water-soluble gel can be helpful at the time of coitus.

3. Osteoporosis—(See also discussion in Chapter 26.) Women should ingest at least 800 mg of calcium daily throughout life. In addition, 1200 mg of elemental calcium should be taken as a daily supplement at the time of the menopause and thereafter; calcium supplements should be taken with meals to increase their absorption. Vitamin D, 800 international units/d from food, sunlight, or supplements, is necessary to enhance calcium absorption and maintain bone mass. A daily program of energetic walking and exercise to strengthen the arms and upper body helps maintain bone mass.

Women most at risk for osteoporotic fractures should consider bisphosphonates, raloxifene, or hormone replacement therapy. This includes white and Asian women, especially if they have a family history of osteoporosis, are thin, short, cigarette smokers, have a history of hyperthyroidism, use corticosteroid medications long-term, or are physically inactive.

B. Risks of Hormone Therapy

Double-blinded randomized, controlled trials have shown no overall cardiovascular benefit with estrogen-progestin

replacement therapy in a group of postmenopausal women with or without established coronary disease. Both in the WHI trial and the Heart and Estrogen/Progestin Replacement Study (HERS), the overall health risks (increased risk of coronary heart events; strokes; thromboembolic disease; gallstones; and breast cancer, including an increased risk of mortality from breast cancer) exceeded the benefits from the use of combination estrogen and progesterone. An ancillary study of the WHI study showed that not only did estrogen-progestin hormone replacement therapy not benefit cognitive function but there was a small increased risk of cognitive decline in that group compared with women in the placebo group. The unopposed estrogen arm of the WHI trial demonstrated a decrease in the risk of hip fracture, a small but nonsignificant decrease in breast cancer, but an increased risk of stroke and no evidence of protection from coronary heart disease. The study also showed a small increase in the combined risk of mild cognitive impairment and dementia with estrogen use compared with placebo, similar to the estrogen-progestin arm. Women who have been receiving long-term estrogen-progestin hormone replacement therapy, even in the absence of complications, should be encouraged to stop, especially if they do not have menopausal symptoms. However, the risks appear to be lower in women starting therapy at the time of menopause and higher in previously untreated women starting therapy long after menopause. Therapy should be individualized as the risk-benefit profile varies with age and individual risk factors. (See also discussions of estrogen and progestin replacement therapy in Chapter 26.)

C. Surgical Menopause

The abrupt hormonal decrease resulting from oophorectomy generally results in severe vasomotor symptoms and rapid onset of dyspareunia and osteoporosis unless treated. If not contraindicated, estrogen replacement is generally started immediately after surgery. Conjugated estrogens 1.25 mg orally, estrone sulfate 1.25 mg orally, or estradiol 2 mg orally is given for 25 days of each month. After age 45–50 years, this dose can be tapered to 0.625 mg of conjugated estrogens or equivalent.

DIAGNOSIS OF PREGNANCY

It is advantageous to diagnose pregnancy as promptly as possible when a sexually active woman misses a menstrual period or has symptoms suggestive of pregnancy. In the event of a desired pregnancy, prenatal care can begin early, and potentially harmful medications and activities such as drug and alcohol use, smoking, and occupational chemical exposure can be halted. In the event of an unwanted pregnancy, counseling about adoption or termination of the pregnancy can be provided at an early stage.

► Pregnancy Tests

All urine or blood pregnancy tests rely on the detection of human chorionic gonadotropin (hCG) produced by the placenta. hCG levels increase shortly after implantation, approximately double every 48 hours, reach a peak at 50–75 days, and fall to lower levels in the second and third trimesters. Laboratory and home pregnancy tests use monoclonal antibodies specific for hCG. These tests are performed on serum or urine and are accurate at the time of the missed period or shortly after it.

Compared with intrauterine pregnancies, **ectopic pregnancies** may show lower levels of hCG that plateau or fall in serial determinations. Quantitative assays of hCG repeated at 48-hour intervals are used in the diagnosis of ectopic pregnancy as well as in cases of molar pregnancy, threatened abortion, and missed abortion. Comparison of hCG levels between laboratories may be misleading in a given patient because different international standards may produce results that vary by as much as twofold. hCG levels can also be problematic because they require a series of measurements. Progesterone levels, however, remain relatively stable in the first trimester. A single measurement of progesterone is the best indicator of whether a pregnancy is viable, although there is a broad indeterminate zone. A value < 5 ng/mL (16 nmol/L) predicts pregnancy failure while a value > 25 ng/mL (80 nmol/L) indicates a pregnancy will be successful. There is uncertainty when the value is between these two points. Combining several serum biomarkers may provide a better prediction of pregnancy viability. **Pregnancy of unknown location** is a term used to describe a situation where a woman has a positive

pregnancy test but the location and viability of the pregnancy is not known because nothing is seen on ultrasound.

Kirk E et al. Pregnancies of unknown location. *Best Pract Res Clin Obstet Gynaecol.* 2009 Aug;23(4):493–9. [PMID: 19345646]

► Manifestations of Pregnancy

The following symptoms and signs are usually due to pregnancy, but none are diagnostic. A record of the time and frequency of coitus is helpful for diagnosing and dating a pregnancy.

A. Symptoms

Amenorrhea, nausea and vomiting, breast tenderness and tingling, urinary frequency and urgency, “quickening” (perception of first movement noted at about the 18th week), weight gain.

B. Signs (in Weeks from Last Menstrual Period)

Breast changes (enlargement, vascular engorgement, colostrum) start to occur very early in pregnancy and continue until the postpartum period. Cyanosis of the vagina and cervical portio and softening of the cervix occur in about the seventh week. Softening of the cervicouterine junction takes place in the eighth week, and generalized enlargement and diffuse softening of the corpus occurs after the eighth week. When a woman’s abdomen will start to enlarge depends on her body habitus but typically starts in the sixteenth week.

The uterine fundus is palpable above the pubic symphysis by 12–15 weeks from the last menstrual period and reaches the umbilicus by 20–22 weeks. Fetal heart tones can be heard by Doppler at 10–12 weeks of gestation.

► Differential Diagnosis

The nonpregnant uterus enlarged by myomas can be confused with the gravid uterus, but it is usually very firm and irregular. An ovarian tumor may be found midline, displacing the nonpregnant uterus to the side or posteriorly. Ultrasonography and a pregnancy test will provide accurate diagnosis in these circumstances.

ESSENTIALS OF PRENATAL CARE

The first prenatal visit should occur as early as possible after the diagnosis of pregnancy and should include the following: history, physical examination, laboratory tests, advice to the patient, and tests and procedures.

► History

The patient's age, ethnic background, and occupation should be obtained. The onset of the last menstrual period and its normality, possible conception dates, bleeding after the last menstruation, medical history, all prior pregnancies (duration, outcome, and complications), and symptoms of present pregnancy should be documented. The patient's nutritional habits should be discussed with her, as well as any use of caffeine, tobacco, alcohol, or drugs (Table 19–1 and 19–2). Whether there is any family history of congenital anomalies and heritable diseases, a personal history of childhood varicella, prior sexually transmitted diseases (STDs), or risk factors for HIV infection should be determined.

► Physical Examination

Height, weight, and blood pressure should be measured, and a general physical examination should be done, including a breast examination. Abdominal and pelvic

Table 19–1. Common drugs that are teratogenic or fetotoxic.¹

ACE inhibitors	Lithium
Alcohol	Methotrexate
A-II antagonists	Misoprostol
Androgens	NSAIDs (third trimester)
Antiepileptics (phenytoin, valproic acid, carbamazepine)	Opioids (prolonged use)
Benzodiazepines	Progestins
Carbarsone (amebicide)	Radioiodine (antithyroid)
Chloramphenicol (third trimester)	Reserpine
Cyclophosphamide	Ribavirin
Diazoxide	Sulfonamides (third trimester)
Diethylstilbestrol	SSRIs
Disulfiram	Tetracycline (third trimester)
Ergotamine	Thalidomide
Estrogens	Tobacco smoking
Griseofulvin	Trimethoprim (third trimester)
Isotretinoin	Warfarin and other coumarin anticoagulants

¹Many other drugs are also contraindicated during pregnancy. Evaluate any drug for its need versus its potential adverse effects. Further information can be obtained from the manufacturer or from any of several teratogenic registries around the country. ACE, angiotensin-converting enzyme; A-II antagonists, angiotensin II receptor blocking agents; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

Table 19–2. Drugs and substances that require a careful assessment of risk before they are prescribed for breastfeeding women.

Category of Drug	Specific Drug	Concern
ACE inhibitors	Lisinopril	Unknown effects.
Alkylating agents	Cyclophosphamide	Neonatal neutropenia. No breastfeeding.
Analgesic	Aspirin	High doses associated with neonatal salicylate toxicity.
Antibiotics	Ciprofloxacin	Case of neonatal <i>Clostridium difficile</i> pseudomembranous colitis.
	Nitrofurantoin	Avoid if family history of glucose-6-phosphate dehydrogenase deficiency.
Antiepileptics	Carbamazepine, diazepam	Neonatal hepatitis, dose-dependent effects.
Antidepressants	Fluoxetine, sertraline	Present in breast milk. Watch for adverse effects.
Antihistamine	Cetirizine, diphenhydramine	Irritability of the newborn.
Antihypertensives	Methyldopa	Possible neonatal hypoglycemia.
Antimetabolites	Methotrexate	Unknown effects. No breastfeeding.
Anticholinergic	Atropine	Unknown effects.
Hormones	Danazol	Unknown effects. No breastfeeding.
Mood stabilizer	Lithium	High circulating level in the neonate.
Retinoids	Isotretinoin	Unknown effects. No breastfeeding.
Radioactive compounds	Radioiodine	No breastfeeding.

The above list is not all-inclusive. For additional information, see the below references from which this information is adapted or the online drug and lactation database, Lactmed, at <http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT>
 Data from Buhimschi CS et al. Medications in pregnancy and lactation: part 1. Teratology. Obstet Gynecol. 2009 Jan;113(1):166-88; and Buhimschi CS et al. Medications in pregnancy and lactation: Part 2. Drugs with minimal or unknown human teratogenic effect. Obstet Gynecol. 2009 Feb;113(2 Pt 1):417-32.

examination should include the following: (1) estimate of uterine size or measure of fundal height; (2) evaluation of bony pelvis for symmetry and adequacy; (3) evaluation of cervix for structural anatomy, infection, effacement, dilation; (4) detection of fetal heart tones by Doppler device after 10 weeks.

► Laboratory Tests

Urinalysis; culture of a clean-voided midstream urine sample; random blood glucose; complete blood count with red cell indices; serologic test for syphilis, rubella antibody titer; varicella immunity; blood group; Rh type; antibody screening for anti-Rh₀(D), hepatitis B surface antigen (HBsAg), and the HIV should be performed. Cervical cultures are usually obtained for Chlamydia and possibly *Neisseria gonorrhoeae*, along with a Papanicolaou smear of the cervix. All black women should have sickle cell screening. Women of African, Asian, or Mediterranean ancestry with anemia or low mean corpuscular volume (MCV) values should have hemoglobin electrophoresis performed to identify abnormal hemoglobins (Hb S, C, F, α -thalassemia, β -thalassemia). Tuberculosis skin testing is indicated for high-risk populations. Fetal aneuploidy screening is available in the first and second trimester and should be offered to all women, ideally before 20 weeks gestation. Noninvasive first trimester screening for Down syndrome includes ultrasonographic nuchal translucency and serum levels of PAPP-A (pregnancy-associated plasma protein A) and the free β subunit of hCG. In the second trimester, a “quad screen” blood test can be performed; it measures serum alpha-fetoprotein (msAFP), β -hCG, unconjugated estriol, and inhibin A. First and second trimester tests have similar detection rates. When first and second trimester screening are combined (integrated screening), the detection rates are even higher. Women at increased risk for aneuploidy can then be offered chorionic villus sampling or genetic amniocentesis, depending on gestational age and availability. Blood screening for Tay-Sachs, Canavan disease, and familial dysautonomia is offered to couples who are of Eastern European Jewish (Ashkenazi) descent. Couples of French-Canadian or Cajun ancestry should also be screened as possible Tay-Sachs carriers. Screening for cystic fibrosis is offered to all pregnant women. Hepatitis C antibody screening should be offered to pregnant women who are at high risk for infection.

► Advice to Patients

A. Prenatal Visits

Prenatal care should begin early and maintain a schedule of regular prenatal visits: 0–28 weeks, every 4 weeks; 28–36 weeks, every 2 weeks; 36 weeks on, weekly.

B. Diet

The patient should be counseled to eat a balanced diet containing the major food groups.

1. Prenatal vitamins with iron and folic acid should be prescribed. Supplements that are not specified for pregnant women should be avoided as they may contain dangerous amounts of certain vitamins.

2. The average weight pregnant woman should be expected to gain is 20–40 lb. A pregnant woman should not diet to lose weight during pregnancy, although obese women do seem to benefit from gaining less weight, perhaps 10–15 lb.
3. Caffeine intake should be decreased to 0–1 cup of coffee, tea, or caffeinated cola daily.
4. The patient should be advised to avoid eating raw or rare meat as well as fish known to contain elevated levels of mercury.
5. Patients should be encouraged to eat fresh fruits and vegetables (washed before eating).

C. Medications

Only medications prescribed or authorized by the obstetric provider should be taken.

D. Alcohol and Other Drugs

Patients should be encouraged to abstain from alcohol, tobacco, and all recreational (“street”) drugs. No safe level of alcohol intake has been established for pregnancy. Fetal effects are manifest in the **fetal alcohol syndrome**, which includes growth restriction; facial, skeletal, and cardiac abnormalities; and serious central nervous system dysfunction. These effects are thought to result from direct toxicity of ethanol as well as of its metabolites such as acetaldehyde.

Cigarette smoking results in fetal exposure to carbon monoxide and nicotine, and this is thought to eventuate in a number of adverse pregnancy outcomes. An increased risk of abruptio placentae, placenta previa, and premature rupture of the membranes is documented among women who smoke. Preterm delivery, low birth weight, and ectopic pregnancy are also more likely among smokers. Women who smoke should quit smoking or at least reduce the number of cigarettes smoked per day to as few as possible. Clinicians should ask all pregnant women about their smoking history and offer smoking cessation counseling during pregnancy, since women are more motivated to change at this time. Pregnant women should also avoid exposure to environmental smoke (“passive smoking”) and smokeless tobacco.

Sometimes compounding the above effects on pregnancy outcome are the independent adverse effects of illicit drugs. Cocaine use in pregnancy is associated with an increased risk of premature rupture of membranes, preterm delivery, placental abruption, intrauterine growth restriction, neurobehavioral deficits, and sudden infant death syndrome. Similar adverse pregnancy effects are associated with amphetamine use, perhaps reflecting the vasoconstrictive potential of both amphetamines and cocaine. Adverse effects associated with opioid use include intrauterine growth restriction, prematurity, and fetal death.

E. Radiographs and Noxious Exposures

Radiographs should be avoided unless essential and approved by a clinician. Abdominal shielding should be used whenever possible. The patient should be told to inform her dentist and providers that she is pregnant.

Chemical or radiation hazards should be avoided as should excessive heat in hot tubs or saunas. Patients should be told to avoid handling cat feces or cat litter and to wear gloves when gardening.

F. Rest and Activity

The patient should be encouraged to obtain adequate rest each day. She should abstain from strenuous physical work or activities, particularly when heavy lifting or weight bearing is required. Regular exercise can be continued at a mild to moderate level; however exhausting or hazardous exercises or new athletic training programs should be avoided during pregnancy. Exercises that require a great deal of balance should also be done with caution.

G. Birth Classes

The patient should be encouraged to enroll in a childbirth preparation class with her partner well before her due date.

▶ Tests & Procedures

A. Each Visit

Weight, blood pressure, fundal height, and fetal heart rate are measured, and a urine specimen is obtained and tested for protein and glucose. Any concerns the patient may have about pregnancy, health, and nutrition should be reviewed.

B. 6–12 Weeks

Confirm uterine size and growth by pelvic examination. Document fetal heart tones (audible at 10–12 weeks of gestation by Doppler). First trimester screening and a discussion of choices of aneuploidy screening should be discussed at this time (see Laboratory Tests, above). Chorionic villus sampling is performed during this period (11–13 weeks).

C. 16–20 Weeks

The “quad screen” and amniocentesis are performed as indicated and requested by the patient during this time (see Laboratory Tests, above). Fetal ultrasound examination to determine pregnancy dating and evaluate fetal anatomy is also done. An earlier examination provides the most accurate dating, and a later examination demonstrates fetal anatomy in greatest detail. The best compromise is at 18–20 weeks of gestation.

D. 20–24 Weeks

Instruct the patient about symptoms and signs of preterm labor and rupture of membranes. Consider cervical length measurement by ultrasound after 18 weeks with history of prior preterm delivery (> 2.5 cm is normal).

E. 24 Weeks to Delivery

Ultrasound examination is performed as indicated. Typically, fetal size and growth are evaluated when fundal height is 3 cm less than or more than expected for gestational age. In multiple pregnancies, ultrasound should be performed every 4–6 weeks to evaluate for discordant growth.

F. 24–28 Weeks

Screening for gestational diabetes is performed using a 50-g glucose load (Glucola) and a 1-hour post-Glucola blood glucose determination. Abnormal values (≥ 140 mg/dL) should be followed up with a 3-hour glucose tolerance test (see Table 19–4).

G. 28 Weeks

If initial antibody screen for anti-Rh₀(D) is negative, repeat antibody testing for Rh-negative patients is performed, but the result is not required before Rh₀(D) immune globulin is administered (see below).

H. 28–32 Weeks

A complete blood count is done to evaluate for anemia of pregnancy. Screening for syphilis and possibly HIV is also frequently performed at this time. Providers should familiarize themselves with the laws in their state since testing requirements vary.

I. 28 Weeks to Delivery

Fetal position and presentation are determined. The patient is asked about symptoms or signs of preterm labor or rupture of membranes at each visit. Maternal perception of fetal movement should be assessed at each visit. Antepartum fetal testing can be performed as medically indicated.

J. 36 Weeks to Delivery

Repeat syphilis and HIV testing (depending on state laws), cervical cultures for *N gonorrhoeae* and *Chlamydia trachomatis* should be performed in at-risk patients. The indicators of onset of labor, admission to the hospital, management of labor and delivery, and options for analgesia and anesthesia should be discussed with the patient. Weekly cervical examinations are not necessary unless indicated to assess a specific clinical situation. Elective delivery (whether by induction or cesarean section) prior to 39 weeks of gestation requires confirmation of fetal lung maturity.

The CDC recommends universal prenatal culture-based screening for group B streptococcal colonization in pregnancy. A single standard culture of the distal vagina and anorectum is collected at 35–37 weeks. No prophylaxis is needed if the screening culture is negative. Patients whose cultures are positive receive intrapartum penicillin prophylaxis during labor. Except when group B streptococci are found in urine, asymptomatic colonization is not to be treated before labor. Patients who have had a previous infant with invasive group B streptococcal disease or who have group B streptococcal bacteriuria during this pregnancy should receive intrapartum prophylaxis regardless, so rectovaginal cultures are not needed. Patients whose cultures at 35–37 weeks were not done or whose results are not known should receive prophylaxis if they have a risk factor for early-onset neonatal disease, including intrapartum temperature $\geq 38^{\circ}\text{C}$, membrane rupture > 18 hours, or delivery before 37 weeks gestation.

The routine recommended regimen for prophylaxis is penicillin G, 5 million units intravenously as a loading dose and then 2.5 million units intravenously every 4 hours until delivery. In penicillin-allergic patients not at high risk for anaphylaxis, 2 g of cefazolin can be given intravenously as an initial dose and then 1 g intravenously every 8 hours until delivery. In patients at high risk for anaphylaxis, vancomycin 1 g intravenously every 12 hours until delivery is used or, after confirmed susceptibility testing of group B streptococcal isolate, clindamycin 900 mg intravenously every 8 hours or erythromycin 500 mg intravenously every 6 hours until delivery.

K. 41 Weeks

The patient should have a cervical examination to determine the probability of successful induction of labor. Based on this, induction of labor is undertaken if the cervix is favorable (generally, cervix \geq 2 cm dilated \geq 50% effaced, vertex at -1 station, soft cervix, and midposition); if unfavorable, antepartum fetal testing is begun. Induction is performed at 42 weeks gestation regardless of the cervical examination findings; some providers elect induction at 41 weeks regardless of the cervical examination findings.

NUTRITION IN PREGNANCY

Nutrition in pregnancy can affect maternal health and infant size and well-being. Pregnant women should have nutrition counseling early in prenatal care and access to supplementary food programs if necessary. Counseling should stress abstinence from alcohol, smoking, and recreational drugs. Caffeine and artificial sweeteners should be used only in small amounts. “Empty calories” should be avoided, and the diet should contain the following foods: protein foods of animal and vegetable origin, milk and milk products, whole-grain cereals and breads, and fruits and vegetables—especially green leafy vegetables.

Weight gain in pregnancy should be 20–40 lb, which includes the added weight of the fetus, placenta, and amniotic fluid and of maternal reproductive tissues (fluid, blood, increased fat stores, and increased lean body mass). Maternal fat stores are a caloric reserve for pregnancy and lactation; weight restriction in pregnancy to avoid developing such fat stores may affect the development of other fetal and maternal tissues and is not advisable. Obese women can have normal infants with less weight gain (15–20 lb) but should be encouraged to eat high-quality foods. Normally, a pregnant woman gains 2–5 lb in the first trimester and slightly <1 lb/wk thereafter. She needs

approximately an extra 200–300 kcal/d (depending on energy output) and 30 g/d of additional protein for a total protein intake of about 75 g/d. Appropriate caloric intake in pregnancy helps prevent the problems associated with low birth weight.

Rigid salt restriction is not necessary. While consumption of highly salted snack foods and prepared foods is not desirable, 2–3 g/d of sodium is permissible. The increased calcium needs of pregnancy (1200 mg/d) can be met with milk, milk products, green vegetables, soybean products, corn tortillas, and calcium carbonate supplements.

The increased need for iron and folic acid should be met with foods as well as vitamin and mineral supplements. (See section on Anemia in pregnancy.) Megavitamins should not be taken in pregnancy, as they may result in fetal malformation or disturbed metabolism. However, a balanced prenatal supplement containing 30–60 mg of elemental iron, 0.5–0.8 mg of folate, and the recommended daily allowances of various vitamins and minerals is widely used in the United States and is probably beneficial to many women with marginal diets. There is evidence that periconceptional folic acid supplements can decrease the risk of neural tube defects in the fetus. For this reason, the United States Public Health Service recommends the consumption of 0.4 mg of folic acid per day for all pregnant and reproductive age women. Women with a prior pregnancy complicated by neural tube defect may require higher supplemental doses as determined by their providers. Lactovegetarians and ovo-lactovegetarians do well in pregnancy; vegetarian women who eat neither eggs nor milk products should have their diets assessed for adequate calories and protein and should take oral vitamin B₁₂ supplements during pregnancy and lactation.

Rasmussen KM et al. Recommendations for weight gain during pregnancy in the context of the obesity epidemic. *Obstet Gynecol.* 2010 Nov;116(5):1191–5. [PMID: 20966705]

PREVENTION OF RHESUS ALLOIMMUNIZATION

The antibody anti-Rh₀(D) is responsible for most severe instances of hemolytic disease of the newborn. About 15% of whites and much lower proportions of blacks and Asians are Rh₀(D)–negative. If an Rh₀(D)–negative woman carries an Rh₀(D)–positive fetus, antibodies against Rh₀(D) may develop in the mother when fetal red cells enter her circulation during small fetomaternal bleeding episodes in the early third trimester or during delivery, abortion, ectopic pregnancy, abruptio placentae, or other instances of antepartum bleeding. This antibody, once produced, remains in the woman’s circulation and poses the threat of hemolytic disease for subsequent Rh-positive fetuses.

Passive immunization against hemolytic disease of the newborn is achieved with Rh₀(D) immune globulin, a purified concentrate of antibodies against Rh₀(D) antigen. The Rh₀(D)

immune globulin (one vial of 300 mcg intramuscularly) is given to the mother within 72 hours after delivery (or spontaneous or induced abortion or ectopic pregnancy). The antibodies in the immune globulin destroy fetal Rh-positive cells so that the mother will not produce anti-Rh₀(D). During her next Rh-positive gestation, erythroblastosis will be prevented. An additional safety measure is the routine administration of the immune globulin at the 28th week of pregnancy. The passive antibody titer that results is too low to significantly affect an Rh-positive fetus. The maternal clearance of the globulin is slow enough that protection will continue for 12 weeks.

Hemolytic disease of varying degrees, from mild to serious, continues to occur in association with Rh subgroups (C, c, or E) or Kell, Kidd, and other factors. Therefore, the presence of atypical antibodies should be checked in the third trimester of all pregnancies.

Moise KJ Jr. Management of rhesus alloimmunization in pregnancy. *Obstet Gynecol.* 2008 Jul;112(1):164–76. [PMID: 18591322]

LACTATION

Breastfeeding should be encouraged by education throughout pregnancy and the puerperium. Mothers should be told the benefits of breastfeeding, including infant immunity, emotional satisfaction, mother-infant bonding, and economic savings. The period of amenorrhea associated with frequent and consistent breastfeeding provides some (although not completely reliable) birth control until menstruation begins at 6–12 months postpartum or the intensity of breastfeeding diminishes. If the mother must return to work, even a brief period of nursing is beneficial. Transfer of immunoglobulins in colostrum and breast milk protects the infant against many systemic and enteric infections. Macrophages and lymphocytes transferred to the infant from breast milk play an immunoprotective role. The intestinal flora of breastfed infants inhibits the growth of pathogens. Breastfed infants have fewer bacterial and viral infections, less severe diarrhea, and fewer allergy problems than bottle-fed infants. Furthermore, they are less apt to be obese as children and adults.

Frequent breastfeeding on an infant-demand schedule enhances milk flow and successful breastfeeding. Mothers breastfeeding for the first time need help and encouragement from providers, nurses, and other nursing mothers. Milk supply can be increased by increased suckling and increased rest.

Nursing mothers should have a fluid intake of over 2 L/d. The United States RDA calls for 21 g of extra protein (over the 44 g/d baseline for an adult woman) and 550 extra kcal/d in the first 6 months of nursing. Calcium intake should be 1200 mg/d. Continuation of a prenatal vitamin and mineral supplement is wise. Strict vegetarians who eschew both milk and eggs should always take vitamin B₁₂ supplements during pregnancy and lactation.

1. Effects of Drugs in a Nursing Mother

Drugs taken by a nursing mother may accumulate in milk and be transmitted to the infant (Table 19–2). The amount of drug entering the milk depends on the drug's lipid solubility, mechanism of transport, and degree of ionization.

2. Suppression of Lactation

A. Mechanical Suppression

The simplest and safest method of suppressing lactation after it has started is to gradually transfer the baby to a bottle or a cup over a 3-week period. Milk supply will decrease with decreased demand, and minimal discomfort ensues. If nursing must be stopped abruptly, the mother should avoid nipple stimulation, refrain from expressing milk, and use a snug brassiere. Ice packs and analgesics can be helpful. This same technique can be used in cases where suppression is desired before nursing has begun. Engorgement will gradually recede over a 2- to 3-day period.

B. Hormonal Suppression

Oral and long-acting injections of hormonal preparations were used at one time to suppress lactation. Because of their questionable efficacy and particularly because of associated side effects such as thromboembolic episodes and hair growth, their use for this purpose has been abandoned. Similarly, lactation suppression with bromocriptine is to be avoided because of reports of severe hypertension, seizures, strokes, and myocardial infarctions associated with its use.

Rautava S et al. Academy of Breastfeeding Medicine founder's lecture 2008: breastfeeding—an extrauterine link between mother and child. *Breastfeed Med.* 2009 Mar;4(1):3–10. [PMID: 19292608]

TRAVEL & IMMUNIZATIONS DURING PREGNANCY

During an otherwise normal low-risk pregnancy, travel can be planned most safely up to the 32nd week. Commercial flying in pressurized cabins does not pose a threat to the fetus. An aisle seat will allow frequent walks. Adequate fluids should be taken during the flight.

It is not advisable to travel to endemic areas of yellow fever in Africa or Latin America; similarly, it is inadvisable to travel to areas of Africa or Asia where chloroquine-resistant falciparum malaria is a hazard, since complications of malaria are more common in pregnancy.

Ideally, all immunizations should precede pregnancy. Live virus products are contraindicated during pregnancy (measles, rubella, yellow fever and smallpox.) Inactivated polio vaccine (IPV) should be given subcutaneously instead of the oral live-attenuated vaccine. The varicella vaccine should be given 1–3 months before becoming pregnant. Vaccines against pneumococcal pneumonia, meningococcal meningitis, and hepatitis A can be used as indicated. Pregnant women who are considered to be at high-risk for hepatitis B and who have not been previously vaccinated should be vaccinated during pregnancy.

Annual influenza vaccination is indicated in all women who are pregnant or will be pregnant during “flu season.” It can be given in the first trimester. The CDC lists pregnant women as a high-risk group. Pregnant women who have not previously received the tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) immunization should be given the vaccine after 20 weeks gestation or immediately postpartum. Further, any teenagers or adults not previously vaccinated who will have close contact with the infant should also receive it, ideally 2 weeks before exposure to the child. This vaccination strategy is referred to as “cocooning,” and its purpose is to protect the infant aged < 12 months who is at particularly high risk for lethal pertussis.

Hepatitis A vaccine contains formalin-inactivated virus and can be given in pregnancy when needed. Chloroquine can be used for malaria prophylaxis in pregnancy, and proguanil is also safe. Pooled immune globulin to prevent hepatitis A is safe and does not carry a risk of HIV-transmission.

Water should be purified by boiling, since iodine purification may provide more iodine than is safe during pregnancy.

Prophylactic antibiotics or bismuth subsalicylate should not be used during pregnancy to prevent diarrhea. Oral rehydration and treatment of bacterial diarrhea with erythromycin or ampicillin if necessary is preferred.

Centers for Disease Control and Prevention (CDC). Updated recommendations for use of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine (Tdap) in pregnant women and persons who have or anticipate having close contact with an infant aged < 12 months—Advisory Committee on Immunization Practices (ACIP), 2011. *MMWR Morb Mortal Wkly Rep.* 2011 Oct 21;60(41):1424–6. [PMID: 22012116]

OBSTETRIC COMPLICATIONS OF THE FIRST & SECOND TRIMESTERS

VOMITING OF PREGNANCY (Morning Sickness) & HYPEREMESIS GRAVIDARUM (Pernicious Vomiting of Pregnancy)

ESSENTIALS OF DIAGNOSIS

- ▶ Morning or evening nausea and vomiting.
- ▶ Persistent vomiting severe enough to result in weight loss, dehydration, starvation ketosis, hypochloremic alkalosis, hypokalemia.
- ▶ May have transient elevation of liver enzymes.
- ▶ Appears related to high or rising serum hCG.
- ▶ More common with multiple gestation or hydatidiform mole.

▶ General Considerations

Nausea and vomiting begin soon after the first missed period and cease by the fifth month of gestation. Up to three-fourths of women complain of nausea and vomiting

during early pregnancy, with the vast majority noting nausea throughout the day. This problem exerts no adverse effects on the pregnancy and does not presage other complications.

Persistent, severe vomiting during pregnancy—hyperemesis gravidarum—can be disabling and require hospitalization. Thyroid dysfunction can be associated with hyperemesis gravidarum, so it is advisable to determine thyroid-stimulating hormone (TSH) and free thyroxine (T_4) values in these patients.

▶ Treatment

A. Mild Nausea and Vomiting of Pregnancy

In most instances, only reassurance and dietary advice are required. Because of possible teratogenicity, drugs used during the first half of pregnancy should be restricted to those of major importance to life and health. Antiemetics, antihistamines, and antispasmodics are generally unnecessary to treat nausea of pregnancy. Vitamin B_6 (pyridoxine), 50–100 mg/d orally, is nontoxic and may be helpful in some patients.

B. Hyperemesis Gravidarum

With more severe nausea and vomiting, it may become necessary to hospitalize the patient. In this case, a private room with limited activity is preferred. Give nothing by mouth for 48 hours, and maintain hydration and electrolyte balance by giving appropriate parenteral fluids and vitamin supplements as indicated. Antiemetics such as promethazine (25 mg orally, rectally, or intravenously every 4–6 hours), metoclopramide (10 mg orally or intravenously every 6 hours), or ondansetron (4–8 mg orally or intravenously every 8 hours) should be started. Antiemetics will likely need to be given intravenously initially. Rarely, total parenteral nutrition may become necessary. As soon as possible, place the patient on a dry diet consisting of six small feedings daily plus clear liquids 1 hour after eating. Antiemetics may be continued orally as needed. After in-patient stabilization, the patient can be maintained at home even if she requires intravenous fluids in addition to her oral intake. There are conflicting studies regarding the use of corticosteroids for the control of hyperemesis gravidarum. Therefore, this treatment should be withheld until more accepted treatments have been exhausted.

▶ When to Refer

- Patient is unable to tolerate any food or water.
- There is concern for other pathology (ie, hydatidiform mole).
- Patient requires hospitalization.

▶ When to Admit

- Patient is unable to tolerate any food or water.
- Condition precludes the patient from ingesting necessary medications.
- Weight loss.
- Presence of a hydatidiform mole.

SPONTANEOUS ABORTION

ESSENTIALS OF DIAGNOSIS

- ▶ Intrauterine pregnancy at < 20 weeks.
- ▶ Low or falling levels of hCG.
- ▶ Bleeding, midline cramping pain.
- ▶ Open cervical os.
- ▶ Complete or partial expulsion of products of conception.

▶ General Considerations

About three-fourths of spontaneous abortions occur before the 16th week; of these, three-fourths occur before the eighth week. Almost 20% of all clinically recognized pregnancies terminate in spontaneous abortion.

More than 60% of spontaneous abortions result from chromosomal defects due to maternal or paternal factors; about 15% appear to be associated with maternal trauma, infections, dietary deficiencies, diabetes mellitus, hypothyroidism, the lupus anticoagulant-anticardiolipin-antiphospholipid antibody syndrome, or anatomic malformations. There is no reliable evidence that abortion may be induced by psychic stimuli such as severe fright, grief, anger, or anxiety. In about one-fourth of cases, the cause of abortion cannot be determined. There is no evidence that video display terminals or associated electromagnetic fields are related to an increased risk of spontaneous abortion.

It is important to distinguish women with a history of incompetent cervix from those with more typical early abortion. Characteristically, incompetent cervix presents as “silent” cervical dilation (ie, with minimal uterine contractions) in the second trimester. Women with incompetent cervix often present with significant cervical dilation (2 cm or more) and minimal symptoms. When the cervix reaches 4 cm or more, active uterine contractions or rupture of the membranes may occur secondary to the degree of cervical dilation. This does not change the primary diagnosis. Factors that predispose to incompetent cervix are a history of incompetent cervix with a previous pregnancy, cervical conization or surgery, cervical injury, diethylstilbestrol (DES) exposure, and anatomic abnormalities of the cervix. Prior to pregnancy or during the first trimester, there are no methods for determining whether the cervix will eventually be incompetent. After 14–16 weeks, ultrasound may be used to evaluate the internal anatomy of the lower uterine segment and cervix for the funneling and shortening abnormalities consistent with cervical incompetence.

▶ Clinical Findings

A. Symptoms and Signs

1. Threatened abortion—Bleeding or cramping occurs, but the pregnancy continues. The cervix is not dilated.

2. Inevitable abortion—The cervix is dilated and the membranes may be ruptured, but passage of the products of conception has not yet occurred. Bleeding and cramping persist, and passage of the products of conception is considered inevitable.

3. Complete abortion—Products of conception are completely expelled. Pain ceases, but spotting may persist. Cervical os is closed.

4. Incomplete abortion—The cervix is dilated. Some portion of the products of conception (usually placental) remain in the uterus. Only mild cramps are reported, but bleeding is persistent and often excessive.

5. Missed abortion—The pregnancy has ceased to develop, but the conceptus has not been expelled. Symptoms of pregnancy disappear. There may be a brownish vaginal discharge but no free bleeding. Pain does not develop. The cervix is semifirm and slightly patulous; the uterus becomes smaller and irregularly softened; the adnexa are normal.

B. Laboratory Findings

Pregnancy tests show low or falling levels of hCG. A complete blood count should be obtained if bleeding is heavy. Determine Rh type, and give Rh₀(D) immune globulin if Rh-negative. All tissue recovered should be assessed by a pathologist and may be sent for genetic analysis in selected cases.

C. Ultrasonographic Findings

The gestational sac can be identified at 5–6 weeks from the last menstruation, a fetal pole at 6 weeks, and fetal cardiac activity at 6–7 weeks by transvaginal ultrasound. Serial observations are often required to evaluate changes in size of the embryo. A small, irregular sac without a fetal pole with accurate dating is diagnostic of an abnormal pregnancy.

▶ Differential Diagnosis

The bleeding that occurs in abortion of a uterine pregnancy must be differentiated from the abnormal bleeding of an ectopic pregnancy and anovular bleeding in a non-pregnant woman. The passage of hydropic villi in the bloody discharge is diagnostic of hydatidiform mole.

▶ Treatment

A. General Measures

1. Threatened abortion—The patient should be placed on bed rest for 24–48 hours followed by gradual resumption of usual activities, with abstinence from coitus and douching. Hormonal treatment is contraindicated. Antibiotics should be used only if there are signs of infection.

2. Missed abortion—This calls for counseling regarding the fate of the pregnancy and planning for its elective

termination at a time chosen by the patient and clinician. Insertion of laminaria to dilate the cervix followed by aspiration has historically been the method of choice for a missed abortion. Medically induced first-trimester termination with prostaglandins (ie, misoprostol given vaginally or orally in a dose of 200–800 mcg) combined with an antiprogesterone (ie, mifepristone 600 mg orally) has grown in popularity because it has been shown to be safe, effective, less invasive, and more private. If it is unsuccessful or if there is excessive bleeding, a surgical procedure may still be needed. Patients must be counseled about the different therapeutic options with a thorough explanation of all risks and benefits.

B. Surgical Measures

1. Incomplete or inevitable abortion—Prompt removal of any products of conception remaining within the uterus is required to stop bleeding and prevent infection. Analgesia and a paracervical block are useful, followed by uterine exploration with ovum forceps or uterine aspiration. Regional anesthesia may be required.

2. Cerclage and restriction of activities—A cerclage is the treatment of choice for incompetent cervix, but a viable intrauterine pregnancy should be confirmed prior to placement of the cerclage.

A variety of suture materials including a 5-mm Mersilene band can be used to create a purse-string type of stitch around the cervix, using either the McDonald or Shirodkar method. Cerclage should be undertaken with caution when there is advanced cervical dilation or when the membranes are prolapsed into the vagina. Rupture of the membranes and infection are specific contraindications to cerclage. Cervical cultures for *N gonorrhoeae*, *Chlamydia*, and group B streptococci should be obtained before elective placement of a cerclage. *N gonorrhoeae* and *Chlamydia* should be treated before placement.

► When to Refer

- Patient with history of two second-trimester losses.
- Vaginal bleeding in a pregnant patient that resembles menstruation in a nonpregnant woman.
- Patient with an open cervical os.
- No signs of uterine growth in serial examinations of a pregnant patient.
- Leakage of amniotic fluid.

► When to Admit

- Open cervical os.
- Heavy vaginal bleeding.
- Leakage of amniotic fluid.

Hamoda H et al. Medical and surgical options for induced abortion in first trimester. *Best Pract Res Clin Obstet Gynaecol*. 2010 Aug;24(4):503–16. [PMID: 20418168]

RECURRENT (Habitual) ABORTION

Recurrent abortion has been defined as the loss of three or more preivable (<20 weeks gestation or 500 g) pregnancies in succession. Recurrent abortion occurs in about 1% of all couples. Abnormalities related to recurrent abortion can be identified in approximately half of these instances. If a woman has lost three previous pregnancies without identifiable cause, she still has at least a 65% chance of carrying a fetus to viability.

Recurrent abortion is a clinical rather than pathologic diagnosis. The clinical findings are similar to those observed in other types of abortion (see above).

► Treatment

A. Preconception Therapy

Preconception therapy is aimed at detection of maternal or paternal defects that may contribute to abortion. A thorough history and examination is essential. A random blood glucose test and thyroid function studies (including thyroid antibodies) can be done if history indicates a possible predisposition to diabetes mellitus or thyroid disease. Detection of lupus anticoagulant and other hemostatic abnormalities (proteins S and C and antithrombin deficiency, hyperhomocysteinemia, anticardiolipin antibody, factor V Leiden mutations) and an antinuclear antibody test may be indicated. Hysteroscopy or hysterothorography can be used to exclude submucosal myomas and congenital anomalies of the uterus. In women with recurrent losses, resection of a uterine septum, if present, has been recommended. Chromosomal (karyotype) analysis of both partners can be done to rule out balanced translocations (found in 5% of infertile couples), but karyotyping is expensive and may not be helpful.

Many therapies have been tried to prevent recurrent pregnancy loss from immunologic causes. Low-molecular-weight heparin (LMWH), aspirin, intravenous immunoglobulin, and corticosteroids have all been used but the definitive treatment has not yet been determined. LMWH and low-dose aspirin have been recommended for women with antiphospholipid antibodies and recurrent pregnancy loss.

Shetty S et al. Anti-phospholipid antibodies and other immunological causes of recurrent fetal loss—a review of literature of various therapeutic protocols. *Am J Reprod Immunol*. 2009 Jul;62(1):9–24. [PMID: 19527228]

B. Postconception Therapy

The patient should be provided early prenatal care and scheduled frequent office visits. Bed rest is justified only for bleeding or pain. Empiric sex steroid hormone therapy is contraindicated.

► Prognosis

The prognosis is excellent if the cause of abortion can be corrected or treated.

Branch DW et al. Clinical practice. Recurrent miscarriage. *N Engl J Med.* 2010 Oct;363(18):1740–7. [PMID: 20979474]

ECTOPIC PREGNANCY

ESSENTIALS OF DIAGNOSIS

- ▶ Amenorrhea or irregular bleeding and spotting.
- ▶ Pelvic pain, usually adnexal.
- ▶ Adnexal mass by clinical examination or ultrasound.
- ▶ Failure of serum level of β -hCG to double every 48 hours.
- ▶ No intrauterine pregnancy on transvaginal ultrasound with serum β -hCG > 2000 mU/mL.

▶ General Considerations

Ectopic implantation occurs in about one out of 150 live births. About 98% of ectopic pregnancies are tubal. Other sites of ectopic implantation are the peritoneum or abdominal viscera, the ovary, and the cervix. Any condition that prevents or retards migration of the fertilized ovum to the uterus can predispose to an ectopic pregnancy, including a history of infertility, pelvic inflammatory disease, ruptured appendix, and prior tubal surgery. Combined intrauterine and extrauterine pregnancy (heterotopic) may occur rarely. In the United States, undiagnosed or undetected ectopic pregnancy is currently the most common cause of maternal death during the first trimester.

▶ Clinical Findings

A. Symptoms and Signs

Severe lower quadrant pain occurs in almost every case. It is sudden in onset, stabbing, intermittent, and does not radiate. Backache may be present during attacks. Shock occurs in about 10%, often after pelvic examination. At least two-thirds of patients give a history of abnormal menstruation; many have been infertile.

Blood may leak from the tubal ampulla over a period of days, and considerable blood may accumulate in the peritoneum. Slight but persistent vaginal spotting is usually reported, and a pelvic mass may be palpated. Abdominal distention and mild paralytic ileus are often present.

B. Laboratory Findings

Blood studies may show anemia and slight leukocytosis. Quantitative serum pregnancy tests will show levels generally lower than expected for normal pregnancies of the same duration. If β -hCG levels are followed over a few days, there may be a slow rise or a plateau rather than the near doubling every 2 days associated with normal early intrauterine pregnancy or the falling levels that occur with spontaneous abortion. A progesterone level can also be measured to assess the viability of the pregnancy.

C. Imaging

Ultrasonography can reliably demonstrate a gestational sac 5–6 weeks from the last menstruation and a fetal pole at 6 weeks if located in the uterus. An empty uterine cavity raises a strong suspicion of extrauterine pregnancy, which can occasionally be revealed by transvaginal ultrasound. Specified levels of serum β -hCG have been reliably correlated with ultrasound findings of an intrauterine pregnancy. For example, a β -hCG level of 6500 mU/mL with an empty uterine cavity by transabdominal ultrasound is highly suspicious for an ectopic pregnancy. Similarly, a β -hCG value of 2000 mU/mL or more can be indicative of an ectopic pregnancy if no products of conception are detected within the uterine cavity by transvaginal ultrasound. Serum β -hCG values can vary by laboratory.

D. Special Examinations

With the advent of high-resolution transvaginal ultrasound, culdocentesis is rarely used in evaluation of possible ectopic pregnancy. Laparoscopy is the surgical procedure of choice both to confirm an ectopic pregnancy and in most cases to permit removal of the ectopic pregnancy without the need for exploratory laparotomy.

▶ Differential Diagnosis

Clinical and laboratory findings suggestive or diagnostic of pregnancy will distinguish ectopic pregnancy from many acute abdominal illnesses such as acute appendicitis, acute pelvic inflammatory disease, ruptured corpus luteum cyst or ovarian follicle, and urinary calculi. Uterine enlargement with clinical findings similar to those found in ectopic pregnancy is also characteristic of an aborting uterine pregnancy or hydatidiform mole. Ectopic pregnancy should be suspected when postabortal tissue examination fails to reveal chorionic villi. Steps must be taken for immediate diagnosis, including prompt microscopic tissue examination, ultrasonography, and serial β -hCG titers every 48 hours.

▶ Treatment

Patients must be warned about the complications of an ectopic pregnancy and monitored closely. In a stable patient, methotrexate (50 mg/m²) intramuscularly—given as single or multiple doses—is acceptable medical therapy for early ectopic pregnancy. Favorable criteria are that the pregnancy should be < 3.5 cm in largest dimension and unruptured, with no active bleeding and no fetal heart tones.

When a patient with an ectopic pregnancy is unstable or when surgical therapy is planned, the patient is hospitalized. Blood is typed and cross-matched. Ideally, diagnosis and operative treatment should precede frank rupture of the tube and intra-abdominal hemorrhage. The use of methotrexate in an unstable patient is absolutely contraindicated.

Surgical treatment is definitive. In most patients, diagnostic laparoscopy is the initial surgical procedure performed. Depending on the size of the ectopic pregnancy

and whether or not it has ruptured, salpingostomy with removal of the ectopic or a partial or complete salpingectomy can usually be performed. Clinical conditions permitting, patency of the contralateral tube can be established by injection of indigo carmine into the uterine cavity and flow through the contralateral tube confirmed visually by the surgeon.

Iron therapy for anemia may be necessary during convalescence. Rh₀(D) immune globulin (300 mcg) should be given to Rh-negative patients.

► Prognosis

Repeat tubal pregnancy occurs in about 10% of cases. This should not be regarded as a contraindication to future pregnancy, but the patient requires careful observation and early ultrasound confirmation of an intrauterine pregnancy.

► When to Refer

- Severe abdominal pain.
- Palpation of an adnexal mass on pelvic examination.
- Abdominal pain and vaginal bleeding in a pregnant patient.

► When to Admit

- Presence of symptoms or signs of a ruptured ectopic pregnancy.

Barnhart KT. Clinical practice. Ectopic pregnancy. *N Engl J Med*. 2009 Jul 23;361(4):379–87. [PMID: 19625718]

GESTATIONAL TROPHOBLASTIC DISEASE (Hydatidiform Mole & Choriocarcinoma)

ESSENTIALS OF DIAGNOSIS

Hydatidiform mole.

- ▶ Amenorrhea.
- ▶ Irregular uterine bleeding.
- ▶ Serum β -hCG > 40,000 mU/mL.
- ▶ Passage of grapelike clusters of enlarged edematous villi per vagina.
- ▶ Ultrasound of uterus shows characteristic heterogeneous echogenic image and no fetus or placenta.
- ▶ Cytogenetic composition is 46, XX (85%), completely of paternal origin.

Choriocarcinoma.

- ▶ Persistence of detectable β -hCG after mole evacuation.

► General Considerations

Gestational trophoblastic disease is a spectrum of disorders that includes hydatidiform mole (partial and complete),

invasive mole (local extension into the uterus or vagina), choriocarcinoma (a malignant tumor often complicated by distant metastases), and placental site trophoblastic tumor. Complete moles show no evidence of a fetus on ultrasonography. The majority are 46, XX with all chromosomes of paternal origin. Partial moles generally show evidence of an embryo or gestational sac; are triploid, slower-growing, and less symptomatic; and often present clinically as a missed abortion. Partial moles tend to follow a benign course, while complete moles have a greater tendency to become choriocarcinomas.

The highest rates of gestational trophoblastic disease occur in Asians. In the United States, the frequency is 1:1500 pregnancies. Risk factors include prior spontaneous abortion, a history of mole, and age younger than 21 or older than 35. Approximately 10% of women require further treatment after evacuation of the mole; choriocarcinoma develops in 2–3% of women.

► Clinical Findings

A. Symptoms and Signs

Uterine bleeding, beginning at 6–16 weeks, is observed in most instances. In some cases, the uterus is larger than would be expected in a normal pregnancy of the same duration. Excessive nausea and vomiting may occur. Bilaterally enlarged cystic ovaries are sometimes palpable. They are the result of ovarian hyperstimulation due to excess β -hCG.

Preeclampsia-eclampsia may develop during the second trimester of an untreated molar pregnancy, but this is unusual because most are diagnosed early.

Choriocarcinoma may be manifested by continued or recurrent uterine bleeding after evacuation of a mole or following delivery, abortion, or ectopic pregnancy. The presence of an ulcerative vaginal tumor, pelvic mass, or evidence of distant metastatic tumor may be the presenting observation.

B. Laboratory Findings

Hydatidiform moles are generally characterized by high serum β -hCG values, which can range from high normal to the millions. Levels are higher with complete moles than with partial moles. Serum β -hCG values, if extremely high, can assist in making the diagnosis, but they are more helpful in managing response to treatment. Hematocrit, creatinine, blood type, liver function tests, and thyroid function tests should also be measured. High β -hCG levels can cause the release of thyroid hormone, and rarely, symptoms of hyperthyroidism will be present. Patients with hyperthyroidism may require β -blocker therapy until the mole has been evacuated.

C. Imaging

Ultrasound has virtually replaced all other means of preoperative diagnosis of hydatidiform mole. Placental vesicles can be easily seen on transvaginal ultrasound. A preoperative chest film is indicated to rule out pulmonary metastases of the trophoblast.

► Treatment

A. Specific (Surgical) Measures

The uterus should be emptied as soon as the diagnosis of hydatidiform mole is established, preferably by suction curettage. Ovarian cysts should not be resected nor ovaries removed; spontaneous regression of theca lutein cysts will occur with elimination of the mole. The products of conception removed from the uterus should be sent to a pathologist for review. In patients who have completed their childbearing, hysterectomy is an acceptable alternative. Hysterectomy does not preclude the need for follow up of β -hCG levels.

B. Follow-Up Measures

Weekly quantitative β -hCG level measurements are initially required. Following successful surgical evacuation, moles show a progressive decline in β -hCG. After three negative weekly tests (< 5 mU/mL), the interval may be increased to every 3 months for an additional 6 months. The purpose of this follow up is to identify persistent metastatic and nonmetastatic disease, including choriocarcinoma, which is more likely to occur if the initial β -hCG is high and the uterus is large. If levels plateau or begin to rise, the patient should be evaluated by repeat laboratory tests, chest film, and dilatation and curettage (D&C) before the initiation of chemotherapy. Effective contraception (preferably birth control pills) should be prescribed to avoid the hazard and confusion of elevated β -hCG from a new pregnancy. The β -hCG levels should be negative for 6 months before pregnancy is attempted again. Because the risk of recurrence of a molar pregnancy is 1%, an ultrasound should be performed in the first trimester of the pregnancy following a mole to ensure that the pregnancy is normal. In addition, a β -hCG level should then be checked 6 weeks postpartum (after the subsequent normal pregnancy) to ensure there is no persistent trophoblastic tissue, and the placenta should be examined by a pathologist.

C. Antitumor Chemotherapy

If malignant tissue is discovered at surgery or during the follow-up examination, chemotherapy is indicated. For low-risk patients with a good prognosis, methotrexate is considered first-line therapy followed by actinomycin (see Table 39–11). The side effects—anorexia, nausea and vomiting, stomatitis, rash, diarrhea, and bone marrow suppression—usually are reversible in about 3 weeks and can be ameliorated by the administration of folinic acid (0.1 mg/kg) intramuscularly. Repeated courses of methotrexate 2 weeks apart generally are required to destroy the trophoblast and maintain a zero chorionic gonadotropin titer, as indicated by β -hCG determination. Patients with a poor prognosis should be referred to a cancer center, where multiple-agent chemotherapy probably will be given.

► Prognosis

Five-year survival after courses of chemotherapy, even when metastases have been demonstrated, can be expected in at least 85% of cases of choriocarcinoma.

► When to Refer

- Uterine size exceeds that anticipated for gestational age.
- Vaginal bleeding similar to menstruation.
- Pregnant patient with a history of a molar pregnancy.

► When to Admit

- Confirmed molar pregnancy by ultrasound and laboratory studies.
- Heavy vaginal bleeding in a pregnant patient under evaluation.

OBSTETRIC COMPLICATIONS OF THE SECOND & THIRD TRIMESTERS

PREECLAMPSIA-ECLAMPSIA

ESSENTIALS OF DIAGNOSIS

Preeclampsia

- Blood pressure of ≥ 140 mm Hg systolic or ≥ 90 mm Hg diastolic after 20 weeks of gestation.
- Proteinuria of ≥ 0.3 g in 24 hours.

Severe Preeclampsia

- Blood pressure of ≥ 160 mm Hg systolic or ≥ 110 mm Hg diastolic.
- Proteinuria ≥ 5 g in 24 hours or 4+ on dipstick.
- Thrombocytopenia.
- Hemolysis, elevated liver enzymes, low platelets (HELLP).
- Pulmonary edema.
- Fetal growth restriction.

Eclampsia

- Seizures in a patient with evidence of preeclampsia.

► General Considerations

Preeclampsia is defined as the presence of newly elevated blood pressure and proteinuria during pregnancy. Eclampsia is diagnosed when seizures develop in a patient with evidence of preeclampsia. Historically, the presence of three elements was required for the diagnosis of preeclampsia: hypertension, proteinuria, and edema. Edema was difficult to objectively quantify and is no longer a required element.

Preeclampsia-eclampsia can occur any time after 20 weeks of gestation and up to 6 weeks postpartum. It is a disease unique to pregnancy, with the only cure being delivery of the fetus and placenta. Preeclampsia-eclampsia develops in approximately 7% of pregnant women in the United States. Primiparas are most frequently affected; however, the incidence of preeclampsia-eclampsia is increased with multiple gestation pregnancies, chronic hypertension, diabetes, kidney disease, collagen-vascular and autoimmune disorders, and gestational trophoblastic disease. Five percent of women with preeclampsia progress to eclampsia. Uncontrolled eclampsia is a significant cause of maternal death.

The cause of preeclampsia-eclampsia is not known, but it is likely a multifactorial, two-stage process. The first stage is thought to be a disturbance in placental implantation involving the spiral arteries very early in gestation. The abnormal placental perfusion that results leads to the formation of noxious free radicals. The second stage is characterized by excessive inflammation causing endothelial damage, vasospasm, and finally clinical signs and symptoms. An immunologic component to preeclampsia-eclampsia has been proposed, citing the increased incidence in primigravidas. This entire process is likely enhanced by environmental factors, genetic predisposition, and preexisting maternal disease.

► Clinical Findings

Clinically, the severity of preeclampsia-eclampsia can be measured with reference to the six major sites in which it exerts its effects: the central nervous system, the kidneys, the liver, the hematologic and vascular systems, and the fetal-placental unit. By evaluating each of these areas for the presence of mild to severe preeclampsia, the degree of involvement can be assessed, and an appropriate management plan can be formulated that balances the severity of disease and gestational age (Table 19–3).

A. Preeclampsia

1. Mild—Patients usually have few complaints, and the diastolic blood pressure is < 110 mm Hg. Edema may be present. The platelet count is over 100,000/mcL, antepartum fetal testing is reassuring, central nervous system irritability is minimal, epigastric pain is not present, and liver enzymes are not elevated.

2. Severe—Symptoms are more dramatic and persistent. Patients may complain of headache and vision changes. The blood pressure is often quite high, with readings at or above 160/110 mm Hg. Thrombocytopenia (platelet counts < 100,000/mcL) may be present and progress to disseminated intravascular coagulation. Severe epigastric pain may

Table 19–3. Indicators of mild versus severe preeclampsia-eclampsia.

Site	Indicator	Mild to Moderate	Severe
Central nervous system	Symptoms and signs	Hyperreflexia	Seizures Blurred vision Scotomas Headache Clonus Irritability
Kidney	Proteinuria Uric acid Urinary output	0.3-5 g/24 h > 4.5 mg/dL > 30 mL/h	> 5 g/24 h or catheterized urine with 4+ protein > 4.5 mg/dL < 30 mL/h
Liver	AST, ALT, LD	Normal	Elevated LFTs Epigastric pain Ruptured liver
Hematologic	Platelets Hemoglobin	> 100,000/mcL Normal range	< 100,000/mcL Elevated
Vascular	Blood pressure Retina	< 160/110 mm Hg Arteriolar spasm	> 160/110 mm Hg Retinal hemorrhages
Fetal-placental unit	Growth restriction Oligohydramnios Fetal distress	Absent Absent Absent	Present Present Present

ALT, alanine aminotransferase; AST, aspartate aminotransferase; LD, lactate dehydrogenase; LFTs, liver function tests.

be present from hepatic subcapsular hemorrhage with significant stretch or rupture of the liver capsule. HELLP syndrome (hemolysis, elevated liver enzymes, low platelets) is a form of severe preeclampsia.

B. Eclampsia

The occurrence of seizures defines eclampsia. It is a manifestation of severe central nervous system involvement. Other findings of preeclampsia are observed.

► Differential Diagnosis

Preeclampsia-eclampsia can mimic and be confused with many other diseases, including chronic hypertension, chronic kidney disease, primary seizure disorders, gallbladder and pancreatic disease, immune thrombocytopenia, thrombotic thrombocytopenic purpura, and hemolytic-uremic syndrome. It must always be considered a possibility in any pregnant woman beyond 20 weeks of gestation. It is particularly difficult to diagnose when a preexisting disease such as hypertension is present. Uric acid values can be quite helpful in such situations, since hyperuricemia is uncommon in pregnancy except with gout, kidney disease, or preeclampsia-eclampsia.

► Treatment

The use of diuretics, dietary restriction or enhancement, sodium restriction, aspirin, and vitamin-mineral supplements such as calcium or vitamin C and E have not been confirmed to be useful in clinical studies. The only cure is delivery of the fetus at a time as favorable as possible for its survival.

A. Preeclampsia

Early recognition is the key to treatment. This requires careful attention to the details of prenatal care—especially subtle changes in blood pressure and weight. The objectives are to prolong pregnancy if possible, to allow fetal lung maturity while preventing progression to severe disease and eclampsia. The critical factors are the gestational age of the fetus, fetal pulmonary maturity, and the severity of maternal disease. Preeclampsia-eclampsia at term is managed by delivery. Prior to term, severe preeclampsia-eclampsia requires delivery with very few exceptions. Epigastric pain, severe range blood pressures, thrombocytopenia, and visual disturbances are strong indications for delivery of the fetus. Severe disease by protein alone can be managed more conservatively.

For mild preeclampsia, bed rest is the cornerstone of therapy. This increases central blood flow to the kidneys, heart, brain, liver, and placenta and may stabilize or even improve the degree of preeclampsia-eclampsia for a period of time.

Bed rest may be attempted at home or in the hospital. Prior to making this decision, the clinician should evaluate the six sites of involvement listed in Table 19-3 and make an assessment about the severity of disease.

1. Home management—Home management with bed rest may be attempted for patients with mild preeclampsia and a stable home situation. This requires assistance at

home, rapid access to the hospital, a reliable patient, and the ability to obtain frequent blood pressure readings. A home health nurse can often provide frequent home visits and assessment.

2. Hospital care—Hospitalization is required for women with severe preeclampsia or those with unreliable home situations. Regular assessment of blood pressure, reflexes, urine protein, and fetal heart tones and activity are required. A complete blood count, platelet count, and electrolyte panel including liver enzymes should be checked regularly, with frequency dependent on severity. A 24-hour urine collection for creatinine clearance and total protein should be obtained on admission and repeated as indicated. Magnesium sulfate is not used until the diagnosis of severe preeclampsia is made and delivery planned (see Eclampsia, below).

Fetal evaluation should be obtained as part of the workup. If the patient is being admitted to the hospital, fetal testing should be performed on the same day to assess fetal wellbeing. This may be done by fetal heart rate testing with nonstress testing or by biophysical profile. A regular schedule of fetal surveillance must then be followed. Daily fetal kick counts can be recorded by the patient herself. Consideration can be given to amniocentesis to evaluate fetal lung maturity if hospitalization occurs at 30–37 weeks of gestation. If immaturity is suspected, corticosteroids (betamethasone 12 mg intramuscularly every 24 h for two doses, or dexamethasone 6 mg intramuscularly every 12 h for four doses) can be administered to the mother. Fetuses between 26 and 30 weeks of gestation can be presumed to be immature, and corticosteroids should be given.

The method of delivery is determined by the maternal and fetal status. A vaginal delivery is preferred because it has less blood loss than a cesarean section and requires less coagulation factors. Cesarean section is reserved for the usual fetal indications.

B. Eclampsia

1. Emergency care—If the patient is convulsing, she is turned on her side to prevent aspiration and to improve blood flow to the placenta. Fluid or food is aspirated from the glottis or trachea. The seizure may be stopped by giving an intravenous bolus of either magnesium sulfate, 4–6 g, or lorazepam, 2–4 mg over 4 minutes or until the seizure stops. Magnesium sulfate is the preferred agent, and alternatives should only be used if magnesium sulfate is unavailable. A continuous intravenous infusion of magnesium sulfate is then started at a rate of 2–3 g/h unless the patient is known to have significantly reduced kidney function. Magnesium blood levels are then checked every 4–6 hours and the infusion rate adjusted to maintain a therapeutic blood level (4–6 mEq/L). Urinary output is checked hourly and the patient assessed for signs of possible magnesium toxicity such as loss of deep tendon reflexes or decrease in respiratory rate and depth, which can be reversed with calcium gluconate, 1 g intravenously over 2 minutes.

2. General care—Magnesium sulfate should be given intravenously, 4- to 6-g load over 15–20 minutes followed by 2–3 g/h maintenance, for seizure prophylaxis in patients with severe preeclampsia. The occurrence of eclampsia

necessitates delivery once the patient is stabilized. It is important, however, that assessment of the status of the patient and fetus take place first. Continuous fetal monitoring must be performed and blood typed and cross-matched quickly. A urinary catheter is inserted to monitor urinary output, and blood is tested for complete blood count, platelets, liver enzymes, uric acid, creatinine, and electrolytes. If hypertension is present with systolic values of ≥ 160 mm Hg or diastolic values ≥ 110 mm Hg, antihypertensive medications should be administered to reduce the blood pressure to 140–150/90–100 mm Hg. Lower blood pressures than this may induce placental insufficiency through reduced perfusion. Hydralazine given in 5- to 10-mg increments intravenously every 20 minutes is frequently used to lower blood pressure. Labetalol, 10–20 mg intravenously, every 20 minutes as needed, can also be used.

3. Delivery—Delivery is mandated once eclampsia has occurred. Vaginal delivery is preferred. The rapidity with which delivery must be achieved depends on the fetal and maternal status following the seizure and the availability of laboratory data on the patient. Oxytocin, given intravenously and titrated to a dose that results in adequate contractions, may be used to induce or augment labor. Oxytocin should only be administered by a clinician specifically trained in its use. Regional analgesia or general anesthesia is acceptable. Cesarean section is used for the usual obstetric indications.

4. Postpartum—Magnesium sulfate infusion (2–3 g/h) should be continued until preeclampsia-eclampsia has begun to resolve postpartum (which may take 1–7 days), but in any case for at least 24 hours. The most reliable indicator of this resolution is the onset of diuresis with urinary output of over 100–200 mL/h. When this occurs, magnesium sulfate can be discontinued. Late-onset preeclampsia-eclampsia can occur during the postpartum period. It is usually manifested by either hypertension or seizures. Treatment is the same as prior to delivery—ie, with hydralazine and magnesium sulfate.

► When to Refer

- New onset of hypertension and proteinuria in a pregnant patient > 20 weeks' gestation.
- New onset of seizure activity in a pregnant patient.
- Symptoms of severe preeclampsia in a pregnant patient with elevated blood pressure above baseline.

► When to Admit

- Evidence of severe preeclampsia or eclampsia.
- Evaluation for preeclampsia when severe disease is suspected.
- Evaluation for preeclampsia in a patient with an unstable home environment.

ACUTE FATTY LIVER OF PREGNANCY

Acute fatty liver of pregnancy is a disorder limited to the gravid state. It occurs in the third trimester of pregnancy and involves acute hepatic failure. With improved recognition and immediate delivery, the mortality rate is now 7–23%. The disorder is usually seen after the 35th week of gestation and is more common in primigravidas and those with twins. The incidence is about 1:14,000 deliveries.

The cause of acute fatty liver of pregnancy is just now being elucidated, and it likely is the result of poor placental mitochondrial function. Many cases may be due to a homozygous fetal deficiency of long-chain acyl coenzyme A dehydrogenase (LCHAD).

► Clinical Findings

Pathologic findings are unique to the disorder, with fatty engorgement of hepatocytes. Clinical onset is gradual, with flu-like symptoms that progress to the development of abdominal pain, jaundice, encephalopathy, disseminated intravascular coagulation, and death. On examination, the patient shows signs of hepatic failure.

Laboratory findings show marked elevation of alkaline phosphatase but only moderate elevations of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Prothrombin time and bilirubin are also elevated. The white blood cell count is elevated, and the platelet count is depressed. Hypoglycemia may be extreme.

► Differential Diagnosis

The differential diagnosis is that of fulminant hepatitis. However, liver aminotransferases for fulminant hepatitis are higher (> 1000 units/mL) than those for acute fatty liver of pregnancy (usually 500–1000 units/mL). It is also important to review the appropriate history and perform the appropriate tests for toxins that cause liver failure. Preeclampsia may involve the liver but typically does not cause jaundice. The elevations in liver function tests in patients with preeclampsia usually do not reach the levels seen in patients with acute fatty liver of pregnancy.

► Treatment

Diagnosis of acute fatty liver of pregnancy mandates immediate delivery. Supportive care during labor includes administration of glucose, platelets, and fresh frozen plasma as needed. Vaginal delivery is preferred. Resolution of encephalopathy occurs over days, and supportive care with a low-protein diet is needed.

► Prognosis

Recurrence rates for this liver disorder are unclear but probably increased in families with proven LCHAD deficiency. Most authorities advise against subsequent pregnancy, but there have been reported cases of successful outcomes in later pregnancies.

PRETERM LABOR

ESSENTIALS OF DIAGNOSIS

- ▶ Regular uterine contractions approximately 5 minutes apart.
- ▶ Cervical dilatation or effacement, or both.

▶ General Considerations

Preterm birth is defined as delivery prior to 37 weeks gestation, and spontaneous preterm labor with or without premature rupture of the fetal membranes is responsible for at least two-thirds or all preterm births. Prematurity is the largest single contributor to infant mortality. Recognized risk factors for spontaneous preterm labor include a past history of spontaneous preterm delivery, premature rupture of the membranes, multiple gestation, black race, intrauterine infections, müllerian anomalies (including those caused by exposure to DES), bacterial vaginosis, and certain socioeconomic conditions (such as limited access to prenatal care). It has also been consistently demonstrated that women with a shortened cervical length as measured by transvaginal ultrasound in the midtrimester are at increased risk for spontaneous preterm delivery. Strategies aimed at preventing preterm birth in high-risk women—principally those with a history of preterm birth or a shortened cervix (or both)—have focused on the administration of progesterone. Prospective randomized controlled trials have demonstrated reductions in rates of preterm birth in women with singleton pregnancies who received progesterone supplementation, although the optimal dose and route of administration (intramuscular injection versus vaginal suppository) is unclear. In twin pregnancies, however, progesterone administration has not been effective at prolonging pregnancy, suggesting that the mechanism for preterm birth may be different in multiple gestations. Although somewhat controversial, there is also evidence to suggest that women with shortened cervixes may benefit from placement of a cervical cerclage. The use of cervical cerclage in conjunction with progesterone supplementation has not been adequately studied.

▶ Clinical Findings

Cervical softening and remodeling likely precede symptoms of uterine contractions in preterm labor. Symptoms such as pelvic pressure, cramping, or vaginal discharge may be the first complaints in high-risk patients who later develop preterm labor. Because these complaints may be vague and irregular uterine contractions are common, distinguishing which patients merit further evaluation can be problematic. In some cases, this distinction can be facilitated by the use of fetal fibronectin measurement in cervicovaginal specimens. This test is most useful when it is negative (<50 ng/mL), since the negative predictive value for delivery within 7–14 days is 93–97%. A negative test, therefore, usually means the patient can be reassured and discharged home.

▶ Treatment

Patients must be educated to identify symptoms associated with preterm labor to avoid unnecessary delay in their evaluation. In high-risk patients who become symptomatic, limited activity and bed rest continues to be recommended despite limited evidence to support such recommendations.

Numerous pharmacologic agents (eg, tocolytics) have been given in an attempt to forestall preterm birth, although none are completely effective. **Magnesium sulfate** is commonly used, and there is evidence that it may also be protective against cerebral palsy. Magnesium sulfate is given intravenously as a 4- to 6-g bolus followed by a continuous infusion of 2–3 g/h. Magnesium levels should be determined every 4–6 hours to monitor for evidence of toxicity. Magnesium sulfate is entirely cleared by the kidney and must, therefore, be used with caution in women with any degree of kidney injury. After contractions have ceased for 12–24 hours, magnesium can be stopped and the situation reassessed.

β-Adrenergic drugs such as **terbutaline** have also been used. Terbutaline can be given as an intravenous infusion starting at 2.5 mcg/min or as a subcutaneous injection starting at 250 mcg given every 30 minutes. Oral terbutaline therapy following parenteral treatment is often elected and consists of giving 2.5–5 mg every 4–6 hours. With terbutaline, a dose-related elevation of heart rate of 20–40 beats/min may occur. If maternal tachycardia is significant (>120 beats/min) or it is accompanied by chest pain or palpitations, cessation of therapy should be considered. Pulmonary edema is also a well-documented serious side effect and occurs with increased frequency with concomitant administration of corticosteroids, large volume intravenous fluid infusion, maternal sepsis, or prolonged tocolysis. Unfortunately, these serious side effects are idiosyncratic and not dose-related. Certain metabolic derangements have also been associated with β-adrenergic drugs, most commonly hyperglycemia and hypokalemia.

Nifedipine, 20 mg orally every 6 hours, and **indomethacin**, 50 mg orally once then 25 mg orally every 6 hours up to 48 hours, have also been used with limited success. Nifedipine should not be given in conjunction with magnesium sulfate.

Before attempts are made to prevent preterm delivery with tocolytic agents, the patient should be assessed for conditions in which delivery would be indicated. Severe preeclampsia, lethal fetal anomalies, placental abruption, and intrauterine infection are all examples of indications for preterm delivery. In these cases, attempts to forestall delivery would be inappropriate.

In pregnancies between 24 and 34 weeks gestation where preterm birth is anticipated, betamethasone, 12 mg intramuscularly repeated once 24 hours later, or dexamethasone, 6 mg intramuscularly repeated every 12 hours for four doses, is administered to hasten fetal lung maturation. Repeat courses are not recommended. Women in preterm labor should also receive antimicrobial prophylaxis against group B streptococcus. Recommendations for group B streptococcus prophylaxis are discussed above.

► When to Refer

- Symptoms of increased pelvic pressure or cramping in high-risk patients.
- Regular uterine contractions.
- Rupture of membranes.
- Vaginal bleeding.

► When to Admit

- Cervical dilation of ≥ 2 cm prior to 34 weeks gestation.
- Contractions that cause cervical change.
- Rupture of membranes.

THIRD-TRIMESTER BLEEDING

Five to 10 percent of women have vaginal bleeding in late pregnancy. The clinician must distinguish between placental causes (placenta previa, placental abruption, vasa previa) and nonplacental causes (labor, infection, disorders of the lower genital tract, systemic disease). The approach to bleeding in late pregnancy generally should be conservative and expectant unless fetal distress or excessive maternal hemorrhage occurs.

► Treatment

A. General Measures

The patient should be hospitalized and placed on bed rest. Initially, continuous fetal monitoring is indicated to assess for fetal distress. A complete blood count (including platelets) should be obtained and repeated serially if the bleeding continues. If the hemorrhage is significant, the need for blood replacement should be anticipated and two to four units of red cells typed and cross-matched. Coagulation studies can be ordered as clinically indicated. Ultrasound examination should be performed to determine placental location. Digital pelvic examinations are done only after ultrasound examination has ruled out placenta previa.

B. Placenta Previa

Placenta previa occurs when the placenta implants over the internal cervical os. Risk factors for this condition include previous cesarean delivery, increasing maternal age, multiparity, and smoking. If the diagnosis is initially made in the first or second trimester, the ultrasound should be repeated

in the third trimester. Persistence of placenta previa at this point is an indication for cesarean as the route of delivery. Painless vaginal bleeding is the characteristic symptom in placenta previa and can range from light spotting to profuse hemorrhage. Hospitalization for extended evaluation is the appropriate initial management approach. For pregnancies that have reached 37 weeks gestation or beyond with continued bleeding, delivery is generally indicated. Pregnancies at 36 weeks or earlier are candidates for expectant management provided the bleeding is not prodigious, and a subset of these women can be discharged if the bleeding and contractions completely subside.

Women with a placenta previa who have one or more previous cesarean deliveries are at increased risk for placenta accreta. In this condition, the placental implantation is abnormally invaded into the endometrium (accreta), myometrium (incretta), or beyond the uterine serosa (percreta). After delivery, the placenta does not separate normally, and hysterectomy is required to stop the postpartum hemorrhage, which can be massive. If this condition is suspected antenatally based on ultrasound findings and clinical risk assessment, delivery should be planned at an institution with appropriate personnel and facilities to manage complex surgical cases and severe postpartum hemorrhage.

C. Placental Abruption

Placental abruption is the premature separation of the placenta from its implantation site before delivery. Hypertension is a known risk factor for abruption, and the patient should be assessed for hypertension. Other risk factors include multiparity, cocaine use, smoking, previous abruption, and thrombophilias. Classic symptoms are vaginal bleeding, uterine tenderness and frequent contractions, but the clinical presentation is highly variable. Ultrasound may be helpful to exclude placenta previa, but failure to identify a retroplacental clot does not exclude abruption. In most cases, abruption is an indication for immediate delivery because of the high risk of fetal death.

OBSTETRIC COMPLICATIONS OF THE PERIPARTUM PERIOD

PUERPERAL MASTITIS (See Also Chapter 17)

Postpartum mastitis occurs sporadically in nursing mothers, usually with symptom onset after discharge from the hospital, or it may occur in epidemic form in the hospital. *Staphylococcus aureus* is usually the causative agent. Inflammation is generally unilateral, and women nursing for the first time are more often affected. Rarely, inflammatory carcinoma of the breast can be mistaken for puerperal mastitis.

Mastitis frequently begins within 3 months after delivery and may start with an engorged breast and a sore or fissured nipple. Cellulitis is usually obvious in the affected area of breast with redness, tenderness, and local warmth. Fever and chills are common complaints as well. Treatment consists of antibiotics effective against penicillin-resistant staphylococci (dicloxacillin 500 mg orally every 6 hours or a cephalosporin for 10–14 days) and regular emptying of the breast by nursing or by using a mechanical suction device. Although nursing of the infected breast is safe for the infant, local inflammation of the nipple may complicate latching. Failure to respond to usual antibiotics within 3 days may represent an organizing abscess or infection with a resistant organism. When the causative organism is methicillin-resistant *S aureus* (MRSA), the risk for abscess formation is increased when compared with infection caused by nonresistant staphylococcal species. If an abscess is suspected, ultrasound of the breast can help confirm the diagnosis. In these cases, surgical evacuation is usually required.

CHORIOAMNIONITIS & METRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever not attributable to another source.
- ▶ Uterine tenderness.
- ▶ Foul smelling vaginal discharge.
- ▶ Tachycardia in the mother, fetus, or both.

▶ General Considerations

Peripartum infection of the uterus is a common problem encountered during labor and the puerperium. Uterine infection in pregnancy is referred to as chorioamnionitis, since the infection involves the chorion. Uterine infection after delivery is often called endometritis or endomyometritis, but the term “metritis” is probably most accurate to emphasize that the infection extends throughout the uterine tissue. These infections are polymicrobial and are most commonly attributed to urogenital pathogens. Risk factors include cesarean delivery, prolonged labor, use of internal monitors, multiple pelvic examinations, prolonged rupture of membranes, and lower genital tract infections.

▶ Clinical Findings

Chorioamnionitis and metritis are diagnosed by the presence of fever ($\geq 38^\circ\text{C}$) in the absence of any other source and one or more of the following signs: maternal tachycardia,

fetal tachycardia, foul-smelling lochia, and uterine tenderness. Cultures of the cervix are not done because of the polymicrobial nature of the infection.

▶ Treatment

Treatment is with broad-spectrum antibiotics that will cover gram-positive organisms and gram-negative organisms if still pregnant and gram-negative organisms and anaerobes if postpartum. A common regimen for chorioamnionitis is ampicillin, 2 g intravenously every 6 hours, and gentamicin, 2 mg/kg intravenous load then 1.5 mg/kg intravenously every 8 hours. A common regimen for metritis is gentamicin, 2 mg/kg intravenous load then 1.5 mg/kg intravenously every 8 hours, and clindamycin, 900 mg intravenously every 8 hours. Antibiotics are stopped when the patient has been afebrile for 24 hours. No oral antibiotics are subsequently needed. Patients with metritis who do not respond in the first 24–48 hours may have enterococcus and require additional gram-positive coverage (such as ampicillin) to the regimen.

MEDICAL CONDITIONS COMPLICATING PREGNANCY

ANEMIA

Normal pregnancy is characterized by an increase in maternal plasma volume of about 50% and in increase in red cell volume of about 25%. Because of these changes, the mean hemoglobin and hematocrit values are lower than in the nonpregnant state. Anemia in pregnancy is often defined as a hemoglobin measurement below 11 g/dL or hematocrit below 33%. Symptoms such as fatigue and dyspnea that would otherwise suggest the presence of anemia in nonpregnant women are normal in pregnant women; therefore, periodic measurement of blood counts in pregnancy is essential so that anemia can be identified and treated.

A. Iron Deficiency Anemia

The increased requirement for iron over the course of pregnancy is appreciable in order to support fetal growth and expansion of maternal blood volume. Dietary intake of iron is generally insufficient to meet this demand, and it is recommended that all pregnant women receive about 30 mg of elemental iron per day in the second and third trimesters. If supplementation is inadequate, iron deficiency anemia develops. The usual findings of hypochromic and microcytic red cells may not initially be evident on the complete blood count, but iron studies can confirm the diagnosis if necessary. Abnormally low ferritin levels ($< 10\text{--}15$ mcg/L) have the highest sensitivity and specificity for diagnosing iron deficiency anemia. However, a serum iron level below 40 mcg/dL and transferrin saturation $< 10\%$ are also consistent with the diagnosis (see Chapter 13). Treatment consists of supplements with 60–100 mg of elemental iron and a diet containing iron-rich foods. Iron is best absorbed if taken with a dietary source of vitamin C (raw fruits or lightly cooked greens).

B. Folic Acid Deficiency Anemia

Megaloblastic anemia in pregnancy is almost always caused by folic acid deficiency, since vitamin B₁₂ deficiency is extremely uncommon in the childbearing years. The daily requirement of folic acid increases in pregnancy, and supplementation with 0.4 mg of folate is recommended. Importantly, this dose taken during the periconceptional period has also been shown to reduce the risk of neural tube defects in the offspring. Multiple gestation, infections, malabsorption, and use of anticonvulsant drugs such as phenytoin can precipitate folic acid deficiency, and additional folate supplementation should be considered in these settings. Lactating women continue to have increased demand for folate, and the diagnosis is sometimes made in the puerperium.

The diagnosis is made by finding macrocytic red cells and hypersegmented neutrophils in a blood smear (see Chapter 13). However, blood smears in pregnancy may be difficult to interpret, since they frequently show iron deficiency changes as well. With established folate deficiency, a supplemental dose of 1 mg/d and a diet with increased folic acid is generally sufficient to correct the anemia.

C. Sickle Cell Anemia

Women with sickle cell anemia are subject to serious complications in pregnancy. The anemia becomes more severe, and acute pain crises often occur more frequently. When compared with women who do not have hemoglobinopathies, women with hemoglobin SS are at increased risk for infections (especially pulmonary and urinary tract), thromboembolic events, pregnancy-related hypertension, transfusion, cesarean delivery, preterm birth, and fetal growth restriction. There also continues to be an increased rate of maternal mortality, despite an increased recognition of the high-risk nature of these pregnancies. Intensive medical treatment may improve the outcomes for both mother and fetus. Prophylactically transfusing packed red cells to lower the level of hemoglobin S and elevate the level of hemoglobin A is a controversial practice without clear benefit. Management decisions should be made in conjunction with a maternal fetal medicine specialist and a hematologist.

Genetic counseling should be offered to patients with sickle cell disease or sickle trait (hemoglobin AS). If the father is a carrier of the sickle cell gene (or his status is unknown), the parents may wish to undergo prenatal diagnosis to determine whether the fetus is affected.

Contraceptive counseling postpartum is important, although the safest and most effective method in women with sickle cell disease is unclear. Progestin-only compounds may be ideal because progesterone has long been recognized to help prevent pain crises in some women. Intrauterine devices carry a risk of infection and combination oral contraceptives are a concern because of the thrombogenic potential; these forms of contraception have not been adequately studied in these patients.

Women with hemoglobin SC disease are also at increased risk for complications, but the morbidity does not appear to be as great as in women with SS disease.

Women with either SC or SS disease are managed similarly. Women with sickle cell trait alone usually have an uncomplicated pregnancy course except for an increased risk of urinary tract infection.

ANTIPHOSPHOLIPID SYNDROME

The antiphospholipid syndrome (APS) is characterized by the presence of specific autoantibodies in association with certain clinical conditions, most notably arterial and venous thrombosis and adverse pregnancy outcomes. Clinically, the diagnosis can be suspected after any of the following outcomes: an episode of thrombosis, three or more consecutive spontaneous abortions prior to 10 weeks gestation, one fetal loss after 10 weeks gestation, or a preterm delivery at less than 34 weeks due to preeclampsia. In addition to these clinical features, laboratory criteria include the identification of at least one of the following antiphospholipid antibodies: the lupus anticoagulant, anticardiolipin antibodies, or anti- β_2 -glycoprotein I antibodies. The lupus anticoagulant cannot be directly assayed, but it is tested for in several different phospholipid-dependent clotting tests and is interpreted as either present or absent. Anticardiolipin antibodies may be detected with enzyme-linked immunosorbent assay (ELISA) testing but should only be considered diagnostic when the IgG or IgM isotypes are present in medium to high titer (40 GPL or MPL, respectively). Likewise, anti- β_2 -glycoprotein I antibodies are detected with ELISA but should only be considered positive when they are present in a titer that is greater than 99th percentile for a normal population. The diagnosis of APS requires two positive antiphospholipid antibody test results at least 12 weeks apart since transient positive results can occur.

Treatment for APS in pregnancy generally involves administration of a heparin compound and low-dose aspirin (81 mg). In women with recurrent pregnancy loss and APS, it has been demonstrated that unfractionated heparin and low-dose aspirin can reduce the risk for spontaneous abortion. Outside of the first trimester, heparin is generally continued through pregnancy and the early postpartum period for thromboprophylaxis. LMWH is also commonly used for this indication; however, it is not clear that LMWH has the same effect on reducing the risk of recurrent abortion as unfractionated heparin. Either prophylactic or therapeutic dosing strategies may be appropriate depending on the patient's history and clinical risk factors. Infusions of intravenous immunoglobulin are of unclear benefit in these patients, and this treatment is not recommended.

THYROID DISEASE

Thyroid disease is relatively common in pregnancy, and in their overt states, both hypothyroidism and hyperthyroidism have been consistently associated with adverse pregnancy outcomes. Fortunately, these risks are mitigated by adequate treatment of the thyroid condition. The impact of pregnancy on thyroid physiology is appreciable. It is essential to understand the gestational age-specific effects that pregnancy has on thyroid function tests, since these biochemical markers are required to make the diagnosis of thyroid dysfunction. Failure to recognize these alterations can result in misclassification or misdiagnosis.

Overt hypothyroidism is defined by an elevated serum thyrotropin level with a depressed thyroxine level. The condition in pregnancy has been associated with an increase in complications such as preterm birth, preeclampsia, placental abruption, and impaired neuropsychological development in the offspring. The most common etiology is Hashimoto (autoimmune) thyroiditis. Many of the symptoms of hypothyroidism mimic those of normal pregnancy, making its clinical identification difficult. Initial treatment is empiric with levothyroxine started at 75–100 mcg/d. Thyroid function tests can be repeated at 4–6 weeks and the dose adjusted as necessary with the goal of normalizing the TSH level. An increase in the dose of levothyroxine may be required in the second and third trimesters.

Subclinical hypothyroidism is defined as an increased TSH and a normal thyroxine level. There is insufficient data at this time to recommend screening for or treating subclinical hypothyroidism in pregnancy.

Overt hyperthyroidism, defined as excessive production of thyroxine with a depressed (usually undetectable) serum thyrotropin level, is also associated with increased risks in pregnancy. Spontaneous abortion, preterm birth, preeclampsia, and maternal heart failure occur with increased frequency with untreated thyrotoxicosis. Thyroid storm, although rare, can be a life-threatening complication. Medical treatment of thyrotoxicosis is usually accomplished with the antithyroid drugs propylthiouracil or methimazole. Although teratogenicity has not been clearly established, in utero exposure to methimazole has been associated with aplasia cutis and choanal and esophageal atresia in the offspring of pregnancies so treated. Propylthiouracil is not believed to be teratogenic, but it has been associated with the rare complications of hepatotoxicity and agranulocytosis. Recommendations by the American Thyroid Association are to treat with propylthiouracil in the first trimester and convert to methimazole for the remainder of the pregnancy. The therapeutic target for

the free T_4 level is the upper limit of the normal reference range. The TSH levels generally stay suppressed even with adequate treatment. A β -blocker can be used for such symptoms as palpitations or tremors. Fetal hypothyroidism or hyperthyroidism is uncommon but can occur with maternal Graves disease, which is the most common cause of hyperthyroidism in pregnancy. Radioiodine ablation is absolutely contraindicated in pregnancy because it may destroy the fetal thyroid as well.

Transient autoimmune thyroiditis can occur in the postpartum period and is evident within the first year after delivery. The first phase, occurring up to 4 months postpartum, is a hyperthyroid state. Over the next few months, there is a transition to a hypothyroid state, which may require treatment with levothyroxine. Spontaneous resolution to a euthyroid state is the rule in most cases.

DIABETES MELLITUS

Normal pregnancy can be characterized as a state of increased insulin resistance that helps ensure a steady stream of glucose delivery to the developing fetus. Thus, both mild fasting hypoglycemia and postprandial hyperglycemia are physiologic. These metabolic changes are felt to be hormonally mediated with likely contributions from human placental lactogen, estrogen, and progesterone.

A. Gestational Diabetes

Gestational diabetes is abnormal glucose tolerance in pregnancy and is generally believed to be an exaggeration of the pregnancy-induced physiologic changes in carbohydrate metabolism. Alternatively, pregnancy may unmask an underlying propensity for glucose intolerance, which will be evident in the nonpregnant state at some future time if not in the immediate postpartum period. Indeed, at least 50% of women with gestational diabetes are diagnosed with overt diabetes at some point in their lifetime. During the pregnancy, the principal concern in women identified to have gestational diabetes is excessive fetal growth, which can result in increased maternal and perinatal morbidity. Shoulder dystocia occurs more frequently in infants of diabetic mothers because of fetal overgrowth and increased fat deposition on the shoulders. Cesarean delivery and preeclampsia are also significantly increased in women with diabetes, both gestational and overt.

Although the diagnostic thresholds for glucose tolerance tests vary somewhat by region, most practitioners elect to offer testing to all pregnant women. A screening 50-g glucose load is administered at 24–28 weeks' gestation, and if this

Table 19-4. Screening and diagnostic criteria for gestational diabetes mellitus.**Screening for gestational diabetes mellitus**

1. 50-g oral glucose load, administered between the 24th and 28th weeks, without regard to time of day or time of last meal. Universal blood glucose screening is indicated for patients who are of Hispanic, African, Native American, South or East Asian, Pacific Island, or indigenous Australian ancestry. Screening may be omitted for women of a low-prevalence ethnic group who have no family history of diabetes, are under 25 years of age, have normal weight before pregnancy, and have no history of abnormal glucose metabolism or poor obstetric outcome.
2. Venous plasma glucose measure 1 hour later.
3. Value of 140 mg/dL (7.8 mmol/L) or above in venous plasma indicates the need for a full diagnostic glucose tolerance test.

Diagnosis of gestational diabetes mellitus

1. 100-g oral glucose load, administered in the morning after overnight fast lasting at least 8 hours but not more than 14 hours, and following at least 3 days of unrestricted diet (> 150 g carbohydrate) and physical activity.
2. Venous plasma glucose is measured fasting and at 1, 2, and 3 hours. Subject should remain seated and should not smoke throughout the test.
3. Two or more of the following venous plasma concentrations must be equal or exceeded for a diagnosis of gestational diabetes: fasting, 95 mg/dL (5.3 mmol/L); 1 hour, 180 mg/dL (10 mmol/L); 2 hours, 155 mg/dL (8.6 mmol/L); 3 hours, 140 mg/dL (7.8 mmol/L).

test is abnormal, the diagnostic test is a 100-g oral glucose tolerance test (Table 19-4). Women in whom gestational diabetes is diagnosed should undergo nutrition counseling, and insulin should be given to those with persistent fasting hyperglycemia. Insulin can be injected in a split dose mix of NPH and regular, administered twice daily. Insulin has long been regarded as the standard care for women who require medical management. Experience is increasing, however, with the use of oral hypoglycemic agents, such as glyburide and metformin. Randomized controlled trials comparing insulin to oral therapy have identified generally similar maternal and neonatal outcomes with either approach, although the long-term safety of oral agents has not been adequately studied in the women so treated or in their infants. Capillary blood glucose monitoring is checked four times per day, once fasting and three times after meals. Euglycemia is considered to be 60–90 mg/dL while fasting and < 120 mg/dL 2 hours postprandially. Intensive therapy with dietary modifications or insulin therapy, or both, has been demonstrated to decrease rates of macrosomia, shoulder dystocia, and preeclampsia. Because of the increased prevalence of overt diabetes in these women, they should be evaluated 6–12 weeks postpartum by a 2-hour oral glucose tolerance test (75-g glucose load).

B. Overt Diabetes

Overt diabetes is diabetes mellitus that antedates the pregnancy. As in gestational diabetes, fetal overgrowth from inadequately controlled hyperglycemia remains a significant concern because of the increased maternal and

perinatal morbidity that accompany macrosomia. Women with overt diabetes are subject to a number of other complications as well. Spontaneous abortions and third trimester stillbirths occur with increased frequency in these women. There is also a twofold to threefold increased risk for fetal malformations, as hyperglycemia during organogenesis is teratogenic. The most common malformations in offspring of diabetic women are cardiac, skeletal, and neural tube defects. For the mother, the likelihood of infections and pregnancy-related hypertension is increased.

Preconception counseling and evaluation in a diabetic woman is ideal to maximize the pregnancy outcomes. This provides an opportunity to optimize glycemic control and evaluate for evidence of end-organ damage. The initial evaluation of diabetic women should include a complete chemistry panel, HbA_{1c} determination, 24-hour urine collection for total protein and creatinine clearance, fundoscopic examination, and an ECG. Hypertension is common and should be addressed. Euglycemia should be established before conception and maintained during pregnancy with daily home glucose monitoring by the patient. There is an inverse relationship between glycemic control and the occurrence of fetal malformations, and women whose periconceptional glycosylated hemoglobin levels are at or near normal levels have rates of malformations that approach baseline. A well-planned dietary program is a key component, with an intake of 1800–2200 kcal/d divided into three meals and three snacks. Insulin is given subcutaneously in a split-dose regimen as described above for women with gestational diabetes. The use of continuous insulin pump therapy has been found to be very useful during pregnancy in women with type 1 diabetes mellitus.

Throughout the pregnancy, diabetic women should be seen every 2–3 weeks and more frequently depending on the clinical condition. Adjustments in the insulin regimen may be necessary as the pregnancy progresses. A specialized ultrasound is often performed around 20 weeks to detect fetal malformations. Signs and symptoms of infections should be evaluated and promptly treated. In the third trimester, fetal surveillance is indicated, and women with diabetes should receive serial antenatal testing (usually in the form of a nonstress test or biophysical profile). The timing of delivery is dictated by the quality of diabetic control, the presence or absence of medical complications, and fetal status. The goal is to reach 39 weeks (38 completed weeks) and then proceed with delivery. Confirmation of lung maturity may be appropriate if preterm delivery is contemplated.

CHRONIC HYPERTENSIVE DISEASE

Chronic hypertension is estimated to complicate approximately 3% of pregnancies. To establish this diagnosis, hypertension should antedate the pregnancy or be evident before 20 weeks' gestation to differentiate it from pregnancy-related hypertension. This distinction can be problematic when the initial presentation is after 20 weeks, but chronic hypertension is confirmed if the blood pressure remains elevated beyond 12 weeks postpartum. Risk factors for chronic hypertension include older maternal age, African American race, and obesity. While essential hypertension is by far the most common etiology, secondary causes should be sought when clinically indicated.

Women with chronic hypertension are at increased risk for adverse maternal and perinatal outcomes. Superimposed preeclampsia develops in up to 25% of women with chronic hypertension, and the risk appears to increase with greater degrees of baseline hypertension. In these situations, there is a tendency for preeclampsia to occur at an earlier gestational age, be more severe, and be associated with fetal growth restriction. Women with chronic hypertension are also at increased risk for placental abruption and preterm birth.

Pregnant women with chronic hypertension require medication only if the blood pressure is sustained at or above 150/100 mm Hg. Treatment of hypertension has not been demonstrated to improve pregnancy outcomes, but it is indicated in women with significant hypertension for long-term maternal cardiovascular health. For initiation of treatment, methyldopa has the longest record of safety at a starting dosage of 250 mg orally two to three times daily. Therapy with β -blockers or calcium channel blockers is also acceptable (see Tables 11–7, 11–9). Care must be taken not to excessively reduce the blood pressure, as this may decrease uteroplacental perfusion. The goal is a modest reduction in blood pressure and avoidance of severe hypertension ($\geq 160/110$ mm Hg).

If a woman with chronic hypertension is stable on a medical regimen when she becomes pregnant, it is usually appropriate to continue this therapy. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers, however, are contraindicated in all trimesters of pregnancy. In addition to causing fetal hypocalcemia and renal failure with exposure in the second and third trimesters, it is now recognized that these medications are teratogenic in the first trimester. Diuretics, although not typically initiated in pregnancy, may be continued in patients who are taking them when they become pregnant.

When there is sustained severe hypertension despite multiple medications or significant end-organ damage from hypertensive disease, pregnancy is not likely to be tolerated well. In these situations, therapeutic abortion may be appropriate. If the pregnancy is continued, the woman must be counseled that the maternal and perinatal risks are appreciable, and complications such as superimposed preeclampsia and fetal growth restriction should be anticipated.

HEART DISEASE

Normal pregnancy physiology is characterized by cardiovascular adaptations in the mother. Cardiac output increases markedly as a result of both augmented stroke volume and an increase in the resting heart rate, and the maternal blood volume expands by up to 50%. These changes may not be tolerated well in women with functional or structural abnormalities of the heart. Thus, although only a small number of pregnancies are complicated by cardiac disease, these contribute disproportionately to overall rates of maternal morbidity and mortality. Most heart disease seen in women of childbearing age in the United States is caused by congenital heart disease.

For practical purposes, the functional capacity of the heart is the best single measurement of cardiopulmonary status (see box, Functional Cardiac Assessment). Most pregnant women with cardiac disease have class I or II functional disability, and although good outcomes are generally anticipated in this group, complications such as preeclampsia, preterm birth, and low birth weight appear to occur with increased frequency. Women with more severe disability (class III or IV) are rare in contemporary obstetrics; however, the maternal mortality is markedly increased in this setting and is usually the result of congestive heart failure. Because of these risks, therapeutic abortion for maternal health should be considered in women who are severely disabled from cardiac disease. Specific conditions that have been associated with a particularly high risk for maternal death include Eisenmenger syndrome, primary pulmonary hypertension, Marfan syndrome with aortic root dilatation, and severe aortic or mitral stenosis. In general, these conditions should be considered contraindications to pregnancy.

Pregnant women with cardiac disease are best treated by a team of practitioners with experience in caring for such patients. Symptoms of volume overload should be evaluated and treated promptly. Labor management may

FUNCTIONAL CARDIAC ASSESSMENT

Class I	Uncompromised: No limitation on physical activity.
Class II	Slightly limited: Symptoms present with ordinary physical activity but asymptomatic at rest.
Class III	Markedly limited: Symptoms present with less than ordinary activity but asymptomatic at rest.
Class IV	Severely compromised: Inability to perform any activity without developing symptoms, which may also develop at rest.

differ slightly depending on the specific cardiac lesion, but cesarean section is generally reserved for obstetric indications. The early postpartum period is a critical time for fluid management. Patients who are predisposed to heart failure should be monitored closely during the puerperium.

Infective endocarditis prophylaxis is not recommended for a vaginal or cesarean delivery in the absence of infection, except in the very small subset of patients at highest risk for adverse outcomes from endocarditis. The women at highest risk include those with cyanotic heart disease, prosthetic valves, or both. If infection is present, such as chorioamnionitis, the underlying infection should be treated with the usual regimen and additional agents are not needed specifically for endocarditis prophylaxis. Prophylaxis, if required, should be given intravenously (see Table 33–6).

ASTHMA

Asthma is one of the most common medical conditions encountered in pregnancy. Women with mild to moderate asthma can generally expect excellent pregnancy outcomes, but severe or poorly controlled asthma has been associated with adverse maternal and perinatal outcomes. The effects of pregnancy on asthma are likely minimal as asthma severity in the pregnancy has been reported to be similar to its severity during the year preceding the pregnancy. Strategies for treatment are similar to that in nonpregnant women. Patients should be educated about symptom management and avoidance of asthma triggers. Baseline pulmonary function tests can provide an objective assessment of lung function and may help the patient with self-monitoring of her asthma severity using a peak flow meter. Medications used commonly in the nonpregnant population are acceptable in pregnancy, and none are absolutely contraindicated. Inhaled β_2 -agonists are indicated for all asthma patients, and inhaled corticosteroids are added for persistent symptoms when a rescue inhaler alone is inadequate. Budesonide is the preferred inhaled corticosteroid based on its documented safety in pregnancy. The primary goals of management in pregnancy include minimizing symptoms and avoiding hypoxic episodes to the fetus.

SEIZURE DISORDERS

Epilepsy is one of the most common serious neurologic disorders in pregnant women. Many of the commonly used antiepileptic drugs are known human teratogens. Therefore, the principal objectives in managing pregnancy in epileptic women are achieving adequate control of seizures while minimizing exposure to medications that can cause congenital malformations. Women contemplating pregnancy who have not had a seizure for 5 years should consider a prepregnancy trial of withdrawal from antiepileptic therapy. For those who continue to require treatment, therapy with one medication is preferred. Selecting a regimen should be based on the type of seizure disorder and the risks associated with each medication. Valproic acid should not be considered first-line therapy because it has consistently been associated with higher rates of malformations than most other commonly used antiepileptic drugs, and there are data to suggest that it is also associated with impairments of cognitive development in the offspring. Phenytoin and carbamazepine are also older medications that are still used, and both have established patterns of associated fetal malformations. Concerns about teratogenicity have prompted increasing use of the newer antiepileptic drugs such as lamotrigine, topiramate, oxcarbazepine, and levetiracetam. Although the safety of these medications in pregnancy continues to be evaluated, experiences from large, population-based studies suggest that in utero exposure to the newer antiepileptic drugs in the first trimester of pregnancy does not appear to increase the risk for major birth defects. Supplemental folate may decrease the risk of congenital malformations, and it is recommended that pregnant women with epilepsy be given at least 0.4 mg/d of folic acid. It is unclear if higher doses of folate offer greater protective benefit.

INFECTIOUS CONDITIONS COMPLICATING PREGNANCY

URINARY TRACT INFECTION

The urinary tract is especially vulnerable to infections during pregnancy because the altered secretions of steroid sex

hormones and the pressure exerted by the gravid uterus on the ureters and bladder cause hypotonia and congestion and predispose to urinary stasis. Labor and delivery and urinary retention postpartum also may initiate or aggravate infection. *Escherichia coli* is the offending organism in over two-thirds of cases.

From 2% to 8% of pregnant women have asymptomatic bacteriuria, which some believe to be associated with an increased risk of preterm birth. It is estimated that pyelonephritis will develop in 20–40% of these women if untreated.

An evaluation for asymptomatic bacteriuria at the first prenatal visit is recommended for all pregnant women. If a urine culture is positive, treatment should be initiated. Nitrofurantoin (100 mg orally twice daily), ampicillin (250 mg orally four times daily), and cephalexin (250 mg orally four times daily) are acceptable medications for 3–7 days. Sulfonamides should be avoided in the third trimester because they may interfere with bilirubin binding and thus impose a risk of neonatal hyperbilirubinemia and kernicterus. Fluoroquinolones are also contraindicated because of their potential teratogenic effects on fetal cartilage and bone. Patients with recurrent bacteriuria should receive suppressive medication (once daily dosing of an appropriate antibiotic) for the remainder of the pregnancy. Acute pyelonephritis requires hospitalization for intravenous administration of antibiotics and crystalloids until the patient is afebrile; this is followed by a full course of oral antibiotics.

Schnarr J et al. Asymptomatic bacteriuria and symptomatic urinary tract infections in pregnancy. *Eur J Clin Invest*. 2008 Oct;38(Suppl 2):50–7. [PMID: 18826482]

GROUP B STREPTOCOCCAL INFECTION

Group B streptococci frequently colonize the lower female genital tract, with an asymptomatic carriage rate in pregnancy of 10–30%. This rate depends on maternal age, gravidity, and geographic variation. Vaginal carriage is asymptomatic and intermittent, with spontaneous clearing in approximately 30% and recolonization in about 10% of women. Adverse perinatal outcomes associated with group B streptococcal colonization include urinary tract infection, intrauterine infection, premature rupture of membranes, preterm delivery, and postpartum metritis.

Women with postpartum metritis due to infection with group B streptococci, especially after cesarean section, develop fever, tachycardia, and abdominal pain, usually within 24 hours after delivery. Approximately 35% of these women are bacteremic.

Group B streptococcal infection is a common cause of neonatal sepsis. Transmission rates are high, yet the rate of neonatal sepsis is surprisingly low at < 1:1000 live births. Unfortunately, the mortality rate associated with early-onset disease can be as high as 20–30% in premature infants. In contrast, it is approximately 2–3% in those at term. Moreover, these infections can contribute markedly to chronic morbidity, including mental retardation and neurologic disabilities. Late-onset disease develops through contact with hospital nursery personnel. Up to 45% of

these health care workers can carry the bacteria on their skin and transmit the infection to newborns.

CDC recommendations for screening and prophylaxis for group B streptococcal colonization are set forth in this chapter in the section on Essentials of Prenatal Care: Tests and Procedures.

VARICELLA

Commonly known as chickenpox, varicella-zoster virus (VZV) infection has a fairly benign course when incurred during childhood but may result in serious illness in adults, particularly during pregnancy. Infection results in lifelong immunity. Approximately 95% of women born in the United States have VZV antibodies by the time they reach reproductive age. The incidence of VZV infection during pregnancy has been reported as up to 7:10,000.

► Clinical Findings

A. Symptoms and Signs

The incubation period for this infection is 10–20 days. A primary infection follows and is characterized by a flu-like syndrome with malaise, fever, and development of a pruritic maculopapular rash on the trunk which becomes vesicular and then crusts. Pregnant women are prone to the development of VZV pneumonia, often a fulminant infection sometimes requiring respiratory support. After primary infection, the virus becomes latent, ascending to dorsal root ganglia. Subsequent reactivation can occur as zoster, often under circumstances of immunocompromise, although this is rare during pregnancy.

Two types of fetal infection have been documented. The first is congenital VZV syndrome, which typically occurs in 0.4–2% of fetuses exposed to primary VZV infection during the first trimester. Anomalies include limb and digit abnormalities, microphthalmos, and microcephaly.

Infection during the second and third trimesters is less threatening. Maternal IgG crosses the placenta, protecting the fetus. The only infants at risk for severe infection are those born after maternal viremia but before development of maternal protective antibody. Maternal infection manifesting 5 days before or up to 2 days after delivery is the time period believed to be most hazardous for transmission to the fetus.

B. Laboratory Findings

Diagnosis is commonly made on clinical grounds. Laboratory verification of recent infection is made most often by antibody detection techniques, including ELISA, fluorescent antibody, and hemagglutination inhibition. Serum obtained by cordocentesis may be tested for VZV IgM to document fetal infection.

► Treatment

Varicella-zoster immune globulin (VZIG) has been shown to prevent or modify the symptoms of infection in some women but is no longer readily available. Treatment success depends on identification of susceptible women at or just following exposure. Women with a questionable or negative history of chickenpox should be checked for antibody, since the overwhelming majority will have been previously exposed. If the antibody is negative, VZIG (625 units intramuscularly) should be given within 96 hours after exposure. There are no known adverse effects of VZIG administration during pregnancy, although the incubation period for disease can be lengthened. Infants born within 5 days after onset of maternal infection should also receive VZIG (125 units).

Infected pregnant women should be closely observed and hospitalized at the earliest signs of pulmonary involvement. Intravenous acyclovir (10 mg/kg intravenously every 8 hours) is recommended in the treatment of VZV pneumonia.

Lamont RF et al. Varicella-zoster virus (chickenpox) infection in pregnancy. *BJOG*. 2011 Sep;118(10):1155–62. [PMID: 21585641]

TUBERCULOSIS

The diagnosis of tuberculosis in pregnancy is made by history taking, physical examination, and skin testing, with special attention to women in high-risk groups. Women at high risk include those who are from endemic areas, those infected with HIV, drug users, health care workers, and close contacts of people with tuberculosis. Chest radiographs should not be obtained as a routine screening measure in pregnancy but should be used only in patients with a skin test conversion or with suggestive findings in the history and physical examination. Abdominal shielding must be used if a chest radiograph is obtained.

Decisions on treatment depend on whether the patient has active disease or is at high risk for progression to active disease. Women who are purified protein derivative (PPD)–positive but not at high risk for disease progression can receive treatment postpartum, which does not preclude breastfeeding. The concentration of medication in breast milk is neither toxic nor adequate for treatment of the newborn. Treatment is with isoniazid and ethambutol or isoniazid and rifampin (see Chapters 9 and 33). Because isoniazid therapy may result in vitamin B₆ deficiency, a supplement of 50 mg/d of vitamin B₆ should be given simultaneously. Isoniazid, particularly in pregnant women, can cause hepatitis. Liver function tests should be performed regularly in pregnant women who receive treatment. Streptomycin, ethionamide, and most other antituberculous drugs should be avoided in pregnancy. If adequately treated, tuberculosis in pregnancy has an excellent prognosis.

Nhan-Chang CL et al. Tuberculosis in pregnancy. *Clin Obstet Gynecol*. 2010 Jun;53(2):311–21. [PMID: 20436306]

HIV/AIDS DURING PREGNANCY

Heterosexual acquisition and injection drug use are the principal identified modes of HIV infection in women. Asymptomatic infection is associated with a normal pregnancy rate and no increased risk of adverse pregnancy outcomes. There is no evidence that pregnancy causes AIDS progression.

Previously, two-thirds of HIV-positive neonates acquired their infection close to, or during, the time of delivery. Routine HIV screening in pregnancy, including the use of rapid HIV tests in Labor and Delivery units, and the use of highly active antiretroviral therapy (HAART) therapy has markedly reduced this transmission risk. Zidovudine alone (500 mg/d orally) given to the mother antenatally starting at 14 weeks of gestation and during labor (1 mg/kg/h intravenously) and then to the infant (4 mg/kg orally two times daily) for the first 6 weeks of life reduces the transmission rate from 25% to 8%. HAART reduced the risk even further, to approximately 2%, and is the standard of care. In an HIV-positive pregnant woman, a CD4 count, plasma RNA level, and resistance testing (if virus is detectable) should be obtained at the first prenatal visit. Prior or current antiretroviral use should be reviewed. A woman already taking and tolerating an acceptable HAART regimen does not have to discontinue it in the first trimester. Patients should also be tested for hepatitis C, toxoplasmosis, and cytomegalovirus.

Women not receiving therapy should be offered HAART with three drugs (commonly two nucleoside analogues and one protease inhibitor, including zidovudine whenever possible) after counseling regarding the potential impact of therapy on both mother and fetus. HAART should be offered regardless of viral load and CD4 count, and it should be started in the second trimester unless there is a maternal indication to start earlier. The majority of drugs used to treat HIV/AIDS have thus far proven to be safe in pregnancy with an acceptable risk/benefit ratio. Efavirenz has been clearly linked with anomalies (myelomeningocele) and should not be used in pregnancy, specifically the first trimester.

The use of prophylactic elective cesarean section before the onset of labor or rupture of the membranes to prevent vertical transmission of HIV infection from mother to fetus has been shown to further reduce the transmission rate. There is limited information on the impact of elective cesarean section on transmission rates in infants of mothers on HAART or with viral loads <1000 copies/mL. However, with HAART therapy and undetectable viral loads (< 50 copies/mL), the transmission risk has been estimated to be 1% or less, and there may be no additional benefit of cesarean delivery. Women with viral loads < 1000 copies/mL on HAART can be offered a vaginal delivery. Amniotomy should not be performed, and internal monitors, particularly the fetal scalp electrode, should be avoided. HIV-infected women should be advised not to breastfeed their infants.

The Public Health Task Force provides guidelines for the management of HIV/AIDS in pregnancy that are regularly updated and available at <http://www.aidsinfo.nih.gov/>. In addition, there is the National Perinatal HIV

Hotline, which provides free consultation regarding perinatal HIV care (1-888-448-8765).

MATERNAL HEPATITIS B & C CARRIER STATE

There are an estimated 350 million chronic carriers of **hepatitis B virus** worldwide. Among these people, there is an increased incidence of chronic active hepatitis, cirrhosis, and hepatocellular carcinoma. In the United States, 1.4 million people are infected, with the highest rate among Asian Americans. All pregnant women should be screened for HBsAg. Transmission of the virus to the baby after delivery is likely if both surface antigen and e antigen are positive. Vertical transmission can be blocked by the immediate postdelivery administration to the newborn of hepatitis B immunoglobulin and hepatitis B vaccine intramuscularly. The vaccine dose is repeated at 1 and 6 months of age. Successful, but limited, experience has also been reported with lamivudine during the third trimester to prevent vertical transmission of hepatitis B in mothers with high HBV viral loads. Pregnant women with chronic hepatitis B should have liver function tests during the pregnancy. Hepatitis B infection is not a contraindication to breastfeeding.

Hepatitis C virus infection is the most common chronic blood-borne infection in the United States. Risk factors for transmission include blood transfusion, injection drug use, employment in patient care or clinical laboratory work, exposure to a sex partner or household member who has had a history of hepatitis, exposure to multiple sex partners, and low socioeconomic level. The average rate of hepatitis C virus (HCV) infection among infants born to HCV-positive, HIV-negative women is 5–6%. However, the average infection rate increases to 14% when mothers are coinfecting with HCV and HIV. The principal factor associated with transmission is the presence of HCV RNA in the mother at the time of birth.

Esposti SD et al. Hepatitis B in pregnancy: challenges and treatment. *Gastroenterol Clin North Am*. 2011 Jun;40(2):355–72. [PMID: 21601784]

HERPES GENITALIS

Infection of the lower genital tract by herpes simplex virus type 2 (HSV-2) (see also Chapter 6) is a common STD with potentially serious consequences to pregnant women and their newborn infants. Although up to 20% of women in an obstetric practice may have antibodies to

HSV-2, a history of the infection is unreliable and the incidence of neonatal infection is low (8–60/100,000 live births). Most infected neonates are born to women with no symptoms, signs, or history of infection.

Women who have had *primary* herpes infection late in pregnancy are at high risk for shedding virus at delivery. Some authors suggest use of prophylactic acyclovir, 400 mg orally two to three times daily, to decrease the likelihood of active lesions at the time of labor and delivery.

Women with a history of *recurrent* genital herpes have a lower neonatal attack rate than women infected during the pregnancy, but they should still be monitored with clinical observation and culture of any suspicious lesions. Since asymptomatic viral shedding is not predictable by antepartum cultures, current recommendations do not include routine cultures in individuals with a history of herpes without active disease. However, when labor begins, vulvar and cervical inspection should be performed. Cesarean section is indicated at the time of labor if there are prodromal symptoms, active genital lesions, or a positive cervical culture obtained within the preceding week.

For treatment, see Chapter 32. The use of acyclovir in pregnancy is acceptable, and prophylaxis starting at 36 weeks gestation has been shown to decrease the number of cesarean sections performed for active disease.

SYPHILIS, GONORRHEA, & CHLAMYDIA TRACHOMATIS INFECTION (See also Chapters 33 and 34)

These STDs have significant consequences for mother and child. Untreated syphilis in pregnancy can cause late abortion, stillbirth, transplacental infection, and congenital syphilis. Gonorrhea can produce large-joint arthritis by hematogenous spread as well as ophthalmia neonatorum. Maternal chlamydial infections are largely asymptomatic but are manifested in the newborn by inclusion conjunctivitis and, at age 2–4 months, by pneumonia. The diagnosis of each can be reliably made by appropriate laboratory tests. All women should be tested for syphilis and *Chlamydia* as part of their routine prenatal care. Repeat testing is dependent on risk factors, prevalence, and state laws. Women at risk should be tested for gonorrhea. The sexual partners of women with STDs should be identified and treated also if possible; the local health department can assist with this process.

Workowski KA et al; Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2010. *MMWR Recomm Rep*. 2010 Dec 17;59(RR-12):1–110. [PMID: 21160459]

SURGICAL COMPLICATIONS DURING PREGNANCY

Although purely elective surgery should be avoided during pregnancy, women who undergo surgical procedures for an urgent or emergent indication during pregnancy do not appear to be at increased risk for adverse outcomes. Obstetric complications, when they occur, are more likely to be associated with the underlying maternal illness. Recommendations have held that the optimal time for semi-elective surgery is the second trimester to avoid exposure to anesthesia in the first trimester and the enlarged uterus in the third. Importantly, however, there is no convincing evidence that general anesthesia induces malformations or increases the risk for abortion.

CHOLELITHIASIS, CHOLECYSTITIS, & INTRAHEPATIC CHOLESTASIS OF PREGNANCY

Cholelithiasis is common in pregnancy as physiologic changes such as incomplete gallbladder emptying predispose to gallstone formation. The diagnosis is usually suspected based on classic symptoms of right upper quadrant pain, usually after meals, and is confirmed with right upper quadrant ultrasound. Symptomatic cholelithiasis without cholecystitis is usually managed conservatively, but recurrent symptoms are common. Cholecystitis results from obstruction of the cystic duct and often is accompanied by bacterial infection. Medical management with antibiotics is reasonable in selected cases, but definitive treatment with cholecystectomy will help prevent complications such as gallbladder perforation and pancreatitis. Cholecystectomy has successfully been performed in all trimesters of pregnancy and should not be withheld based on the stage of pregnancy if clinically indicated. Laparoscopy is preferred in the first half of pregnancy but becomes technically difficult in the last trimester due to the enlarged uterus and cephalad displacement of abdominal contents.

Obstruction of the common duct can lead to cholangitis requiring surgical removal of gallstones and establishment of biliary drainage. Endoscopic retrograde cholangiopancreatography (ERCP) and endoscopic retrograde sphincterotomy can be performed safely in pregnant women if precautions are taken to minimize exposure to radiation. There does, however, appear to be a slightly higher rate of post-procedure pancreatitis in pregnant women who undergo ERCP.

Intrahepatic cholestasis of pregnancy is characterized by incomplete clearance of bile acids in genetically susceptible women. The main symptom of generalized pruritus usually occurs in the third trimester. Laboratory studies reveal hepatic dysfunction with elevations in serum bile acids. Hepatic transaminase levels may also be modestly elevated, and mild bilirubin elevations may even result in clinical jaundice. Ursodeoxycholic acid (8–10 mg/kg/d) is the treatment of choice and results in decreased pruritus in most women. Cholestyramine has also been used, but it does not appear to be as effective and impairs absorption of fat-soluble vitamins. Vitamin K supplementation is therefore required to help prevent hemorrhagic disease in the fetus. Symptoms ultimately resolve after delivery but

often recur in subsequent pregnancies. Adverse fetal outcomes, particularly fetal distress, meconium-stained amniotic fluid, and stillbirth, have been reported in women with cholestasis of pregnancy. Because of these risks, many clinicians recommend antenatal testing in the third trimester and delivery around 38 weeks gestation. Evidence-based recommendations, however, are not available.

Tang SJ et al. Safety and utility of ERCP during pregnancy. *Gastrointest Endosc.* 2009 Mar;69(3 Pt 1):453–61. [PMID: 19136111]

APPENDICITIS

Appendicitis occurs in about 1 of 1500 pregnancies. The diagnosis is often difficult to make clinically since the appendix is displaced cephalad from McBurney point. Furthermore, nausea, vomiting, and mild leukocytosis occur in normal pregnancy, so with or without these findings, any complaint of right-sided pain should raise suspicion. CT scanning can help confirm the diagnosis when clinical findings are equivocal, and proper shielding can minimize radiation exposure to the fetus. MRI is also being increasingly used to evaluate for appendicitis in pregnant women and appears to be a reasonable alternative to CT scanning. Unfortunately, the diagnosis of appendicitis is not made until the appendix has ruptured in at least 20% of obstetric patients. Peritonitis in these cases can lead to preterm labor or abortion. With early diagnosis and appendectomy, the prognosis is good for mother and baby.

Blumenfeld YJ et al. MR imaging in cases of antenatal suspected appendicitis—a meta-analysis. *J Matern Fetal Neonatal Med.* 2011 Mar;24(3):485–8. [PMID: 20695758]
Parangi S et al. Surgical gastrointestinal disorders during pregnancy. *Am J Surg.* 2007 Feb;193(2):223–32. [PMID: 17236852]

CARCINOMA OF THE BREAST

Carcinoma of the breast (see also Chapter 17) is one of the most commonly diagnosed cancers in pregnancy. Although the effects of pregnancy on breast cancer progression are unclear, it has been consistently reported that breast cancers diagnosed during pregnancy are more likely to have higher grade disease with associated nodal involvement when compared with those diagnosed in nonpregnant women. This observation underscores the importance of expeditious evaluation of any breast mass in a pregnant woman. Although breast enlargement and glandular hyperplasia during pregnancy and the puerperium may limit the radiographic evaluation, both ultrasonography and mammography are useful for characterizing a mass. Ultimately, however, biopsy is required for any suspicious lesion. If breast biopsy confirms the diagnosis of cancer, surgery should not be withheld based on the stage of the pregnancy. If chemotherapy is indicated and the pregnancy is early, termination can be considered. If the pregnancy is more advanced, it may be appropriate to

administer chemotherapeutic agents during the pregnancy to avoid a delay in treatment. Cases need to be individualized and should be managed by a multidisciplinary team with experience in treating both patients with cancer and high-risk pregnancies.

Guidroz JA et al. Management of pregnant women with breast cancer. *J Surg Oncol.* 2011 Mar 15;103(4):337–40. [PMID: 21337568]

OVARIAN TUMORS

The management of an adnexal mass in pregnancy depends on the gestational age at which it is diagnosed and the likelihood that complications will develop. In early pregnancy, the corpus luteum is frequently observed using transvaginal ultrasound and appears as a simple cyst. The corpus luteum provides progesterone support of the pregnancy until the placenta assumes this role in the latter part of the first trimester. Although uncommon, corpus luteum cysts may enlarge and undergo hemorrhage or torsion and become symptomatic. If resection is required prior to 10 weeks gestation, supplementation with progesterone should be given through the 10th week.

The management of asymptomatic adnexal masses identified in early pregnancy depends on the size and

sonographic appearance of the mass. In general, masses that are small (< 5 cm), cystic, and simple require no follow-up. Larger masses or those with complex features are usually followed with repeat ultrasound in the early second trimester. Those that persist may require surgical resection, particularly if they are large (≥ 5 cm) or have features that are suspicious for malignancy, such as thick internal septations or papillary excrescences. Larger masses, even when benign, increase the risk for ovarian torsion, which can result in adnexal necrosis, peritonitis and preterm labor. The risk for ovarian torsion appears to be greatest in the first half of pregnancy as the gravid uterus grows out of the pelvis. Elective removal in the early second trimester can prevent this complication. It should be emphasized, however, that the optimal management of persistent masses of intermediate size (5–10 cm) that are believed to be benign is unclear, and decisions should be made on an individual basis. If there is suspicion for ovarian cancer, preoperative consultation with a practitioner experienced in treating gynecologic malignancies is appropriate.

► Diagnosis & Evaluation

A. Examination of the Patient

In the patient with arthritis, the two clinical clues most helpful for diagnosis are the **joint pattern** and the **presence or absence of extra-articular manifestations**. The joint pattern is defined by the answers to three questions: (1) Is inflammation present? (2) How many joints are involved? and (3) What joints are affected? Joint inflammation manifests as redness, warmth, swelling, and morning stiffness of at least 30 minutes' duration. Both the number of affected joints and the specific sites of involvement affect the differential diagnosis (Table 20–1). Some diseases—gout, for example—are characteristically monoarticular, whereas other diseases, such as rheumatoid arthritis, are usually polyarticular. The location of joint involvement can also be distinctive. Only two diseases frequently cause prominent involvement of the distal interphalangeal (DIP) joint: osteoarthritis and psoriatic arthritis. Extra-articular manifestations such as fever (eg, gout, Still disease, endocarditis), rash (eg, systemic lupus erythematosus, psoriatic arthritis, Still disease), nodules (eg, rheumatoid arthritis, gout), or neuropathy (eg, polyarteritis nodosa, granulomatosis with polyangiitis [formerly Wegener granulomatosis]) narrow the differential diagnosis further.

B. Arthrocentesis and Examination of Joint Fluid

If the diagnosis is uncertain, synovial fluid should be examined whenever possible (Table 20–2). Most large joints are easily aspirated, and contraindications to arthrocentesis are few. The aspirating needle should never be passed through an overlying cellulitis or psoriatic plaque because of the risk of introducing infection. For patients who are receiving long-term anticoagulation therapy with warfarin, joints can be aspirated with a small-gauge needle (eg, 22F) if the international normalized ratio (INR) is < 3.0.

1. Types of studies

A. GROSS EXAMINATION—Clarity is an approximate guide to the degree of inflammation. Noninflammatory fluid is transparent, mild inflammation produces translucent fluid, and purulent effusions are opaque. Bleeding disorders,

trauma, and traumatic taps are the most common causes of bloody effusions.

B. CELL COUNT—The synovial fluid white cell count discriminates between **noninflammatory** (< 2000 white cells/mcL), **inflammatory** (2000–75,000 white cells/mcL), and **purulent** (> 100,000 white cells/mcL) joint effusions. Synovial fluid glucose and protein levels add little information and should not be ordered.

C. MICROSCOPIC EXAMINATION—Compensated polarized light microscopy identifies and distinguishes monosodium urate (gout, negatively birefringent) and calcium pyrophosphate (pseudogout, positive birefringent) crystals. Gram stain has specificity but limited sensitivity (50%) for septic arthritis.

D. CULTURE—Bacterial cultures as well as special studies for gonococci, tubercle bacilli, or fungi are ordered as appropriate.

2. Interpretation—Synovial fluid analysis is diagnostic in infectious or microcrystalline arthritis. Although the severity of inflammation in synovial fluid can overlap among various conditions, the synovial fluid white cell count is a helpful guide to diagnosis (Table 20–3).

DEGENERATIVE & CRYSTAL-INDUCED ARTHRITIS

DEGENERATIVE JOINT DISEASE (Osteoarthritis)

ESSENTIALS OF DIAGNOSIS

- ▶ A degenerative disorder with minimal articular inflammation.
- ▶ No systemic symptoms.
- ▶ Pain relieved by rest; morning stiffness brief.
- ▶ Radiographic findings: narrowed joint space, osteophytes, increased density of subchondral bone, bony cysts.

Table 20-1. Diagnostic value of the joint pattern.

Characteristic	Status	Representative Disease
Inflammation	Present	Rheumatoid arthritis, systemic lupus erythematosus, gout
	Absent	Osteoarthritis
Number of involved joints	Monarticular	Gout, trauma, septic arthritis, Lyme disease, osteoarthritis
	Oligoarticular (2-4 joints)	Reactive arthritis, psoriatic arthritis, inflammatory bowel disease
	Polyarticular (≥ 5 joints)	Rheumatoid arthritis, systemic lupus erythematosus
Site of joint involvement	Distal interphalangeal	Osteoarthritis, psoriatic arthritis (not rheumatoid arthritis)
	Metacarpophalangeal, wrists	Rheumatoid arthritis, systemic lupus erythematosus, calcium pyrophosphate deposition disease (not osteoarthritis)
	First metatarsal phalangeal	Gout, osteoarthritis

► General Considerations

Osteoarthritis, the most common form of joint disease, is chiefly a disease of aging. Ninety percent of all people have radiographic features of osteoarthritis in weight-bearing joints by age 40. Symptomatic disease also increases with age. Gender is also a risk factor, because osteoarthritis develops in women more frequently than in men.

This arthropathy is characterized by degeneration of cartilage and by hypertrophy of bone at the articular margins. Inflammation is usually minimal. Hereditary and mechanical factors may be involved in the pathogenesis.

Obesity is a risk factor for osteoarthritis of the knee, hand, and probably of the hip. Recreational running does

not increase the incidence of osteoarthritis, but participation in competitive contact sports does. Jobs requiring frequent bending and carrying increase the risk of knee osteoarthritis.

► Clinical Findings

A. Symptoms and Signs

Degenerative joint disease is divided into two types: (1) primary, which most commonly affects some or all of the following: the DIP and the proximal interphalangeal (PIP) joints of the fingers, the carpometacarpal joint of the thumb, the hip, the knee, the metatarsophalangeal (MTP) joint of the big toe, and the cervical and lumbar spine; and (2) secondary, which may occur in any joint as a sequela to articular injury resulting from either intra-articular (including rheumatoid arthritis) or extra-articular causes. The injury may be acute, as in a fracture; or chronic, as that due to occupational overuse of a joint, metabolic disease (eg, hyperparathyroidism, hemochromatosis, ochronosis), or neurologic disorders (syringomyelia; see below).

The onset is insidious. Initially, there is articular stiffness, seldom lasting more than 15 minutes; this develops later into pain on motion of the affected joint and is made worse by activity or weight bearing and relieved by rest. Flexion contracture or varus deformity of the knee is not unusual, and bony enlargements of the DIP (Heberden nodes) and PIP (Bouchard nodes) are occasionally prominent (Figure 20-1). There is no ankylosis, but limitation of motion of the affected joint or joints is common. Crepitus may often be felt over the knee. Joint effusion and other articular signs of inflammation are mild. There are no systemic manifestations.

B. Laboratory Findings

Osteoarthritis does not cause elevation of the erythrocyte sedimentation rate (ESR) or other laboratory signs of inflammation. Synovial fluid is noninflammatory.

Table 20-2. Examination of joint fluid.

Measure	(Normal)	Group I (Noninflammatory)	Group II (Inflammatory)	Group III (Purulent)
Volume (mL) (knee)	< 3.5	Often > 3.5	Often > 3.5	Often > 3.5
Clarity	Transparent	Transparent	Translucent to opaque	Opaque
Color	Clear	Yellow	Yellow to opalescent	Yellow to green
WBC (per mL)	< 200	< 2000	2000-75,000 ¹	> 100,000 ²
Polymorphonuclear leukocytes	< 25%	< 25%	50% or more	75% or more
Culture	Negative	Negative	Negative	Usually positive ²

¹Gout, rheumatoid arthritis, and other inflammatory conditions occasionally have synovial fluid WBC counts > 75,000/mcL but rarely > 100,000/mcL.

²Most purulent effusions are due to septic arthritis. Septic arthritis, however, can present with group II synovial fluid, particularly if infection is caused by organisms of low virulence (eg, *Neisseria gonorrhoeae*) or if antibiotic therapy has been started.

WBC, white blood cell count.

Table 20-3. Differential diagnosis by joint fluid groups.

Group I (Noninflammatory) (< 2000 white cells/mcl)	Group II (Inflammatory) (2000 – $75,000$ white cells/mcl)	Group III (Purulent) ($> 100,000$ white cells/mcl)	Hemorrhagic
Degenerative joint disease Trauma ¹ Osteochondritis dissecans Osteochondromatosis Neuropathic arthropathy ¹ Subsiding or early inflammation Hypertrophic osteoarthropathy ² Pigmented villonodular synovitis ¹	Rheumatoid arthritis Acute crystal-induced synovitis (gout and pseudogout) Reactive arthritis Ankylosing spondylitis Rheumatic fever ² Tuberculosis	Pyogenic bacterial infections	Hemophilia or other hemorrhagic diathesis Trauma with or without fracture Neuropathic arthropathy Pigmented villonodular synovitis Synovioma Hemangioma and other benign neoplasms

¹May be hemorrhagic.

²Noninflammatory or inflammatory group.

Reproduced, with permission, from Rodnan GP (editor). Primer on the rheumatic diseases, 7th ed. JAMA. 1973;224(Suppl):662.

C. Imaging

Radiographs may reveal narrowing of the joint space; osteophyte formation and lipping of marginal bone; and thickened, dense subchondral bone. Bone cysts may also be present.

Differential Diagnosis

Because articular inflammation is minimal and systemic manifestations are absent, degenerative joint disease should seldom be confused with other arthritides. The distribution of joint involvement in the hands also helps distinguish osteoarthritis from rheumatoid arthritis. Osteoarthritis chiefly affects the DIP and PIP joints and spares the wrist and metacarpophalangeal (MCP) joints; rheumatoid arthritis involves the wrists and MCP joints and spares the DIP joints. Furthermore, the joint enlargement is bony-hard and

▲ Figure 20-1. Osteoarthritis with bony enlargement of the distal interphalangeal (DIP) joints (Heberden nodes) and proximal interphalangeal (PIP) joints (Bouchard nodes). (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

cool in osteoarthritis but spongy and warm in rheumatoid arthritis. Skeletal symptoms due to degenerative changes in joints—especially in the spine—may cause coexistent metastatic neoplasia, osteoporosis, multiple myeloma, or other bone disease to be overlooked.

Prevention

Weight reduction reduces the risk of developing symptomatic knee osteoarthritis. Correcting leg length discrepancy of > 1 cm with shoe modification may prevent knee osteoarthritis from developing in the shorter leg. Maintaining normal vitamin D levels may reduce the occurrence and progression of osteoarthritis, in addition to being important for bone health.

Treatment

A. General Measures

For patients with mild to moderate osteoarthritis of weight-bearing joints, moderate physical activity (eg, a supervised walking program, hydrotherapy classes, or Tai Chi classes), and use of assistive devices (eg, a cane on the contralateral side) may result in clinical improvement of functional status without aggravating the joint pain. Weight loss can also improve the symptoms.

B. Analgesic and Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) (see Table 5-3) are more effective (and more toxic) than acetaminophen for osteoarthritis of the knee or hip. Their superiority is most convincing in persons with severe disease. Patients with mild disease should start with acetaminophen (2.6–4 g/d). NSAIDs should be considered for patients who do not respond to acetaminophen. (See discussion of NSAID toxicity in the section on treatment of rheumatoid arthritis.) High doses of NSAIDs, as used in the inflammatory arthritides, are unnecessary. A topical NSAID—diclofenac gel 1% is approved by the US Food and Drug Administration (FDA) for treatment of osteoarthritis; the recommended dose is 4 g applied to the affected

joint four times daily. Topical diclofenac appears more effective than placebo for knee and hand osteoarthritis. Rates of systemic side effects are lower with topical than with oral diclofenac. Few studies have compared the efficacy of oral and topical NSAIDs. Chondroitin sulfate and glucosamine, alone or in combination, are no better than placebo in reducing pain in patients with knee or hip osteoarthritis.

For many patients, it is possible eventually to reduce the dosage or limit use of drugs to periods of exacerbation. For patients with knee osteoarthritis and effusion, intra-articular injection of triamcinolone (20–40 mg) may obviate the need for analgesics or NSAIDs. Corticosteroid injections up to four times a year appear to be safe. Intra-articular injections of sodium hyaluronate reduce symptoms moderately in some patients. Capsaicin cream 0.025–0.075% applied three or four times a day can also reduce knee pain without NSAIDs.

C. Surgical Measures

Total hip and knee replacements provide excellent symptomatic and functional improvement when involvement of that joint severely restricts walking or causes pain at rest, particularly at night. Arthroscopic surgery for knee osteoarthritis is ineffective.

► Prognosis

Marked disability is less common in patients with osteoarthritis than in those with rheumatoid arthritis, but symptoms may be quite severe and limit activity considerably (especially with involvement of the hips, knees, and cervical spine).

► When to Refer

- Refer patients to an orthopedic surgeon when recalcitrant symptoms or functional impairment, or both, warrant consideration of joint replacement surgery of the hip or knee.

CRYSTAL DEPOSITION ARTHRITIS

1. Gouty Arthritis

ESSENTIALS OF DIAGNOSIS

- ▶ Acute onset, usually monarticular, recurring attacks, often involving the first MTP joint.
- ▶ Polyarticular involvement more common in patients with long-standing disease.
- ▶ Identification of urate crystals in joint fluid or tophi is diagnostic.
- ▶ Dramatic therapeutic response to NSAIDs.
- ▶ With chronicity, urate deposits in subcutaneous tissue, bone, cartilage, joints, and other tissues.

► General Considerations

Gout is a metabolic disease of a heterogeneous nature, often familial, associated with abnormal amounts of urates in the body and characterized early by a recurring acute arthritis, usually monarticular, and later by chronic deforming arthritis. The associated hyperuricemia is due to overproduction or underexcretion of uric acid—sometimes both. The disease is especially common in Pacific islanders, eg, Filipinos and Samoans. Primary gout has a heritable component, and genome-wide surveys have linked risk of gout to several genes whose products regulate urate handling by the kidney. Secondary gout, which may have a heritable component, is related to acquired causes of hyperuricemia, eg, medication use (especially diuretics, low-dose aspirin, cyclosporine, and niacin), myeloproliferative disorders, multiple myeloma, hemoglobinopathies, chronic kidney disease, hypothyroidism, psoriasis, sarcoidosis, and lead poisoning (Table 20–4). Alcohol ingestion promotes hyperuricemia by increasing urate production and decreasing the renal excretion of uric acid. Finally, hospitalized patients frequently suffer attacks of gout because of changes in diet, fluid intake, or medications that lead either to rapid reductions or increases in the serum urate level.

About 90% of patients with primary gout are men, usually over 30 years of age. In women, the onset is typically postmenopausal. The characteristic lesion is the tophus, a nodular deposit of monosodium urate monohydrate crystals with an associated foreign body reaction. Tophi are found in cartilage, subcutaneous and periarticular tissues, tendon, bone, the kidneys, and elsewhere. Urates have been demonstrated in the synovial tissues (and fluid) during acute arthritis; indeed, the acute inflammation of gout is believed to be initiated by the ingestion of uncoated urate crystals by monocytes and synoviocytes. Once inside the cells, the gout crystals are processed through Toll-like receptors and activate NALP-3 inflammasomes which in turn release a variety of chemotactic agents and cytokines capable of mediating inflammation. The precise relationship of hyperuricemia to gouty arthritis is still obscure, since chronic hyperuricemia is found in people who never

Table 20-4. Origin of hyperuricemia.**Primary hyperuricemia**

- A. Increased production of purine
 1. Idiopathic
 2. Specific enzyme defects (eg, Lesch-Nyhan syndrome, glycogen storage diseases)
- B. Decreased renal clearance of uric acid (idiopathic)

Secondary hyperuricemia

- A. Increased catabolism and turnover of purine
 1. Myeloproliferative disorders
 2. Lymphoproliferative disorders
 3. Carcinoma and sarcoma (disseminated)
 4. Chronic hemolytic anemias
 5. Cytotoxic drugs
 6. Psoriasis
- B. Decreased renal clearance of uric acid
 1. Intrinsic kidney disease
 2. Functional impairment of tubular transport
 - a. Drug-induced (eg, thiazides, low-dose aspirin)
 - b. Hyperlactacidemia (eg, lactic acidosis, alcoholism)
 - c. Hyperketoacidemia (eg, diabetic ketoacidosis, starvation)
 - d. Diabetes insipidus (vasopressin-resistant)
 - e. Bartter syndrome

Modified, with permission, from Rodnan GP. Gout and other crystalline forms of arthritis. *Postgrad Med.* 1975 Oct;58(5):6-14.

develop gout or uric acid stones. Rapid fluctuations in serum urate levels, either increasing or decreasing, are important factors in precipitating acute gout. The mechanism of the late, chronic stage of gouty arthritis is better understood. This is characterized pathologically by tophaceous invasion of the articular and periarticular tissues, with structural derangement and secondary degeneration (osteoarthritis).

Uric acid kidney stones are present in 5–10% of patients with gouty arthritis. Hyperuricemia correlates highly with the likelihood of developing stones, with the risk of stone formation reaching 50% in patients with a serum urate level > 13 mg/dL. Chronic urate nephropathy is caused by the deposition of monosodium urate crystals in the renal medulla and pyramids. Although progressive chronic kidney disease occurs in a substantial percentage of patients with chronic gout, the role of hyperuricemia in causing this outcome is controversial, because many patients with gout have numerous confounding risk factors for chronic kidney disease (eg, hypertension, alcohol use, lead exposure, and other risk factors for vascular disease).

▶ Clinical Findings

A. Symptoms and Signs

Acute gouty arthritis is sudden in onset and frequently nocturnal. It may develop without apparent precipitating cause or may follow rapid increases or decreases in serum urate levels. Common precipitants are alcohol excess (particularly beer), changes in medications that affect urate metabolism, and, in the hospitalized patient, fasting before medical procedures. The MTP joint of the great toe is the most susceptible

joint (“podagra”), although others, especially those of the feet, ankles, and knees, are commonly affected. Gouty attacks may develop in periarticular soft tissues such as the arch of the foot. Hips and shoulders are rarely affected. More than one joint may occasionally be affected during the same attack; in such cases, the distribution of the arthritis is usually asymmetric. As the attack progresses, the pain becomes intense. The involved joints are swollen and exquisitely tender and the overlying skin tense, warm, and dusky red. Fever is common and may reach 39°C. Local desquamation and pruritus during recovery from the acute arthritis are characteristic of gout but are not always present. Tophi may be found in the external ears, feet, olecranon and prepatellar bursae, and hands (Figure 20–2). They usually develop years after the initial attack of gout.

Asymptomatic periods of months or years commonly follow the initial acute attack. After years of recurrent severe monoarthritis attacks of the lower extremities and untreated hyperuricemia, gout can evolve into a chronic, deforming polyarthritis of upper and lower extremities that mimics rheumatoid arthritis.

B. Laboratory Findings

The serum uric acid is elevated (> 7.4 mg/dL) in 95% of patients who have serial measurements during the course of an attack. However, a single uric acid determination is normal in up to 25% of cases, so it does not exclude gout,

▲ **Figure 20-2.** Acute gouty arthritis superimposed on tophaceous gout. (Courtesy of the Western Journal of Medicine and JM Geiderman, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ, Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

especially in patients taking urate-lowering drugs. During an acute attack, the peripheral blood white cell count is frequently elevated. Identification of sodium urate crystals in joint fluid or material aspirated from a tophus establishes the diagnosis. The crystals, which may be extracellular or found within neutrophils, are needle-like and negatively birefringent when examined by polarized light microscopy.

C. Imaging

Early in the disease, radiographs show no changes. Later, punched-out erosions with an overhanging rim of cortical bone (“rat bite”) develop. When these are adjacent to a soft tissue tophus, they are diagnostic of gout.

► Differential Diagnosis

Acute gout is often confused with cellulitis. Bacteriologic studies usually exclude acute pyogenic arthritis. Pseudogout is distinguished by the identification of calcium pyrophosphate crystals (positive birefringence) in the joint fluid, usually normal serum uric acid, and the radiographic appearance of chondrocalcinosis.

Chronic tophaceous arthritis may resemble chronic rheumatoid arthritis; gout is suggested by an earlier history of monarthritis and is established by the demonstration of urate crystals in a suspected tophus. Likewise, hips and shoulders are generally spared in tophaceous gout. Biopsy may be necessary to distinguish tophi from rheumatoid nodules. A radiographic appearance similar to that of gout may be found in rheumatoid arthritis, sarcoidosis, multiple myeloma, hyperparathyroidism, or Hand-Schüller-Christian disease. Chronic lead intoxication may result in attacks of gouty arthritis (saturnine gout).

► Treatment

A. Asymptomatic Hyperuricemia

Asymptomatic hyperuricemia should not be treated; uric acid-lowering drugs need not be instituted until arthritis, renal calculi, or tophi become apparent.

B. Acute Attack

Arthritis is treated first and hyperuricemia weeks or months later, if at all. Sudden reduction of serum uric acid often precipitates further episodes of gouty arthritis.

1. NSAIDs—These drugs (see Table 5–3) are the treatment of choice for acute gout. Traditionally, indomethacin has been the most frequently used agent, but all of the other newer NSAIDs are probably equally effective. Indomethacin is initiated at a dosage of 25–50 mg orally every 8 hours and continued until the symptoms have resolved (usually 5–10 days). Active peptic ulcer disease, impaired kidney function, and a history of allergic reaction to NSAIDs are contraindications. For patients at high risk for upper gastrointestinal bleeding, celecoxib (200 mg twice a day on day 1 then 100 mg twice daily until resolution), a cyclooxygenase type 2 (COX-2) inhibitor, may be an appropriate first choice for management of an acute gout attack. Long-term

use of COX-2 inhibitors is not advised because of the association with increased risk of cardiovascular events, which has led to the removal of some drugs (eg, rofecoxib and valdecoxib) from the US market.

2. Colchicine—Neither oral nor intravenous colchicine should be used for the treatment of acute gout flares. A patient who is taking prophylactic doses of colchicine may continue it through the flare. The use of oral colchicine during the intercritical period to prevent gout attacks is discussed below.

3. Corticosteroids—Corticosteroids often give dramatic symptomatic relief in acute episodes of gout and will control most attacks. They are most useful in patients with contraindications to the use of NSAIDs. Corticosteroids may be given intravenously (eg, methylprednisolone, 40 mg/d tapered over 7 days) or orally (eg, prednisone, 40–60 mg/d tapered over 7 days). If the patient’s gout is monarticular, intra-articular administration (eg, triamcinolone, 10–40 mg depending on the size of the joint) is very effective. Because gouty and septic arthritis can coexist, albeit rarely, joint aspiration and Gram stain with culture of synovial fluid should be performed when intra-articular corticosteroids are given.

4. Anakinra—Uncontrolled studies suggest that this interleukin-1 receptor antagonist has efficacy for the management of acute gout.

C. Management between Attacks

Treatment during symptom-free periods is intended to minimize urate deposition in tissues, which causes chronic tophaceous arthritis, and to reduce the frequency and severity of recurrences. Patients with a single episode of gout who are willing to lose weight and stop drinking alcohol are at low risk for another attack and unlikely to benefit from long-term medical therapy. In contrast, older individuals with mild chronic kidney disease who require diuretic use and have a history of multiple attacks of gout are more likely to benefit from pharmacologic treatment. In general, the higher the uric acid level and the more frequent the attacks, the more likely that long-term medical therapy will be beneficial.

1. Diet—Potentially reversible causes of hyperuricemia are a high-purine diet, obesity, alcohol consumption, and use of certain medications (see below). Beer consumption appears to confer a higher risk of gout than does whiskey or wine. Higher levels of meat and seafood consumption are associated with increased risks of gout, whereas a higher level of dairy products consumption is associated with a decreased risk. Although dietary purines usually contribute only 1 mg/dL to the serum uric acid level, moderation in eating foods with high purine content is advisable (Table 20–5). A high liquid intake and, more importantly, a daily urinary output of 2 L or more will aid urate excretion and minimize urate precipitation in the urinary tract.

2. Avoidance of hyperuricemic medications—Thiazide and loop diuretics inhibit renal excretion of uric acid and

Table 20-5. The purine content of foods.¹**Low-purine foods**

Refined cereals and cereal products, cornflakes, white bread, pasta, flour, arrowroot, sago, tapioca, cakes
 Milk, milk products, and eggs
 Sugar, sweets, and gelatin
 Butter, polyunsaturated margarine, and all other fats
 Fruit, nuts, and peanut butter
 Lettuce, tomatoes, and green vegetables (except those listed below)
 Cream soups made with low-purine vegetables but without meat or meat stock
 Water, fruit juice, cordials, and carbonated drinks

High-purine foods

All meats, including organ meats, and seafood
 Meat extracts and gravies
 Yeast and yeast extracts, beer, and other alcoholic beverages
 Beans, peas, lentils, oatmeal, spinach, asparagus, cauliflower, and mushrooms

¹The purine content of a food reflects its nucleoprotein content and turnover. Foods containing many nuclei (eg, liver) have many purines, as do rapidly growing foods such as asparagus. The consumption of large amounts of a food containing a small concentration of purines may provide a greater purine load than consumption of a small amount of a food containing a large concentration of purines.

Reproduced, with permission, from Emmerson BT. The management of gout. *N Engl J Med.* 1996 Feb 15;334(7):445-51.

should be avoided in patients with gout. Similarly, low doses of aspirin aggravate hyperuricemia, as does niacin.

3. Colchicine—There are two indications for daily colchicine administration. First, colchicine can be used to prevent future attacks. For the person who has mild hyperuricemia and occasional attacks of gouty arthritis, long-term colchicine prophylaxis may be all that is needed. Second, colchicine can also be used when uricosuric drugs or allopurinol (see below) are started, to suppress attacks precipitated by abrupt changes in the serum uric acid level. For either indication, the usual dose is 0.6 mg either once or twice a day. Colchicine is renally cleared. Patients who have coexisting moderate chronic kidney disease should take colchicine only once a day or once every other day in order to avoid the peripheral neuromyopathy and other complications of colchicine toxicity.

4. Reduction of serum uric acid—Indications for a urate lowering intervention include frequent acute arthritis not controlled by colchicine prophylaxis, tophaceous deposits, or kidney damage. Hyperuricemia with infrequent attacks of arthritis may not require treatment. If instituted, the goal of medical treatment is to maintain the serum uric acid at or below 6 mg/dL, which allows urate crystals to solubilize.

Three classes of agents may be used to lower the serum uric acid—the uricosuric drugs, xanthine oxidase inhibitors (allopurinol or febuxostat), and uricase (pegloticase); none is of value in the treatment of acute gout. Choosing between uricosuric drugs and allopurinol depends on the

result of a 24-hour urine uric acid determination. A value under 800 mg/d indicates undersecretion of uric acid, which is amenable to uricosuric agents if kidney function is preserved or to a xanthine oxidase inhibitor (allopurinol or febuxostat) if kidney function is limited. Patients with > 800 mg of uric acid in a 24-hour urine collection are overproducers and require a xanthine oxidase inhibitor. The uricase, pegloticase, requires intravenous administration and is indicated only in patients with chronic gout refractory to other treatments.

A. URICOSURIC DRUGS—Uricosuric drugs, which block the tubular reabsorption of filtered urate thereby reducing the metabolic urate pool, prevent the formation of new tophi and reduce the size of those already present. When administered concomitantly with colchicine, they may lessen the frequency of recurrences of acute gout. The indication for uricosuric treatment is the increasing frequency or severity of acute attacks. Uricosuric agents are ineffective in patients with an estimated glomerular filtration rate of < 60 mL/min.

The following uricosuric drugs may be used: (1) Probenecid, 0.5 g orally daily initially, with gradual increase to 1–2 g daily; or (2) sulfinpyrazone, 50–100 mg orally twice daily initially, with gradual increase to 200–400 mg twice daily. Hypersensitivity to either with fever and rash occurs in 5% of cases; gastrointestinal complaints are observed in 10%. Probenecid also inhibits the excretion of penicillin, indomethacin, dapsone, and acetazolamide.

Precautions with uricosuric drugs include maintaining a daily urinary output of 2000 mL or more in order to minimize the precipitation of uric acid in the urinary tract. This can be further prevented by giving alkalinizing agents (eg, potassium citrate, 30–80 mEq/d orally) to maintain a urine pH of > 6.0. Uricosuric drugs should not be used in patients with a history of uric acid nephrolithiasis. Aspirin in moderate doses antagonizes the action of uricosuric agents, but low doses (325 mg or less per day) do not; doses of aspirin > 3 g daily are themselves uricosuric.

B. XANTHINE OXIDASE INHIBITORS—The xanthine oxidase inhibitors promptly lower plasma urate and urinary uric acid concentrations and facilitate tophus mobilization. Inhibitors of xanthine oxidase are of special value in uric acid overproducers; in tophaceous gout; in patients unresponsive to the uricosuric regimen; and in gouty patients with uric acid renal calculi. Asymptomatic hyperuricemia should not be treated. Two xanthine oxidase inhibitors are available for treating chronic gout: allopurinol and febuxostat. One or the other should be chosen; allopurinol and febuxostat are not to be used together. The most frequent adverse effect with either medication is the precipitation of an acute gouty attack; thus, patients generally should be receiving prophylactic doses of colchicine and should not be experiencing an acute flare when xanthine oxidase inhibitors are initiated. Hypersensitivity to allopurinol occurs in 2% of cases and can be life-threatening. The most common sign of hypersensitivity is a pruritic rash that may progress to toxic epidermal necrolysis, particularly if allopurinol is continued; vasculitis and hepatitis are other manifestations. Patients should be instructed to stop

allopurinol immediately if a rash develops. Febuxostat apparently does not cause the hypersensitivity reactions seen with allopurinol and can be given without dose adjustment to patients with mild to moderate renal disease. However, 2–3% of patients taking febuxostat may develop abnormal liver function tests. In addition, one clinical study showed that febuxostat was associated with a slightly higher rate of fatal and non-fatal cardiovascular events than allopurinol (0.97 vs 0.58 per 100 patient-years).

The initial daily dose of allopurinol is 300 mg/d orally for most patients who have normal kidney function; the dose of allopurinol should be increased in 100-mg increments to achieve the desired serum uric acid level of ≤ 6.0 mg/dL. Successful treatment usually requires a dose of 300–400 mg of allopurinol daily. The maximum daily dose is 800 mg. Allopurinol can be used in chronic kidney disease, but the dose must be reduced to decrease the chance of side effects. For patients with renal impairment, the initial dose should be 50–100 mg daily.

Allopurinol interacts with other drugs. The combined use of allopurinol and ampicillin causes a drug rash in 20% of patients. Allopurinol can increase the half-life of probenecid, while probenecid increases the excretion of allopurinol. Thus, a patient taking both drugs may need to use slightly higher than usual doses of allopurinol and lower doses of probenecid. The initial dose of febuxostat is 40 mg/d orally. If the target serum uric acid is not reached within 2 weeks, then the dose of febuxostat can be increased to its maximum of 80 mg/d.

C. URICASE—Nonprimate mammals do not develop gout because they have an enzyme—uricase—that ensures that purine metabolism does not end with urate but the much more soluble metabolite, allantoin. In humans, the gene for uricase has been inactivated by a missense mutation, so purine metabolism dead ends with the production of uric acid, which becomes insoluble above a level of 6.8 mg/dL. Pegloticase, a recombinant uricase that must be administered intravenously (8 mg every 2 weeks), is indicated for the rare patient with chronic tophaceous gout who is refractory to all other therapies. Pegloticase carries a “Black Box Warning,” which advises administering the drug only in healthcare settings and by healthcare professionals prepared to manage anaphylactic and other serious infusion reactions.

D. Chronic Tophaceous Arthritis

With rigorous medical compliance, allopurinol or febuxostat or pegloticase shrinks tophi and in time can lead to their disappearance. Resorption of extensive tophi requires maintaining a serum uric acid below 6 mg/dL. Surgical excision of large tophi offers mechanical improvement in selected deformities.

E. Gout in the Transplant Patient

Hyperuricemia and gout commonly develop in many transplant patients because they have decreased kidney function and require drugs that inhibit uric acid excretion (especially cyclosporine and diuretics). Treating acute gout in these patients is challenging; NSAIDs are usually

contraindicated because of underlying chronic kidney disease; intravenous colchicine should not be used because of its narrow therapeutic index (particularly in kidney dysfunction); and corticosteroids are already being used. Often the best approach for monarticular gout—after excluding infection—is injecting corticosteroids into the joint (see above). For polyarticular gout, increasing the dose of systemic corticosteroid may be the only alternative. Since transplant patients often have multiple attacks of gout, long-term relief requires lowering the serum uric acid with allopurinol or febuxostat. (Kidney dysfunction seen in many transplant patients makes uricosuric agents ineffective.) Both allopurinol and febuxostat inhibit the metabolism of azathioprine and should be avoided in patients who must take azathioprine.

▶ Prognosis

Without treatment, the acute attack may last from a few days to several weeks. The intervals between acute attacks vary up to years, but the asymptomatic periods often become shorter if the disease progresses. Chronic gouty arthritis occurs after repeated attacks of acute gout, but only after inadequate treatment. The younger the patient at the onset of disease, the greater the tendency to a progressive course. Destructive arthropathy is rarely seen in patients whose first attack is after age 50.

Patients with gout are anecdotally thought to have an increased incidence of hypertension, kidney disease (eg, nephrosclerosis, interstitial nephritis, pyelonephritis), diabetes mellitus, hypertriglyceridemia, and atherosclerosis.

2. Chondrocalcinosis & Pseudogout

Chondrocalcinosis is the presence of calcium-containing salts in articular cartilage. Diagnosed radiologically, it may be familial and is commonly associated with a wide variety of metabolic disorders (eg, hemochromatosis, hyperparathyroidism, ochronosis, diabetes mellitus, hypothyroidism, Wilson disease, and gout). Pseudogout (also called calcium pyrophosphate dihydrate [CPPD] deposition disease) is most often seen in persons age 60 or older, is characterized by acute, recurrent and rarely chronic arthritis involving large joints (most commonly the knees and the wrists) and is almost always accompanied by chondrocalcinosis of the affected joints. Other joints frequently affected are the

MCPs, hips, shoulders, elbows, and ankles. Involvement of the DIP and PIP joints is no more common in CPPD deposition disease than in other age-matched controls. Pseudogout, like gout, frequently develops 24–48 hours after major surgery. Identification of calcium pyrophosphate crystals in joint aspirates is diagnostic of pseudogout. With light microscopy, the rhomboid-shaped crystals differ from the needle-shaped gout crystals. A red compensator is used for positive identification, since pseudogout crystals are blue when parallel and yellow when perpendicular to the axis of the compensator. Urate crystals give the opposite pattern. X-ray examination shows not only calcification (usually symmetric) of cartilaginous structures but also signs of degenerative joint disease (osteoarthritis). Unlike gout, pseudogout is usually associated with normal serum urate levels.

NSAIDs (salicylates, indomethacin, naproxen, and other drugs) are helpful in the treatment of acute episodes. Patients at increased risk for upper gastrointestinal bleeding may use a COX-2 inhibitor to treat acute attacks of pseudogout. Long-term use of COX-2 inhibitors is not advised because of the association with increased risk of cardiovascular events. Colchicine, 0.6 mg orally twice daily, is more effective for prophylaxis than for acute attacks. Aspiration of the inflamed joint and intra-articular injection of triamcinolone, 10–40 mg, depending on the size of the joint, are also of value in resistant cases.

PAIN SYNDROMES

NECK PAIN

ESSENTIALS OF DIAGNOSIS

- ▶ Most chronic neck pain is caused by degenerative joint disease and responds to conservative approaches.
- ▶ Whiplash is the most common type of traumatic injury to the neck.
- ▶ Serious erosive disease of the atlantoaxial joint (C1–2) may lead to neurologic complications in patients with rheumatoid arthritis and ankylosing spondylitis.

▶ General Considerations

At any point in time, about 15% of adults are experiencing neck pain, which develops more commonly in women than in men. The prevalence of neck pain peaks at age 50. A large group of articular and extra-articular disorders are characterized by pain that may involve simultaneously the

neck, shoulder girdle, and upper extremity. Diagnostic differentiation may be difficult. Some represent primary disorders of the cervicobrachial region; others are local manifestations of systemic disease. It is frequently not possible to make a specific diagnosis.

▶ Clinical Findings

A. Symptoms and Signs

Neck pain may be limited to the posterior region or, depending on the level of the symptomatic joint, may radiate segmentally to the occiput, anterior chest, shoulder girdle, arm, forearm, and hand. It may be intensified by active or passive neck motions. The general distribution of pain and paresthesias corresponds roughly to the involved dermatome in the upper extremity. Radiating pain in the upper extremity is often intensified by hyperextension of the neck and deviation of the head to the involved side. Limitation of cervical movements is the most common objective finding. Neurologic signs depend on the extent of compression of nerve roots or the spinal cord. Compression of the spinal cord may cause paraparesis or paraplegia.

B. Imaging

The radiographic findings depend on the cause of the pain; many plain radiographs are completely normal in patients who have suffered an acute cervical strain. Loss of cervical lordosis is often seen but is nonspecific. In osteoarthritis, comparative reduction in height of the involved disk space is a frequent finding. The most common late radiographic finding is osteophyte formation anteriorly, adjacent to the disk; other chronic abnormalities occur around the apophysial joint clefts, chiefly in the lower cervical spine.

Use of advanced imaging techniques is indicated in the patient who has severe pain of unknown cause that fails to respond to conservative therapy or in the patient who has evidence of myelopathy. MRI is more sensitive than CT in detecting disk disease, extradural compression, and intramedullary cord disease. CT is preferable for demonstration of fractures.

▶ Differential Diagnosis & Treatment

The causes of neck pain include acute and chronic cervical strain or sprains, herniated nucleus pulposus, osteoarthritis, ankylosing spondylitis, rheumatoid arthritis, fibromyalgia, osteomyelitis, neoplasms, polymyalgia rheumatica, compression fractures, pain referred from visceral structures (eg, angina), and functional disorders.

A. Nonspecific Neck Pain

In the absence of trauma or evidence of infection, malignancy, neurologic findings, or systemic inflammation, the patient can be treated conservatively. Conservative therapy can include rest, analgesics, or physical therapy.

B. Acute Cervical Musculotendinous Strain

Cervical strain is generally caused by mechanical postural disorders, overexertion, or injury (eg, whiplash). Acute

episodes are associated with pain, decreased cervical spine motion, and paraspinal muscle spasm, resulting in stiffness of the neck and loss of motion. Muscle trigger points can often be localized. After whiplash injury, patients often experience not only neck pain but also shoulder girdle discomfort and headache. Management includes administration of analgesics. Soft cervical collars are commonly recommended, but evidence suggests they may delay recovery. Acupuncture, manipulation, or physical therapy can help some patients, but the precise role of these treatments is not well established. Corticosteroid injection into cervical facet joints is ineffective. Gradual return to full activity is encouraged.

C. Herniated Nucleus Pulposus

Rupture or prolapse of the nucleus pulposus of the cervical disks into the spinal canal causes pain radiating at a C6–7 level. When intra-abdominal pressure is increased by coughing, sneezing, or other movements, symptoms are aggravated, and cervical muscle spasm may occur. Neurologic abnormalities include decreased reflexes of the deep tendons of the biceps and triceps and decreased sensation and muscle atrophy or weakness in the forearm or hand. Cervical traction, bed rest, and other conservative measures are usually successful. Radicular symptoms usually respond to conservative therapy, including NSAIDs, activity modification, intermittent cervical traction, and neck immobilization. Cervical epidural corticosteroid injections may help those who fail conservative therapy. Surgery is indicated for unremitting pain and progressive weakness despite a full trial of conservative therapy and if a surgically correctable abnormality is identified by MRI or CT myelography. Surgical decompression achieves excellent results in 70–80% of such patients.

D. Arthritic Disorders

Cervical spondylosis (degenerative arthritis) is a collective term describing degenerative changes that occur in the apophysial joints and intervertebral disk joints, with or without neurologic signs. Osteoarthritis of the articular facets is characterized by progressive thinning of the cartilage, subchondral osteoporosis, and osteophytic proliferation around the joint margins. Degeneration of cervical disks and joints may occur in adolescents but is more common after age 40. Degeneration is progressive and is marked by gradual narrowing of the disk space, as demonstrated by radiography. Osteocartilaginous proliferation occurs around the margin of the vertebral body and gives rise to osteophytic ridges that may encroach upon the intervertebral foramina and spinal canal, causing compression of the neurovascular contents.

Osteoarthritis of the cervical spine is often asymptomatic but may cause diffuse neck pain. A minority of patients with neck pain also suffer from radicular pain or myelopathy. Myelopathy develops insidiously and is manifested by sensory dysfunction and clumsy hands. Some patients also complain of unsteady walking, urinary frequency and urgency, or electrical shock sensations with neck flexion or extension (Lhermitte sign). Weakness, sensory loss, and

spasticity with exaggerated reflexes develop below the level of spinal cord compression. Amyotrophic lateral sclerosis, multiple sclerosis, syringomyelia, spinal cord tumors, and tropical spastic paresis from HTLV-1 infection can mimic myelopathy from cervical arthritis. The mainstay of conservative therapy is immobilizing the cervical spine with a collar. With moderate to severe neurologic symptoms, surgical treatment is indicated.

Atlantoaxial subluxation may occur in patients with either rheumatoid arthritis or ankylosing spondylitis. Inflammation of the synovial structures resulting from erosion and laxity of the transverse ligament can lead to neurologic signs of spinal cord compression. Treatment may vary from use of a cervical collar or more rigid bracing to operative treatment, depending on the degree of subluxation and neurologic progression. Surgical treatment for stabilization of the cervical spine is a last resort.

E. Other Disorders

Osteomyelitis and neoplasms are discussed below. Osteoporosis is discussed in Chapter 26.

THORACIC OUTLET SYNDROMES

Thoracic outlet syndromes result from compression of the neurovascular structures supplying the upper extremity. Symptoms and signs arise from intermittent or continuous pressure on elements of the brachial plexus (> 90% of cases) or the subclavian or axillary vessels (veins or arteries) by a variety of anatomic structures of the shoulder girdle region. The neurovascular bundle can be compressed between the anterior or middle scalene muscles and a normal first thoracic rib or a cervical rib. Most commonly thoracic outlet syndromes are caused by scarred scalene neck muscle secondary to neck trauma or sagging of the shoulder girdle resulting from aging, obesity, or pendulous breasts. Faulty posture, occupation, or thoracic muscle hypertrophy from physical activity (eg, weight-lifting, baseball pitching) may be other predisposing factors.

Thoracic outlet syndromes present in most patients with some combination of four symptoms involving the upper extremity, namely pain, numbness, weakness, and swelling. The predominant symptoms depend on whether the compression chiefly affects neural or vascular structures. The onset of symptoms is usually gradual but can be

sudden. Some patients spontaneously notice aggravation of symptoms with specific positioning of the arm. Pain radiates from the point of compression to the base of the neck, the axilla, the shoulder girdle region, arm, forearm, and hand. Paresthesias are common and distributed to the volar aspect of the fourth and fifth digits. Sensory symptoms may be aggravated at night or by prolonged use of the extremities. Weakness and muscle atrophy are the principal motor abnormalities. Vascular symptoms consist of arterial ischemia characterized by pallor of the fingers on elevation of the extremity, sensitivity to cold, and, rarely, gangrene of the digits or venous obstruction marked by edema, cyanosis, and engorgement.

The symptoms of thoracic outlet syndromes can be provoked within 60 seconds over 90% of the time by having a patient elevate the arms in a “stick-em-up” position (ie, abducted 90 degrees in external rotation). Reflexes are usually not altered. Obliteration of the radial pulse with certain maneuvers of the arm or neck, once considered a highly sensitive sign of thoracic outlet obstruction, does not occur in most cases.

Chest radiography will identify patients with cervical rib (although most patients with cervical ribs are asymptomatic). MRI with the arms held in different positions is useful in identifying sites of impaired blood flow. Intra-arterial or venous obstruction is confirmed by angiography. Determination of conduction velocities of the ulnar and other peripheral nerves of the upper extremity may help localize the site of their compression.

Thoracic outlet syndrome must be differentiated from osteoarthritis of the cervical spine, tumors of the superior pulmonary sulcus, cervical spinal cord, or nerve roots, and periarthritis of the shoulder.

Treatment is directed toward relief of compression of the neurovascular bundle. Greater than 95% of patients can be treated successfully with conservative therapy consisting of physical therapy and avoiding postures or activities that compress the neurovascular bundle. Some women will benefit from a support bra. Operative treatment, required by < 5% of patients, is more likely to relieve the neurologic rather than the vascular component that causes symptoms.

LOW BACK PAIN

Up to 80% of the population experience low back pain at some time. The differential diagnosis is broad and includes muscular strain, primary spine disease (eg, disk herniation, degenerative arthritis), systemic diseases (eg, metastatic cancer), and regional diseases (eg, aortic aneurysm). A

precise diagnosis cannot be made in the majority of cases. Even when anatomic defects—such as vertebral osteophytes or a narrowed disk space—are present, causality cannot be assumed since such defects are common in asymptomatic patients. Most patients with acute onset of low back pain will improve in 1–4 weeks and need no evaluation beyond the initial history and physical examination. The diagnostic challenge is to identify those patients who require more extensive or urgent evaluation. In practice, this means identifying those patients with pain caused by (1) infection, (2) cancer, (3) inflammatory back disease such as ankylosing spondylitis, or (4) pain referred from abdominal or pelvic processes, such as an expanding aortic aneurysm. Significant or progressive neurologic deficits also require identification. If there is no evidence of these problems, conservative therapy is called for.

1. Clinical Approach to Diagnosis

► General History & Physical Examination

Low back pain is a final common pathway of many processes; the pain of vertebral osteomyelitis, for example, is not very different in quality and intensity from that due to back strain of the weekend gardener. Historical factors of importance include smoking, weight loss, age over 50, and cancer, all of which are risk factors for vertebral body metastasis. Osteomyelitis most frequently occurs in adults with a history of recurrent urinary tract infections and is especially common in diabetics and injection drug users. A history of a cardiac murmur should raise concern about endocarditis, since back pain is not an uncommon manifestation. A background of renal calculi might indicate another cause of referred back pain.

► History of Back Pain

Certain qualities of a patient's pain can indicate a specific diagnosis. Low back pain radiating down the buttock and below the knee suggests a herniated disk causing nerve root irritation. Other conditions—including sacroiliitis, facet joint degenerative arthritis, spinal stenosis, or irritation of the sciatic nerve from a wallet—also cause this pattern.

The diagnosis of disk herniation is further suggested by physical examination (see below) and confirmed by imaging techniques. Disk herniation can be asymptomatic, so its presence does not invariably link it to the symptom.

Low back pain at night, unrelieved by rest or the supine position, suggests the possibility of malignancy, either vertebral body metastasis (chiefly from prostate, breast, lung, multiple myeloma, or lymphoma) or a cauda equina tumor. Similar pain can also be caused by compression fractures (from osteoporosis or myeloma).

Symptoms of large or rapidly evolving neurologic deficits identify patients who need urgent evaluation for possible cauda equina tumor, epidural abscess or, rarely, massive disk herniation. When a herniated disk impinges a nerve root, pain is the most prominent symptom; numbness and weakness are less common and, when present, are of the magnitude consistent with compression of a single

nerve root. Symptoms of bilateral leg weakness (from multiple lumbar nerve root compressions) or of saddle area anesthesia, bowel or bladder incontinence, or impotence (indicating multiple sacral nerve root compressions) indicate a cauda equina process.

Low back pain that worsens with rest and improves with activity is characteristic of ankylosing spondylitis or other seronegative spondyloarthropathies, especially when the onset is insidious and begins before age 40. Most degenerative back diseases produce precisely the opposite pattern, with rest alleviating and activity aggravating the pain. Low back pain causing the patient to writhe occurs in renal colic but can also indicate a leaking aneurysm. The pain associated with pseudoclaudication from lumbar spinal stenosis is discussed below.

► Physical Examination of the Back

Several physical findings should be sought because they help identify those few patients who need more than conservative management.

Neurologic examination of the lower extremities will detect the small deficits produced by disk disease and the large deficits complicating such problems as cauda equina tumors. A positive straight leg raising test indicates nerve root irritation. The examiner performs the test on the supine patient by passively raising the patient's ipsilateral leg. The test is positive if radicular pain is produced with the leg raised 60 degrees or less. It has a specificity of 40% but is 95% sensitive in patients with herniation at the L4–5 or L5–S1 level (the sites of 95% of disk herniations). It can be falsely negative, especially in patients with herniation above the L4–5 level. The crossed straight leg sign is positive when raising the contralateral leg reproduces the sciatica. It has a sensitivity of 25% but is 90% specific for disk herniation.

Detailed examination of the sacral and lumbar nerve roots, especially L5 and S1, is essential for detecting neurologic deficits associated with back pain. Disk herniation produces deficits predictable for the site involved (Table 20–6). Deficits of multiple nerve roots suggest a cauda equina tumor or an epidural abscess, both requiring urgent evaluation and treatment.

Measurement of spinal motion in the patient with acute pain is rarely of diagnostic utility and usually simply confirms that pain limits motion. An exception is the decreased range of motion in multiple regions of the spine (cervical, thoracic, and lumbar) in a diffuse spinal disease such as

ankylosing spondylitis. By the time the patient has such limits, however, the diagnosis is usually straightforward.

If back pain is not severe and does not itself limit motion, the modified Schober test of lumbar motion is helpful in early diagnosis of ankylosing spondylitis. To perform this test, two marks are made with the patient upright: one 10 cm above the sacral dimples and another 5 cm below. The patient then bends forward as far as possible, and the distance between the points is measured. Normally, the distance increases from 15 cm to at least 20 cm. Anything less indicates reduced lumbar motion.

Palpation of the spine usually does not yield diagnostic information. Point tenderness over a vertebral body is reported to suggest osteomyelitis, but this association is uncommon. A step-off noted between the spinous process of adjacent vertebral bodies may indicate spondylolisthesis, but the sensitivity of this finding is extremely low. Tenderness of the soft tissues overlying the greater trochanter of the hip is a manifestation of trochanteric bursitis.

Inspection of the spine is not often of value in identifying serious causes of low back pain. The classic posture of ankylosing spondylitis is a late finding. Scoliosis of mild degree is not associated with an increased risk of clinical back disease. Cutaneous neurofibromas can identify the rare patient with nerve root encasement.

Examination of the hips should be part of the complete examination. While hip arthritis usually produces pain chiefly in the groin area, some patients have buttock or low back symptoms.

► Further Examination

If the history and physical examination do not suggest the presence of infection, cancer, inflammatory back disease, major neurologic deficits, or pain referred from abdominal or pelvic disease, further evaluation can be deferred while conservative therapy is tried. The great majority of patients will improve with conservative care over 1–4 weeks.

Regular radiographs of the lumbosacral spine give 20 times the radiation dose of a chest radiograph and provide limited, albeit important, information. Oblique films double the radiation dose and are not routinely needed. Radiographs can provide evidence of vertebral body osteomyelitis, cancer, fractures, or ankylosing spondylitis. Degenerative changes in the lumbar spine are ubiquitous in patients over 40 and do not prove clinical disease. Plain radiographs have very low sensitivity or specificity for disk disease. Thus, plain radiographs are warranted promptly for patients suspected of having infection, cancer, or fractures; selected other patients who do not improve after 2–4 weeks of conservative therapy are also candidates. The Agency for Healthcare Research and Quality guidelines for obtaining lumbar radiographs are summarized in Table 20–7.

MRI provides exquisite anatomic detail but is reserved for patients who are considering surgery or have evidence of a systemic disease. For example, MRI is needed urgently for any patient in whom an epidural mass or cauda equina tumor is suspected but not for a patient believed to have a routine disk herniation, since most will improve over 4–6 weeks of conservative therapy. Noncontrast CT does not

AHRQ, Agency for Healthcare Research and Quality. Reproduced, with permission, from Suarez-Almazor et al. Use of lumbar radiographs for the early diagnosis of low back pain. Proposed guidelines would increase utilization. *JAMA*. 1997 Jun; 277:1782-6.

image cauda equina tumors or other intradural lesions, and if used instead of MRI it must include intrathecal contrast.

Radionuclide bone scanning has limited usefulness. It is most useful for early detection of vertebral body osteomyelitis or osteoblastic metastases. The bone scan is normal in multiple myeloma because lytic lesions do not take up isotope.

2. Management

While any management plan must be individualized, key elements of most conservative treatments for back pain include analgesia and education. Analgesia can usually be provided with NSAIDs (see Table 5-3), but severe pain may require opioids (see Table 5-4). Rarely does the need for opioids extend beyond 1-2 weeks.

Diazepam, cyclobenzaprine, carisoprodol, and methocarbamol have been prescribed as muscle relaxants, though their sedative effects may limit their use. They should be reserved for patients who do not respond to NSAIDs and usually are needed only for 1-2 weeks, which reduces the chance of dependence. Their use should be avoided in older patients, who are at risk for falling. All patients should be taught how to protect the back in daily activities—ie, not to lift heavy objects, to use the legs rather than the back when lifting, to use a chair with arm rests, and to rise from bed by first rolling to one side and then using the arms to push to an upright position. Back manipulation for benign, mechanical low back pain appears safe and as effective as therapies provided by clinicians.

Rest and back exercises, once thought to be cornerstones of conservative therapy, are now known to be ineffective for acute back pain. Advice to rest in bed is less effective than advice to remain active. No bed rest with

continuation of ordinary activities as tolerated is superior to 2 days of bed rest, 7 days of bed rest, and back mobilizing exercises. Similarly, for acute back pain, exercise therapy is not effective. The value of corsets or traction is dubious. Epidural corticosteroid injections can provide short-term relief of sciatica but do not improve functional status or reduce the need for surgery. In double-blind studies, repeated injections have been no more effective than a single injection. For chronic low back pain, yoga is as effective as a back exercise program and more effective than a self-care book. Corticosteroid injections into facet joints are ineffective for chronic low back pain. Massage therapy is effective for treatment of chronic back pain, with benefits lasting at least 6 months.

Surgical consultation is needed urgently for any patient with a major or evolving neurologic deficit. Randomized controlled trials have shown that for sciatica caused by disk herniation, conservative treatment and surgery achieve similar 1-year outcomes; however, pain relief and perceived recovery were obtained more quickly with surgery. Surgery tends to ameliorate leg pain more quickly and fully than back pain.

Complaints without objective findings suggest a psychological role in symptom formation. Treatment includes reassurance and nonopioid analgesics.

▶ When to Refer

- Suspected malignancy.
- Inflammatory low back pain.

▶ When to Admit

- Neurologic signs indicative of cauda equina syndrome.
- Vertebral osteomyelitis.

LUMBAR SPINAL STENOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Most patients are older than 60 years.
- ▶ Presenting symptom is often back pain radiating to the buttocks and thighs.
- ▶ Pain often interferes with walking, worsens with lumbar extension, and improves with lumbar flexion.
- ▶ Back and leg pain often associated with numbness and paresthesias.
- ▶ Preservation of pedal pulses helps exclude vascular claudication.
- ▶ Diagnosis best confirmed by MRI.

▶ General Considerations

Lumbar spinal stenosis, defined as narrowing of the spinal canal with compression of the nerve roots, may be congenital or (more commonly) acquired. It most frequently results from enlarging osteophytes at the facet joints, hypertrophy of the ligamentum flavum, and protrusion or bulging of intervertebral disks. Lumbar spinal stenosis may produce symptoms by directly compressing nerve roots or by compressing nutrient arterioles that supply the nerve roots.

▶ Clinical Findings

A. Symptoms and Signs

Most patients with lumbar spinal stenosis are over 60 years old and complain of either leg pain or trouble walking. The pain may originate in the low back but will extend below the buttock into the thigh in nearly 90% of patients. In approximately 50% of patients, the pain will extend below the knee. The pain is often a combination of aching and numbness, which characteristically worsens with walking. The pain can also be brought on by prolonged standing. Not infrequently the symptoms are bilateral. Many patients are more troubled by poor balance, unsteadiness of gait, or leg weakness that develops as they walk. Some describe these neuroclaudication symptoms as developing “spaghetti legs” or “walking like a drunk sailor.” Because the lumbar spinal canal volume increases with back flexion and decreases with extension, some patients observe that they have fewer symptoms walking uphill than down. The back and lower extremity examination in patients with lumbar spinal stenosis is often unimpressive. Less than 10% have a positive straight leg raise sign, 25% have diminished deep tendon reflexes, and 60% have slight proximal weakness. Walking with the patient may reveal unsteadiness, although usually the patient’s perception of gait disturbance is greater than that of an observer.

B. Imaging

The diagnosis of spinal stenosis in a patient with symptoms is best confirmed by MRI.

▶ Differential Diagnosis

The onset of symptoms with standing, the location of the maximal discomfort to the thighs, and the preservation of pedal pulses help distinguish the “pseudoclaudication” of spinal stenosis from true claudication caused by vascular insufficiency. Distinguishing spinal stenosis from disk herniation can be challenging since both conditions can produce pain radiating down the back of the leg. Features that favor spinal stenosis are the gradual onset of symptoms, the marked exacerbation with walking, and the amelioration of symptoms with sitting or lumbar flexion. Complaints of bilateral aching in the buttocks associated with stiffness may make some practitioners consider the diagnosis of polymyalgia rheumatica. However, patients with lumbar spinal stenosis do not have the shoulder or neck symptoms characteristic of polymyalgia rheumatica.

▶ Treatment

Weight loss and exercises aimed at reducing lumbar lordosis, which aggravates symptoms of spinal stenosis, can help. Lumbar epidural corticosteroid injections provide some immediate relief for about 50% of patients and more sustained relief for approximately 25%. When disabling symptoms persist, surgery will reduce pain and improve function substantially in approximately 75% of patients at 1 and 2 years; only about 25% of patients treated conservatively will experience a similar improvement.

FIBROMYALGIA

ESSENTIALS OF DIAGNOSIS

- ▶ Most frequent in women aged 20–50.
- ▶ Chronic widespread musculoskeletal pain syndrome with multiple tender points.
- ▶ Fatigue, headaches, numbness common.
- ▶ Objective signs of inflammation absent; laboratory studies normal.

▶ General Considerations

Fibromyalgia is one of the most common rheumatic syndromes in ambulatory general medicine affecting 3–10% of the general population. It shares many features with the chronic fatigue syndrome, namely, an increased frequency

among women aged 20–50, absence of objective findings, and absence of diagnostic laboratory test results. While many of the clinical features of the two conditions overlap, musculoskeletal pain predominates in fibromyalgia whereas lassitude dominates the chronic fatigue syndrome.

The cause is unknown, but aberrant perception of painful stimuli, sleep disorders, depression, and viral infections have all been proposed. Fibromyalgia can be a rare complication of hypothyroidism, rheumatoid arthritis or, in men, sleep apnea.

► Clinical Findings

The patient complains of chronic aching pain and stiffness, frequently involving the entire body but with prominence of pain around the neck, shoulders, low back, and hips. Fatigue, sleep disorders, subjective numbness, chronic headaches, and irritable bowel symptoms are common. Even minor exertion aggravates pain and increases fatigue. Physical examination is normal except for “trigger points” of pain produced by palpation of various areas such as the trapezius, the medial fat pad of the knee, and the lateral epicondyle of the elbow.

► Differential Diagnosis

Fibromyalgia is a diagnosis of exclusion. A detailed history and repeated physical examination can obviate the need for extensive laboratory testing. Rheumatoid arthritis and systemic lupus erythematosus (SLE) present with objective physical findings or abnormalities on routine testing. Thyroid function tests are useful, since hypothyroidism can produce a secondary fibromyalgia syndrome. Polymyositis produces weakness rather than pain. The diagnosis of fibromyalgia probably should be made hesitantly in a patient over age 50 and should never be invoked to explain fever, weight loss, or any other objective signs. Polymyalgia rheumatica produces shoulder and pelvic girdle pain, is associated with anemia and an elevated ESR, and occurs after age 50. Hypophosphatemic states, such as oncogenic osteomalacia, should also be included in the differential diagnosis of musculoskeletal pain unassociated with physical findings. In contrast to fibromyalgia, oncogenic osteomalacia usually produces pain in only a few areas and is associated with a low serum phosphate level.

► Treatment

A multidisciplinary approach is most effective. Patient education is essential. Patients can be comforted that they have a diagnosable syndrome treatable by specific though imperfect therapies and that the course is not progressive. Cognitive behavioral therapy, including programs that emphasize mindfulness meditation is often helpful. There is modest efficacy of amitriptyline, fluoxetine, duloxetine, milnacipran, chlorpromazine, cyclobenzaprine, pregabalin, or gabapentin. Amitriptyline is initiated at a dosage of 10 mg orally at bedtime and gradually increased to 40–50 mg depending on efficacy and toxicity. Less than 50% of the patients experience a sustained improvement. Exercise programs are also beneficial. NSAIDs are generally ineffective. Tramadol and

acetaminophen combinations have ameliorated symptoms modestly in short-term trials. Opioids and corticosteroids are ineffective and should not be used to treat fibromyalgia. Acupuncture is also ineffective.

► Prognosis

All patients have chronic symptoms. With treatment, however, many do eventually resume increased activities. Progressive or objective findings do not develop.

CARPAL TUNNEL SYNDROME

ESSENTIALS OF DIAGNOSIS

- Begins as pain, burning, and tingling in the distribution of the median nerve.
- Symptoms initially most bothersome at night.
- Weakness or atrophy, especially of the thenar eminence, appears later.
- Common in occupations that require repetitive wrist motion and in pregnancy, diabetes, and rheumatoid arthritis.

► General Considerations

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be compressed by synovitis of the tendon sheaths or carpal joints, recent or malhealed fractures, tumors, and occasionally congenital anomalies. Even though no anatomic lesion is apparent, flattening or even circumferential constriction of the median nerve may be observed during operative section of the ligament. The disorder may occur in pregnancy, is seen in individuals with a history of repetitive use of the hands, and may follow injuries of the wrists. There is a familial type of carpal tunnel syndrome in which no etiologic factor can be identified.

Carpal tunnel syndrome can also be a feature of many systemic diseases: rheumatoid arthritis and other rheumatic disorders (inflammatory tenosynovitis); myxedema,

localized amyloidosis in chronic kidney disease, sarcoidosis, and leukemia (tissue infiltration); acromegaly; and hyperparathyroidism.

► Clinical Findings

The initial symptoms are pain, burning, and tingling in the distribution of the median nerve (the palmar surfaces of the thumb, the index and long fingers, and the radial half of the ring finger). Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Pain is exacerbated by manual activity, particularly by extremes of volar flexion or dorsiflexion of the wrist. It is most bothersome at night. Impairment of sensation in the median nerve distribution may or may not be demonstrable. Subtle disparity between the affected and opposite sides can be shown by testing for two-point discrimination or by requiring the patient to identify different textures of cloth by rubbing them between the tips of the thumb and the index finger. Tinel or Phalen sign may be positive. (Tinel sign is tingling or shock-like pain elicited by tapping the volar surface of the wrist; Phalen sign is pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees for 60 seconds.) The carpal compression test, in which numbness and tingling are induced by the direct application of pressure over the carpal tunnel, may be more sensitive and specific than the Tinel and Phalen tests. Muscle weakness or atrophy, especially of the thenar eminence, appears later than sensory disturbances. Specific examinations include electromyography and determinations of segmental sensory and motor conduction delay. Sensory conduction delay is evident before motor delay.

► Differential Diagnosis

This syndrome should be differentiated from other cervicobrachial pain syndromes, from compression syndromes of the median nerve in the forearm or arm, and from mononeuritis multiplex. When left-sided, it may be confused with angina pectoris.

► Treatment

Treatment is directed toward relief of pressure on the median nerve. When a causative lesion is discovered, it is treated appropriately. Otherwise, patients in whom carpal tunnel syndrome is suspected should modify their hand activities and have the affected wrist splinted for 2–6 weeks. NSAIDs can also be added. Patients should be referred to a specialist for injection of corticosteroid into the carpal tunnel or for operation when they do not improve or when thenar muscle atrophy or weakness develops. Muscle strength returns gradually, but complete recovery cannot be expected when atrophy is pronounced.

► When to Refer

- Refer to a hand surgeon if symptoms persist despite the use of wrist splints.
- Refer to a hand surgeon if weakness or thenar atrophy develops.

DUPUYTREN CONTRACTURE

This relatively common disorder is characterized by hyperplasia of the palmar fascia and related structures, with nodule formation and contracture of the palmar fascia. The cause is unknown, but the condition has a genetic predisposition and occurs primarily in white men over 50 years of age. The incidence is higher among alcoholic patients and those with chronic systemic disorders (especially cirrhosis). It is also associated with systemic fibrosing syndrome, which includes Peyronie disease, mediastinal and retroperitoneal fibrosis, and Riedel struma. The onset may be acute, but slowly progressive chronic disease is more common.

Dupuytren contracture manifests itself by nodular or cord-like thickening of one or both hands, with the fourth and fifth fingers most commonly affected. The patient may complain of tightness of the involved digits, with inability to satisfactorily extend the fingers, and on occasion there is tenderness. The resulting cosmetic problems may be unappealing, but in general the contracture is well tolerated since it exaggerates the normal position of function of the hand. Fasciitis involving other areas of the body may lead to plantar fibromatosis (10% of patients) or Peyronie disease (1–2%).

If the palmar nodule is growing rapidly, injections of triamcinolone or collagenase into the nodule may be of benefit. Surgical intervention is indicated in patients with significant flexion contractures, depending on the location, but recurrence is not uncommon.

Hurst LC et al; CORD I Study Group. Injectable collagenase clostridium histolyticum for Dupuytren's contracture. *N Engl J Med.* 2009 Sep 3;361(10):968–79. [PMID: 19726771]

COMPLEX REGIONAL PAIN SYNDROME

Complex regional pain syndrome (formerly called reflex sympathetic dystrophy) is a rare disorder of the extremities characterized by autonomic and vasomotor instability. The cardinal symptoms and signs are pain localized to an arm or leg, swelling of the involved extremity, disturbances of color and temperature in the affected limb, dystrophic changes in the overlying skin and nails, and limited range of motion. Strikingly, the findings are not limited to the distribution of a single peripheral nerve. Most cases are preceded by direct physical trauma, often of relatively

minor nature, to the soft tissues, bone, or nerve. Early mobilization after injury or surgery reduces the likelihood of developing the syndrome. Vitamin C, 500 mg/d orally, is effective in reducing the risk of complex regional pain syndrome following wrist fracture. Any extremity can be involved, but the syndrome most commonly occurs in the hand and is associated with ipsilateral restriction of shoulder motion (shoulder-hand syndrome). The syndrome proceeds through phases: pain, swelling, and skin color and temperature changes develop early and, if untreated, lead to atrophy and dystrophy. The swelling in complex regional pain syndrome is diffuse (“catcher’s mitt hand”) and not restricted to joints. Pain is often burning in quality, intense, and often greatly worsened by minimal stimuli such as light touch. The shoulder-hand variant of this disorder sometimes complicates myocardial infarction or injuries to the neck or shoulder. Complex regional pain syndrome may occur after a knee injury or after arthroscopic knee surgery. There are no systemic symptoms. In the early phases of the syndrome, bone scans are sensitive, showing diffuse increased uptake in the affected extremity. Radiographs eventually reveal severe generalized osteopenia. In the posttraumatic variant, this is known as Sudeck atrophy. Symptoms and findings are bilateral in some. This syndrome should be differentiated from other cervicobrachial pain syndromes, rheumatoid arthritis, thoracic outlet obstruction, and scleroderma, among others.

Early treatment offers the best prognosis for recovery. For mild cases, NSAIDs (eg, naproxen 250–500 mg twice daily orally) can be effective. For more severe cases associated with edema, prednisone, 30–60 mg/d orally for 2 weeks and then tapered over 2 weeks, can be effective. Pain management is important and facilitates physical therapy, which plays a critical role in efforts to restore function. Some patients will also benefit from antidepressant agents (eg, nortriptyline initiated at a dosage of 10 mg orally at bedtime and gradually increased to 40–75 mg at bedtime) or from anticonvulsants (eg, gabapentin 300 mg three times daily orally). Bisphosphonates, calcitonin, intravenous immunoglobulin, regional nerve blocks and dorsal-column stimulation have also been demonstrated to be helpful. Patients who have restricted shoulder motion may benefit from the treatment described for scapulohumeral periarthritis. The prognosis partly depends on the stage in which the lesions are encountered and the extent and severity of associated organic disease.

BURSITIS

Inflammation of bursae—the synovium-like cellular membranes overlying bony prominences—may be secondary to trauma, infection, or arthritic conditions such as gout, rheumatoid arthritis, or osteoarthritis. The most common

▲ **Figure 20-3.** Aseptic olecranon bursitis secondary to repetitive trauma. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

locations are the subdeltoid, olecranon (Figure 20-3), ischial, trochanteric, semimembranosus-gastrocnemius (Baker cyst), and prepatellar bursae.

There are several ways to distinguish bursitis from arthritis. Bursitis is more likely than arthritis to cause focal tenderness and swelling and less likely to affect range of motion of the adjacent joint. Olecranon bursitis, for example, causes an oval (or, if chronic, bulbous) swelling at the tip of the elbow and does not affect elbow motion, whereas an elbow joint inflammation produces more diffuse swelling and reduces range of motion. Similarly, a patient with prepatellar bursitis has a small focus of swelling over the kneecap but no distention of the knee joint itself and preserved knee motion. A patient with trochanteric bursitis will have tenderness over the greater trochanter and normal internal rotation of the hip; a patient with hip arthritis usually will have reduced internal rotation. Bursitis caused by trauma responds to local heat, rest, NSAIDs, and local corticosteroid injections.

Bursitis can result from infection. The two most common sites are the olecranon and prepatellar bursae. Acute swelling and redness at either of these two sites calls for aspiration to rule out infection. The absence of fever does not exclude infection; one-third of those with septic olecranon bursitis are afebrile. A bursal fluid white blood cell count of >1000/mcL indicates inflammation from infection, rheumatoid arthritis, or gout. In septic bursitis, the white cell count averages over 50,000/mcL. Most cases are caused by *Staphylococcus aureus*; the Gram stain is positive in two-thirds. Treatment involves antibiotics and aspiration for tense effusions.

Chronic, stable olecranon bursa swelling usually does not require aspiration. Aspiration of the olecranon bursa runs the risk of creating a chronic drainage site, which can be reduced by using a “zig-zag” approach with a small needle (25-gauge if possible) and pulling the skin over the bursa before introducing it. Applying a pressure bandage may also help prevent chronic drainage. Surgical removal of the bursa is indicated only for cases in which repeated infections occur. Repetitive minor trauma to the olecranon bursa should be eliminated by avoiding resting the elbow on a hard surface or by wearing an elbow pad.

A bursa can also become symptomatic when it ruptures. This is particularly true for Baker cyst, whose rupture can cause calf pain and swelling that mimic thrombophlebitis. Ruptured Baker cysts are imaged easily by sonography or MRI. In most cases, imaging is unnecessary because the cyst and an associated knee effusion are detectable on physical examination. It may be important to exclude a deep venous thrombosis, which can be mimicked by a ruptured Baker cyst. Treatment of a ruptured cyst includes rest, leg elevation, and injection of triamcinolone, 20–40 mg into the knee anteriorly (the knee compartment communicates with the cyst). Rarely, Baker cyst can compress vascular structures and cause leg edema and true thrombophlebitis.

Rowand M et al. Clinical inquiries. How should you treat trochanteric bursitis? *J Fam Pract.* 2009 Sep;58(9):494–500. [PMID: 19744419]

AUTOIMMUNE DISEASES

RHEUMATOID ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Usually insidious onset with morning stiffness and pain in affected joints.
- ▶ Symmetric polyarthritis with predilection for small joints of the hands and feet; deformities common with progressive disease.
- ▶ Radiographic findings: juxta-articular osteoporosis, joint erosions, and joint space narrowing.
- ▶ Rheumatoid factor and antibodies to cyclic citrullinated peptides (anti-CCP) are present in 70–80%.
- ▶ Extra-articular manifestations: subcutaneous nodules, interstitial lung disease, pleural effusion, pericarditis, splenomegaly with leukopenia, and vasculitis.

▶ General Considerations

Rheumatoid arthritis is a chronic systemic inflammatory disease whose major manifestation is synovitis of multiple joints. It has a prevalence of 1% and is more common in women than men (female:male ratio of 3:1). Rheumatoid

arthritis can begin at any age, but the peak onset is in the fourth or fifth decade for women and the sixth to eighth decades for men. The cause is not known. Susceptibility to rheumatoid arthritis is genetically determined with multiple genes contributing. Inheritance of class II HLA molecules with a distinctive five-amino-acid sequence known as the “shared epitope” is the best characterized genetic risk factor. Untreated, rheumatoid arthritis causes joint destruction with consequent disability and shortens life expectancy. Early, aggressive treatment is the standard of care.

The pathologic findings in the joint include chronic synovitis with formation of a pannus, which erodes cartilage, bone, ligaments, and tendons. In the acute phase, effusion and other manifestations of inflammation are common. In the late stage, organization may result in fibrous ankylosis; true bony ankylosis is rare.

▶ Clinical Findings

A. Symptoms and Signs

1. Joint symptoms—The clinical manifestations of rheumatoid disease are highly variable, but joint symptoms usually predominate. Although acute presentations may occur, the onset of articular signs of inflammation is usually insidious, with prodromal symptoms of vague periarticular pain or stiffness. Symmetric swelling of multiple joints with tenderness and pain is characteristic. Monarticular disease is occasionally seen initially. Stiffness persisting for > 30 minutes (and usually many hours) is prominent in the morning. Stiffness may recur after daytime inactivity and be much more severe after strenuous activity. Although any diarthrodial joint may be affected, PIP joints of the fingers, MCP joints (Figure 20–4), wrists, knees, ankles, and MTP joints

▲ **Figure 20–4.** Rheumatoid arthritis with ulnar deviation at the metacarpophalangeal (MCP) joints. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine.* McGraw-Hill, 2009.)

are most often involved. Synovial cysts and rupture of tendons may occur. Entrapment syndromes are not unusual—particularly of the median nerve at the carpal tunnel of the wrist. Rheumatoid arthritis can affect the neck but spares the other components of the spine and does not involve the sacroiliac joints. In advanced disease, atlantoaxial (C1–C2) subluxation can lead to myelopathy.

2. Rheumatoid nodules—Twenty percent of patients have subcutaneous rheumatoid nodules, most commonly situated over bony prominences but also observed in the bursae and tendon sheaths (Figure 20–5). Nodules are occasionally seen in the lungs, the sclerae, and other tissues. Nodules correlate with the presence of rheumatoid factor in serum (“seropositivity”), as do most other extra-articular manifestations.

3. Ocular symptoms—Dryness of the eyes, mouth, and other mucous membranes is found especially in advanced disease (see Sjögren syndrome). Other ocular manifestations include episcleritis, scleritis, and scleromalacia due to scleral nodules.

4. Other symptoms—Interstitial lung disease is not uncommon (estimates of prevalence vary widely according to method of detection) and manifests clinically as cough and progressive dyspnea. Pericarditis and pleural disease, when present, are usually silent clinically. Patients with active joint disease often have palmar erythema. Occasionally, a small vessel vasculitis develops and manifests as tiny hemorrhagic infarcts in the nail folds or finger pulps. Although necrotizing arteritis is well reported, it is

▲ **Figure 20–5.** Rheumatoid nodules over the extensor surface of the forearm. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

rare. A small subset of patients with rheumatoid arthritis have Felty syndrome, the occurrence of splenomegaly and neutropenia, usually in the setting of severe, destructive arthritis. Felty syndrome must be distinguished from the large granular lymphocyte syndrome, with which it shares many features.

Aortitis is a rare late complication that can result in aortic regurgitation or rupture and is usually associated with evidence of rheumatoid vasculitis elsewhere in the body.

B. Laboratory Findings

Anti-CCP antibodies and rheumatoid factor, an IgM antibody directed against the Fc fragment of IgG, are present in 70–80% of patients with established rheumatoid arthritis but have sensitivities of only 50% in early disease. Anti-CCP antibodies are the most specific blood test for rheumatoid arthritis (specificity ~95%). Rheumatoid factor can occur in other autoimmune disease and in chronic infections, including hepatitis C, syphilis, subacute bacterial endocarditis, and tuberculosis. The prevalence of rheumatoid factor positivity also rises with age in healthy individuals. Approximately 20% of rheumatoid patients have antinuclear antibodies.

The ESR and levels of C-reactive protein are typically elevated in proportion to disease activity. A moderate hypochromic normocytic anemia is common. The white cell count is normal or slightly elevated, but leukopenia may occur, often in the presence of splenomegaly (eg, Felty syndrome). The platelet count is often elevated, roughly in proportion to the severity of overall joint inflammation. Initial joint fluid examination confirms the inflammatory nature of the arthritis. (See Table 20–2.) Arthrocentesis is needed to diagnose superimposed septic arthritis, which is a common complication of rheumatoid arthritis and should be considered whenever a patient with rheumatoid arthritis has one joint inflamed out of proportion to the rest.

C. Imaging

Of all the laboratory tests, radiographic changes are the most specific for rheumatoid arthritis. Radiographs obtained during the first 6 months of symptoms, however, are usually normal. The earliest changes occur in the wrists or feet and consist of soft tissue swelling and juxta-articular demineralization. Later, diagnostic changes of uniform joint space narrowing and erosions develop. The erosions are often first evident at the ulnar styloid and at the juxta-articular margin, where the bony surface is not protected by cartilage. Diagnostic changes also occur in the cervical spine, with C1–2 subluxation, but these changes usually take many years to develop. Although both MRI and ultrasonography are more sensitive than radiographs in detecting bony and soft tissue changes in rheumatoid arthritis, their value in early diagnosis relative to that of plain radiographs has not been established.

► Differential Diagnosis

The differentiation of rheumatoid arthritis from other joint conditions and immune-mediated disorders can be difficult.

In 2010, the American College of Rheumatology updated their classification criteria for rheumatoid arthritis. In contrast to rheumatoid arthritis, osteoarthritis spares the wrist and the MCP joints. Osteoarthritis is not associated with constitutional manifestations, and the joint pain is characteristically relieved by rest, unlike the morning stiffness of rheumatoid arthritis. Signs of articular inflammation, prominent in rheumatoid arthritis, are usually minimal in degenerative joint disease. CPPD deposition disease can cause a degenerative arthropathy of the MCPs and wrists; radiographs are usually diagnostic. Although gouty arthritis is almost always intermittent and monoarticular in the early years, it may evolve with time into a chronic polyarticular process that mimics rheumatoid arthritis. Gouty tophi can resemble rheumatoid nodules both in typical location and appearance. The early history of intermittent monoarthritis and the presence of synovial urate crystals are distinctive features of gout. Spondyloarthropathies, particularly earlier in their course, can be a source of diagnostic uncertainty; predilection for lower extremities and involvement of the spine and sacroiliac joints point to the correct diagnosis. Chronic Lyme arthritis typically involves only one joint, most commonly the knee, and is associated with positive serologic tests (see Chapter 34). Human parvovirus B19 infection in adults can mimic early rheumatoid arthritis. However, arthralgias are more prominent than arthritis, fever is common, IgM antibodies to parvovirus B19 are present, and the arthritis usually resolves within weeks. Infection with hepatitis C can cause a chronic nonerosive polyarthritis associated with rheumatoid factor; tests for anti-CCP antibodies are negative.

Malar rash, photosensitivity, discoid skin lesions, alopecia, high titer antibodies to double-stranded DNA, glomerulonephritis, and central nervous system abnormalities point to the diagnosis of SLE. Polymyalgia rheumatica occasionally causes polyarthralgias in patients over age 50, but these patients remain rheumatoid factor–negative and have chiefly proximal muscle pain and stiffness, centered on the shoulder and hip girdles. Rheumatic fever is characterized by the migratory nature of the arthritis, an elevated antistreptolysin titer, and a more dramatic and prompt response to aspirin; carditis and erythema marginatum may occur in adults, but chorea and subcutaneous nodules virtually never do. Finally, a variety of cancers produce paraneoplastic syndromes, including polyarthritis. One form is hypertrophic pulmonary osteoarthropathy most often produced by lung and gastrointestinal carcinomas, characterized by a rheumatoid-like arthritis associated with clubbing, periosteal new bone formation, and a negative rheumatoid factor. Diffuse swelling of the hands with palmar fasciitis occurs in a variety of cancers, especially ovarian carcinoma.

► Treatment

The primary objectives in treating rheumatoid arthritis are reduction of inflammation and pain, preservation of function, and prevention of deformity. Success requires early, effective pharmacologic intervention. Disease-modifying antirheumatic drugs (DMARDs) should be started as soon as the diagnosis of rheumatoid disease is certain and then

adjusted with the aim of suppressing disease activity. The American College of Rheumatology recommends using standardized assessments, such as the Disease Activity Score 28 Joints (DAS28), to gauge therapeutic responses, with the target of mild disease activity or remission by these measures. In advanced disease, surgical intervention may help improve function of damaged joints and to relieve pain.

A. Nonsteroidal Anti-inflammatory Drugs

NSAIDs provide some symptomatic relief in rheumatoid arthritis but do not prevent erosions or alter disease progression. They are not appropriate for monotherapy and should only be used in conjunction with DMARDs. A large number of NSAIDs are available; all appear equivalent in terms of efficacy (see Table 5–3).

Celecoxib, a selective COX-2 inhibitor, is FDA-approved for the treatment of osteoarthritis and rheumatoid arthritis. Compared with traditional NSAIDs, COX-2 inhibitors are as effective for treating rheumatoid arthritis but less likely in some circumstances to cause upper gastrointestinal tract adverse events (eg, obstruction, perforation, hemorrhage, or ulceration). Long-term use of COX-2 inhibitors, particularly in the absence of concomitant aspirin use, has been associated with an increased risk of cardiovascular events, leading to the removal of some COX-2 inhibitors from the US market and intense scrutiny of all drugs in that class.

1. Gastrointestinal side effects—For traditional NSAIDs that inhibit both COX-1 and COX-2, gastrointestinal side effects, such as gastric ulceration, perforation, and gastrointestinal hemorrhage, are the most common serious side effects. The overall rate of bleeding with NSAID use in the general population is low (1:6000 users or less) but is increased by long-term use, higher NSAID dose, concomitant corticosteroids or anticoagulants, the presence of rheumatoid arthritis, history of peptic ulcer disease or alcoholism, and age over 70. Twenty-five percent of all hospitalizations and deaths from peptic ulcer disease result from traditional NSAID therapy. Each year, 1:1000 patients with rheumatoid arthritis will require hospitalization for NSAID-related gastrointestinal bleeding or perforation. Although all traditional NSAIDs can cause massive gastrointestinal bleeding, the risk may be higher with indomethacin and piroxicam, probably because these drugs preferentially inhibit COX-1 in the stomach.

One approach to reducing the gastrointestinal toxicity of traditional NSAIDs is to add a proton pump inhibitor (eg, omeprazole 20 mg orally daily). Sucralfate, antacids, and H₂-blockers (such as ranitidine) either do not work or do not work as well as proton pump inhibitors. The expense of proton pump inhibitors and misoprostol dictates that their use should be reserved for patients with risk factors for NSAID-induced gastrointestinal toxicity (noted above). Patients who have recently recovered from an NSAID-induced bleeding gastric ulcer appear to be at high risk for rebleeding (about 5% in 6 months) when an NSAID is reintroduced, even if prophylactic measures such as proton pump inhibitors are used. NSAIDs can also affect

the lower intestinal tract, causing perforation or aggravating inflammatory bowel disease.

Acute liver injury from NSAIDs is rare, occurring in about 1 of every 25,000 patients using these agents. Having rheumatoid arthritis or taking sulindac may increase the risk.

2. Renal side effects—All of the NSAIDs, including aspirin and the COX-2 inhibitors, can produce renal toxicity, including interstitial nephritis, nephrotic syndrome, prerenal azotemia, and aggravation of hypertension. Hyperkalemia due to hyporeninemic hypoaldosteronism may also be seen rarely. The risk of renal toxicity is low but is increased by age over 60, a history of kidney disease, congestive heart failure, ascites, and diuretic use. COX-2 inhibitors appear to cause as much nephrotoxicity as traditional NSAIDs.

3. Platelet effects—All NSAIDs except the nonacetylated salicylates and the COX-2 inhibitors interfere with platelet function and prolong bleeding time. For all older NSAIDs except aspirin, the effect on bleeding time resolves as the drug is cleared. Aspirin irreversibly inhibits platelet function, so the bleeding time effect resolves only as new platelets are made. Concomitant administration of a traditional NSAID can interfere with the ability of aspirin to acetylate platelets and thus may interfere with the cardioprotective effects of low-dose aspirin. COX-2 inhibitors, which differ from other NSAIDs in not inhibiting platelet function, do not increase the risk of bleeding with surgical procedures as most NSAIDs do. Unfortunately, this failure to inhibit platelets is now known to lead to increased risks of myocardial infarction and stroke, particularly when the medications are used in high doses for prolonged periods of time. Patients requiring low-dose aspirin who are not compliant have a greater risk of developing a thrombotic event while taking a COX-2 inhibitor than while taking a traditional NSAID. Whether combination therapy with low-dose aspirin and a COX-2 inhibitor maintains the gastrointestinal advantage of selective COX-2 inhibitors is not yet known.

Although groups of patients with rheumatoid arthritis respond similarly to NSAIDs, individuals may respond differently—an NSAID that works for one patient may not work for another. Thus, if the first NSAID chosen is not effective after 2–3 weeks of use, another should be tried.

B. Corticosteroids

Low-dose corticosteroids (eg, oral prednisone 5–10 mg daily) produce a prompt anti-inflammatory effect in rheumatoid arthritis and slow the rate of articular erosion. However, their multiple side effects limit their long-term use.

Low-dose corticosteroids often are used as a “bridge” to reduce disease activity until the slower acting DMARDs take effect or as adjunctive therapy for active disease that persists despite treatment with DMARDs. No more than 10 mg of prednisone or equivalent per day is appropriate for articular disease. Many patients do reasonably well on 5–7.5 mg daily. (The use of 1 mg tablets, to facilitate doses of < 5 mg/d, is encouraged.) Higher doses are used to manage serious extra-articular manifestations (eg, pericarditis,

necrotizing scleritis). When the corticosteroids are to be discontinued, they should be tapered gradually on a planned schedule appropriate to the duration of treatment. All patients receiving long-term corticosteroid therapy should take measures to prevent osteoporosis.

Intra-articular corticosteroids may be helpful if one or two joints are the chief source of difficulty. Intra-articular triamcinolone, 10–40 mg depending on the size of the joint to be injected, may be given for symptomatic relief but not more than four times a year.

C. Synthetic DMARDs

1. Methotrexate—Methotrexate is usually the initial synthetic DMARD of choice for patients with rheumatoid arthritis. It is generally well tolerated and often produces a beneficial effect in 2–6 weeks. The usual initial dose is 7.5 mg of methotrexate orally once weekly. If the patient has tolerated methotrexate but has not responded in 1 month, the dose can be increased to 15 mg orally once per week. The maximal dose is usually 20–25 mg/wk. The most frequent side effects are gastric irritation and stomatitis. Cytopenia, most commonly leukopenia or thrombocytopenia but rarely pancytopenia, due to bone marrow suppression is another important potential problem. The risk of developing pancytopenia is much higher in patients with elevation of the serum creatinine (≥ 2 mg/dL). Hepatotoxicity with fibrosis and cirrhosis is an important toxic effect that correlates with cumulative dose and is uncommon with appropriate monitoring of liver function tests. Methotrexate is contraindicated in a patient with any form of chronic hepatitis. Heavy alcohol use increases the hepatotoxicity, so patients should be advised to drink alcohol in extreme moderation, if at all. Diabetes, obesity, and kidney disease also increase the risk of hepatotoxicity. Liver function tests should be monitored at least every 12 weeks, along with a complete blood count. The dose of methotrexate should be reduced if aminotransferase levels are elevated, and the drug should be discontinued if abnormalities persist despite dosage reduction. Gastric irritation, stomatitis, cytopenias, and hepatotoxicity are reduced by prescribing either daily folate (1 mg orally) or weekly leucovorin calcium (2.5–5 mg taken orally 24 hours after the dose of methotrexate). Hypersensitivity to methotrexate can cause an acute or subacute interstitial pneumonitis that can be life-threatening but which usually responds to cessation of the drug and institution of corticosteroids. Because methotrexate is teratogenic, women of child-bearing age as well as men must use effective contraception while taking the medication. Methotrexate is associated with an increased risk of B cell lymphomas, some of which resolve following the discontinuation of the medication. The combination of methotrexate and other folate antagonists, such as trimethoprim-sulfamethoxazole, should be used cautiously, since pancytopenia can result. Probenecid should also be avoided since it increases methotrexate drug levels and toxicity.

2. Sulfasalazine—This drug is a second-line agent for rheumatoid arthritis. It is usually introduced at a dosage of 0.5 g orally twice daily and then increased each week by

0.5 g until the patient improves or the daily dose reaches 3 g. Side effects, particularly neutropenia and thrombocytopenia, occur in 10–25% and are serious in 2–5%. Sulfasalazine also causes hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, so a G6PD level should be checked before initiating sulfasalazine. Patients with aspirin sensitivity should not be given sulfasalazine. Patients taking sulfasalazine should have complete blood counts monitored every 2–4 weeks for the first 3 months, then every 3 months.

3. Leflunomide—Leflunomide, a pyrimidine synthesis inhibitor, is also FDA-approved for treatment of rheumatoid arthritis and is administered as a single oral daily dose of 20 mg. The most frequent side effects are diarrhea, rash, reversible alopecia, and hepatotoxicity. Some patients experience dramatic unexplained weight loss. The drug is carcinogenic, teratogenic, and has a half-life of 2 weeks. Thus, it is contraindicated in premenopausal women or in men who wish to father children.

4. Antimalarials—Hydroxychloroquine sulfate is the antimalarial agent most often used against rheumatoid arthritis. Monotherapy with hydroxychloroquine should be reserved for patients with mild disease because only a small percentage will respond and in some of those cases only after 3–6 months of therapy. Hydroxychloroquine is often used in combination with other conventional DMARDs, particularly methotrexate and sulfasalazine. The advantage of hydroxychloroquine is its comparatively low toxicity, especially at a dosage of 200–400 mg/d orally (not to exceed 6.5 mg/kg/d). The most important reaction, pigmentary retinitis causing visual loss, is rare at this dose. Ophthalmologic examinations every 12 months are required when this drug is used for long-term therapy. Other reactions include neuropathies and myopathies of both skeletal and cardiac muscle, which usually improve when the drug is withdrawn.

5. Minocycline—Minocycline is more effective than placebo for rheumatoid arthritis. It is reserved for early, mild cases, since its efficacy is modest, and it works better during the first year of rheumatoid arthritis. The mechanism of action is not clear, but tetracyclines do have anti-inflammatory properties, including the ability to inhibit destructive enzymes such as collagenase. The dosage of minocycline is 200 mg orally daily. Adverse effects are uncommon except for dizziness, which occurs in about 10%.

D. Biologic DMARDs

1. Tumor necrosis factor inhibitors—Inhibitors of tumor necrosis factor (TNF)—a pro-inflammatory cytokine—are fulfilling the aim of targeted therapy for rheumatoid arthritis. These medications are frequently added to the treatment of patients who have not responded adequately to methotrexate and are increasingly used as initial therapy in combination with methotrexate for patients with poor prognostic factors.

Five inhibitors are in use: etanercept, infliximab, adalimumab, golimumab, and certolizumab pegol. Etanercept, a soluble recombinant TNF receptor:Fc fusion protein, is

usually administered at a dosage of 50 mg subcutaneously once per week. Infliximab, a chimeric monoclonal antibody, is administered at a dosage of 3–10 mg/kg intravenously; infusions are repeated after 2, 6, 10, and 14 weeks and then are administered every 8 weeks. Adalimumab, a human monoclonal antibody that binds to TNF, is given at a dosage of 40 mg subcutaneously every other week. The dose for golimumab, a human anti-TNF monoclonal antibody, is 50 mg subcutaneously once monthly. Certolizumab pegol is a PEGylated monoclonal antibody TNF inhibitor; the dose is 200–400 mg subcutaneously every 2 to 4 weeks. Each drug produces substantial improvement in more than 60% of patients. Each is usually very well tolerated. Minor irritation at injection sites is the most common side effect of etanercept and adalimumab. Rarely, nonrecurrent leukopenia develops in patients. TNF plays a physiologic role in combating many types of infection; TNF inhibitors have been associated with a several-fold increased risk of serious bacterial infections and a striking increase in granulomatous infections, particularly reactivation of tuberculosis. Screening for latent tuberculosis (see Chapter 9) is mandatory before the initiation of TNF blockers. It is prudent to suspend TNF blockers when a fever or other manifestations of a clinically important infection develops in a patient. Demyelinating neurologic complications that resemble multiple sclerosis have been reported rarely in patients taking etanercept, but the true magnitude of this risk—likely quite small—has not been determined with precision. While there are conflicting data with respect to increased risk of malignancy, in 2009, the FDA issued a safety alert about case reports of malignancies, including leukemias, in patients treated with TNF inhibitors. Contrary to expectation, TNF inhibitors were not effective in the treatment of congestive heart failure. The use of infliximab, in fact, was associated with increased morbidity in a congestive heart failure trial. Consequently, TNF inhibitors should be used with extreme caution in patients with congestive heart failure. Infliximab can rarely cause anaphylaxis and induce anti-DNA antibodies (but rarely clinically evident SLE). A final concern about TNF inhibitors is the expense, which is more than \$10,000 per year.

2. Abatacept—Abatacept, a recombinant protein made by fusing a fragment of the Fc domain of human IgG with the extracellular domain of a T cell inhibitory receptor (CTLA4), blocks T-cell costimulation. It is approved by the FDA for use in rheumatoid arthritis and produces clinically meaningful responses in approximately 50% of individuals whose disease is active despite the combination of methotrexate and a TNF inhibitor.

3. Rituximab—Rituximab is a humanized mouse monoclonal antibody that depletes B cells. It is approved by the FDA to be used in combination with methotrexate for patients whose disease has been refractory to treatment with a TNF inhibitor.

4. Tocilizumab—Tocilizumab is a monoclonal antibody that blocks the receptor for IL-6, an inflammatory cytokine involved in the pathogenesis of rheumatoid arthritis. It also is approved by the FDA to be used in combination with

methotrexate for patients whose disease has been refractory to treatment with a TNF inhibitor.

E. DMARD Combinations

As a general rule, DMARDs have greater efficacy when administered in combination than when used individually. Currently, the most commonly used combination is that of methotrexate with one of the TNF inhibitors, which clearly is superior to methotrexate alone. The urge to use combination therapies with TNF inhibitors as the initial treatment for rheumatoid arthritis, however, has been tempered by concerns about their safety and cost. The American College of Rheumatology has published detailed recommendations on the initiation of DMARD combinations.

► Course & Prognosis

After months or years, deformities may occur; the most common are ulnar deviation of the fingers, boutonnière deformity (hyperextension of the DIP joint with flexion of the PIP joint), “swan-neck” deformity (flexion of the DIP joint with extension of the PIP joint), valgus deformity of the knee, and volar subluxation of the MTP joints. The excess mortality associated with rheumatoid arthritis is largely due to cardiovascular disease that is unexplained by traditional risk factors and that appears to be a result of deleterious effects of chronic systemic inflammation on the vascular system.

► When to Refer

Early referral to a rheumatologist is essential for appropriate diagnosis and the timely introduction of effective pharmacologic and nonpharmacologic (physical and occupational) therapy.

ADULT STILL DISEASE

Still disease is a systemic form of juvenile chronic arthritis in which high spiking fevers are much more prominent, especially at the outset, than arthritis. This syndrome also occurs in adults. Most adults are in their 20s or 30s; onset after age 60 is rare. The fever is dramatic, often with daily spikes to 40°C, associated with sweats and chills, and then plunging to normal or several degrees below normal in the absence of antipyretics. Many patients initially complain of sore throat. An evanescent salmon-colored nonpruritic rash, chiefly on the chest and abdomen, is a characteristic feature. The rash can easily be missed since it often appears only with the fever spike. Many patients also have lymphadenopathy and pericardial effusions. Joint symptoms are mild or absent in the beginning, but a destructive arthritis, especially of the wrists, may develop months later. Anemia and leukocytosis, with white blood counts sometimes exceeding 40,000/mcL, are the rule. Ferritin levels are exceptionally high (> 3000 mg/mL) in more than 70% of cases of adult Still disease—for reasons that are not clear. A low percentage (< 20%) of serum ferritin that is glycosylated may be even more specific for adult Still disease. Although there must be exclusion of other causes of fever, the diagnosis of adult Still disease is strongly suggested by the fever pattern, sore throat, and the classic rash. About half of the patients respond to high-dose aspirin (eg, 1 g three times orally daily) or other NSAIDs, and half require prednisone, sometimes in doses > 60 mg/d orally. TNF inhibitors may be helpful for some patients with refractory adult Still disease, but most patients treated with these agents achieve only partial remissions. More complete and dramatic responses have been achieved with the IL-1 receptor antagonist anakinra.

SYSTEMIC LUPUS ERYTHEMATOSUS

ESSENTIALS OF DIAGNOSIS

- Occurs mainly in young women.
- Rash over areas exposed to sunlight.
- Joint symptoms in 90% of patients. Multiple system involvement.
- Anemia, leukopenia, thrombocytopenia.
- Glomerulonephritis, central nervous system disease, and complications of antiphospholipid antibodies are major sources of disease morbidity.
- Serologic findings: antinuclear antibodies (100%), anti-double-stranded DNA antibodies (approximately two-thirds), and low serum complement levels (particularly during disease flares).

► General Considerations

SLE is an inflammatory autoimmune disorder characterized by autoantibodies to nuclear antigens. It can affect multiple organ systems. Many of its clinical manifestations are secondary to the trapping of antigen-antibody complexes in capillaries of visceral structures or to autoantibody-mediated destruction of host cells (eg, thrombocytopenia). The clinical course is marked by spontaneous remission and relapses. The severity may vary from a mild episodic disorder to a rapidly fulminant, life-threatening illness.

The incidence of SLE is influenced by many factors, including gender, race, and genetic inheritance. About 85% of patients are women. Sex hormones appear to play some role; most cases develop after menarche and before menopause. Among older individuals, the gender distribution is more equal. Race is also a factor, as SLE occurs in 1:1000 white women but in 1:250 black women. Familial occurrence of SLE has been repeatedly documented, and the disorder is concordant in 25–70% of identical twins. If a mother has SLE, her daughters' risks of developing the disease are 1:40 and her sons' risks are 1:250. Aggregation of serologic abnormalities (positive antinuclear antibody) is seen in asymptomatic family members, and the prevalence of other rheumatic diseases is increased among close relatives of patients. The importance of specific genes in SLE is emphasized by the high frequency of certain HLA haplotypes, especially DR2 and DR3, and null complement alleles.

Before making a diagnosis of SLE, it is imperative to ascertain that the condition has not been induced by a drug (Table 20–8). Procainamide, hydralazine, and isoniazid are the best-studied drugs. While antinuclear antibody tests

and other serologic findings become positive in many persons receiving these agents, clinical manifestations occur in only a few.

Four features of **drug-induced lupus** separate it from SLE: (1) the sex ratio is nearly equal; (2) nephritis and central nervous system features are not ordinarily present; (3) hypocomplementemia and antibodies to double-stranded DNA are absent; and (4) the clinical features and most laboratory abnormalities usually revert toward normal when the offending drug is withdrawn.

The diagnosis of SLE should be suspected in patients having a multisystem disease with a positive test for antinuclear antibodies. Differential diagnosis includes rheumatoid arthritis, systemic vasculitis, scleroderma, inflammatory myopathies, viral hepatitis, sarcoidosis, acute drug reactions, and drug-induced lupus.

The diagnosis of SLE can be made with reasonable probability if 4 of the 11 criteria set forth in Table 20–9 are met. These criteria, developed as guidelines for the inclusion of patients in research studies, do not supplant clinical judgment in the diagnosis of SLE.

► Clinical Findings

A. Symptoms and Signs

The systemic features include fever, anorexia, malaise, and weight loss. Most patients have skin lesions at some time;

Table 20–8. Drugs associated with lupus erythematosus.

Definite association	
Chlorpromazine	Minocycline
Hydralazine	Procainamide
Isoniazid	Quinidine
Methyldopa	
Possible association	
β-Blockers	Nitrofurantoin
Captopril	Penicillamine
Carbamazepine	Phenytoin
Cimetidine	Propylthiouracil
Ethosuximide	Sulfasalazine
Levodopa	Sulfonamides
Lithium	Trimethadione
Methimazole	
Unlikely association	
Allopurinol	Penicillin
Chlorthalidone	Phenylbutazone
Gold salts	Reserpine
Griseofulvin	Streptomycin
Methysergide	Tetracyclines
Oral contraceptives

Table 20–9. Criteria for the classification of SLE.

(A patient is classified as having SLE if any 4 or more of 11 criteria are met.)

- Malar rash
- Discoid rash
- Photosensitivity
- Oral ulcers
- Arthritis
- Serositis
- Kidney disease
 - > 0.5 g/d proteinuria, or
 - ≥ 3⁺ dipstick proteinuria, or
 - Cellular casts
- Neurologic disease
 - Seizures, or
 - Psychosis (without other cause)
- Hematologic disorders
 - Hemolytic anemia, or
 - Leukopenia (< 4000/mcl), or
 - Lymphopenia (< 1500/mcl), or
 - Thrombocytopenia (< 100,000/mcl)
- Immunologic abnormalities
 - Positive LE cell preparation, or
 - Antibody to native DNA, or
 - Antibody to Sm, or
 - False-positive serologic test for syphilis
- Positive ANA

ANA, antinuclear antibody; SLE, systemic lupus erythematosus. Modified and reproduced, with permission, from Tan EM et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum.* 1982 Nov;25(11):1271–7.

the characteristic “butterfly” (malar) rash affects less than half of patients. Other cutaneous manifestations are, discoid lupus, typical fingertip lesions, periungual erythema, nail fold infarcts, and splinter hemorrhages. Alopecia is common. Mucous membrane lesions tend to occur during periods of exacerbation. Raynaud phenomenon, present in about 20% of patients, often antedates other features of the disease.

Joint symptoms, with or without active synovitis, occur in over 90% of patients and are often the earliest manifestation. The arthritis can lead to reversible swan-neck deformities, but erosive changes are almost never noted on radiographs. Subcutaneous nodules are rare.

Ocular manifestations include conjunctivitis, photophobia, transient or permanent monocular blindness, and blurring of vision. Cotton-wool spots on the retina (cytoid bodies) represent degeneration of nerve fibers due to occlusion of retinal blood vessels.

Pleurisy, pleural effusion, bronchopneumonia, and pneumonitis are frequent. Restrictive lung disease can develop. Alveolar hemorrhage is rare but life-threatening.

The pericardium is affected in the majority of patients. Cardiac failure may result from myocarditis and hypertension. Cardiac arrhythmias are common. Atypical verrucous endocarditis of Libman-Sacks is usually clinically silent but occasionally can produce acute or chronic valvular incompetence—most commonly mitral regurgitation.

Mesenteric vasculitis occasionally occurs in SLE and may closely resemble polyarteritis nodosa, including the presence of aneurysms in medium-sized blood vessels. Abdominal pain (particularly postprandial), ileus, peritonitis, and perforation may result.

Neurologic complications of SLE include psychosis, cognitive impairment, seizures, peripheral and cranial neuropathies, transverse myelitis, and strokes. Severe depression and

psychosis are sometimes exacerbated by the administration of large doses of corticosteroids.

Several forms of glomerulonephritis may occur, including mesangial, focal proliferative, diffuse proliferative, and membranous (see Chapter 22). Some patients may also have interstitial nephritis. With appropriate therapy, the survival rate even for patients with serious chronic kidney disease (proliferative glomerulonephritis) is favorable, albeit a substantial portion of patients with severe lupus nephritis still eventually require renal replacement therapy.

B. Laboratory Findings

(Tables 20–10 and 20–11.) SLE is characterized by the production of many different autoantibodies. Antinuclear antibody tests based on immunofluorescence assays are sensitive but not specific for SLE—ie, they are positive in virtually all patients with lupus but are positive also in many patients with nonlupus conditions such as rheumatoid arthritis, autoimmune thyroid disease, scleroderma, and Sjögren syndrome. False-negative results can occur with tests for antinuclear antibodies based on enzyme-linked immunosorbent assays (ELISA). Therefore, SLE should not be excluded on the basis of a negative ELISA for antinuclear antibodies. Antibodies to double-stranded DNA and to Sm are specific for SLE but not sensitive, since they are present in only 60% and 30% of patients, respectively. Depressed serum complement—a finding suggestive of disease activity—often returns toward normal in remission. Anti-double-stranded DNA antibody levels also correlate with disease activity in some patients; anti-Sm levels do not.

Three types of antiphospholipid antibodies occur (Table 20–11). The first causes the biologic false-positive tests for syphilis; the second is the lupus anticoagulant, which despite

ANA, antinuclear antibody; Anti-Sm, anti-Smith antibody. Modified and reproduced, with permission, from Hochberg MC et al. Systemic lupus erythematosus: a review of clinicolaboratory features and immunologic matches in 150 patients with emphasis on demographic subsets. *Medicine* (Baltimore). 1985 Sep;64(5):285-95.

its name is a risk factor for venous and arterial thrombosis and for miscarriage. The lupus anticoagulant often causes prolongation of the activated partial thromboplastin time, and its presence is confirmed by an abnormal Russell viper venom time (RVVT) that corrects with the addition of phospholipid but not normal plasma. Anticardiolipin antibodies are the third type of antiphospholipid antibodies. In many cases, the “antiphospholipid antibody” appears to be directed at a serum cofactor (β_2 -glycoprotein-I) rather than at phospholipid itself. Abnormality of urinary sediment is almost always found in association with renal lesions. Showers of red blood cells, with or without casts, and proteinuria (varying from mild to nephrotic range) are frequent during exacerbation of the disease.

► Treatment

Patient education and emotional support, are especially important for patients with lupus. Since the various manifestations of SLE affect prognosis differently and since SLE activity often waxes and wanes, drug therapy—both the choice of agents and the intensity of their use—must be tailored to match disease severity. Patients with photosensitivity should be cautioned against sun exposure and should apply a protective lotion to the skin while out of doors. Skin lesions often respond to the local administration of corticosteroids. Minor joint symptoms can usually be alleviated by rest and NSAIDs.

Antimalarials (hydroxychloroquine) may be helpful in treating lupus rashes or joint symptoms and appear to reduce the incidence of severe disease flares. The dose of

hydroxychloroquine is 200 or 400 mg/d orally and should not exceed 6.5 mg/kg/d; annual monitoring for retinal changes is recommended. Drug-induced neuropathy and myopathy may be erroneously ascribed to the underlying disease. The androgenic corticosteroid danazol may be effective therapy for thrombocytopenia not responsive to corticosteroids. Although dehydroepiandrosterone (DHEA) can improve a patient's sense of well being, the drug is not used often because it has little to no impact on other measures of disease activity and frequently causes troubling side effects (particularly acne and hirsutism).

Corticosteroids are required for the control of certain complications. (Systemic corticosteroids are not usually given for minor arthritis, skin rash, leukopenia, or the anemia associated with chronic disease.) Glomerulonephritis, hemolytic anemia, pericarditis or myocarditis, alveolar hemorrhage, central nervous system involvement, and thrombotic thrombocytopenic purpura all require corticosteroid treatment and often other interventions as well. Forty to 60 mg of oral prednisone is often needed initially; however, the lowest dose of corticosteroid that controls the condition should be used. Central nervous system lupus may require higher doses of corticosteroids than are usually given; however, corticosteroid psychosis may mimic lupus cerebritis, in which case reduced doses are appropriate. Immunosuppressive agents such as cyclophosphamide, mycophenolate mofetil, and azathioprine are used in cases resistant to corticosteroids. Treatment of severe lupus nephritis includes an induction phase and a maintenance phase. Cyclophosphamide, which improves renal survival but not patient survival, has been for many years the standard treatment for both phases of lupus nephritis. Mycophenolate mofetil appears to be an effective alternative treatment for many patients with lupus nephritis. Very close follow-up is needed to watch for potential side effects when immunosuppressants are given; these agents should be administered by clinicians experienced in their use. When cyclophosphamide is required, gonadotropin-releasing hormone analogs can be given to protect a woman against the risk of premature ovarian failure. Belimumab, a monoclonal antibody that inhibits the activity of a B cell growth factor, has received FDA approval for treating antibody-positive SLE patients with active disease who have not responded to standard therapies (eg, NSAIDs, antimalarials, or immunosuppressive therapies). However, the precise indications for its use have not been defined, and its efficacy in severe disease activity is unknown. Belimumab appears less effective in blacks. While observations studies suggested that rituximab was effective in SLE, one large randomized-controlled trial demonstrated it was no more effective than placebo. For patients with the **antiphospholipid syndrome**—the presence of antiphospholipid antibodies and compatible clinical events—anticoagulation is the treatment of choice (see Antiphospholipid Antibody Syndrome, below). Moderate intensive anticoagulation with warfarin to achieve an INR of 2.0–3.0 is as effective as more intensive regimens. Pregnant patients with recurrent fetal loss associated with antiphospholipid antibodies should be treated with low-molecular-weight heparin plus aspirin.

▶ Course & Prognosis

Ten-year survival rates exceeding 85% are routine. In most patients, the illness pursues a relapsing and remitting course. Prednisone, often needed in doses of 40 mg/d orally or more during severe flares, can usually be tapered to low doses (5–10 mg/d) when the disease is inactive. However, there are some in whom the disease pursues a virulent course, leading to serious impairment of vital structures such as lung, heart, brain, or kidneys, and the disease may lead to death. With improved control of lupus activity and with increasing use of corticosteroids and immunosuppressive drugs, the mortality and morbidity patterns in lupus have changed. Mortality in SLE shows a bimodal pattern. In the early years after diagnosis, infections—especially with opportunistic organisms—are the leading cause of death, followed by active SLE, chiefly due to kidney or central nervous system disease. In later years, accelerated atherosclerosis, linked to chronic inflammation, becomes a major cause of death. Indeed, the incidence of myocardial infarction is five times higher in persons with SLE than in the general population. Therefore, it is especially important for SLE patients to avoid smoking and to minimize other conventional risk factors for atherosclerosis (eg, hypercholesterolemia, hypertension, obesity, and inactivity). Patients with SLE should receive influenza vaccination every year and pneumococcal vaccination every 5 years. Since SLE patients have a higher risk of developing malignancy (especially lymphoma, lung cancer, and cervical cancer), preventive cancer screening recommendations should be followed assiduously. With more patients living longer, it has become evident that avascular necrosis of bone, affecting most commonly the hips and knees, is responsible for substantial morbidity. Nonetheless, the outlook for most patients with SLE has become increasingly favorable.

▶ When to Refer

- Appropriate diagnosis and management of SLE requires the active participation of a rheumatologist.
- The severity of organ involvement dictates referral to other subspecialists, such as nephrologists and pulmonologists.

▶ When to Admit

- Rapidly progressive glomerulonephritis, pulmonary hemorrhage, transverse myelitis, and other severe organ-threatening manifestations of lupus usually require inpatient assessment and management.
- Severe infections, particularly in the setting of immunosuppressant therapy, should prompt admission.

ANTIPHOSPHOLIPID SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Hypercoagulability, with recurrent thromboses in either the venous or arterial circulation.
- ▶ Thrombocytopenia is common.
- ▶ Pregnancy complications, specifically pregnancy losses after the first trimester.
- ▶ Lifelong anticoagulation with warfarin is recommended currently for patients with serious complications of this syndrome because recurrent events are common.

▶ General Considerations

A primary **antiphospholipid syndrome** (APS) is diagnosed in patients who have venous or arterial occlusions, recurrent fetal loss, or thrombocytopenia in the presence of persistent antiphospholipid antibodies but not other features of SLE. In < 1% of patients with antiphospholipid antibodies, a potentially devastating syndrome known as the “catastrophic antiphospholipid syndrome” occurs, leading to diffuse thromboses, thrombotic microangiopathy, and multiorgan system failure.

▶ Clinical Findings

A. Symptoms and Signs

Patients are often asymptomatic until suffering a thrombotic complication of this syndrome or a pregnancy loss. Thrombotic events may occur in either the arterial or venous circulations. Thus, deep venous thromboses, pulmonary emboli, cerebrovascular accidents are typical clinical events among patients with the APS. Budd-Chiari syndrome, cerebral sinus vein thrombosis, myocardial or digital infarctions, and other thrombotic events also occur. A variety of other symptoms and signs are often attributed to the APS, including mental status changes, livedo reticularis, skin ulcers, microangiopathic nephropathy, and cardiac valvular dysfunction—typically mitral regurgitation

that may mimic Libman-Sacks endocarditis. Livedo reticularis is strongly associated with the subset of patients with APS in whom arterial ischemic events develop. Pregnancy losses that are associated with APS include unexplained fetal death after the first trimester, one or more premature births before 34 weeks because of eclampsia or preeclampsia, or three or more unexplained miscarriages during the first trimester.

B. Laboratory Findings

As noted in the discussion of SLE, three types of antiphospholipid antibody are believed to contribute to this syndrome: (1) anti-cardiolipin antibodies; (2) a “lupus anticoagulant” that prolongs certain coagulation tests (see below); and (3) an antibody associated with a biologic false-positive test for syphilis. Anti-cardiolipin antibodies are typically measured with enzyme immunoassays for either IgG or IgM. In general, IgG anti-cardiolipin antibodies are believed to be more pathologic than IgM. A clue to the presence of a lupus anticoagulant, which may occur in individuals who do not have SLE, may be detected by a prolongation of the partial thromboplastin time (which, paradoxically, is associated with a thrombotic tendency rather than a bleeding risk). A finding more sensitive for a lupus anticoagulant, however, is prolongation of the coagulation assay known as the Russell viper venom time (RVVT). In the presence of a lupus anticoagulant, the RVVT is prolonged and does not correct with mixing studies but does with the addition of excess phospholipid. With the last type of antiphospholipid antibody, the patient has a positive rapid plasma reagin (RPR), but negative specific anti-treponemal assays.

► Differential Diagnosis

The exclusion of other autoimmune disorders, particularly those in the SLE spectrum, is essential because such disorders may be associated with additional complications requiring alternative treatments. Other genetic or acquired conditions associated with hypercoagulability such as protein C, protein S, factor V Leiden, and antithrombin deficiency should be excluded. Catastrophic APS has a broad differential, including sepsis, pulmonary-renal syndromes, systemic vasculitis, disseminated intravascular coagulation, and thrombotic thrombocytopenic purpura.

► Treatment

Present recommendations for anticoagulation are to treat patients with warfarin to maintain an INR of 2.0–3.0. Patients who have recurrent thrombotic events on this level of anticoagulation may require higher INRs (> 3.0), but the bleeding risk increases substantially with this degree of anticoagulation. Guidelines indicate that patients with APS should be treated with anticoagulation for life. Because of the teratogenic effects of warfarin, subcutaneous heparin and low dose aspirin (81 mg) is the usual approach to prevent pregnancy complications in women with APS. In patients with catastrophic APS, a three-pronged approach is taken in the acute setting: intravenous heparin, high doses of corticosteroids, and either intravenous immune globulin or plasmapheresis.

RAYNAUD PHENOMENON

ESSENTIALS OF DIAGNOSIS

- Paroxysmal bilateral digital pallor and cyanosis followed by rubor.
- Precipitated by cold or emotional stress; relieved by warmth.
- Primarily affects young women.
- Primary form benign; secondary form can cause digital ulceration or gangrene.

► General Considerations

Raynaud phenomenon (RP) is a syndrome of paroxysmal digital ischemia, most commonly caused by an exaggerated response of digital arterioles to cold or emotional stress. The initial phase of RP, mediated by excessive vasoconstriction, consists of well-demarcated digital pallor or cyanosis; the subsequent (recovery) phase of RP, caused by vasodilation, leads to intense hyperemia and rubor. Although RP chiefly affects fingers, it can also affect toes and other acral areas such as the nose and ears. RP is classified as primary (idiopathic or Raynaud disease) or secondary. Nearly one-third of the population reports being “sensitive to the cold” but does not experience the paroxysms of digital pallor, cyanosis, and erythema characteristic of RP. Primary RP occurs in 2–6% of adults, is especially common in young women, and poses more of a nuisance than a threat to good health. In contrast, secondary RP is less common, is chiefly associated with rheumatic diseases (especially scleroderma), and is frequently severe enough to cause digital ulceration or gangrene.

► Clinical Findings

In early attacks of RP, only one or two fingertips may be affected; as it progresses, all fingers down to the distal palm may be involved. The thumbs are rarely affected. During recovery there may be intense rubor, throbbing, paresthesia, pain, and slight swelling. Attacks usually terminate spontaneously or upon returning to a warm room or putting the extremity in warm water. The patient is usually asymptomatic between attacks. Sensory changes that often accompany vasomotor manifestations include numbness, stiffness, diminished sensation, and aching pain.

Primary RP appears first between ages 15 and 30, almost always in women. It tends to be mildly progressive and, unlike secondary RP (which may be unilateral and may involve only one or two fingers), symmetric involvement of the fingers of both hands is the rule. Spasm becomes more frequent and prolonged. Unlike secondary RP, primary RP does not cause digital pitting, ulceration, or gangrene.

Nailfold capillary abnormalities are among the earliest clues that a person has secondary rather than primary RP. The nailfold capillary pattern can be visualized by placing a drop of grade B immersion oil at the patient's cuticle and then viewing the area with an ophthalmoscope set to 20–40 diopters. Dilation or dropout of the capillary loops indicates the patient has a secondary form of RP, most commonly scleroderma (Table 20–12). While highly specific for secondary RP, nailfold capillary changes have a low sensitivity. Digital pitting or ulceration or other abnormal physical findings (eg, skin tightening, loss of extremity pulse, rash, swollen joints) can also provide evidence of secondary RP.

Primary RP must be differentiated from the numerous causes of secondary RP (Table 20–12). The history and examination may suggest the diagnosis of systemic sclerosis (including its CREST variant), SLE, and mixed connective tissue disease; RP is occasionally the first manifestation of these disorders. The diagnosis of many of these rheumatic diseases can be confirmed with specific serologic tests (see Table 20–10).

Table 20–12. Causes of secondary Raynaud phenomenon.

Rheumatic diseases
Scleroderma

Polycythemia vera
Paraproteinemia
Cold agglutinins
Endocrine disorders
Hypothyroidism
Pheochromocytoma
Miscellaneous
Atherosclerosis
Embolic disease
Migraine
Exposure to epoxy resins
Sequela of frostbite

RP may occur in patients with the thoracic outlet syndromes. In these disorders, involvement is generally unilateral, and symptoms referable to brachial plexus compression tend to dominate the clinical picture. Carpal tunnel syndrome should also be considered, and nerve conduction tests are appropriate in selected cases.

A particularly severe form of RP occurs in up to one-third of patients receiving bleomycin and vincristine in combination, often for testicular cancer. Treatment is unsuccessful, and the problem persists even with discontinuation of the drugs.

► Differential Diagnosis

The differentiation from Buerger disease (thromboangiitis obliterans) is usually not difficult, since thromboangiitis obliterans is generally a disease of men, particularly smokers; peripheral pulses are often diminished or absent; and, when RP occurs in association with thromboangiitis obliterans, it is usually in only one or two digits.

In acrocyanosis, cyanosis of the hands is permanent and diffuse; the sharp and paroxysmal line of demarcation with pallor does not occur with acrocyanosis. Frostbite may lead to chronic RP. Ergot poisoning, particularly due to prolonged or excessive use of ergotamine, must also be considered but is unusual.

RP may be mimicked by type I cryoglobulinemia, in which a monoclonal antibody cryoprecipitates in the cooler distal circulation. Type I cryoglobulinemia is usually associated with multiple myeloma or with lymphoproliferative disorders.

Erythromelalgia can mimic the rubor phase of RP; exacerbation by heat and relief with cold readily distinguish erythromelalgia from RP.

► Treatment

A. General Measures

Patients should wear gloves or mittens whenever outside in temperatures that precipitate attacks. Keeping the body warm is also a cornerstone of initial therapy. Wearing warm shirts, coats, and hats will help prevent the exaggerated vasospasm that causes RP and that is not prevented by warming only the hands. The hands should be protected from injury at all times; wounds heal slowly, and infections are consequently hard to control. Softening and lubricating lotion to control the fissured dry skin should be applied to the hands frequently. Smoking should be stopped and sympathomimetic drugs (eg, decongestants, diet pills, and amphetamines) should be avoided. For most patients with primary RP, general measures alone are sufficient to control symptoms. Medical or surgical therapy should be considered in patients who have severe symptoms or are experiencing tissue injury from digital ischemia.

B. Medications

Calcium channel blockers are first-line therapy for RP. Calcium channel blockers produce a modest benefit and are more effective in primary RP than secondary RP. Slow release nifedipine (30–180 mg/d orally), amlodipine (5–20 mg/d orally), felodipine, or nisoldipine are popular and more effective than verapamil and diltiazem. Other medications that are sometimes effective in treating RP

include angiotensin-converting enzyme inhibitors, sympatholytic agents (eg, prazosin), topical nitrates, phosphodiesterase inhibitors (eg, sildenafil, tadalafil, and vardenafil), selective serotonin reuptake inhibitors (fluoxetine), endothelin-receptor inhibitors (ie, bosentan), statins, parenteral prostaglandins (prostaglandin E₁), and oral prostaglandins (misoprostol).

C. Surgical Measures

Sympathectomy may be indicated when attacks have become frequent and severe, when they interfere with work and well being, and particularly when trophic changes have developed and medical measures have failed. Cervical sympathectomy is modestly effective for primary but not secondary RP. Digital sympathectomy may improve secondary RP.

► Prognosis

Primary RP is benign and largely a nuisance for affected individuals who are exposed to cold winters or excessive air conditioning. The prognosis of secondary RP depends on the severity of the underlying disease. Unfortunately, severe pain from ulceration and gangrene are not rare with scleroderma, especially the CREST variant.

► When to Refer

- Appropriate management of patients with secondary RP often requires consultation with a rheumatologist.

► When to Admit

- Patients with severe digital ischemia as evidenced by demarcation should be admitted for intensive therapy.

SCLERODERMA (Systemic Sclerosis)

ESSENTIALS OF DIAGNOSIS

- Limited disease (80% of patients): thickening of skin confined to the face, neck, and distal extremities.
- Diffuse disease (20%): widespread thickening of skin, including truncal involvement, with areas of increased pigmentation and depigmentation.
- Raynaud phenomenon and antinuclear antibodies are present in virtually all patients.
- Systemic features of gastroesophageal reflux, hypomotility of gastrointestinal tract, pulmonary fibrosis, pulmonary hypertension, and renal involvement.

► General Considerations

Scleroderma (systemic sclerosis) is a rare chronic disorder characterized by diffuse fibrosis of the skin and internal organs. Symptoms usually appear in the third to fifth decades, and women are affected two to three times as frequently as men.

Two forms of scleroderma are generally recognized: limited (80% of patients) and diffuse (20%). In limited scleroderma, which is also known as the CREST syndrome (representing calcinosis cutis, Raynaud phenomenon, esophageal motility disorder, sclerodactyly, and telangiectasia), the hardening of the skin (scleroderma) is limited to the face and hands. In contrast, in diffuse scleroderma, the skin changes also involve the trunk and proximal extremities. Tendon friction rubs over the forearms and shins occur uniquely (but not universally) in diffuse scleroderma. In general, patients with limited scleroderma have better outcomes than those with diffuse disease, largely because kidney disease or interstitial lung disease rarely develops in patients with limited disease. Cardiac disease is also more characteristic of diffuse scleroderma. Patients with limited disease, however, are more susceptible to digital ischemia, leading to finger loss, and to life-threatening pulmonary hypertension. Small and large bowel hypomotility, which may occur in either form of scleroderma, can cause constipation alternating with diarrhea, malabsorption due to bacterial overgrowth, pseudoobstruction, and severe bowel distension with rupture.

► Clinical Findings

A. Symptoms and Signs

Raynaud phenomenon is usually the initial manifestation and can precede other signs and symptoms by years in cases of limited scleroderma. Polyarthralgia, weight loss, and malaise are common early features of diffuse scleroderma but are infrequent in limited scleroderma. Cutaneous disease usually, but not always, develops before visceral involvement and can manifest initially as non-pitting subcutaneous edema associated with pruritus. With time the skin becomes thickened and hidebound, with loss of normal folds. Telangiectasia, pigmentation, and depigmentation are characteristic. Ulceration about the fingertips and subcutaneous calcification are seen. Dysphagia and symptoms of reflux due to esophageal dysfunction are common and result from abnormalities in motility and later from fibrosis. Fibrosis and atrophy of the gastrointestinal tract cause hypomotility. Large-mouthed diverticuli occur in the jejunum, ileum, and colon. Diffuse pulmonary fibrosis and pulmonary vascular disease are reflected in restrictive lung physiology and low diffusing capacities. Cardiac abnormalities include pericarditis, heart block, myocardial fibrosis, and right heart failure secondary to pulmonary hypertension. Scleroderma renal crisis, resulting from intimal proliferation of smaller renal arteries and usually associated with hypertension, is a marker for a poor outcome even though many cases can be treated effectively with angiotensin-converting enzyme inhibitors.

B. Laboratory Findings

Mild anemia is often present. In scleroderma renal crisis, the peripheral blood smear shows findings consistent with a microangiopathic hemolytic anemia (due to mechanical damage to red cells from diseased small vessels). Elevation of the ESR is unusual. Proteinuria appears in association with renal involvement. Antinuclear antibody tests are nearly always positive, frequently in high titers (Table 20–10). The scleroderma antibody (anti-SCL-70), directed against topoisomerase III, is found in one-third of patients with diffuse systemic sclerosis and in 20% of those with CREST syndrome. Although present in only a small number of patients with diffuse scleroderma, anti-SCL-70 antibodies may portend a poor prognosis, with a high likelihood of serious internal organ involvement (eg, interstitial lung disease). Anticentromere antibodies are seen in 50% of those with CREST syndrome and in 1% of individuals with diffuse scleroderma (Table 20–10). Anticentromere antibodies are highly specific for limited scleroderma, but they also occur occasionally in overlap syndromes. Anti-RNA polymerase III antibodies develop in 10–20% of scleroderma patients overall and correlate with the development of diffuse skin disease and renal hypertensive crisis.

► Differential Diagnosis

Early in its course, scleroderma can cause diagnostic confusion with other causes of Raynaud phenomenon, particularly SLE, mixed connective tissue disease, and the inflammatory myopathies. Scleroderma can be mistaken for other disorders characterized by skin hardening. Eosinophilic fasciitis is a rare disorder presenting with skin changes that resemble diffuse scleroderma. The inflammatory abnormalities, however, are limited to the fascia rather than the dermis and epidermis. Moreover, patients with eosinophilic fasciitis are distinguished from those with scleroderma by the presence of peripheral blood eosinophilia, the absence of Raynaud phenomenon, the good response to prednisone, and an association (in some cases) with paraproteinemias. Diffuse skin thickening and visceral involvement are features of scleromyxedema; the presence of a paraprotein, the absence of Raynaud phenomenon, and distinct skin histology point to scleromyxedema. Diabetic cheiropathy typically develops in long-standing, poorly controlled diabetes and can mimic sclerodactyly. Nephrogenic fibrosing dermopathy produces thickening and hardening of the skin of the trunk and extremities in patients with chronic kidney disease; exposure to gadolinium may play a pathogenic role. Morphea and linear scleroderma cause sclerodermatous changes limited to circumscribed areas of the skin and usually have excellent outcomes.

► Treatment

Treatment of scleroderma is symptomatic and supportive and focuses on the organ systems involved. There is no effective therapy for the underlying disease process. However, interventions for management of specific organ manifestations of this disease have improved substantially. Severe

Raynaud syndrome may respond to calcium channel blockers, eg, long-acting nifedipine, 30–120 mg/d orally, or to losartan, 50 mg/d orally, or to sildenafil 50 mg orally twice daily. Patients with esophageal disease should take medications in liquid or crushed form. Esophageal reflux can be reduced and the risk of scarring diminished by avoidance of late-night meals and by the use of proton pump inhibitors (eg, omeprazole, 20–40 mg/d orally), which achieve near-complete inhibition of gastric acid production and are remarkably effective for refractory esophagitis. Patients with delayed gastric emptying maintain their weight better if they eat small, frequent meals and remain upright for at least 2 hours after eating. Long-term octreotide (0.1 mg subcutaneously twice daily), a somatostatin analog, helps some patients with bacterial overgrowth and pseudoobstruction. Malabsorption due to bacterial overgrowth also responds to antibiotics, eg, tetracycline, 500 mg four times orally daily, often prescribed cyclically. The hypertensive crises associated with systemic sclerosis renal crisis must be treated early and aggressively (in the hospital) with angiotensin-converting enzyme inhibitors, eg, captopril, initiated at 25 mg orally every 6 hours and titrated up as tolerated to a maximum of 100 mg every 6 hours. Apart from the patient with myositis, prednisone has little or no role in the treatment of scleroderma; high doses (> 15 mg daily) have been associated with scleroderma renal crisis. Cyclophosphamide improves dyspnea and pulmonary function tests modestly in patients with severe interstitial lung disease; this highly toxic drug should only be administered by physicians familiar with its use. Mycophenolate mofetil, 1 g twice daily, stabilized lung function in small, uncontrolled studies of patients with interstitial lung disease. Bosentan, an endothelin receptor antagonist, improves exercise capacity and cardiopulmonary hemodynamics in patients with pulmonary hypertension and helps prevent digital ulceration. Sildenafil or prostaglandins (delivered by continuous intravenous infusion or intermittent inhalation) may also be useful in treating pulmonary hypertension. At an experimental level, immunoablative therapy with or without stem cell rescue has achieved promising results for some patients with severe, rapidly progressive diffuse scleroderma.

The 9-year survival rate in scleroderma averages approximately 40%. The prognosis tends to be worse in those with diffuse scleroderma, in blacks, in males, and in older patients. Lung disease—in the form of pulmonary fibrosis or pulmonary arterial hypertension—is now the number one cause of mortality. Death from advanced heart failure or chronic kidney disease is also common. Those persons in whom severe internal organ involvement does not develop in the first 3 years have a substantially better prognosis, with 72% surviving at least 9 years. Breast and lung cancer may be more common in patients with scleroderma.

► When to Refer

- Appropriate management of scleroderma requires frequent consultations with a rheumatologist.
- Severity of organ involvement dictates referral to other subspecialists, such as pulmonologists or gastroenterologists.

IDIOPATHIC INFLAMMATORY MYOPATHIES (Polymyositis & Dermatomyositis)

ESSENTIALS OF DIAGNOSIS

- ▶ Bilateral proximal muscle weakness.
- ▶ Characteristic cutaneous manifestations in dermatomyositis (Gottron papules, heliotrope rash).
- ▶ Diagnostic tests: elevated creatine kinase, muscle biopsy, electromyography, MRI.
- ▶ Increased risk of malignancy, particularly in dermatomyositis.
- ▶ Inclusion body myositis can mimic polymyositis but is less responsive to treatment.

▶ General Considerations

Polymyositis and dermatomyositis are systemic disorders of unknown cause whose principal manifestation is muscle weakness. Although their clinical presentations (aside from the presence of certain skin findings in dermatomyositis, some of which are pathognomonic) and treatments are similar, the two diseases are pathologically quite distinct. They affect persons of any age group, but the peak incidence is in the fifth and sixth decades of life. Women are affected twice as commonly as men, and the diseases (particularly polymyositis) also occur more often among blacks than whites. There is an increased risk of malignancy in adult patients with dermatomyositis. Indeed, up to one patient in four with dermatomyositis has an occult malignancy. Malignancies may be evident at the time of presentation with the muscle disease but may not be detected until months afterward in some cases. Rare patients with dermatomyositis have skin disease without overt muscle involvement, a condition termed “dermatomyositis sine myositis.” Myositis may also be associated with other connective tissue diseases, especially scleroderma, lupus, mixed connective tissue disease, and Sjögren syndrome.

▶ Clinical Findings

A. Symptoms and Signs

Polymyositis may begin abruptly, but the usual presentation is one of gradual and progressive muscle weakness. The weakness chiefly involves proximal muscle groups of the upper and lower extremities as well as the neck. Leg weakness (eg, difficulty in rising from a chair or climbing stairs) typically precedes arm symptoms. In contrast to myasthenia

gravis, polymyositis and dermatomyositis do not cause facial or ocular muscle weakness. Pain and tenderness of affected muscles occur in one-fourth of cases, but these are rarely the chief complaints. About one-fourth of patients have dysphagia. In contrast to scleroderma, which affects the smooth muscle of the lower esophagus and can cause a “sticking” sensation below the sternum, polymyositis or dermatomyositis involves the striated muscles of the upper pharynx and can make initiation of swallowing difficult. Muscle atrophy and contractures occur as late complications of advanced disease. Clinically significant myocarditis is uncommon even though there is often creatine kinase-MB elevation. Patients who are bed-bound from myositis should be screened for respiratory muscle weakness that can be severe enough to cause CO₂ retention and can progress to require mechanical ventilation.

The characteristic rash of **dermatomyositis** is dusky red and may appear in a malar distribution mimicking the classic rash of SLE. Facial erythema beyond the malar distribution is also characteristic of dermatomyositis. Erythema also occurs over other areas of the face, neck, shoulders, and upper chest and back (“shawl sign”). Periorbital edema and a purplish (heliotrope) suffusion over the eyelids are typical signs (Figure 20–6). Coloration of the heliotrope and other rashes of dermatomyositis can be affected by skin tone. In blacks, the rashes may appear more hyperpigmented than erythematous or violaceous. Periungual erythema, dilations of nailbed capillaries, and scaly patches over the dorsum of PIP and MCP joints (Gottron sign) are highly suggestive. Scalp involvement by dermatomyositis may mimic psoriasis. Infrequently, the cutaneous findings of this disease precede the muscle inflammation by weeks or months. Diagnosing polymyositis in patients over age 70 years can be difficult because weakness may be overlooked or attributed erroneously to idiopathic frailty. Polymyositis can remain undiagnosed or will be misdiagnosed as hepatitis because of elevations in alanine aminotransferase (ALT) and aspartate

▲ **Figure 20–6.** Heliotrope (violaceous) rash around the eyes in a patient with dermatomyositis. (Courtesy of Richard P. Usatine, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

aminotransferase (AST) levels. A subset of patients with polymyositis and dermatomyositis develop the “**antisynthetase syndrome**,” a group of findings including inflammatory arthritis, fever, Raynaud phenomenon, “mechanic’s hands” (hyperkeratosis along the radial and palmar aspects of the fingers) interstitial lung disease, and often severe muscle disease associated with certain autoantibodies (eg, anti-Jo1 antibodies).

B. Laboratory Findings

Measurement of serum levels of muscle enzymes, especially creatine kinase and aldolase, is most useful in diagnosis and in assessment of disease activity. Anemia is uncommon. The ESR and C-reactive protein are often normal and are not reliable indicators of disease activity. Rheumatoid factor is found in a minority of patients. Antinuclear antibodies are present in many patients, especially those who have an associated connective tissue disease (Table 20–10). A number of autoantibodies are seen exclusively in patients with myositis and are associated with distinctive clinical features. The most common myositis-specific antibody, anti-Jo-1 antibody, is seen in the subset of patients who have associated interstitial lung disease (Table 20–10). The other myositis-specific autoantibodies are anti-Mi-2, associated with dermatomyositis; anti-SRP (anti-signal recognition particle), associated with rapidly progressive, severe polymyositis, and dysphagia; and anti-155/140, strongly associated with dermatomyositis with malignancy (malignancy in 71% with versus 11% without this antibody). In the absence of the anti-synthetase syndrome, chest radiographs are usually normal. Electromyographic abnormalities consisting of polyphasic potentials, fibrillations, and high-frequency action potentials point toward a myopathic, rather than a neurogenic, cause of weakness. MRI can detect early and patchy muscle involvement, can guide biopsies, and often is more useful than electromyography. The malignancies most commonly associated with dermatomyositis in descending order of frequency are ovarian, lung, pancreatic, stomach, colorectal, and non-Hodgkin lymphoma. The search for an occult malignancy should begin with a history and physical examination, supplemented with a complete blood count, comprehensive biochemical panel, serum protein electrophoresis, and urinalysis, and should include age- and risk-appropriate cancer screening tests. Given the especially strong association of ovarian carcinoma and dermatomyositis, transvaginal ultrasonography, CT scanning, and CA-125 levels may be useful in women. No matter how extensive the initial screening, some malignancies will not become evident for months after the initial presentation.

C. Muscle Biopsy

Biopsy of clinically involved muscle is the only specific diagnostic test. The pathology findings in polymyositis and dermatomyositis are distinct. Although both include lymphoid inflammatory infiltrates, the findings in dermatomyositis are localized to perivascular regions and there is evidence of humoral and complement-mediated destruction of microvasculature associated with the

muscle. In addition to its vascular orientation, the inflammatory infiltrate in dermatomyositis centers on the interfascicular septa and is located around, rather than in, muscle fascicles. A pathologic hallmark of dermatomyositis is perifascicular atrophy. In contrast, the pathology of polymyositis characteristically includes endomysial infiltration of the inflammatory infiltrate. Owing to the sometimes patchy distribution of pathologic abnormalities, however, false-negative biopsies sometimes occur in both disorders.

► Differential Diagnosis

Muscle inflammation may occur as a component of SLE, scleroderma, Sjögren syndrome, and overlap syndromes. In those cases, associated findings usually permit the precise diagnosis of the primary condition.

Inclusion body myositis, because of its tendency to mimic polymyositis, is a common cause of “treatment-resistant polymyositis.” In contrast to the epidemiologic features of polymyositis, however, the typical inclusion body myositis patient is white, male, and over the age of 50. The onset of inclusion body myositis is more insidious than that of polymyositis or dermatomyositis (eg, occurring over years rather than months), and asymmetric distal motor weakness is common in inclusion body myositis. Creatine kinase levels in inclusion body myositis are often minimally elevated and are normal in 25%. Electromyography may show a mixed picture of myopathic and neurogenic abnormalities. Muscle biopsy shows characteristic intracellular vacuoles by light microscopy and either tubular or filamentous inclusions in the nucleus or cytoplasm by electron microscopy. Inclusion body myositis is less likely to respond to therapy.

Hypothyroidism is a common cause of proximal muscle weakness associated with elevations of serum creatine kinase. Hyperthyroidism and Cushing disease may both be associated with proximal muscle weakness with normal levels of creatine kinase. Patients with polymyalgia rheumatica are over the age of 50 and—in contrast to patients with polymyositis—have pain but no objective weakness; creatine kinase levels are normal. Disorders of the peripheral and central nervous systems (eg, chronic inflammatory polyneuropathy, multiple sclerosis, myasthenia gravis, Eaton-Lambert disease, and amyotrophic lateral sclerosis) can produce weakness but are distinguished by characteristic symptoms and neurologic signs and often by distinctive electromyographic abnormalities. A number of systemic vasculitides (polyarteritis nodosa, microscopic polyangiitis, the Churg-Strauss syndrome, granulomatosis with polyangiitis, and mixed cryoglobulinemia) can produce profound weakness through vasculitic neuropathy. The muscle weakness associated with these disorders, however, is typically distal and asymmetric, at least in the early stages.

Many drugs, including corticosteroids, alcohol, clofibrate, penicillamine, tryptophan, and hydroxychloroquine, can produce proximal muscle weakness. Long-term use of colchicine at doses as low as 0.6 mg twice a day in patients with moderate chronic kidney disease can produce a mixed neuropathy-myopathy that mimics polymyositis. The weakness and muscle enzyme elevation reverse

with cessation of the drug. Polymyositis can occur as a complication of HIV or HTLV-1 infection and with zidovudine therapy as well.

HMG-CoA reductase inhibitors can cause myopathy and rhabdomyolysis. Although only about 0.1% of patients taking a statin drug alone develop myopathy, concomitant administration of other drugs (especially gemfibrozil, cyclosporine, niacin, macrolide antibiotics, azole antifungals, and protease inhibitors) increases the risk. Statin use has also been linked to the development of an autoimmune-mediated necrotizing myositis, which persists after the statin has been discontinued and is associated with autoantibodies to HMG-CoA reductase.

► Treatment

Most patients respond to corticosteroids. Often a daily dose of 40–60 mg or more of oral prednisone is required initially. The dose is then adjusted downward while monitoring muscle strength and serum levels of muscle enzymes. Long-term use of corticosteroids is often needed, and the disease may recur or reemerge when they are withdrawn. Patients with an associated neoplasm have a poor prognosis, although remission may follow treatment of the tumor; corticosteroids may or may not be effective in these patients. In patients resistant or intolerant to corticosteroids, therapy with methotrexate or azathioprine may be helpful. Intravenous immune globulin is effective for dermatomyositis resistant to prednisone. Mycophenolate mofetil (1–1.5 g orally twice daily) may be useful as a steroid-sparing agent. Rituximab has achieved encouraging results in some patients with inflammatory myositis unresponsive to prednisone. Since the rash of dermatomyositis is often photosensitive, patients should limit sun exposure. Hydroxychloroquine (200–400 mg/d orally not to exceed 6.5 mg/kg) can also help ameliorate the skin disease.

► When to Refer

- Appropriate management of myositis usually requires frequent consultations with a rheumatologist or neurologist.
- Severe lung disease may require consultation with a pulmonologist.

► When to Admit

- Signs of rhabdomyolysis.
- Respiratory insufficiency with hypoxia or carbon dioxide retention.

MIXED CONNECTIVE TISSUE DISEASE & OVERLAP SYNDROMES

Many patients with symptoms and signs compatible with a connective tissue disease have features consistent with more than one type of rheumatic disease. Special attention has been drawn to antinuclear antibody–positive patients who have overlapping features of SLE, scleroderma, and inflammatory myopathy together with autoantibodies to ribonuclear protein (RNP). Some consider these patients to have a distinct entity (“mixed connective tissue disease”), and others view this as a subset of SLE characterized by a higher prevalence of Raynaud phenomenon, polyarthritides, myositis, and pulmonary hypertension and a lower incidence of renal involvement. Other patients have features of more than one connective tissue disease (eg, rheumatoid arthritis and SLE, SLE and scleroderma) in the absence of anti-RNP antibodies and are referred to as having an “overlap syndrome.” Treatments are guided more by the distribution and severity of patients’ organ system involvement than by therapies specific to these overlap syndromes.

Tsai YY et al. Fifteen-year experience of pediatric-onset mixed connective tissue disease. *Clin Rheumatol.* 2010 Jan;29(1): 53–8. [PMID: 19756834]

SJÖGREN SYNDROME

ESSENTIALS OF DIAGNOSIS

- Women are 90% of patients; the average age is 50 years.
- Dryness of eyes and dry mouth (sicca components) are the most common features; they occur alone or in association with rheumatoid arthritis or other connective tissue disease.
- Rheumatoid factor and other autoantibodies are common.
- Increased incidence of lymphoma.

► General Considerations

Sjögren syndrome is a systemic autoimmune disorder whose clinical presentation is usually dominated by dryness of the eyes and mouth due to immune-mediated dysfunction of the lacrimal and salivary glands. The disorder is predominantly seen in women, with a ratio of 9:1; most cases develop between the ages of 40 and 60 years. Sjögren syndrome can occur in isolation (“primary” Sjögren syndrome) or in association with another rheumatic disease. Sjögren syndrome is most frequently associated with rheumatoid arthritis but also occurs with SLE, primary biliary cirrhosis, scleroderma, polymyositis, Hashimoto thyroiditis, polyarteritis, and interstitial pulmonary fibrosis.

► Clinical Findings

A. Symptoms and Signs

Keratoconjunctivitis sicca results from inadequate tear production caused by lymphocyte and plasma cell infiltration of the lacrimal glands. Ocular symptoms are usually mild. Burning, itching, and the sensation of having a foreign body or a grain of sand in the eye occur commonly. For some patients, the initial manifestation is the inability to tolerate wearing contact lenses. Many patients with more severe ocular dryness notice ropy secretions across their eyes, especially in the morning. Photophobia may signal corneal ulceration resulting from severe dryness. For most patients, symptoms of dryness of the mouth (xerostomia) dominate those of dry eyes. Patients frequently complain of a “cotton mouth” sensation and difficulty swallowing foods, especially dry foods like crackers, unless they are washed down with liquids. The persistent oral dryness causes most patients to carry water bottles or other liquid dispensers from which they sip constantly. A few patients have such severe xerostomia that they have difficulty speaking. Persistent xerostomia results often in rampant dental caries; caries at the gum line strongly suggest Sjögren syndrome. Some patients are most troubled by loss of taste and smell. Parotid enlargement, which may be chronic or relapsing, develops in one-third of patients. Desiccation may involve the nose, throat, larynx, bronchi, vagina, and skin.

Systemic manifestations include dysphagia, small vessel vasculitis, pleuritis, obstructive airways disease and interstitial lung disease (in the absence of smoking), neuropsychiatric dysfunction (most commonly peripheral neuropathies), and pancreatitis; they may be related to the associated diseases noted above. Renal tubular acidosis (type I, distal) occurs in 20% of patients. Chronic interstitial nephritis, which may result in impaired kidney function, may be seen.

B. Laboratory Findings

Laboratory findings include mild anemia, leukopenia, and eosinophilia. Polyclonal hypergammaglobulinemia, rheumatoid factor positivity (70%), and antinuclear antibodies (95%) are all common findings. Antibodies against the cytoplasmic antigens SS-A and SS-B (also called Ro and La, respectively) are often present in primary Sjögren syndrome and tend to correlate with the presence of extraglandular manifestations (Table 20–10). Thyroid-associated autoimmunity is a common finding among patients with Sjögren syndrome.

Useful ocular diagnostic tests include the Schirmer test, which measures the quantity of tears secreted. Lip biopsy, a simple procedure, reveals characteristic lymphoid foci in accessory salivary glands. Biopsy of the parotid gland should be reserved for patients with atypical presentations such as unilateral gland enlargement that suggest a neoplastic process.

► Differential Diagnosis

Isolated complaints of dry mouth are most commonly due to medication side effects. Chronic hepatic C can cause sicca symptoms and rheumatoid factor positivity. Minor

salivary gland biopsies reveal lymphocytic infiltrates but not to the extent of Sjögren syndrome, and tests for anti-SS-A and anti-SS-B are negative. Diffuse infiltration of CD8 T cells producing parotid gland enlargement can develop in HIV-infected individuals. Involvement of the lacrimal or salivary glands, or both in sarcoidosis can mimic Sjögren syndrome; biopsies reveal noncaseating granulomas. Rarely, amyloid deposits in the lacrimal and salivary glands produce sicca symptoms. IgG4-related systemic disease (characterized by high serum IgG₄ levels and infiltration of tissues with IgG₄ plasma cells) can result in lacrimal and salivary gland enlargement that mimics Sjögren syndrome.

► Treatment & Prognosis

Treatment of sicca symptoms is symptomatic and supportive. Artificial tears applied frequently will relieve ocular symptoms and avert further desiccation. Topical ocular 0.05% cyclosporine also improves ocular symptoms and signs of dryness. The mouth should be kept well lubricated. Sipping water frequently or using sugar-free gums and hard candies usually relieves dry mouth symptoms. Pilocarpine (5 mg orally four times daily) and the acetylcholine derivative cevimeline (30 mg orally three times daily) may improve xerostomia symptoms. Atropinic drugs and decongestants decrease salivary secretions and should be avoided. A program of oral hygiene, including fluoride treatment, is essential in order to preserve dentition. If there is an associated rheumatic disease, its systemic treatment is not altered by the presence of Sjögren syndrome.

Although Sjögren syndrome may compromise patients' quality of life significantly, the disease is usually consistent with a normal life span. Poor prognoses are influenced mainly by the presence of systemic features associated with underlying disorders, the development in some patients of lymphocytic vasculitis, the occurrence of a painful peripheral neuropathy, and the complication (in a minority of patients) of lymphoma. Severe systemic inflammatory manifestations are treated with prednisone or various immunosuppressive medications. The patients (3–10% of the total Sjögren population) at greatest risk for developing lymphoma are those with severe exocrine dysfunction, marked parotid gland enlargement, splenomegaly, vasculitis, peripheral neuropathy, anemia, and mixed monoclonal cryoglobulinemia.

► When to Refer

- Presence of systemic symptoms or signs.
- Symptoms or signs of ocular dryness not responsive to artificial tears.

► When to Admit

- Presence of severe systemic signs such as vasculitis unresponsive to outpatient management.

RHABDOMYOLYSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Associated with crush injuries to muscle, prolonged immobility, drug toxicities, hypothermia, and other causes.
- ▶ Massive acute elevations of muscle enzymes that peak quickly and usually resolve within days once the inciting injury has been identified and removed.

▶ General Considerations

Rhabdomyolysis is a syndrome of acute necrosis of skeletal muscle associated with myoglobinuria and markedly elevated creatine kinase levels. Acute tubular necrosis is a common complication of rhabdomyolysis and is due to the toxic effects of filtering excessive quantities of myoglobin in the setting of hypovolemia (See Acute Tubular Necrosis in Chapter 22). Many patients in whom rhabdomyolysis develops are volume-contracted and, therefore, oliguric renal failure is encountered routinely.

Rhabdomyolysis was first recognized as a complication of crush injuries to muscle among victims of the London Blitz during the World War II. Cocaine use and alcohol intoxication, particularly in the setting of prolonged immobility and exposure hypothermia, are leading causes of admissions due to rhabdomyolysis on the medical services of inner city hospitals. Use of statins is another important cause of rhabdomyolysis. The presence of compromised kidney and liver function, diabetes mellitus, and hypothyroidism as well as concomitant use of other medications increase the risk of rhabdomyolysis in patients taking statins. The cytochrome P450 liver enzymes metabolize all statins except for pravastatin and rosuvastatin. Drugs that block the action of cytochrome P450 include protease inhibitors, erythromycin, itraconazole, clarithromycin, diltiazem, and verapamil. Use of these drugs concomitantly with the statins (but not pravastatin or rosuvastatin) can increase the risk of development of rhabdomyolysis. The likelihood of rhabdomyolysis also increases when statins are used with niacin and fibric acids (gemfibrozil, clofibrate, and fenofibrate). Rhabdomyolysis is an uncommon complication of polymyositis, dermatomyositis, and the myopathy of hypothyroidism, despite the high levels of creatine kinase often seen in these conditions.

Often there is little evidence for muscle injury on clinical assessment of the patients with rhabdomyolysis—specifically, myalgias and weakness are usually absent. The first clue to muscle necrosis in such individuals may be a

urinary dipstick testing positive for “blood” (actually myoglobin) in the absence of red cells in the sediment. This positive finding is due to myoglobinuria, which results in a false-positive reading for hemoglobin. Such an abnormality should prompt determination of the serum creatine kinase level, which invariably is elevated (usually markedly so). Other commonly encountered laboratory abnormalities in rhabdomyolysis include elevated serum levels of ALT and lactate dehydrogenase due to release of these enzymes from skeletal muscle.

▶ Treatment

Vigorous fluid resuscitation (4–6 L/d, with careful monitoring for volume overload) is indicated. Infusion of mannitol (100 mg/d) and urine alkalinization (to minimize precipitation of myoglobin within tubules) have been recommended as measures to reduce kidney injury, but definitive evidence for the efficacy of these measures is lacking. Myopathic complications of statins usually resolve within several weeks of discontinuing the drug.

VASCULITIS SYNDROMES

“Vasculitis” is a heterogeneous group of disorders characterized by inflammation within the walls of affected blood vessels. The major forms of primary systemic vasculitis are listed in Table 20–13. The first consideration in classifying cases of vasculitis is the size of the major vessels involved: large, medium, or small. The presence of the clinical signs and symptoms shown in Table 20–14 help distinguish among these three groups. After determining the size of the major vessels involved, other issues that contribute to the classification include the following:

- Does the process involve arteries, veins, or both?
- What are the patient’s demographic characteristics (age, gender, ethnicity, smoking status)?
- Which organs are involved?
- Is there hypocomplementemia or other evidence of immune complex deposition?
- Is there granulomatous inflammation on tissue biopsy?
- Are antineutrophil cytoplasmic antibodies (ANCA) present?

In addition to the disorders considered to be primary vasculitides, there are also multiple forms of vasculitis that are associated with other known underlying conditions. These “secondary” forms of vasculitis occur in the setting of chronic infections (eg, hepatitis B or C, subacute bacterial endocarditis), connective tissue disorders, inflammatory bowel disease, malignancies, and reactions to medications. Only the major primary forms of vasculitis are discussed here.

Table 20-13. Classification scheme of primary vasculitides according to size of predominant blood vessels involved.

<p>Predominantly large-vessel vasculitides</p> <ul style="list-style-type: none"> Takayasu arteritis Giant cell arteritis (temporal arteritis) Behçet disease¹ <p>Predominantly medium-vessel vasculitides</p> <ul style="list-style-type: none"> Polyarteritis nodosa Buerger disease Primary angiitis of the central nervous system <p>Predominantly small-vessel vasculitides</p> <ul style="list-style-type: none"> Immune-complex mediated <ul style="list-style-type: none"> Cutaneous leukocytoclastic angiitis (“hypersensitivity vasculitis”) Henoch-Schönlein purpura Essential cryoglobulinemia² “ANCA-associated” disorders³ Granulomatosis with polyangiitis (formerly Wegener granulomatosis)² Microscopic polyangiitis² Churg-Strauss syndrome²

POLYMYALGIA RHEUMATICA & GIANT CELL ARTERITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Age over 50 years.
- ▶ Giant cell (temporal) arteritis is characterized by headache, jaw claudication, polymyalgia rheumatica, visual abnormalities, and a markedly elevated ESR.
- ▶ The hallmark of polymyalgia rheumatica is pain and stiffness in shoulders and hips lasting for several weeks without other explanation.

▶ General Considerations

Polymyalgia rheumatica and giant cell arteritis probably represent a spectrum of one disease: Both affect the same population (patients over the age of 50), show preference for the same HLA haplotypes, and show similar patterns of cytokines in blood and arteries. Polymyalgia rheumatica and giant cell arteritis also frequently coexist. The important differences between the two conditions are that polymyalgia rheumatica alone does not cause blindness and responds to low-dose (10–20 mg/d orally) prednisone

Table 20-14. Typical clinical manifestations of large-, medium-, and small-vessel involvement by vasculitis.

Large	Medium	Small
Constitutional symptoms: fever, weight loss, malaise, arthralgias/arthrits		
Limb claudication	Cutaneous nodules	Purpura
Asymmetric blood pressures	Ulcers	Vesiculobullous lesions
Absence of pulses	Livedo reticularis	Urticaria
Bruits	Digital gangrene	Glomerulonephritis
Aortic dilation	Mononeuritis multiplex	Alveolar hemorrhage
	Microaneurysms	Cutaneous extravascular necrotizing granulomas
		Splinter hemorrhages
		Uveitis
		Episcleritis
		Scleritis

therapy, whereas giant cell arteritis can cause blindness and large artery complications and requires high-dose (40–60 mg/d) prednisone.

▶ Clinical Findings

A. Polymyalgia Rheumatica

Polymyalgia rheumatica is a clinical diagnosis based on pain and stiffness of the shoulder and pelvic girdle areas, frequently in association with fever, malaise, and weight loss. In approximately two-thirds of cases, polymyalgia occurs in the absence of giant cell arteritis. Because of the stiffness and pain in the shoulders, hips, and lower back, patients have trouble combing their hair, putting on a coat, or rising from a chair. In contrast to polymyositis and polyarteritis nodosa, polymyalgia rheumatica does not cause muscular weakness either through primary muscle inflammation or secondary to nerve infarction. A few patients have joint swelling, particularly of the knees, wrists, and sternoclavicular joints.

B. Giant Cell Arteritis

Giant cell arteritis is a systemic panarteritis affecting medium-sized and large vessels in patients over the age of 50. The incidence of this disease increases with each decade of life. The mean age at onset is approximately 79 years. Giant cell arteritis is also called temporal arteritis because that artery is frequently involved, as are other extracranial branches of the carotid artery. About 50% of patients with giant cell arteritis also have polymyalgia rheumatica. The classic symptoms suggesting that a patient has arteritis are headache, scalp tenderness, visual symptoms (particularly amaurosis fugax or diplopia), jaw claudication, or throat pain. Of these symptoms, jaw claudication has the highest positive predictive value. The temporal artery is usually normal on physical examination but may be nodular, enlarged, tender, or pulseless. Blindness usually results from the syndrome of anterior ischemic optic neuropathy, caused by occlusive arteritis of the posterior ciliary branch

of the ophthalmic artery. The ischemic optic neuropathy of giant cell arteritis may produce no fundoscopic findings for the first 24–48 hours after the onset of blindness.

Asymmetry of pulses in the arms, a murmur of aortic regurgitation, or bruits heard near the clavicle resulting from subclavian artery stenoses identify patients in whom giant cell arteritis has affected the aorta or its major branches. Clinically evident large vessel involvement—characterized chiefly by aneurysm of the thoracic aorta or stenosis of the subclavian, vertebral, carotid, and basilar arteries—occurs in approximately 25% of patients with giant cell arteritis, sometimes years after the diagnosis. Subclinical large artery disease is the rule: positron emission tomography scans reveal inflammation in the aorta and its major branches in nearly 85% of untreated patients. Forty percent of patients with giant cell arteritis have non-classic symptoms at presentation, chiefly respiratory tract problems (most frequently dry cough), mononeuritis multiplex (most frequently with painful paralysis of a shoulder), or fever of unknown origin. Giant cell arteritis accounts for 15% of all cases of fever of unknown origin in patients over the age of 65. The fever can be as high as 40°C and is frequently associated with rigors and sweats. In contrast to patients with infection, patients with giant cell arteritis and fever usually have normal white blood cell counts (before prednisone is started). Thus, in an older patient with fever of unknown origin, marked elevations of acute phase reactants, and a normal white blood count, giant cell arteritis must be considered even in the absence of specific features such as headache or jaw claudication. In some cases, instead of having the well-known symptom of jaw claudication, patients complain of vague pain affecting other locations, including the tongue, nose, or ears. Indeed, unexplained head or neck pain in an older patient may signal the presence of giant cell arteritis.

C. Laboratory Findings

1. Polymyalgia rheumatica—Anemia and elevated acute phase reactants (often markedly elevated ESRs, for example) are present in the most cases, but cases of polymyalgia rheumatica occurring with normal acute phase reactants are well documented.

2. Giant cell arteritis—Nearly 90% of patients with giant cell arteritis have ESRs > 50 mm/h. The ESR in this disorder is often > 100 mm/h, but cases in which the ESR is low or even normal do occur. In one series, 5% of patients with biopsy-proven giant cell arteritis had ESRs < 40 mm/h. Although the C-reactive protein is slightly more sensitive, patients with biopsy-proven giant cell arteritis with normal C-reactive proteins have also been described. Most patients also have a mild normochromic, normocytic anemia and thrombocytosis. The alkaline phosphatase (liver source) is elevated in 20% of patients with giant cell arteritis.

► Differential Diagnosis

The differential diagnosis of malaise, anemia, and striking acute phase reactant elevations includes rheumatic diseases (such as rheumatoid arthritis, other systemic vasculitides,

multiple myeloma, and other malignant disorders) and chronic infections (such as bacterial endocarditis and osteomyelitis).

► Treatment

A. Polymyalgia Rheumatica

Patients with isolated polymyalgia rheumatica (ie, those not having “above the neck” symptoms of headache, jaw claudication, scalp tenderness, or visual symptoms) are treated with prednisone, 10–20 mg/d orally. If the patient does not experience a dramatic improvement within 72 hours, the diagnosis should be revisited. Usually after 2–4 weeks of treatment, slow tapering of the prednisone can be attempted. Most patients require some dose of prednisone for a minimum of approximately 1 year; 6 months is too short in most cases. Disease flares are common (50% or more) as prednisone is tapered. The addition of weekly methotrexate may increase the chance of successfully tapering prednisone in some patients.

B. Giant Cell Arteritis

The urgency of early diagnosis and treatment in giant cell arteritis relates to the prevention of blindness. Once blindness develops, it is usually permanent. Therefore, when a patient has symptoms and findings suggestive of temporal arteritis, therapy with prednisone (60 mg/d orally) should be initiated immediately and a temporal artery biopsy performed promptly. For patients who seek medical attention for visual loss, intravenous pulse methylprednisolone (eg, 1 g daily for 3 days) has been advocated; unfortunately, few patients recover vision no matter what the initial treatment. One study—too small and too preliminary to change the standard therapy recommendations mentioned above—suggested that initiating treatment with intravenous pulse methylprednisolone may increase the chance that a patient with giant cell arteritis will achieve remission and be able to taper off of prednisone. Retrospective studies suggest that low-dose aspirin (~81 mg/d orally) may reduce the chance of visual loss or stroke in patients with giant cell arteritis and should be added to prednisone in the initial treatment. Although it is prudent to obtain a temporal artery biopsy as soon as possible after instituting treatment, diagnostic findings of giant cell arteritis may still be present 2 weeks (or even considerably longer) after starting corticosteroids. Typically, a positive biopsy shows inflammatory infiltrate in the media and adventitia with lymphocytes, histiocytes, plasma cells, and giant cells. An adequate biopsy specimen is essential (at least 2 cm in length is ideal), because the disease may be segmental. Unilateral temporal artery biopsies are positive in approximately 80–85% of patients, but bilateral biopsies add incrementally to the yield (10–15% in some studies, less in others). Ultrasonography can detect abnormalities in inflamed temporal arteries, but it has not displaced temporal artery biopsy as the gold standard for diagnosis in most cases because results are highly operator dependent. Temporal artery biopsy is abnormal in only 50% of patients with large artery disease (eg, arm claudication and unequal upper extremity blood pressures). In these

patients, magnetic resonance angiography or CT angiography will establish the diagnosis by demonstrating long stretches of narrowing of the subclavian and axillary arteries. Prednisone should be continued in a dosage of 60 mg/d orally for about 1 month before tapering. When only the symptoms of polymyalgia rheumatica are present, temporal artery biopsy is not necessary.

After 1 month of high-dose prednisone, almost all patients will have a normal ESR. When tapering and adjusting the dosage of prednisone, the ESR (or C-reactive protein) is a useful but not absolute guide to disease activity. A common error is treating the ESR rather than the patient. The ESR often rises slightly as the prednisone is tapered, even as the disease remains quiescent. Because elderly individuals often have baseline ESRs that are above the normal range, mild ESR elevations should not be an occasion for renewed treatment with prednisone in patients who are asymptomatic. Unfortunately, no highly effective prednisone-sparing therapy has been identified. Methotrexate was modestly effective in one double-blind, placebo-controlled treatment trial but ineffective in another. Anti-TNF therapies do not work in giant cell arteritis. Thoracic aortic aneurysms occur 17 times more frequently in patients with giant cell arteritis than in normal individuals and can result in aortic regurgitation, dissection, or rupture. The aneurysms can develop at any time but typically occur 7 years after the diagnosis of giant cell arteritis is made.

POLYARTERITIS NODOSA

ESSENTIALS OF DIAGNOSIS

- ▶ Medium-sized arteries are always affected; smaller arterioles are sometimes involved; lung is spared but kidney often affected, causing renin-mediated hypertension.
- ▶ Clinical findings depend on the arteries involved.
- ▶ Common features include fever, abdominal pain, extremity pain, livedo reticularis, mononeuritis multiplex, anemia, and elevated acute phase reactants (ESR or C-reactive protein or both).
- ▶ Associated with hepatitis B (10% of cases).

▶ General Considerations

Polyarteritis nodosa, described in 1866, is acknowledged widely as the first form of vasculitis reported in the medical literature. For many years, all forms of inflammatory vascular disease were termed “polyarteritis nodosa.” In recent

decades, numerous subtypes of vasculitis have been recognized, greatly narrowing the spectrum of vasculitis called polyarteritis nodosa. Currently, the term is reserved for necrotizing arteritis of medium-sized vessels that has a predilection for involving the skin, peripheral nerves, mesenteric vessels (including renal arteries), heart, and brain, but polyarteritis nodosa can actually involve almost any organ. Polyarteritis nodosa is relatively rare, with a prevalence of about 30 per 1 million people. Approximately 10% of cases of polyarteritis nodosa are caused by hepatitis B. Most cases of hepatitis B–associated disease occur within 6 months of hepatitis B infection.

▶ Clinical Findings

A. Symptoms and Signs

The clinical onset is usually insidious, with fever, malaise, weight loss, and other symptoms developing over weeks to months. Pain in the extremities is often a prominent early feature caused by arthralgia, myalgia (particularly affecting the calves), or neuropathy. The combination of mononeuritis multiplex (with the most common finding being foot-drop) and features of a systemic illness is one of the earliest specific clues to the presence of an underlying vasculitis. Polyarteritis nodosa is among the forms of vasculitis most commonly associated with vasculitic neuropathy.

In polyarteritis nodosa, the typical skin findings—livedo reticularis, subcutaneous nodules, and skin ulcers—reflect the involvement of deeper, medium-sized blood vessels. Digital gangrene is not an unusual occurrence. The most common cutaneous presentation is lower extremity ulcerations, usually occurring near the malleoli. Involvement of the renal arteries leads to a renin-mediated hypertension (much less characteristic of vasculitides involving smaller blood vessels). For unclear reasons, classic polyarteritis nodosa seldom (if ever) involves the lung, with the occasional exception of the bronchial arteries.

Abdominal pain—particularly diffuse periumbilical pain precipitated by eating—is common but often difficult to attribute to mesenteric vasculitis in the early stages. Nausea and vomiting are common symptoms. Infarction compromises the function of major viscera and may lead to acalculous cholecystitis or appendicitis. Some patients present dramatically with an acute abdomen caused by mesenteric vasculitis and gut perforation or with hypotension resulting from rupture of a microaneurysm in the liver, kidney, or bowel.

Subclinical cardiac involvement is common in polyarteritis nodosa, and overt cardiac dysfunction occasionally occurs (eg, myocardial infarction secondary to coronary vasculitis, or myocarditis).

B. Laboratory Findings

Most patients with polyarteritis nodosa have a slight anemia, and leukocytosis is common. Acute phase reactants are often (but not always) strikingly elevated. A major challenge in making the diagnosis of polyarteritis nodosa, however, is the absence of a disease-specific serologic test (eg, an autoantibody). Patients with classic polyarteritis nodosa are

ANCA-negative and may have low titers of rheumatoid factor or antinuclear antibodies, both of which are nonspecific findings. In patients with polyarteritis nodosa, appropriate serologic tests for active hepatitis B infection must be performed.

C. Biopsy and Angiography

The diagnosis of polyarteritis nodosa requires confirmation with either a tissue biopsy or an angiogram. Biopsies of symptomatic sites such as skin (from the edge of an ulcer or the center of a nodule), nerve, or muscle have sensitivities of approximately 70%. The least invasive tests should usually be obtained first, but biopsy of an involved organ is essential. If performed by experienced clinicians, tissue biopsies normally have high benefit-risk ratios because of the importance of establishing the diagnosis. Patients in whom polyarteritis nodosa is suspected—eg, on the basis of mesenteric ischemia or new-onset hypertension occurring in the setting of a systemic illness—may be diagnosed by the angiographic finding of aneurysmal dilations in the renal, mesenteric, or hepatic arteries. Angiography must be performed cautiously in patients with baseline renal dysfunction.

▶ Treatment

For polyarteritis nodosa, corticosteroids in high doses (up to 60 mg of oral prednisone daily) may control fever and constitutional symptoms and heal vascular lesions. Pulse methylprednisolone (eg, 1 g intravenously daily for 3 days) may be necessary for patients who are critically ill at presentation. Immunosuppressive agents, especially cyclophosphamide, lower the risk of disease-related death and morbidity among patients who have severe disease. For patients with polyarteritis nodosa associated with hepatitis B, the preferred treatment regimen is a short course of prednisone accompanied by antiviral therapy and plasmapheresis (three times a week for up to 6 weeks).

▶ Prognosis

Without treatment, the 5-year survival rate in these disorders is poor—on the order of 10%. With appropriate therapy, remissions are possible in many cases and the 5-year survival rate has improved to 60–90%. Poor prognostic factors are chronic kidney disease with serum creatinine > 1.6 mg/dL, proteinuria > 1 g/d, gastrointestinal ischemia, central nervous system disease, and cardiac involvement. In the absence of any of these five factors, 5-year survival is nearly 90%. Survival at 5 years drops to 75% with one poor prognostic factor present and to about 50% with two or more factors. Substantial morbidity and even death may result from adverse effects of cyclophosphamide and corticosteroids. Consequently, these therapies require careful monitoring and expert management. In contrast to many other forms of systemic vasculitis, disease relapses in polyarteritis following the successful induction of remission are the exception rather than the rule, occurring in only about 20% of cases.

GRANULOMATOSIS WITH POLYANGIITIS (Formerly Wegener Granulomatosis)

ESSENTIALS OF DIAGNOSIS

- ▶ Classic triad of upper and lower respiratory tract disease and glomerulonephritis.
- ▶ Suspect if mild respiratory symptoms (eg, nasal congestion, sinusitis) are refractory to usual treatment.
- ▶ Pathology defined by the triad of small vessel vasculitis, granulomatous inflammation, and necrosis.
- ▶ ANCA, usually directed against proteinase-3 (less commonly against myeloperoxidase present in severe, active disease) (90% of patients).
- ▶ Kidney disease often rapidly progressive without treatment.

▶ General Considerations

Granulomatosis with polyangiitis, which has an estimated incidence of approximately 12 cases per million individuals per year, is the prototype of diseases associated with antineutrophil cytoplasmic antibodies (ANCA). (Other “ANCA-associated vasculitides” include microscopic polyangiitis and the Churg-Strauss syndrome.) Granulomatosis with polyangiitis is characterized in its full expression by vasculitis of small arteries, arterioles, and capillaries, necrotizing granulomatous lesions of both upper and lower respiratory tract, glomerulonephritis, and other organ manifestations. Without treatment, generalized disease is invariably fatal, with most patients surviving < 1 year after diagnosis. It occurs most commonly in the fourth and fifth decades of life and affects men and women with equal frequency.

▶ Clinical Findings

A. Symptoms and Signs

The disorder usually develops over 4–12 months. Upper respiratory tract symptoms develop in 90% of patients and lower respiratory tract symptoms develop in 60% of patients; some patients may have both upper and lower respiratory tract symptoms. Upper respiratory tract symptoms can include nasal congestion, sinusitis, otitis media, mastoiditis, inflammation of the gums, or stridor due to subglottic stenosis. Since many of these symptoms are common, the

▲ **Figure 20-7.** Scleritis in a patient with granulomatosis with polyangiitis (formerly Wegener granulomatosis). (Courtesy of Everett Allen, MD; used, with permission, from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H, Tysinger J. *The Color Atlas of Family Medicine*. McGraw-Hill, 2009.)

underlying disease is not often suspected until the patient develops systemic symptoms or the original problem is refractory to treatment. The lungs are affected initially in 40% and eventually in 80%, with symptoms including cough, dyspnea, and hemoptysis. Other early symptoms can include a migratory oligoarthritis with a predilection for large joints; a variety of symptoms related to ocular disease (unilateral proptosis from orbital pseudotumor; red eye from scleritis [Figure 20-7], episcleritis, anterior uveitis, or peripheral ulcerative keratitis); purpura or other skin lesions; and dysesthesia due to neuropathy. Renal involvement, which develops in three-fourths of the cases, may be subclinical until kidney disease is advanced. Fever, malaise, and weight loss are common.

Physical examination can be remarkable for congestion, crusting, ulceration, bleeding, and even perforation of the nasal septum. Destruction of the nasal cartilage with “saddle nose” deformity occurs late. Otitis media, proptosis, scleritis, episcleritis, and conjunctivitis are other common findings. Newly acquired hypertension, a frequent feature of polyarteritis nodosa, is rare in granulomatosis with polyangiitis. Venous thrombotic events (eg, deep venous thrombosis and pulmonary embolism) are a common occurrence in granulomatosis with polyangiitis, at least in part because of the tendency of the disease to involve veins as well as arteries. Although limited forms of granulomatosis with polyangiitis have been described in which the kidney is spared initially, kidney disease will develop in the majority of untreated patients.

B. Laboratory Findings

1. Serum tests and urinalysis—Most patients have slight anemia, mild leukocytosis, and elevated acute phase reactants.

If there is renal involvement, there is proteinuria and the urinary sediment contains red cells, with or without white cells, and often has red cell casts.

Serum tests for ANCA help in the diagnosis of granulomatosis with polyangiitis and related forms of vasculitis (Table 20-10). Several different types of ANCA are recognized, but the two subtypes relevant to systemic vasculitis are those directed against proteinase-3 (PR3) and myeloperoxidase (MPO). Antibodies to these two antigens are termed “PR3-ANCA” and “MPO-ANCA,” respectively. The cytoplasmic pattern of immunofluorescence (c-ANCA) caused by PR3-ANCA has a high specificity (> 90%) for either granulomatosis with polyangiitis or a closely related disease, microscopic polyangiitis (or, less commonly, the Churg-Strauss syndrome). In the setting of active disease, particularly cases in which the disease is severe and generalized to multiple organ systems, the sensitivity of PR3-ANCA is > 95%. A substantial percentage of patients with “limited” granulomatosis with polyangiitis—disease that does not pose an immediate threat to life and is often confined to the respiratory tract—are ANCA-negative. Although ANCA testing may be very helpful when used properly, it does not eliminate the need in most cases for confirmation of the diagnosis by tissue biopsy. Furthermore, ANCA levels correlate erratically with disease activity, and changes in titer should not dictate changes in therapy in the absence of supporting clinical data. The perinuclear (p-ANCA) pattern, caused by MPO-ANCA, is more likely to occur in microscopic polyangiitis or Churg-Strauss but may also be found in granulomatosis with polyangiitis. Approximately 10–25% of patients with classic granulomatosis with polyangiitis have MPO-ANCA. All positive immunofluorescence assays for ANCA should be confirmed by enzyme immunoassays for the specific autoantibodies directed against PR3 or MPO.

2. Histologic findings—Histologic features of granulomatosis with polyangiitis include vasculitis, granulomatous inflammation, geographic necrosis, and acute and chronic inflammation. The full range of pathologic changes is usually evident only on thoracoscopic lung biopsy. Granulomas, observed only rarely in renal biopsy specimens, are found much more commonly on lung biopsy specimens. Nasal biopsies often do not show vasculitis but may show chronic inflammation and other changes which, interpreted by an experienced pathologist, can serve as convincing evidence of the diagnosis. Renal biopsy discloses a segmental necrotizing glomerulonephritis with multiple crescents; this is characteristic but not diagnostic. Pathologists characterize the renal lesion of granulomatosis with polyangiitis (and other forms of “ANCA-associated vasculitis”) as a pauci-immune glomerulonephritis because of the relative absence (compared with immune complex-mediated disorders) of immunoreactants—IgG, IgM, IgA, and complement proteins—within glomeruli.

C. Imaging

Chest CT is more sensitive than chest radiography; lesions include infiltrates, nodules, masses, and cavities. Pleural effusions are uncommon. Often the radiographs prompt

concern about lung cancer. Hilar adenopathy is unusual in granulomatosis with polyangiitis; if present, sarcoidosis, tumor, or infection is more likely. Other common radiographic abnormalities include extensive sinusitis and even bony sinus erosions.

► Differential Diagnosis

In most patients with granulomatosis with polyangiitis, refractory sinusitis or otitis media is initially suspected. When upper respiratory tract inflammation persists and is accompanied by additional systemic inflammatory signs (eg, red eye from scleritis, joint pain and swelling), the diagnosis of granulomatosis with polyangiitis should be considered. Rheumatoid arthritis will wrongly be suspected in a substantial minority of patients who chiefly complain of joint pain. Arriving at the correct diagnosis is aided by awareness that rheumatoid arthritis typically involves small joints of the hand, whereas granulomatosis with polyangiitis favors large joints, such as the hip, knee, elbow, and shoulder. Lung cancer may be the first diagnostic consideration for some middle-aged patients in whom cough, hemoptysis, and lung masses are presenting symptoms and signs; typically, evidence of glomerulonephritis, a positive ANCA or, ultimately, the lung biopsy findings will point to the proper diagnosis. Granulomatosis with polyangiitis shares with SLE, anti-glomerular basement membrane disease, and microscopic polyangiitis the ability to cause an acute pulmonary-renal syndrome. Approximately 10–25% of patients with classic granulomatosis with polyangiitis have MPO-ANCA. Owing to involvement of the same types of blood vessels, similar patterns of organ involvement, and the possibility of failing to identify granulomatous pathology on tissue biopsies because of sampling error, granulomatosis with polyangiitis is often difficult to differentiate from microscopic polyangiitis. The crucial distinctions between the two disorders are the tendencies for granulomatosis with polyangiitis to involve the upper respiratory tract (including the ears) and to cause granulomatous inflammation.

► Treatment

Early treatment is crucial in preventing the devastating end-organ complications of this disease, and often in preserving life. While granulomatosis with polyangiitis may involve the sinuses or lung for months, once proteinuria or hematuria develops, progression to advanced chronic kidney disease can be rapid (over several weeks). For patients with severe disease, the combination of cyclophosphamide and prednisone is the standard of care. Remissions can be induced in more than 90% of patients treated with prednisone (1 mg/kg daily) plus cyclophosphamide (2 mg/kg/d orally with adjustments required for renal insufficiency and age > 70 years old). Cyclophosphamide is best given daily by mouth; intermittent high-dose intravenous cyclophosphamide is less effective. The current approach to remission induction in severe cases is to use cyclophosphamide for 3–6 months, followed by a switch to a regimen more likely to be tolerated well. Unfortunately, disease relapses occur in a substantial proportion of those patients who achieve remission. In

patients with remission induced by 3–6 months of cyclophosphamide and corticosteroids, azathioprine (up to 2 mg/kg/d orally) has been shown to be as effective as cyclophosphamide in maintaining disease remissions (at least for up to 12–15 months). Before the institution of azathioprine, patients should be tested (through a commercially available blood test) for deficiencies in the level of thiopurine methyltransferase, an enzyme essential to the metabolism of azathioprine. Another option for remission maintenance is methotrexate, 20–25 mg/wk (administered either orally or intramuscularly). Because of its superior side-effect profile, methotrexate is viewed as an appropriate substitute for cyclophosphamide for initial treatment in patients who do not have significant renal dysfunction (of any cause) or immediately life-threatening disease. Treatment with TNF inhibitors, particularly etanercept, is not effective. Rituximab, a B-cell-depleting monoclonal antibody, has been shown to be as effective as cyclophosphamide for patients who have never been treated and may be more effective than cyclophosphamide for treating relapses. However, rituximab's high cost, its undefined long-term health effects, and its association with opportunistic infections (including progressive multifocal leukoencephalopathy [PML]) indicate that defining rituximab's precise role in treating ANCA-associated vasculitis requires additional study.

MICROSCOPIC POLYANGIITIS

ESSENTIALS OF DIAGNOSIS

- Necrotizing vasculitis of small- and medium-sized arteries and veins.
- Most common cause of pulmonary-renal syndrome: diffuse alveolar hemorrhage and glomerulonephritis.
- Associated with ANCA in 75% of cases, usually anti-myeloperoxidase antibodies (MPO-ANCA) that cause a p-ANCA pattern on immunofluorescence testing. ANCA directed against proteinase-3 (PR3-ANCA) can also be observed.

► General Considerations

Microscopic polyangiitis is a pauci-immune nongranulomatous necrotizing vasculitis that (1) affects small blood vessels (capillaries, venules, or arterioles), (2) often causes

glomerulonephritis and pulmonary capillaritis, and (3) is often associated with ANCA on immunofluorescence testing (directed against MPO, a constituent of neutrophil granules). Because microscopic polyangiitis may involve medium-sized as well as small blood vessels and because it tends to affect capillaries within the lungs and kidneys, its spectrum overlaps those of both polyarteritis nodosa and granulomatosis with polyangiitis.

In rare instances, medications, particularly propylthiouracil, hydralazine, allopurinol, penicillamine, minocycline, and sulfasalazine, induce a systemic vasculitis associated with high titers of MPO-ANCA and features of microscopic polyangiitis.

► Clinical Findings

A. Symptoms and Signs

A wide variety of findings suggesting vasculitis of small blood vessels may develop in microscopic polyangiitis. These include “palpable” (or “raised”) purpura and other signs of cutaneous vasculitis (ulcers, splinter hemorrhages, vesiculobullous lesions).

Microscopic polyangiitis is the most common cause of pulmonary-renal syndromes, being several times more common than anti-glomerular basement membrane disease. Interstitial lung fibrosis that mimics usual interstitial pneumonitis is the presenting condition. Pulmonary hemorrhage may occur. The pathologic findings in the lung are typically those of capillaritis.

Vasculitic neuropathy (mononeuritis multiplex) is also common in microscopic polyangiitis.

B. Laboratory Findings

As noted, three-fourths of patients with microscopic polyangiitis are ANCA-positive. Elevated acute phase reactants are also typical of active disease. Microscopic hematuria, proteinuria, and red blood cell casts in the urine may occur. The renal lesion is a segmental, necrotizing glomerulonephritis, often with localized intravascular coagulation and the observation of intraglomerular thrombi upon renal biopsy.

► Differential Diagnosis

Distinguishing this disease from granulomatosis with polyangiitis may be challenging in some cases. Microscopic polyangiitis is not associated with the chronic destructive upper respiratory tract disease often found in granulomatosis with polyangiitis. Moreover, as noted, a critical difference between the two diseases is the absence of granulomatous inflammation in microscopic polyangiitis. Because their treatments may differ, microscopic polyangiitis must also be differentiated from polyarteritis nodosa.

► Treatment

In microscopic polyangiitis, patients are likely to require prednisone and cyclophosphamide because of the urgency in treating pulmonary hemorrhage and glomerulonephritis. Cyclophosphamide may be administered either in an oral

daily regimen or via intermittent (usually monthly) intravenous pulses. Whenever cyclophosphamide is used, *Pneumocystis jiroveci* prophylaxis with either single-strength oral trimethoprim-sulfamethoxazole or dapsone 100 mg/d is essential. Following the induction of remission, azathioprine is a reasonable choice to replace cyclophosphamide. In cases of drug-induced MPO-ANCA-associated vasculitis, the offending medication should be discontinued; significant organ involvement (eg, pulmonary hemorrhage, glomerulonephritis) requires immunosuppressive therapy. Rituximab has been shown to be as effective as cyclophosphamide in treating ANCA-associated vasculitis.

► Prognosis

The key to effecting good outcomes is early diagnosis. Compared with patients who have granulomatosis with polyangiitis, those who have microscopic polyangiitis are more likely to have significant fibrosis on renal biopsy because of later diagnosis. The likelihood of disease recurrence following remission in microscopic polyangiitis is about 33%.

Corral-Gudino L et al. Overall survival, renal survival and relapse in patients with microscopic polyangiitis: a systematic review of current evidence. *Rheumatology (Oxford)*. 2011 Aug;50(8):1414–23. [PMID: 21406467]

Silva F et al. Mycophenolate mofetil for induction and maintenance of remission in microscopic polyangiitis with mild to moderate renal involvement—a prospective, open-label pilot trial. *Clin J Am Soc Nephrol*. 2010 Mar;5(3):445–53. [PMID: 20093349]

CRYGLOBULINEMIA

Cryoglobulinemia can be associated with an immune-complex mediated, small-vessel vasculitis. Chronic infection with hepatitis C is the most common underlying condition; cryoglobulinemic vasculitis also can occur in the setting of other chronic infections, such as subacute bacterial endocarditis and osteomyelitis, and with connective tissue diseases, especially Sjögren syndrome. The cryoglobulins associated with vasculitis are cold-precipitable immune complexes consisting of rheumatoid factor and IgG (rheumatoid factor is an autoantibody to the constant region of IgG). The rheumatoid factor component can be monoclonal (type II cryoglobulins) or polyclonal (type III cryoglobulins). (Type I cryoglobulins are cryoprecipitable monoclonal proteins that lack rheumatoid factor activity; these cause cold-induced hyperviscosity syndromes, not vasculitis, and are associated with lymphoproliferative disease.)

► Clinical Findings

Cryoglobulinemic vasculitis typically manifests as recurrent palpable purpura and peripheral neuropathy. A proliferative glomerulonephritis can develop and can manifest as rapidly progressive glomerulonephritis. Abnormal liver function tests, abdominal pain, and pulmonary disease may also occur. The diagnosis is based on a compatible

clinical picture and a positive serum test for cryoglobulins. The presence of a disproportionately low C4 level can be a diagnostic clue to the presence of cryoglobulinemia.

► Treatment

Asymptomatic cryoglobulinemia is common in hepatitis C–infected individuals and does not in itself warrant treatment. The optimal approach to treatment of hepatitis C–associated cryoglobulinemic vasculitis is viral suppression with pegylated forms of interferon- α and ribavirin. Because immunosuppressive agents may facilitate viral replication, corticosteroids, cyclophosphamide, and other interventions (including plasmapheresis) should be reserved for organ-threatening complications. B cell depletion using rituximab appears to be a promising avenue of therapy.

Ferri C et al. Treatment with rituximab in patients with mixed cryoglobulinemia syndrome: results of multicenter cohort study and review of the literature. *Autoimmun Rev*. 2011 Nov;11(1):48–55. [PMID: 21821153]

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura, the most common systemic vasculitis in children, occurs in adults as well. Typical features are palpable purpura (Figure 20–8), arthritis, and hematuria. Abdominal pain occurs less frequently in adults than in children. Pathologic features include leukocytoclastic vasculitis with IgA deposition. The cause is not known.

The purpuric skin lesions are typically located on the lower extremities but may also be seen on the hands, arms, trunk, and buttocks. Joint symptoms are present in the majority of patients, the knees and ankles being most commonly involved. Abdominal pain secondary to vasculitis of the intestinal tract is often associated with gastrointestinal bleeding. Hematuria signals the presence of a renal lesion that is usually reversible, although it occasionally may progress to chronic kidney disease. Children tend to have more frequent and more serious gastrointestinal vasculitis, whereas adults more often suffer from chronic kidney disease. Biopsy of the kidney reveals segmental glomerulonephritis with crescents and mesangial deposition of IgA.

Chronic courses with persistent or intermittent skin disease are more likely to occur in adults than in children. The value of corticosteroids has been controversial. In children or adults, prednisone (1 mg/kg/d orally) may benefit those with severe extrarenal manifestations and with evidence of kidney disease. The incremental efficacy of steroid-sparing drugs such as azathioprine and mycophenolate mofetil—often used in the setting of kidney disease—is not known.

RELAPSING POLYCHONDritis

This disease is characterized by inflammatory destructive lesions of cartilaginous structures, principally the ears, nose, trachea, and larynx. Nearly 40% of cases are associated with another disease, especially either other immunologic disorders (such as SLE, rheumatoid arthritis, or Hashimoto thyroiditis) or cancers (such as multiple myeloma) or hematologic disorders (such as myelodysplastic syndrome). The disease, which is usually episodic, affects males and females equally. The cartilage is painful, swollen, and tender during an attack and subsequently becomes atrophic, resulting in permanent deformity. Biopsy of the involved cartilage shows inflammation and chondrolysis. Noncartilaginous manifestations of the disease include fever, episcleritis, uveitis, deafness, aortic insufficiency, and rarely glomerulonephritis. In 85% of patients, a migratory, asymmetric, and seronegative arthropathy occurs, affecting both large and small joints and the costochondral junctions. Diagnosing this uncommon disease is especially difficult since the signs of cartilage inflammation (such as red ears or nasal pain) may be more subtle than the fever, arthritis, rash, or other systemic manifestations.

Prednisone, 0.5–1 mg/kg/d orally, is often effective. Dapsone (100–200 mg/d orally) or methotrexate (7.5–20 mg orally per week) may also have efficacy, sparing the need for long-term high-dose corticosteroid treatment. Involvement

of the tracheobronchial tree, leading to tracheomalacia, may lead to difficult management issues.

BEHÇET SYNDROME

ESSENTIALS OF DIAGNOSIS

- ▶ Most commonly occurs among persons of Asian, Turkish, or Middle Eastern background, but may affect persons of any demographic profile.
- ▶ Recurrent, painful aphthous ulcers of the mouth and genitals.
- ▶ Erythema nodosum–like lesions; a follicular rash; and the pathergy phenomenon (formation of a sterile pustule at the site of a needle stick).
- ▶ Either anterior or posterior uveitis. Posterior uveitis may be asymptomatic until significant damage to the retina has occurred.
- ▶ Variety of neurologic lesions that can mimic multiple sclerosis, particularly through involvement of the white matter of the brainstem.

▶ General Considerations

Named after the Turkish dermatologist who first described it, this disease is of unknown cause. Its protean manifestations are believed to result from vasculitis that may involve all types of blood vessels: small, medium, and large, on both the arterial and venous side of the circulation.

▶ Clinical Findings

A. Symptoms and Signs

The hallmark of Behçet disease is painful aphthous ulceration in the mouth (see Figure 8–7). These lesions, which usually occur multiply, may be found on the tongue, gums, and inner surfaces of the oral cavity. Genital lesions, similar in appearance, are also common but do not occur in all patients. Other cutaneous lesions of Behçet disease include tender, erythematous, papular lesions that resemble erythema nodosum. (On biopsy, however, many of these lesions are shown to be secondary to vasculitis rather than septal panniculitis.) These erythema nodosum–like lesions have a tendency to ulcerate, a major difference between the lesions of Behçet disease and the erythema nodosum seen in cases of sarcoidosis and inflammatory bowel disease. An erythematous follicular rash that occurs frequently on the upper extremities may be a subtle feature of the disease. The pathergy phenomenon is frequently underappreciated

(unless the patient is asked); in this phenomenon, sterile pustules develop at sites where needles have been inserted into the skin (eg, for phlebotomy) in some patients.

A nonerosive arthritis occurs in about two-thirds of patients, most commonly affecting the knees and ankles. Eye involvement may be one of the most devastating complications of Behçet disease. Posterior uveitis, in essence a retinal venulitis, may lead to the insidious destruction of large areas of the retina before the patient becomes aware of visual problems. Anterior uveitis, associated with photophobia and a red eye, is intensely symptomatic. This complication may lead to a hypopyon, the accumulation of pus in the anterior chamber. If not treated properly with mydriatic agents to dilate the pupil and corticosteroid eye-drops to diminish inflammation, the anterior uveitis may lead to synechial formation between the iris and lens, resulting in permanent pupillary distortion.

Central nervous system involvement is another cause of major potential morbidity. The central nervous system lesions that may mimic multiple sclerosis radiologically often result in serious disability or death. Findings include sterile meningitis (recurrent meningeal headaches associated with a lymphocytic pleocytosis), cranial nerve palsies, seizures, encephalitis, mental disturbances, and spinal cord lesions. Aphthous ulcerations of the ileum and cecum and other forms of gastrointestinal involvement develop in approximately a quarter of patients. Large vessel vasculitis can lead to pulmonary artery aneurysms and life-threatening pulmonary hemorrhage. Finally, patients have a hypercoagulable tendency that may lead to complicated venous thrombotic events, particularly multiple deep venous thrombosis, pulmonary emboli, cerebral sinus thrombosis, and other problems associated with clotting.

The clinical course may be chronic but is often characterized by remissions and exacerbations.

B. Laboratory Findings

There are no pathognomonic laboratory features of Behçet disease. Although acute phase reactants are often elevated, there is no autoantibody or other assay that is distinctive. No markers of hypercoagulability specific to Behçet have been identified.

▶ Treatment

Corticosteroids (1 mg/kg/d of oral prednisone) are a mainstay of therapy for severe disease manifestations. Azathioprine (2 mg/kg/d orally) may be an effective steroid-sparing agent. Cyclophosphamide (2 mg/kg/d orally) or chlorambucil (0.1–0.2 mg/kg/d orally) is indicated for severe ocular and central nervous system complications of Behçet disease. Both colchicine (0.6 mg once to three times daily orally) and thalidomide (100 mg/d orally) help ameliorate the mucocutaneous findings. TNF inhibition and interferon alfa-2a demonstrates some promise as a therapeutic approach, but large studies are lacking to date.

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM

Primary angiitis of the central nervous system is a syndrome with several possible causes that produces small and medium-sized vasculitis limited to the brain and spinal cord. Biopsy-proved cases have predominated in men who have a history of weeks to months of headaches, encephalopathy, and multifocal strokes. Systemic signs and symptoms are absent, and routine laboratory tests are usually normal. MRI of the brain is almost always abnormal, and the spinal fluid often reveals a mild lymphocytosis and a modest increase in protein level. Angiograms classically reveal a “string of beads” pattern produced by alternating segments of arterial narrowing and dilation. However, neither the MRI nor the angiogram appearance is specific for vasculitis. Indeed, in one study, none of the patients who had biopsy-proved central nervous system vasculitis had an angiogram showing “the string of beads,” and none of the patients with the classic angiographic findings had a positive brain biopsy for vasculitis. Many conditions, including vasospasm, can produce the same angiographic pattern as vasculitis. Definitive diagnosis requires a compatible clinical picture; exclusion of infection, neoplasm, or metabolic disorder or drug exposure (eg, cocaine) that can mimic primary angiitis of the central nervous system; and a positive brain biopsy. In contrast to biopsy-proved cases, patients with angiographically defined central nervous system vasculopathy are chiefly women who have had an abrupt onset of headaches and stroke (often in the absence of encephalopathy) with normal spinal fluid findings. Many patients who fit this clinical profile may have reversible cerebral vasoconstriction rather than true vasculitis. Such cases may best be treated with calcium channel blockers (such as nimodipine or verapamil) and possibly a short course of corticosteroids. Biopsy-proved cases usually improve with prednisone therapy and often require cyclophosphamide. In recent years, cases of central nervous system vasculitis associated with cerebral amyloid angiopathy have been reported. These cases often respond well to corticosteroids, albeit the long-term natural history remains poorly defined.

Berlit P. Diagnosis and treatment of cerebral vasculitis. *Ther Adv Neurol Disord*. 2010 Jan;3(1):29–42. [PMID: 21180634]

LIVEDO RETICULARIS

Livedo reticularis produces a mottled, purplish discoloration of the skin with reticulated cyanotic areas surrounding paler central cores. This distinctive “fishnet” pattern is caused by spasm or obstruction of perpendicular arterioles, combined with pooling of blood in surrounding venous plexuses. Livedo reticularis can be idiopathic or a manifestation of a serious underlying condition.

Idiopathic livedo reticularis is a benign condition that worsens with cold exposure, improves with warming, and primarily affects the extremities. Apart from cosmetic concerns, it is usually asymptomatic. Systemic symptoms or the development of cutaneous ulcerations point to the presence of an underlying disease.

Secondary livedo reticularis occurs in association with a variety of diseases that cause vascular obstruction or inflammation. Of particular importance is the link with antiphospholipid antibody syndrome. Livedo reticularis is the presenting manifestation of 25% of patients with antiphospholipid antibody syndrome and is strongly associated with the subgroup that has arterial thromboses, including those with Sneddon syndrome (livedo reticularis and cerebrovascular events). Other underlying causes of livedo reticularis include the vasculitides (particularly polyarteritis nodosa), cholesterol emboli syndrome, thrombocytopenia, cryoglobulinemia, cold agglutinin disease, primary hyperoxaluria (due to vascular deposits of calcium oxalate), and disseminated intravascular coagulation.

SERONEGATIVE SPONDYLOARTHROPATHIES

The seronegative spondyloarthropathies are ankylosing spondylitis, psoriatic arthritis, reactive arthritis, the arthritis associated with inflammatory bowel disease, and undifferentiated spondyloarthropathy. These disorders are noted for male predominance, onset usually before age 40, inflammatory arthritis of the spine and sacroiliac joints, asymmetric oligoarthritis of large peripheral joints, enthesopathy (inflammation of where ligaments, tendons, and joint capsule insert into bone), uveitis in a significant minority, the absence of autoantibodies in the serum, and a striking association with HLA-B27. Present in only 8% of normal whites and 4% of normal blacks, HLA-B27 is positive in 90% of patients with ankylosing spondylitis and 75% with reactive arthritis. HLA-B27 also occurs in 50% of the psoriatic and inflammatory bowel disease patients who have sacroiliitis. Patients with only peripheral arthritis in these latter two syndromes do not show an increase in HLA-B27.

ANKYLOSING SPONDYLITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic low backache in young adults, generally worst in the morning.
- ▶ Progressive limitation of back motion and of chest expansion.
- ▶ Transient (50%) or persistent (25%) peripheral arthritis.
- ▶ Anterior uveitis in 20–25%.
- ▶ Diagnostic radiographic changes in sacroiliac joints.
- ▶ Negative serologic tests for rheumatoid factor and anti-CCP antibodies.
- ▶ HLA-B27 testing is most helpful when there is an intermediate probability of disease.

► General Considerations

Ankylosing spondylitis is a chronic inflammatory disease of the joints of the axial skeleton, manifested clinically by pain and progressive stiffening of the spine. The age at onset is usually in the late teens or early 20s. The incidence is greater in males than in females, and symptoms are more prominent in men, with ascending involvement of the spine more likely to occur.

► Clinical Findings

A. Symptoms and Signs

The onset is usually gradual, with intermittent bouts of back pain that may radiate into the buttocks. The back pain is worse in the morning and usually associated with stiffness that lasts hours. The pain and stiffness improve with activity, in contrast to back pain due to mechanical causes and degenerative disease, which improves with rest and worsens with activity. As the disease advances, symptoms progress in a cephalad direction, and back motion becomes limited, with the normal lumbar curve flattened and the thoracic curvature exaggerated. Chest expansion is often limited as a consequence of costovertebral joint involvement. In advanced cases, the entire spine becomes fused, allowing no motion in any direction. Transient acute arthritis of the peripheral joints occurs in about 50% of cases, and permanent changes in the peripheral joints—most commonly the hips, shoulders, and knees—are seen in about 25%. Enthesopathy, a hallmark of the spondyloarthropathies, can manifest as swelling of the Achilles tendon at its insertion, plantar fasciitis (producing heel pain), or “sausage” swelling of a finger or toe (less common in ankylosing spondylitis than in psoriatic arthritis).

Anterior uveitis is associated in as many as 25% of cases and may be a presenting feature. Spondylitic heart disease, characterized chiefly by atrioventricular conduction defects and aortic regurgitation occurs in 3–5% of patients with long-standing severe disease. Constitutional symptoms similar to those of rheumatoid arthritis are absent in most patients.

B. Laboratory Findings

The ESR is elevated in 85% of cases, but serologic tests for rheumatoid factor and anti-CCP antibodies are negative. Anemia may be present but is often mild. HLA-B27 is found in 90% of white patients and 50% of black patients with ankylosing spondylitis. Because this antigen occurs in 8% of the healthy white population (and 2% of healthy blacks), it is not a specific diagnostic test.

C. Imaging

The earliest radiographic changes are usually in the sacroiliac joints. In the first 2 years of the disease process, the sacroiliac changes may be detectable only by MRI. Later, erosion and sclerosis of these joints are evident on plain radiographs; the sacroiliitis of ankylosing spondylitis is bilateral and symmetric. Inflammation where the annulus fibrosus attaches to the vertebral bodies initially causes

sclerosis (“the shiny corner sign”) and then characteristic squaring of the vertebral bodies. The term “bamboo spine” describes the late radiographic appearance of the spinal column in which the vertebral bodies are fused by vertically oriented, bridging syndesmophytes formed by the ossification of the annulus fibrosus and calcification of the anterior and lateral spinal ligaments. Fusion of the posterior facet joints of the spine is also common.

Additional radiographic findings include periosteal new bone formation on the iliac crest, ischial tuberosities and calcanei, and alterations of the pubic symphysis and sternomanubrial joint similar to those of the sacroiliacs. Radiologic changes in peripheral joints, when present, tend to be asymmetric and lack the demineralization and erosions seen in rheumatoid arthritis.

► Differential Diagnosis

Low back pain due to mechanical causes, disk disease, and degenerative arthritis is very common. Onset of back pain prior to age 30 and an “inflammatory” quality of the back pain (ie, morning stiffness and pain that improve with activity) should raise the possibility of ankylosing spondylitis. In contrast to ankylosing spondylitis, rheumatoid arthritis predominantly affects multiple, small, peripheral joints of the hands and feet. Rheumatoid arthritis spares the sacroiliac joints and only affects the cervical component of the spine. Bilateral sacroiliitis indistinguishable from ankylosing spondylitis is seen with the spondylitis associated with inflammatory bowel disease. Sacroiliitis associated with reactive arthritis and psoriasis, on the other hand, is often asymmetric or even unilateral. Osteitis condensans ilii (sclerosis on the iliac side of the sacroiliac joint) is an asymptomatic, postpartum radiographic finding that is occasionally mistaken for sacroiliitis. Diffuse idiopathic skeletal hyperostosis (DISH) causes exuberant osteophytes of the spine that occasionally are difficult to distinguish from the syndesmophytes of ankylosing spondylitis. The osteophytes of DISH are thicker and more anterior than the syndesmophytes of ankylosing spondylitis, and the sacroiliac joints are normal in DISH.

► Treatment

NSAIDs remain first-line treatment of ankylosing spondylitis and may slow radiographic progression of spinal disease. Because individual patients differ in their response to particular NSAIDs, empiric trials of several different NSAIDs are warranted if the response to any given NSAID is not satisfactory. TNF inhibitors have established efficacy for NSAID-resistant axial disease; responses are often substantial and durable. Etanercept (50 mg subcutaneously once a week), adalimumab (40 mg subcutaneously every other week), or infliximab (5 mg/kg every other month by intravenous infusion) is reasonable for patients whose symptoms are refractory to NSAIDs. Sulfasalazine (1000 mg orally twice daily) is sometimes useful for peripheral arthritis but lacks effectiveness for spinal and sacroiliac joint disease. Corticosteroids have minimal impact on the arthritis—particularly the spondylitis—of ankylosing spondylitis and can worsen osteopenia. All patients should

be referred to a physical therapist for instruction in postural exercises.

► Prognosis

Almost all patients have persistent symptoms over decades; rare individuals experience long-term remissions. The severity of disease varies greatly, with about 10% of patients having work disability after 10 years. Developing hip disease within the first 2 years of disease onset presages a worse prognosis. The availability of TNF inhibitors has provided symptomatic relief and improved quality of life for many patients with ankylosing spondylitis.

PSORIATIC ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Psoriasis precedes onset of arthritis in 80% of cases.
- ▶ Arthritis usually asymmetric, with “sausage” appearance of fingers and toes but a polyarthritis that resembles rheumatoid arthritis also occurs.
- ▶ Sacroiliac joint involvement common; ankylosis of the sacroiliac joints may occur.
- ▶ Radiographic findings: osteolysis; pencil-in-cup deformity; relative lack of osteoporosis; bony ankylosis; asymmetric sacroiliitis and atypical syndesmophytes.

► General Considerations

Although psoriasis usually precedes the onset of arthritis, arthritis precedes (by up to 2 years) or occurs simultaneously with the skin disease in approximately 20% of cases.

► Clinical Findings

A. Symptoms and Signs

The patterns or subsets of psoriatic arthritis include the following:

1. A symmetric polyarthritis that resembles rheumatoid arthritis. Usually, fewer joints are involved than in rheumatoid arthritis.
2. An oligoarticular form that may lead to considerable destruction of the affected joints.

3. A pattern of disease in which the DIP joints are primarily affected. Early, this may be monoarticular, and often the joint involvement is asymmetric. Pitting of the nails and onycholysis frequently accompany DIP involvement.
4. A severe deforming arthritis (arthritis mutilans) in which osteolysis is marked.
5. A spondylitic form in which sacroiliitis and spinal involvement predominate; 50% of these patients are HLA-B27-positive.

Arthritis is at least five times more common in patients with severe skin disease than in those with only mild skin findings. Occasionally, however, patients may have a single patch of psoriasis (typically hidden in the scalp, gluteal cleft, or umbilicus) and are unaware of its presence. Thus, a detailed search for cutaneous lesions is essential in patients with arthritis of new onset. Also, the psoriatic lesions may have cleared when arthritis appears—in such cases, the history is most useful in diagnosing previously unexplained cases of mono- or oligoarthritis. Nail pitting is sometimes a clue. “Sausage” swelling of one or more digits is a common manifestation of enthesopathy in psoriatic arthritis.

B. Laboratory Findings

Laboratory studies show an elevation of the ESR, but rheumatoid factor is not present. Uric acid levels may be high, reflecting the active turnover of skin affected by psoriasis. There is a correlation between the extent of psoriatic involvement and the level of uric acid, but gout is no more common than in patients without psoriasis. Desquamation of the skin may also reduce iron stores.

C. Imaging

Radiographic findings are most helpful in distinguishing the disease from other forms of arthritis. There are marginal erosions of bone and irregular destruction of joint and bone, which, in the phalanx, may give the appearance of a sharpened pencil. Fluffy periosteal new bone may be marked, especially at the insertion of muscles and ligaments into bone. Such changes will also be seen along the shafts of metacarpals, metatarsals, and phalanges. Psoriatic spondylitis causes asymmetric sacroiliitis and syndesmophytes, which are coarser than those seen in ankylosing spondylitis.

► Treatment

NSAIDs are usually sufficient for mild cases. Methotrexate (7.5–20 mg orally once a week) is generally considered the drug of choice for patients who have not responded to NSAIDs; methotrexate can improve both the cutaneous and arthritic manifestations. For cases with disease that is refractory to methotrexate, the addition of TNF inhibitors (at doses similar to the treatment of ankylosing spondylitis) is usually effective for both arthritis and psoriatic skin disease. Corticosteroids are less effective in psoriatic arthritis than in other forms of inflammatory arthritis and may precipitate pustular psoriasis during tapers. Antimalarials may also exacerbate psoriasis. Successful treatment directed at the skin lesions alone (eg, by PUVA

therapy) occasionally is accompanied by an improvement in peripheral articular symptoms.

REACTIVE ARTHRITIS (Formerly Reiter Syndrome)

ESSENTIALS OF DIAGNOSIS

- ▶ Fifty to eighty percent of patients are HLA-B27-positive.
- ▶ Oligoarthritis, conjunctivitis, urethritis, and mouth ulcers most common features.
- ▶ Usually follows dysentery or a sexually transmitted infection.

▶ General Considerations

Reactive arthritis is precipitated by antecedent gastrointestinal and genitourinary infections and manifests as an asymmetric sterile oligoarthritis, typically of the lower extremities. It is frequently associated with enthesitis. Extra-articular manifestations are common and include urethritis, conjunctivitis, uveitis, and mucocutaneous lesions. Reactive arthritis occurs most commonly in young men and is associated with HLA-B27 in 80% of white patients and 50–60% of blacks.

▶ Clinical Findings

A. Symptoms and Signs

Most cases of reactive arthritis develop within 1–4 weeks after either a gastrointestinal infection (with *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*) or a sexually transmitted infection (with *Chlamydia trachomatis* or perhaps *Ureaplasma urealyticum*). Whether the inciting infection is sexually transmitted or dysenteric does not affect the subsequent manifestations but does influence the gender ratio: The ratio is 1:1 after enteric infections but 9:1 with male predominance after sexually transmitted infections. Synovial fluid from affected joints is culture-negative. A clinically indistinguishable syndrome can occur without an apparent antecedent infection, suggesting that subclinical infection can precipitate reactive arthritis or that there are other, as yet unrecognized, triggers.

The arthritis is most commonly asymmetric and frequently involves the large weight-bearing joints (chiefly the knee and ankle); sacroiliitis or ankylosing spondylitis is

▲ **Figure 20-9.** Circinate balanitis due to reactive arthritis (Reiter syndrome). (Courtesy of Susan Lindsley, Dr. M. F. Rein, Public Health Image Library, CDC.)

observed in at least 20% of patients, especially after frequent recurrences. Systemic symptoms including fever and weight loss are common at the onset of disease. The mucocutaneous lesions may include balanitis (Figure 20-9), stomatitis, and keratoderma blennorrhagicum (Figure 20-10), indistinguishable from pustular psoriasis. Involvement of the fingernails in reactive arthritis also mimics psoriatic changes. When present, conjunctivitis is mild and occurs early in the disease course. Anterior uveitis, which can develop at any time in HLA-B27-positive patients, is a more clinically significant ocular complication. Carditis and aortic regurgitation may occur. While most signs of the disease disappear within days or weeks, the arthritis may persist for several months or become chronic. Recurrences involving any combination of the clinical manifestations are common and are sometimes followed by permanent sequelae, especially in the joints (eg, articular destruction).

▲ **Figure 20-10.** Keratoderma blennorrhagica of the soles due to reactive arthritis (Reiter syndrome). (Courtesy of Susan Lindsley, Public Health Image Library, CDC.)

B. Imaging

Radiographic signs of permanent or progressive joint disease may be seen in the sacroiliac as well as the peripheral joints.

► Differential Diagnosis

Gonococcal arthritis can initially mimic reactive arthritis, but the marked improvement after 24–48 hours of antibiotic administration and the culture results distinguish the two disorders. Rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis must also be considered. By causing similar oral, ocular, and joint lesions, Behçet disease may also mimic reactive arthritis. The oral lesions of reactive arthritis, however, are typically painless, in contrast to those of Behçet disease.

The association of reactive arthritis and HIV has been debated, but evidence now indicates that it is equally common in sexually active men regardless of HIV status.

► Treatment

NSAIDs have been the mainstay of therapy. Antibiotics given at the time of a nongonococcal sexually transmitted infection reduce the chance that the individual will develop this disorder. For chronic reactive arthritis associated with chlamydial infection, combination antibiotics taken for 6 months are more effective than placebo. Patients who do not respond to NSAIDs may respond to sulfasalazine, 1000 mg orally twice daily, or to methotrexate, 7.5–20 mg orally per week. For those patients with recent-onset disease that is refractory to NSAIDs and these DMARDs, anti-TNF agents, which are effective in the other spondyloarthropathies, may be effective.

Meyer A et al; Club Rhumatisme et Inflammation. Safety and efficacy of anti-tumor necrosis factor α therapy in ten patients with recent-onset refractory reactive arthritis. *Arthritis Rheum.* 2011 May;63(5):1274–80. [PMID: 21538314]

ARTHRITIS & INFLAMMATORY INTESTINAL DISEASES

One-fifth of patients with **inflammatory bowel disease** have arthritis, which complicates **Crohn disease** somewhat more frequently than it does **ulcerative colitis**. In both diseases, two distinct forms of arthritis occur. The first is peripheral arthritis—usually a nondeforming asymmetric oligoarthritis of large joints—in which the activity of the joint disease parallels that of the bowel disease. The arthritis usually begins months to years after the bowel disease, but occasionally the joint symptoms develop earlier and may be prominent enough to cause the patient to overlook intestinal symptoms. The second form of arthritis is a spondylitis that is indistinguishable by symptoms or radiographs from ankylosing spondylitis and follows a course independent of the bowel disease. About 50% of these patients are HLA-B27-positive.

Controlling the intestinal inflammation usually eliminates the peripheral arthritis. The spondylitis often requires

NSAIDs, which need to be used cautiously since these agents may activate the bowel disease in a few patients. Range-of-motion exercises as prescribed for ankylosing spondylitis can be helpful.

About two-thirds of patients with **Whipple disease** experience arthralgia or arthritis, most often an episodic, large-joint polyarthritis. The arthritis usually precedes the gastrointestinal manifestations by years. In fact, the arthritis resolves as the diarrhea develops. Thus, Whipple disease should be considered in the differential diagnosis of unexplained episodic arthritis.

Papamichael K et al. Low prevalence of antibodies to cyclic citrullinated peptide in patients with inflammatory bowel disease regardless of the presence of arthritis. *Eur J Gastroenterol Hepatol.* 2010 Jun;22(6):705–9. [PMID: 19525851]

INFECTIOUS ARTHRITIS*

NONGONOCOCCAL ACUTE BACTERIAL (Septic) ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- Acute onset of inflammatory monoarticular arthritis, most often in large weight-bearing joints and wrists.
- Common risk factors include previous joint damage and injection drug use.
- Infection with causative organisms commonly found elsewhere in body.
- Joint effusions are usually large, with white blood counts commonly > 50,000/mcL.

► General Considerations

Nongonococcal acute bacterial arthritis is often a disease that occurs when there is an underlying abnormality. The key risk factors are bacteremia (eg, injection drug use, endocarditis, infection at other sites), damaged or prosthetic joints (eg, rheumatoid arthritis), compromised immunity (eg, diabetes, advanced chronic kidney disease, alcoholism, cirrhosis, and immunosuppressive therapy), and loss of skin integrity (eg, cutaneous ulcer or psoriasis). *Staphylococcus aureus* is the most common cause of nongonococcal septic arthritis, accounting for about 50% of all cases. Methicillin-resistant *S aureus* (MRSA) and group B streptococcus have become increasing frequent and important causes of septic arthritis. Gram-negative septic arthritis causes about 10% of cases and is especially common in injection drug users and in immunocompromised persons. *Escherichia coli* and *Pseudomonas aeruginosa* are the most common gram-negative

*Lyme disease is discussed in Chapter 34.

isolates in adults. Pathologic changes include varying degrees of acute inflammation, with synovitis, effusion, abscess formation in synovial or subchondral tissues, and, if treatment is not adequate, articular destruction.

► Clinical Findings

A. Symptoms and Signs

The onset is usually acute, with pain, swelling, and heat of the affected joint worsening over hours. The knee is most frequently involved; other commonly affected sites are the hip, wrist, shoulder, and ankle. Unusual sites, such as the sternoclavicular or sacroiliac joint, can be involved in injection drug users. Chills and fever are common but are absent in up to 20% of patients. Infection of the hip usually does not produce apparent swelling but results in groin pain greatly aggravated by walking. More than one joint is involved in 15% of cases of septic arthritis; risk factors for multiple joint involvement include rheumatoid arthritis, associated endocarditis, and infection with group B streptococci.

B. Laboratory Findings

Synovial fluid analysis is critical for diagnosis. The leukocyte count of the synovial fluid usually exceeds 50,000/mcL and often is > 100,000/mcL, with 90% or more polymorphonuclear cells (Table 20–2). Gram stain of the synovial fluid is positive in 75% of staphylococcal infections and in 50% of gram-negative infections. Synovial fluid cultures are positive in 70–90% of cases; administration of antibiotics prior to arthrocentesis reduces the likelihood of a positive culture result. Blood cultures are positive in approximately 50% of patients.

C. Imaging

Imaging tests generally add little to the diagnosis of septic arthritis. Indeed, other than demonstrating joint effusion, radiographs are usually normal early in the disease; in fact, evidence of demineralization may develop within days of onset. MRI and CT are more sensitive in detecting fluid in joints that are not accessible to physical examination (eg, the hip). Bony erosions and narrowing of the joint space followed by osteomyelitis and periostitis may be seen within 2 weeks.

► Differential Diagnosis

Gout and pseudogout can cause acute, very inflammatory monoarticular arthritis and high-grade fever; the failure to find crystals on synovial fluid analysis excludes these diagnoses. A well-recognized but uncommon initial presentation of rheumatoid arthritis is an acute inflammatory monoarthritis (“pseudoseptic”). Acute rheumatic fever commonly involves several joints; Still disease may mimic septic arthritis, but laboratory evidence of infection is absent. Pyogenic arthritis may be superimposed on other types of joint disease, notably rheumatoid arthritis. Indeed, septic arthritis must be excluded (by joint fluid examination)

in any patient with rheumatoid arthritis who has a joint strikingly more inflamed than the other joints.

► Prevention

There is no evidence that patients with prosthetic joints undergoing procedures should receive antibiotic prophylaxis to prevent joint infection. However, the topic remains controversial. The American Academy of Orthopedic Surgeons advocates prescribing antibiotic prophylaxis for any patient with a prosthetic joint replacement undergoing a procedure that can cause bacteremia.

► Treatment

The effective treatment of septic arthritis requires appropriate antibiotic therapy together with drainage of the infected joint. Hospitalization is always necessary. If the likely causative organism cannot be determined clinically or from the synovial fluid Gram stain, treatment should be started with broad-spectrum antibiotic coverage effective against staphylococci, streptococci, and gram-negative organisms. The recommendation for initial treatment is to give a third-generation cephalosporin: ceftriaxone, 1 g intravenously daily (or every 12 hours if concomitant meningitis or endocarditis is suspected); or cefotaxime, 1 g intravenously every 8 hours; or ceftizoxime, 1 g intravenously every 8 hours. Vancomycin (1 g intravenously every 12 hours, adjusted for age, weight, and renal function) should be used whenever MRSA is reasonably likely. Antibiotic therapy should be adjusted when culture results become available; the duration of antibiotic therapy is usually 4–6 weeks.

Early orthopedic consultation is essential. Effective drainage is usually achieved through early arthroscopic lavage and debridement together with drain placement. Open surgical drainage should be performed when conservative treatment fails, when there is concomitant osteomyelitis requiring debridement, or when the involved joint (eg, hip, shoulder, sacroiliac joint) cannot be drained by more conservative means. Immobilization with a splint and elevation are used at the onset of treatment. Early active motion exercises within the limits of tolerance will hasten recovery.

► Prognosis

The outcome of septic arthritis depends largely on the antecedent health of the patient, the causative organism (eg, *S aureus* bacterial arthritis is associated with a poor functional outcome in about 40% of cases), and the promptness of treatment. Five to 10 percent of patients with an infected joint die of respiratory complications of sepsis. The mortality rate is 30% for patients with polyarticular sepsis. Bony ankylosis and articular destruction commonly also occur if treatment is delayed or inadequate.

Mathews CJ et al. Bacterial septic arthritis in adults. *Lancet*. 2010 Mar 6;375(9717):846–55. [PMID: 20206778]

GONOCOCCAL ARTHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Prodromal migratory polyarthralgias.
- ▶ Tenosynovitis is the most common sign.
- ▶ Purulent monoarthritis in 50%.
- ▶ Characteristic skin lesions.
- ▶ Most common in young women during menses or pregnancy.
- ▶ Symptoms of urethritis frequently absent.
- ▶ Dramatic response to antibiotics.

▶ General Considerations

In contrast to nongonococcal bacterial arthritis, gonococcal arthritis usually occurs in otherwise healthy individuals. Host factors, however, influence the expression of the disease: gonococcal arthritis is two to three times more common in women than in men, is especially common during menses and pregnancy, and is rare after age 40. Gonococcal arthritis is also common in men who have sex with men, whose high incidence of asymptomatic gonococcal pharyngitis and proctitis predisposes them to disseminated gonococcal infection. Recurrent disseminated gonococcal infection should prompt testing of the patient's CH50 level to evaluate for a congenital deficiency of a terminal complement component (C5, C6, C7, or C8).

▶ Clinical Findings

A. Symptoms and Signs

One to 4 days of migratory polyarthralgias involving the wrist, knee, ankle, or elbow are common at the outset. Thereafter, two patterns emerge. The first pattern is characterized by tenosynovitis that most often affects wrists, fingers, ankles, or toes and is seen in 60% of patients. The second pattern is purulent monoarthritis that most frequently involves the knee, wrist, ankle, or elbow and is seen in 40% of patients. Less than half of patients have fever, and less than one-fourth have any genitourinary symptoms. Most patients will have asymptomatic but highly characteristic skin lesions that usually consist of two to ten small necrotic pustules distributed over the extremities, especially the palms and soles.

B. Laboratory Findings

The peripheral blood leukocyte count averages about 10,000 cells/mcL and is elevated in less than one-third of patients. The synovial fluid white blood cell count usually ranges from 30,000 to 60,000 cells/mcL. The synovial fluid Gram stain is positive in one-fourth of cases and culture in less than half. Positive blood cultures are uncommon. Urethral, throat, cervical, and rectal cultures should be done in all patients, since they are often positive in the absence of local symptoms. Urinary nucleic acid amplification tests have excellent sensitivity and specificity for the detection of *Neisseria gonorrhoeae* in genitourinary sites.

C. Imaging

Radiographs are usually normal or show only soft tissue swelling.

▶ Differential Diagnosis

Reactive arthritis can produce acute monoarthritis, urethritis, and fever in a young person but is distinguished by negative cultures and failure to respond to antibiotics. Lyme disease involving the knee is less acute, does not show positive cultures, and may be preceded by known tick exposure and characteristic rash. The synovial fluid analysis will exclude gout, pseudogout, and nongonococcal bacterial arthritis. Rheumatic fever and sarcoidosis can produce migratory tenosynovitis but have other distinguishing features. Infective endocarditis with septic arthritis can mimic disseminated gonococcal infection. Meningococcemia occasionally presents with a clinical picture that resembles disseminated gonococcal infection; blood cultures establish the correct diagnosis.

▶ Treatment

In most cases, patients in whom gonococcal arthritis is suspected should be admitted to the hospital to confirm the diagnosis, to exclude endocarditis, and to start treatment. While outpatient treatment has been recommended in the past, the rapid rise in gonococci resistant to penicillin makes initial inpatient treatment advisable. Approximately 4–5% of all gonococcal isolates produce a β -lactamase that confers penicillin resistance. An additional 15–20% of gonococcal species have chromosomal mutations that result in relative resistance to penicillin. The recommendation for initial treatment is to give a third-generation cephalosporin: ceftriaxone, 1 g intravenously daily (or every 12 hours if concomitant meningitis or endocarditis is suspected); or cefotaxime, 1 g intravenously every 8 hours; or ceftizoxime, 1 g intravenously every 8 hours. Once improvement from parenteral antibiotics has been achieved for 24–48 hours, patients can be switched to cefixime, 400 mg orally twice daily, or cefpodoxime, 400 mg orally twice daily, to complete a 7- to 10-day course. Recently, however, cephalosporin-resistant strains of gonococci have been identified; treatment with gentamicin or the new fluoroketolide, solithromycin (not yet approved by the United States FDA) has been suggested. Fluoroquinolone antibiotics are also not recommended for the initial treatment of gonococcal infections unless because of drug resistance culture results show antibiotic sensitivity.

▶ Prognosis

Generally, gonococcal arthritis responds dramatically in 24–48 hours after initiation of antibiotics, and drainage of the infected joint(s) is required infrequently. Complete recovery is the rule.

RHEUMATIC MANIFESTATIONS OF HIV INFECTION

Infection with HIV has been associated with various rheumatic disorders, most commonly arthralgias and arthritis. HIV painful articular syndrome causes severe arthralgias in an oligoarticular, asymmetric pattern that resolve within 24 hours; the joint examination is normal. HIV-associated arthritis is an asymmetric oligoarticular process with objective findings of arthritis and a self-limited course that ranges from weeks to months. Psoriatic arthritis and reactive arthritis occur in HIV-infected individuals and can be severe; it remains uncertain whether the incidence of these disorders is increased in HIV-infected populations. These spondyloarthropathies can respond to NSAIDs, though many cases are unresponsive. In the era of highly active antiretroviral therapies, immunosuppressive medications can be used if necessary in HIV patients, though with caution. Muscle weakness associated with an elevated creatine kinase can be due to nucleoside reverse transcriptase inhibitor-associated myopathy or HIV-associated myopathy; the clinical presentations of each resemble idiopathic polymyositis but the muscle biopsies show minimal inflammation. Less commonly, an inflammatory myositis indistinguishable from idiopathic polymyositis occurs.

Kaddu-Mukasa M et al. Rheumatic manifestations among HIV positive adults attending the Infectious Disease Clinic at Mulago Hospital. *Afr Health Sci*. 2011 Mar;11(1):24–9. [PMID: 21572853]

VIRAL ARTHRITIS

Arthralgias occur frequently in the course of acute infections with many viruses, but frank arthritis is uncommon. A notable exception is acute parvovirus B19 infection, which leads to acute polyarthritides in 50–60% of adult cases (infected children develop the febrile exanthem known as “slapped cheek fever”). The arthritis can mimic rheumatoid arthritis but is almost always self-limited and resolves within several weeks. The diagnosis is established by the presence of IgM antibodies specific for parvovirus B19. Self-limited polyarthritides is also common in acute hepatitis B infection and typically occurs before the onset of jaundice. Urticaria or other types of skin rash may be present. Indeed, the clinical picture resembles that of serum sickness (see Atopic Disease below). Serum transaminase levels are elevated, and tests for hepatitis B surface antigen are positive. Serum complement levels are often low during active arthritis and become normal after remission of arthritis. The incidence of hepatitis B–associated polyarthritides has fallen substantially with the introduction of hepatitis B vaccination. Effective vaccination programs in the United States have eliminated acute rubella infections, formerly a common cause of virally induced polyarthritides. Changes in the rubella vaccine (an attenuated live vaccine) have greatly reduced the incidence of rubella vaccine–induced polyarthritides as well.

Chronic infection with hepatitis C is associated with chronic polyarthralgia in up to 20% of cases and with

chronic polyarthritides in 3–5%. Both can mimic rheumatoid arthritis, and the presence of rheumatoid factor in most hepatitis C–infected individuals leads to further diagnostic confusion. Indeed, hepatitis C–associated arthritis is frequently misdiagnosed as rheumatoid arthritis. Distinguishing hepatitis C–associated arthritis/arthralgias from the co-occurrence of hepatitis C and rheumatoid arthritis can be difficult. Rheumatoid arthritis always causes objective arthritis (not just arthralgias) and can be erosive (hepatitis C–associated arthritis is nonerosive). The presence of anti-CCP antibodies points to the diagnosis of rheumatoid arthritis.

Ezzat WM et al. Anti-cyclic citrullinated peptide antibodies as a discriminating marker between rheumatoid arthritis and chronic hepatitis C-related polyarthropathy. *Rheumatol Int*. 2011 Jan;31(1):65–9. [PMID: 19882340]

INFECTIONS OF BONES

ACUTE PYOGENIC OSTEOMYELITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever and chills associated with pain and tenderness of involved bone.
- ▶ Diagnosis usually requires culture of bone biopsy.
- ▶ ESR often extremely high (eg, > 100 mm/h).
- ▶ Radiographs early in the course are typically negative.

▶ General Considerations

Osteomyelitis is a serious infection that is often difficult to diagnose and treat. Infection of bone occurs as a consequence of (1) hematogenous dissemination of bacteria, (2) invasion from a contiguous focus of infection, and (3) skin breakdown in the setting of vascular insufficiency.

▶ Clinical Findings

A. Symptoms and Signs

1. Hematogenous osteomyelitis—Osteomyelitis resulting from bacteremia is a disease associated with sickle cell disease, injection drug users, diabetes mellitus, or the elderly. Patients with this form of osteomyelitis often present with sudden onset of high fever, chills, and pain and tenderness of the involved bone. The site of osteomyelitis and the causative organism depend on the host. Among patients with hemoglobinopathies such as sickle cell anemia, osteomyelitis is caused most often by salmonellae; *S aureus* is the second most common cause. Osteomyelitis in injection drug users develops most commonly in the spine. Although in this setting *S aureus* is most common, gram-negative infections, especially *P aeruginosa* and *Serratia* species, are also frequent pathogens. Rapid progression to epidural abscess causing

fever, pain, and sensory and motor loss is not uncommon. In older patients with hematogenous osteomyelitis, the most common sites are the thoracic and lumbar vertebral bodies. Risk factors for these patients include diabetes, intravenous catheters, and indwelling urinary catheters. These patients often have more subtle presentations, with low-grade fever and gradually increasing bone pain.

2. Osteomyelitis from a contiguous focus of infection—Prosthetic joint replacement, decubitus ulcer, neurosurgery, and trauma most frequently cause soft tissue infections that can spread to bone. *S aureus* and *Staphylococcus epidermidis* are the most common organisms. Localized signs of inflammation are usually evident, but high fever and other signs of toxicity are usually absent. Septic arthritis and cellulitis can also spread to contiguous bone.

3. Osteomyelitis associated with vascular insufficiency—Patients with diabetes and vascular insufficiency are susceptible to developing a very challenging form of osteomyelitis. The foot and ankle are the most commonly affected sites. Infection originates from an ulcer or other break in the skin that is usually still present when the patient presents but may appear disarmingly unimpressive. Bone pain is often absent or muted by the associated neuropathy. Fever is also commonly absent. Two of the best bedside clues that the patient has osteomyelitis are the ability to easily advance a sterile probe through a skin ulcer to bone and an ulcer area > 2 cm².

B. Imaging and Laboratory Findings

The plain film is the most readily available imaging procedure to establish the diagnosis of osteomyelitis, but it can be falsely negative early. Early radiographic findings may include soft tissue swelling, loss of tissue planes, and peri-articular demineralization of bone. About 2 weeks after onset of symptoms, erosion of bone and alteration of cancellous bone appear, followed by periostitis.

MRI, CT, and nuclear medicine bone scanning are more sensitive than conventional radiography. MRI is the most sensitive and is particularly helpful in demonstrating the extent of soft tissue involvement. Radionuclide bone scanning is most valuable when osteomyelitis is suspected but no site is obvious. Nuclear medicine studies may also detect multifocal sites of infection. Ultrasound is useful in diagnosing the presence of effusions within joints and extra-articular soft tissue fluid collections but not in detecting bone infections.

Identifying the offending organism is a crucial step in selection of antibiotic therapy. Bone biopsy for culture is required except in those with hematogenous osteomyelitis, who have positive blood cultures. Cultures from overlying ulcers, wounds, or fistulas are unreliable.

► Differential Diagnosis

Acute hematogenous osteomyelitis should be distinguished from suppurative arthritis, rheumatic fever, and cellulitis. More subacute forms must be differentiated from tuberculosis or mycotic infections of bone and Ewing sarcoma or, in the case of vertebral osteomyelitis, from metastatic tumor.

When osteomyelitis involves the vertebrae, it commonly traverses the disk—a finding not observed in tumor.

► Complications

Inadequate treatment of bone infections results in chronicity of infection, and this possibility is increased by delaying diagnosis and treatment. Extension to adjacent bone or joints may complicate acute osteomyelitis. Recurrence of bone infections often results in anemia, a markedly elevated ESR, weight loss, weakness and, rarely, amyloidosis or nephrotic syndrome. Pseudoepitheliomatous hyperplasia, squamous cell carcinoma, or fibrosarcoma may occasionally arise in persistently infected tissues.

► Treatment

Most patients require both debridement of necrotic bone and prolonged administration of antibiotics. Patients with vertebral body osteomyelitis and epidural abscess may require urgent neurosurgical decompression. Depending on the site and extent of debridement, surgical procedures to stabilize, fill in, cover, or revascularize may be needed. Oral therapy with quinolones (eg, ciprofloxacin, 750 mg twice daily) for 6–8 weeks has been shown to be as effective as standard parenteral antibiotic therapy for chronic osteomyelitis with susceptible organisms. When treating osteomyelitis caused by *S aureus*, quinolones are usually combined with rifampin, 300 mg orally twice daily.

► Prognosis

If sterility of the lesion is achieved within 2–4 days, a good result can be expected in most cases if there is no compromise of the patient's immune system. However, progression of the disease to a chronic form may occur. It is especially common in the lower extremities and in patients in whom circulation is impaired (eg, diabetics).

Howell WR et al. Osteomyelitis: an update for hospitalists. *Hosp Pract (Minneap)*. 2011 Feb;39(1):153–60. [PMID: 21441771]
Zimmerli W. Clinical practice. Vertebral osteomyelitis. *N Engl J Med*. 2010 Mar 18;362(11):1022–9. [PMID: 20237348]

MYCOTIC INFECTIONS OF BONES & JOINTS

Fungal infections of the skeletal system are usually secondary to a primary infection in another organ, frequently the lungs (see Chapter 36). Although skeletal lesions have a predilection for the cancellous portions of long bones and vertebral bodies, the predominant lesion—a granuloma with varying degrees of necrosis and abscess formation—does not produce a characteristic clinical picture.

Differentiation from other chronic focal infections depends on culture studies of synovial fluid or tissue obtained from the local lesion. Serologic tests provide presumptive support of the diagnosis.

1. Candidiasis

Candidal osteomyelitis most commonly develops in debilitated, malnourished patients undergoing prolonged

hospitalization for cancer, neutropenia, trauma, complicated abdominal surgical procedures, or injection drug use. Infected intravenous catheters frequently serve as a hematogenous source. Prosthetic joints can also be infected by *Candida*.

For susceptible *Candida* species, fluconazole, 200 mg orally twice daily, is probably as effective as amphotericin B (see Chapter 36).

Dailey NJ et al. *Candida glabrata* spinal osteomyelitis. *Am J Med Sci*. 2011 Jan;341(1):78–82. [PMID: 21030857]

2. Coccidioidomycosis

Coccidioidomycosis of bones and joints is usually secondary to primary pulmonary infection. Arthralgia with periarticular swelling, especially in the knees and ankles, occurring as a nonspecific manifestation of systemic coccidioidomycosis, should be distinguished from actual bone or joint infection. Osseous lesions commonly occur in cancellous bone of the vertebrae or near the ends of long bones at tendinous insertions. These lesions are initially osteolytic and thus may mimic metastatic tumor or myeloma.

The precise diagnosis depends on recovery of *Coccidioides immitis* from the lesion or histologic examination of tissue obtained by open biopsy. Rising titers of complement-fixing antibodies also provide evidence of the disseminated nature of the disease.

Oral azole antifungal agents (fluconazole 200–400 mg daily, or itraconazole 200 mg twice daily) are the treatment of choice for bone and joint coccidioidomycosis. Chronic infection is rarely cured with antifungal agents and may require operative excision of infected bone and soft tissue; amputation may be the only solution for stubbornly progressive infections. Immobilization of joints by plaster casts and avoidance of weight bearing provide benefit. Synovectomy, joint debridement, and arthrodesis are reserved for more advanced joint infections.

Blair JE. State-of-the-art treatment of coccidioidomycosis skeletal infections. *Ann N Y Acad Sci*. 2007 Sep;1111:422–33. [PMID: 17395727]

3. Histoplasmosis

Focal skeletal or joint involvement in histoplasmosis is rare and generally represents dissemination from a primary focus in the lungs. Skeletal lesions may be single or multiple and are not characteristic.

TUBERCULOSIS OF BONES & JOINTS

SPINAL TUBERCULOSIS (Pott Disease)

ESSENTIALS OF DIAGNOSIS

- ▶ Seen primarily in immigrants from developing countries or immunocompromised patients.
- ▶ Back pain and gibbus deformity.
- ▶ Radiographic evidence of vertebral involvement.
- ▶ Evidence of *Mycobacterium tuberculosis* in aspirates or biopsies of spinal lesions.

▶ General Considerations

In the developing world, children primarily bear the burden of musculoskeletal tuberculosis. In the United States, however, musculoskeletal infection is more often seen in adult immigrants from countries where tuberculosis is prevalent, or it develops in the setting of immunosuppression (eg, HIV infection, therapy with TNF inhibitors). Spinal tuberculosis (Pott disease) accounts for about 50% of musculoskeletal infection due to *M tuberculosis* (see Chapter 9). Seeding of the vertebrae may occur through hematogenous spread from the respiratory tract at the time of primary infection, with clinical disease developing years later as a consequence of reactivation. The thoracic and lumbar vertebrae are the most common sites of spinal involvement; vertebral infection is associated with paravertebral cold abscesses in 75% of cases.

▶ Clinical Findings

A. Symptoms and Signs

Patients complain of back pain, often present for months and sometimes associated with radicular pain and lower extremity weakness. Constitutional symptoms are usually absent, and < 20% have active pulmonary disease. Destruction of the anterior aspect of the vertebral body can produce the characteristic gibbus deformity.

B. Laboratory Findings

Most patients have a positive reaction to purified protein derivative (PPD) or a positive interferon-gamma release assay. Cultures of paravertebral abscesses and biopsies of vertebral lesions are positive in up to 70–90%. Biopsies reveal characteristic caseating granulomas in most cases. Isolation of *M tuberculosis* from an extraspinal site is sufficient to establish the diagnosis in the proper clinical setting.

C. Imaging

Radiographs can reveal lytic and sclerotic lesions and bony destruction of vertebrae but are normal early in the disease course. CT scanning can demonstrate paraspinous soft tissue extensions of the infection; MRI is the imaging technique of choice to detect compression of the spinal cord or cauda equina.

► Differential Diagnosis

Spinal tuberculosis must be differentiated from subacute and chronic spinal infections due to pyogenic organisms, *Brucella*, and fungi as well as from malignancy.

► Complications

Paraplegia due to compression of the spinal cord or cauda equina is the most serious complication of spinal tuberculosis.

► Treatment

Antimicrobial therapy should be administered for 6–9 months, usually in the form of isoniazid, rifampin, pyrazinamide, and ethambutol for 2 months followed by isoniazid and rifampin for an additional 4–7 months (see also Chapter 9). Medical management alone is often sufficient. Surgical intervention, however, may be indicated when there is neurologic compromise or severe spinal instability.

Kumar R et al. Role of interferon gamma release assay in the diagnosis of Pott disease. *J Neurosurg Spine.* 2010 May;12(5):462–6. [PMID: 20433293]

TUBERCULOUS ARTHRITIS

Infection of peripheral joints by *M tuberculosis* usually presents as a monoarticular arthritis lasting for weeks to months (or longer), but less often, it can have an acute presentation that mimics septic arthritis. Any joint can be involved; the hip and knee are most commonly affected. Constitutional symptoms and fever are present in only a small number of cases. Tuberculosis also can cause a chronic tenosynovitis of the hand and wrist. Joint destruction occurs far more slowly than in septic arthritis due to pyogenic organisms. Synovial fluid is inflammatory but not to the degree seen in pyogenic infections, with synovial white cell counts in the range of 10,000–20,000 cells/mcL. Smears of synovial fluid are positive for acid-fast bacilli in a minority of cases; synovial fluid cultures, however, are positive in 80% of cases. Because culture results may take weeks, the diagnostic procedure of choice usually is synovial biopsy, which yields characteristic pathologic findings and positive cultures in > 90%. Antimicrobial therapy is the mainstay of treatment. Rarely, a reactive, sterile polyarthritis associated with erythema nodosum (Poncet disease) develops in patients with active pulmonary tuberculosis.

Shu CC et al. Mycobacterial arthritis of large joints. *Ann Rheum Dis.* 2009 Sep;(9):1504–5. [PMID: 19674984]

ARTHRITIS IN SARCOIDOSIS

The frequency of arthritis among patients with sarcoidosis is variously reported between 10% and 35%. It is usually acute in onset, but articular symptoms may appear insidiously and often antedate other manifestations of the disease. Knees

and ankles are most commonly involved, but any joint may be affected. Distribution of joint involvement is usually polyarticular and symmetric. The arthritis is commonly self-limited, resolving after several weeks or months and rarely resulting in chronic arthritis, joint destruction, or significant deformity. Sarcoid arthropathy is often associated with erythema nodosum, but the diagnosis is contingent on the demonstration of other extra-articular manifestations of sarcoidosis and, notably, biopsy evidence of noncaseating granulomas. Despite the clinical appearance of an inflammatory arthritis, synovial fluid often is noninflammatory (ie, < 2000 leukocytes/mcL). In chronic arthritis, radiographs show typical changes in the bones of the extremities with intact cortex and cystic changes.

Treatment of arthritis in sarcoidosis is usually symptomatic and supportive. Colchicine may be of value. A short course of corticosteroids may be effective in patients with severe and progressive joint disease.

Gnanasegaran G et al. Multislice SPECT/CT in benign and malignant bone disease: when the ordinary turns into the extraordinary. *Semin Nucl Med.* 2009 Nov;39(6):431–42. [PMID: 19801222]

OTHER RHEUMATIC DISORDERS

RHEUMATIC MANIFESTATIONS OF CANCER

Rheumatologic syndromes may be the presenting manifestations for a variety of cancers. Dermatomyositis in adults, for example, is often associated with cancer (see Table 39–2). Hypertrophic pulmonary osteoarthropathy, which is characterized by the triad of polyarthritis, new onset of clubbing, and periosteal new bone formation, is associated with both malignant diseases (eg, lung and intrathoracic cancers) and nonmalignant ones (eg, cyanotic heart disease, cirrhosis, and lung abscess). Cancer-associated polyarthritis is rare, has both oligoarticular and polyarticular forms, and should be considered when “seronegative rheumatoid arthritis” develops abruptly in an elderly patient. Palmar fasciitis manifests as bilateral palmar swelling with finger contractures and may be the first indication of cancer, particularly ovarian carcinoma. Remitting seronegative synovitis with non-pitting edema (“RS3PE”) presents with a symmetric small joint polyarthritis associated with non-pitting edema of the hands; it can be idiopathic or associated with malignancy. Palpable purpura due to leukocytoclastic vasculitis may be the presenting complaint in myeloproliferative disorders. Hairy cell leukemia can be associated with medium-sized vessel vasculitis such as polyarteritis nodosa. Acute leukemia can produce joint pains that are disproportionately severe in comparison to the minimal swelling and heat that are present. Leukemic arthritis complicates approximately 5% of cases. Rheumatic manifestations of myelodysplastic syndromes include cutaneous vasculitis, lupus-like syndromes, neuropathy, and episodic

intense arthritis. Erythromelalgia, a painful warmth and redness of the extremities that (unlike Raynaud) improves with cold exposure or with elevation of the extremity, is often associated with myeloproliferative diseases, particularly essential thrombocythemia.

Naschitz JE et al. Musculoskeletal syndromes associated with malignancy (excluding hypertrophic osteoarthropathy). *Curr Opin Rheumatol.* 2008 Jan;20(1):100–5. [PMID: 18281865]

NEUROGENIC ARTHROPATHY (Charcot Joint)

Neurogenic arthropathy is joint destruction resulting from loss or diminution of proprioception, pain, and temperature perception. Although initially described in the knees of patients with tabes dorsalis, it is more frequently seen in association with diabetic neuropathy (foot and ankle) or syringomyelia (shoulder). As normal muscle tone and protective reflexes are lost, secondary degenerative joint disease ensues, resulting in an enlarged, boggy, relatively painless joint with extensive cartilage erosion, osteophyte formation, and multiple loose joint bodies. Radiographs can reveal striking osteolysis that mimics osteomyelitis or dramatic destruction of the joint with subluxation, fragmentation of bone, and bony sclerosis.

Treatment is directed toward the primary disease; mechanical devices are used to assist in weight bearing and prevention of further trauma. In some instances, amputation becomes unavoidable.

Thompson P et al. Diabetic foot: Charcot neuropathic osteoarthropathy. *Adv Skin Wound Care.* 2009 Feb;22(2):72–3. [PMID: 19155710]

PALINDROMIC RHEUMATISM

Palindromic rheumatism is a disease of unknown cause characterized by frequent recurring attacks (at irregular intervals) of acutely inflamed joints. Periarticular pain with swelling and transient subcutaneous nodules may also occur. The attacks cease within several hours to several days. The knee and finger joints are most commonly affected, but any peripheral joint may be involved. Systemic manifestations other than fever do not occur. Although hundreds of attacks may take place over a period of years, there is no permanent articular damage. Laboratory findings are usually normal. Palindromic rheumatism must be distinguished from acute gouty arthritis and an atypical acute onset of rheumatoid arthritis. In some patients, palindromic rheumatism is a prodrome of rheumatoid arthritis.

Symptomatic treatment with NSAIDs is usually all that is required during the attacks. Hydroxychloroquine may be of value in preventing recurrences.

OSTEONECROSIS (Avascular Necrosis of Bone)

Osteonecrosis is a complication of corticosteroid use, alcoholism, trauma, SLE, pancreatitis, gout, sickle cell disease,

dysbaric syndromes (eg, “the bends”), knee meniscectomy, and infiltrative diseases (eg, Gaucher disease). The most commonly affected sites are the proximal and distal femoral heads, leading to hip or knee pain. Other commonly affected sites include the ankle, shoulder, and elbow. Osteonecrosis of the jaw has been rarely associated with use of bisphosphonate therapy, almost always when the bisphosphonate is used for treating metastatic cancer or multiple myeloma rather than osteoporosis. Initially, radiographs are often normal; MRI, CT scan, and bone scan are all more sensitive techniques. Treatment involves avoidance of weight bearing on the affected joint for at least several weeks. The value of surgical core decompression is controversial. For osteonecrosis of the hip, a variety of procedures designed to preserve the femoral head have been developed for early disease, including vascularized and nonvascularized bone grafting procedures. These procedures are most effective in avoiding or forestalling the need for total hip arthroplasty in young patients who do not have advanced disease. Without a successful intervention of this nature, the natural history of avascular necrosis is usually progression of the bony infarction to cortical collapse, resulting in significant joint dysfunction. Total hip replacement is the usual outcome for all patients who are candidates for that procedure.

Turun S et al. A systematic review of rivaroxaban versus enoxaparin in the prevention of venous thromboembolism after hip or knee replacement. *Thromb Res.* 2011 Jun;127(6):525–34. [PMID: 21397931]

ALLERGIC DISEASES

Allergy is an immunologically mediated hypersensitivity reaction to a foreign antigen manifested by tissue inflammation and organ dysfunction. These responses have a genetic basis, but the clinical expression of disease depends on both immunologic responsiveness and antigen exposure. Allergic disorders may be local or systemic. Because the allergen is foreign (ie, environmental), the skin and respiratory tract are the organs most frequently involved in allergic disease. Allergic reactions may also localize to the vasculature, gastrointestinal tract, or other visceral organs. Anaphylaxis is the most extreme form of systemic allergy.

▶ Immunologic Classification

An immunologic classification for hypersensitivity reactions serves as a rational basis for diagnosis and treatment. The classification follows.

A. Type I—IgE-Mediated (Immediate) Hypersensitivity

IgE antibodies occupy receptor sites on mast cells. Within minutes after exposure to the allergen, a multivalent

antigen links adjacent IgE molecules, activating and degranulating mast cells. Clinical manifestations depend on the effects of released mediators on target end organs. Both preformed and newly generated mediators cause vasodilation, visceral smooth muscle contraction, mucous secretory gland stimulation, vascular permeability, and tissue inflammation. Arachidonic acid metabolites, cytokines, and other mediators induce a late-phase inflammatory response that appears several hours later. There are two clinical subgroups of IgE-mediated allergy: atopy and anaphylaxis.

1. Atopy—The term “atopy” is applied to a group of diseases (allergic rhinitis, allergic asthma, atopic dermatitis, and allergic gastroenteropathy) occurring in persons with an inherited tendency to develop antigen-specific IgE reaction to environmental allergens or food antigens. Aeroallergens such as pollens, mold spores, animal danders, and house dust mite antigen are common triggers for allergic conjunctivitis, allergic rhinitis, and allergic asthma. The allergic origin of atopic dermatitis is less well understood, but some patients’ symptoms can be triggered by exposure to dust mite antigen and ingestion of certain foods. There is a strong familial tendency toward the development of atopy.

2. Anaphylaxis—Certain allergens—especially drugs, insect venoms, latex, and foods—may induce an IgE antibody response, causing a generalized release of mediators from mast cells and resulting in systemic anaphylaxis. This is characterized by (1) hypotension or shock from widespread vasodilation, (2) bronchospasm, (3) gastrointestinal and uterine muscle contraction, and (4) urticaria or angioedema. The condition is potentially fatal and can affect both nonatopic and atopic persons. Isolated urticaria and angioedema are cutaneous forms of anaphylaxis, are much more common, and have a better prognosis.

B. Type II—Antibody-Mediated (Cytotoxic) Hypersensitivity

Cytotoxic reactions involve the specific reaction of either IgG or IgM antibody to cell-bound antigens. This results in activation of the complement cascade and the destruction of the cell to which the antigen is bound. Examples include immune hemolytic anemia and Rh hemolytic disease in the newborn.

C. Type III—Immune Complex-Mediated Hypersensitivity

Immune complex-mediated reactions occur when antigen and IgG or IgM antibodies form circulating immune complexes. Deposition of these complexes in tissues or in vascular endothelium can produce immune complex-mediated tissue injury through activation of the complement cascade, anaphylatoxin generation, and chemotaxis of polymorphonuclear leukocytes. Serum sickness is the classic example of type III hypersensitivity. Immune complex disease also can develop in the setting of chronic infections such as subacute bacterial endocarditis and hepatitis B.

D. Type IV—T Cell-Mediated Hypersensitivity (Delayed Hypersensitivity, Cell-Mediated Hypersensitivity)

Type IV delayed hypersensitivity is mediated by activated T cells, which accumulate in areas of antigen deposition. The most common expression of delayed hypersensitivity is allergic contact dermatitis, which develops when a low-molecular-weight sensitizing substance haptens with dermal proteins, becoming a complete antigen. Sensitized T cells release cytokines, activating macrophages and promoting the subsequent dermal inflammation; this occurs 1–2 days after the time of contact. Common topical agents associated with allergic contact dermatitis include nickel, formaldehyde, potassium dichromate, thiurams, mercaptos, parabens, quaternium-15, and ethylenediamine. Rhus (poison oak and ivy) contact dermatitis is caused by cutaneous exposure to oils from the toxicodendron plants. Acute contact dermatitis is characterized by erythema and induration with vesicle formation, often with pruritus, with exudation and crusting in more severe cases. Chronic allergic contact dermatitis may be associated with fissuring, lichenification, or dyspigmentation and may be mistaken for other forms of dermatitis. To diagnose allergic contact dermatitis, patch testing can be performed.

ATOPIC DISEASE

Clinical manifestations resembling allergic hypersensitivity can also occur in the absence of an immunologic mechanism. Therefore, the diagnosis of allergy requires answers to the following questions: (1) What is the nature of the disease? (2) Is the disease caused by an IgE-mediated mechanism? (3) What specific allergens are responsible?

The relevant history includes a survey of allergen exposure associated with home, work, hobbies, and habits as well as medications. Physical examination is most useful if performed during exposure. Demonstration of allergic hypersensitivity by *in vivo* or *in vitro* testing confirms clinical suspicions of allergic disease.

► Specific IgE Antibody Tests

To maximize the positive predictive value of allergy testing, a positive test result must be correlated with the history. Patients selected for testing include those with moderate to severe disease, those who are potential candidates for allergen immunotherapy, and those with strong predisposing factors for atopic diatheses, eg, a strong family history of atopy or ongoing exposure to potential sources of allergen. Since the development of rhinitis precedes the presentation of asthma in over half of cases, early intervention may decrease the risk of more severe clinical allergic disease. The type of immune response must be consistent with the nature of the disease. IgE antibody causes allergic rhinitis but not allergic contact dermatitis. IgE antibodies are detected by *in vivo* (skin tests) or *in vitro* methods.

SERUM SICKNESS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever, pruritic rash, arthralgias, and arthritis; nephritis in severe cases.
- ▶ Occurs 7–10 days following administration of an exogenous antigen (eg, heterologous gamma globulin) when specific IgG antibodies develop against the antigen.
- ▶ Immune complex-mediated small vessel vasculitis and tissue injury.

▶ General Considerations

Serum sickness occurs when an antibody response to exogenously administered antigens results in the formation of immune complexes. Deposition of these complexes in vascular endothelium and tissues produces immune complex-mediated small vessel vasculitis and tissue injury through activation of complement, generation of anaphylatoxins, and chemoattraction of polymorphonuclear leukocytes. The skin, joints, and kidneys are commonly affected. It is self-limited and resolves after the antigen is cleared. First observed in the preantibiotic era when heterologous serum preparations were used for passive immunization, serum sickness is now less common but still occurs with the use of heterologous anti-thymocyte globulin for transplant rejection and, infrequently, after the administration of murine monoclonal antibodies or even non-protein drugs.

▶ Clinical Findings

A. Symptoms and Signs

Sustained high fever (> 101°F) is typical. The earliest manifestation is often a maculopapular or urticarial pruritic rash. Angioedema can occur. Polyarthralgias, frank polyarthritis, and lymphadenopathy are common. Nephritis is usually mild but can progress to acute renal failure.

B. Laboratory Findings

The ESR is increased, and leukocytosis is common. Other nonspecific laboratory findings include elevated hepatic aminotransferases. When nephritis is present, the urinalysis

reveals proteinuria, hematuria, and red cell casts. Hypocomplementemia is usually present in cases due to administration of heterologous gamma globulin but not in milder cases precipitated by non-protein drugs. Circulating immune complexes may be found, but current assays are limited in sensitivity.

▶ Treatment

This disease is self-limited, and treatment is usually conservative for mild cases. NSAIDs help relieve the arthralgias, and antihistamines and topical corticosteroids can be of benefit for the skin manifestation. A high-dose course of corticosteroids is administered for serious reactions, especially those complicated by glomerulonephritis and other manifestations of vasculitis. Plasma exchange may be of benefit for cases refractory to corticosteroids.

PSEUDOALLERGIC REACTIONS

These reactions resemble immediate hypersensitivity reactions but are not mediated by allergen-IgE interaction. Instead, direct mast cell activation occurs. Examples of pseudoallergic or “anaphylactoid” reactions include radiocontrast reactions, direct mast cell activation by opioids, and the now rare “red man syndrome” from rapid infusion of vancomycin. In contrast to IgE-mediated reactions, these can often be prevented by prophylactic medical regimens.

Radiocontrast Media Reactions

Reactions to radiocontrast media do not appear to be mediated by IgE antibodies, yet clinically they are similar to anaphylaxis. If a patient has had an anaphylactoid reaction to conventional radiocontrast media, the risk for a second reaction upon reexposure may be as high as 30%. Patients with asthma or those being treated with β -adrenergic blocking medications may be at increased risk. The management of patients at risk for radiocontrast medium reactions includes use of the low-osmolality contrast preparations and prophylactic administration of prednisone (50 mg orally every 6 hours beginning 18 hours before the procedure) and diphenhydramine (25–50 mg intramuscularly 60 minutes before the procedure). The use of the lower-osmolality radiocontrast media in combination with the pretreatment regimen decreases the incidence of reactions to < 1%.

PRIMARY IMMUNODEFICIENCY DISORDERS

The primary immunologic deficiency diseases include congenital and acquired disorders of humoral immunity (B cell function) or cell-mediated immunity (T cell function). Most of these diseases are rare and, because they are genetically determined, usually present in childhood. Nonetheless, several immunodeficiency disorders can present in adulthood, most notably selective IgA deficiency and common variable immunodeficiency.

Slatter MA et al. Primary immunodeficiency syndromes. *Adv Exp Med Biol*. 2010;685:146–65. [PMID: 20687503]

SELECTIVE IMMUNOGLOBULIN A DEFICIENCY

Selective IgA deficiency is the most common primary immunodeficiency disorder and is characterized by serum IgA levels < 15 mg/dL with normal levels of IgG and IgM; its prevalence is about 1:500 individuals. Most persons are asymptomatic because of compensatory increases in secreted IgG and IgM. Some affected patients have frequent and recurrent infections, such as sinusitis, otitis, and bronchitis. Some cases of IgA deficiency may spontaneously remit. When IgG₂ subclass deficiency occurs in combination with IgA deficiency, affected patients are more susceptible to encapsulated bacteria and the degree of immune impairment can be more severe. Patients with a combined IgA and IgG subclass deficiency should be assessed for functional antibody responses to glycoprotein antigen immunization.

Atopic disease and autoimmune disorders can be associated with IgA deficiency. Occasionally, a sprue-like syndrome with steatorrhea has been associated with an isolated IgA deficit. Treatment with commercial immune globulin is ineffective, since IgA and IgM are present only in trace quantities in these preparations.

Individuals with selective IgA deficiency may have high titers of anti-IgA antibodies and are at risk for anaphylactic reactions following exposure to IgA through infusions of plasma (or blood transfusions). These anti-IgA antibodies develop in the absence of prior exposure to human plasma or blood, possibly due to crossreactivity to bovine IgA in cow's milk or prior sensitization to maternal IgA in breast milk.

Yel L. Selective IgA deficiency. *J Clin Immunol*. 2010 Jan;30(1): 10–6. [PMID: 20101521]

COMMON VARIABLE IMMUNODEFICIENCY

ESSENTIALS OF DIAGNOSIS

- ▶ Defect in terminal differentiation of B cells, with absent plasma cells and deficient synthesis of secreted antibody.
- ▶ Frequent sinopulmonary infections secondary to humoral immune deficiency.
- ▶ Confirmation by evaluation of serum immunoglobulin levels and deficient functional antibody responses.

▶ General Considerations

The most common cause of panhypogammaglobulinemia in adults is common variable immunodeficiency, a heterogeneous immunodeficiency disorder clinically characterized by an increased incidence of recurrent infections, autoimmune phenomena, and neoplastic diseases. The onset generally is during adolescence or early adulthood but can occur at any age. The prevalence of common variable immunodeficiency is about 1:80,000 in the United States. Most cases are sporadic; 10–20% are familial.

▶ Clinical Findings

A. Symptoms and Signs

Increased susceptibility to pyogenic infections is the hallmark of the disease. Virtually all patients suffer from recurrent sinusitis, with bronchitis, otitis, pharyngitis, and pneumonia also being common infections. Infections may be prolonged or associated with unusual complications such as meningitis or sepsis.

Gastrointestinal disorders are commonly associated with common variable immunodeficiency, and a sprue-like syndrome, with diarrhea, steatorrhea, malabsorption, protein-losing enteropathy, and hepatosplenomegaly, may develop in patients. Paradoxically, there is an increased incidence of autoimmune disease (20%), although patients may not display the usual serologic markers. Autoimmune cytopenias are most common, but autoimmune endocrinopathies, seronegative rheumatic disease, and gastrointestinal disorders are also commonly seen. Lymph nodes may be enlarged in these patients, yet biopsies show marked reduction in plasma cells. Noncaseating granulomas are frequently found in the spleen, liver, lungs, or skin. There is an increased propensity for the development of B cell neoplasms (50- to 400-fold increase risk of lymphoma), gastric carcinomas, and skin cancers.

B. Laboratory Findings

The pattern of immunoglobulin isotype deficiency is variable. Most patients present with significantly depressed IgG levels, but over time all antibody classes (IgG, IgA, and IgM) may be affected. Diagnosis is confirmed in patients

with recurrent infections by demonstration of functional or quantitative defects in antibody production. Serum IgG levels are usually < 250 mg/dL; serum IgA and IgM levels are also subnormal. Decreased to absent functional antibody responses to protein antigen immunizations establish the diagnosis.

The causes of the panhypogammaglobulinemia in common variable immunodeficiency patients include intrinsic B cell defects that prevent terminal maturation into antibody-secreting plasma cells. The absolute B cell count in the peripheral blood in most patients, despite the underlying cellular defect, is normal. A subset of these patients have concomitant T cell immunodeficiency with increased numbers of activated CD8 cells, splenomegaly, and decreased delayed-type hypersensitivity.

▶ Treatment

Patients may be treated aggressively with antibiotics at the first sign of infection. Since antibody deficiency predisposes patients to high-risk pyogenic infections, antibiotic coverage should be sure to cover encapsulated bacteria.

Only after the development of bronchiectasis or after sinus surgery do patients become significantly affected by more virulent organisms such as *S aureus* or *P aeruginosa*. Maintenance intravenous immune globulin therapy is indicated, with infusions of 300–500 mg/kg of intravenous immune globulin given at about monthly intervals. Adjustment of dosage or of the infusion interval is made on the basis of clinical responses and steady-state trough serum IgG levels. Such therapy is effective in decreasing the incidence of potentially life-threatening infections and increasing quality of life. The yearly cost of monthly infusions can be in excess of \$20,000–\$30,000.

Electrolyte & Acid-Base Disorders

Kerry C. Cho, MD

ASSESSMENT OF THE PATIENT

The diagnosis and treatment of fluid and electrolyte disorders are based on (1) careful history, (2) physical examination and assessment of total body water and its distribution, (3) serum electrolyte concentrations, (4) urine electrolyte concentrations, and (5) serum osmolality. The pathophysiology of electrolyte disorders is rooted in basic principles of total body water and its distribution across fluid compartments.

A. Body Water and Fluid Distribution

Total body water is different in men than in women, and it decreases with aging (Table 21–1). Approximately 50–60% of total body weight is water; two-thirds (40% of body weight) is intracellular, while one-third (20% of body weight) is extracellular. One-fourth of extracellular fluid (5% of body weight) is intravascular. Water may be lost from either or both compartments (intracellular and extracellular). Changes in total body water content are best evaluated by documenting changes in body weight. Effective circulating volume may be assessed by physical examination (eg, blood pressure, pulse, jugular venous distention). Quantitative measurements of effective circulating volume and intravascular volume may be invasive (ie, central venous pressure or pulmonary wedge pressure) or non-invasive (ie, inferior vena cava diameter and right atrial pressure by echocardiography) but still require careful interpretation.

B. Serum Electrolytes

The cause of electrolyte disorders may be determined by reviewing the history, underlying diseases, and medications.

C. Evaluation of Urine

The urine concentration of an electrolyte indicates renal handling of the electrolyte and whether the kidney is appropriately excreting or retaining the electrolyte. A 24-hour urine collection for daily electrolyte excretion is the gold standard for renal electrolyte handling, but it is slow and onerous. A more convenient method is the fractional

excretion (FE) of an electrolyte X (FE_X) calculated from a spot urine sample:

$$FE_X(\%) = \frac{\text{Urine X/Serum X}}{\text{Urine Cr/Serum Cr}} \times 100$$

A low fractional excretion indicates renal reabsorption (high avidity or electrolyte retention), while a high fractional excretion indicates renal wasting (low avidity or electrolyte excretion). Thus, the fractional excretion helps the clinician determine whether the kidney's response is appropriate for a specific electrolyte disorder.

D. Serum Osmolality

Solute concentration is measured by osmolality. Osmoles per kilogram of water is *osmolality*; osmoles per liter of solution is *osmolarity*. At physiological solute concentrations (normally 285–295 mosm/kg), the two measurements are clinically interchangeable. Tonicity refers to osmolytes that are impermeable to cell membranes. Differences in osmolyte concentration across cell membranes lead to osmosis and fluid shifts, stimulation of thirst, and secretion of antidiuretic hormone (ADH). Substances that easily permeate cell membranes (eg, urea, ethanol) are ineffective osmoles that do not cause fluid shifts across fluid compartments.

Serum osmolality can be estimated from the following formula:

Osmolality =

$$2(\text{Na}^+ \text{ mEq/L}) + \frac{\text{Glucose mg/dL}}{18} + \frac{\text{BUN mg/dL}}{2.8}$$

(1 mosm/L of glucose equals 180 mg/L and 1 mosm/L of urea nitrogen equals 28 mg/L). Sodium is the major extracellular cation; doubling the serum sodium in the formula for estimated osmolality accounts for counterbalancing anions. A discrepancy between measured and estimated osmolality of > 10 mosm/kg suggests an osmol gap, which is the presence of other unmeasured osmoles such as ethanol, methanol, isopropanol, and ethylene glycol (see Table 38–5).

Table 21-1. Total body water (as percentage of body weight) in relation to age and sex.

Age	Male	Female
18-40	60%	50%
41-60	60-50%	50-40%
Over 60	50%	40%

DISORDERS OF SODIUM CONCENTRATION

HYPONATREMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Volume status and serum osmolality are essential to determine etiology.
- ▶ Hyponatremia usually reflects excess water retention relative to sodium rather than sodium deficiency.
- ▶ Hypotonic fluids commonly cause hyponatremia in hospitalized patients.

General Considerations

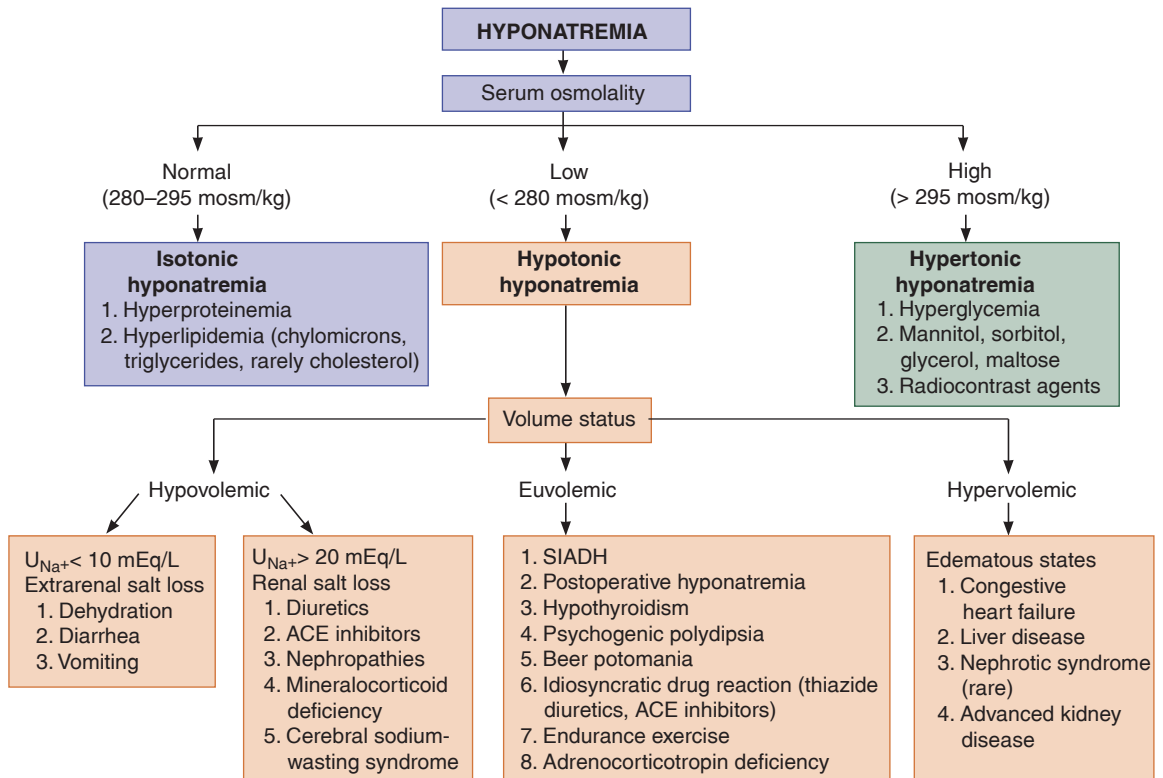

Defined as a serum sodium concentration < 135 mEq/L, hyponatremia is the most common electrolyte abnormality in hospitalized patients. The clinician should be wary about hyponatremia since mismanagement can result in neurologic catastrophes from cerebral osmotic demyelination. Indeed, iatrogenic complications from aggressive or inappropriate therapy can be more harmful than hyponatremia itself.

A common misperception is that the sodium concentration is a reflection of total body sodium or total body water. In fact, total body water and sodium can be low, normal, or high in hyponatremia since the kidney can regulate sodium and water homeostasis independently. Most cases of hyponatremia reflect water imbalance and abnormal water handling, not sodium imbalance, indicating the primary role of ADH in the pathophysiology of hyponatremia. A diagnostic algorithm using serum osmolality and volume status separates the causes of hyponatremia into therapeutically useful categories (Figure 21-1).

Etiology

A. Isotonic & Hypertonic Hyponatremia

Serum osmolality identifies isotonic and hypertonic hyponatremia, although these cases can often be identified by careful history or previous laboratory tests.

▲ **Figure 21-1.** Evaluation of hyponatremia using serum osmolality and extracellular fluid volume status.

ACE, angiotensin-converting enzyme; SIADH, syndrome of inappropriate antidiuretic hormone. (Adapted, with permission, from Narins RG et al. Diagnostic strategies in disorders of fluid, electrolyte and acid-base homeostasis. *Am J Med.* 1982 Mar;72(3):496-520.)

Isotonic hyponatremia is seen with severe hyperlipidemia and hyperproteinemia. Lipids (including chylomicrons, triglycerides, and cholesterol) and proteins (> 10 g/dL, eg, paraproteinemias and intravenous immunoglobulin therapy) interfere with the measurement of serum sodium, causing pseudohyponatremia. Serum osmolality is isotonic because lipids and proteins do not affect osmolality measurement. Newer sodium assays using ion-specific electrodes will not produce pseudohyponatremia.

Hypertonic hyponatremia occurs with hyperglycemia and mannitol administration for increased intracranial pressure. Glucose and mannitol osmotically pull intracellular water into the extracellular space. The translocation of water lowers the serum sodium concentration. Translocational hyponatremia is not pseudohyponatremia or an artifact of sodium measurement. The sodium concentration falls 2 mEq/L for every 100 mg/dL (or 5.56 mmol/L) rise in glucose when the glucose concentration is between 200 mg/dL and 400 mg/dL (11.1 mmol/L and 22.2 mmol/L). If the glucose concentration is > 400 mg/dL, the sodium concentration falls 4 mEq/L for every 100 mg/dL rise in glucose. There is some controversy about the correction factor for the serum sodium in the presence of hyperglycemia. Many guidelines recommend a correction factor, whereby the serum sodium concentration decreases by 1.6 mEq/L for every 100 mg/dL (5.56 mmol/L) rise in plasma glucose above normal, but there is evidence that the decrease may be greater when patients have more severe hyperglycemia (> 400 mg/dL or 22.2 mmol/L) or volume depletion, or both. One group has suggested (based on short-term exposure of normal volunteers to markedly elevated glucose levels) that when the serum glucose is > 200 mg/dL, the serum sodium concentration decreases by at least 2.4 mEq/L.

B. Hypotonic Hyponatremia

Most cases of hyponatremia are hypotonic, highlighting sodium's role as the predominant extracellular osmole. The next step is classifying hypotonic cases by the patient's volume status.

1. Hypovolemic hypotonic hyponatremia—Hypovolemic hyponatremia occurs with renal or extrarenal volume loss and hypotonic fluid replacement (Figure 21–1). Total body sodium and total body water are decreased. To maintain intravascular volume, the pituitary increases ADH secretion, causing free water retention from hypotonic fluid replacement. The body sacrifices serum osmolality to preserve intravascular volume. In short, losses of water and salt are replaced by water alone. Without ongoing hypotonic fluid intake, the renal or extrarenal volume loss would produce hypovolemic hypernatremia.

Cerebral salt wasting is a distinct and rare subset of hypovolemic hyponatremia seen in patients with intracranial disease (eg, infections, cerebrovascular accidents, tumors, and neurosurgery). Clinical features include refractory hypovolemia and hypotension, often requiring continuous infusion of isotonic or hypertonic saline and ICU monitoring. The exact pathophysiology is unclear but includes renal sodium wasting possibly through

brain natriuretic peptide, ADH release, and decreased aldosterone secretion.

2. Euvolemic hypotonic hyponatremia—Euvolemic hyponatremia has the broadest differential diagnosis. Most processes are mediated directly or indirectly through ADH, including hypothyroidism, adrenal insufficiency, medications, and the syndrome of inappropriate ADH (SIADH). The exceptions are primary polydipsia, beer potomania, and reset osmostat.

A. HORMONAL ABNORMALITIES—Hypothyroidism and adrenal insufficiency can cause hyponatremia. Exactly how hypothyroidism induces hyponatremia is unclear but may be related to ADH. Adrenal insufficiency may be associated with the hyperkalemia and metabolic acidosis of hypoaldosteronism. Cortisol provides feedback inhibition for ADH release.

B. THIAZIDE DIURETICS AND OTHER MEDICATIONS—Thiazides induce hyponatremia typically in older female patients within days of initiating therapy. The mechanism appears to be a combination of mild diuretic-induced volume contraction, ADH effect, and intact urinary concentrating ability resulting in water retention and hyponatremia. Loop diuretics do not cause hyponatremia as frequently because of disrupted medullary concentrating gradient and impaired urine concentration.

Nonsteroidal anti-inflammatory drugs (NSAIDs) increase ADH by inhibiting prostaglandin formation. Prostaglandins and selective serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, and citalopram) can cause hyponatremia, especially in geriatric patients. Enhanced secretion or action of ADH may result from increased serotonergic tone. Angiotensin-converting enzyme (ACE) inhibitors do not block the conversion of angiotensin I to angiotensin II in the brain. Angiotensin II stimulates thirst and ADH secretion. Hyponatremia during amiodarone-loading has been reported; it usually improves with dose reduction.

Abuse of 3,4-methylenedioxymethamphetamine (MDMA, also known as Ecstasy) can lead to hyponatremia and severe neurologic symptoms, including seizures, cerebral edema, and brainstem herniation. MDMA and its metabolites increase ADH release from the hypothalamus. Primary polydipsia may contribute to hyponatremia since MDMA users typically increase fluid intake to prevent hyperthermia.

C. NAUSEA, PAIN, SURGERY, AND MEDICAL PROCEDURES—Nausea and pain are potent stimulators of ADH release. Severe hyponatremia can develop after elective surgery in healthy patients, especially premenopausal women. Hypotonic fluids in the setting of elevated ADH levels can produce severe, life-threatening hyponatremia. Medical procedures such as colonoscopy have also been associated with hyponatremia.

D. HIV INFECTION—Hyponatremia is seen in up to 50% of hospitalized HIV patients and 20% of ambulatory HIV patients. The differential diagnosis is broad: medication effect, adrenal insufficiency, hypoaldosteronism, central nervous system or pulmonary disease, SIADH, malignancy, and volume depletion.

E. ENDURANCE EXERCISE HYPONATREMIA—Hyponatremia after endurance exercise (eg, triathlon events and marathons) may be caused by a combination of excessive hypotonic fluid intake and continued ADH secretion. Reperfusion of the exercise-induced ischemic splanchnic bed causes delayed absorption of excessive quantities of hypotonic fluid ingested during exercise. Sustained elevation of ADH prevents water excretion in this setting. Current guidelines suggest that endurance athletes drink water according to thirst rather than according to specified hourly rates of fluid intake.

F. SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION—Under normal circumstances, hypovolemia and hyperosmolality stimulate ADH secretion. ADH release is inappropriate without these physiological cues. Normal regulation of ADH release occurs from both the central nervous system and the chest via baroreceptors and neural input. The major causes of SIADH (Table 21–2) are disorders affecting the central nervous system (structural, metabolic, psychiatric, or pharmacologic processes) or the lungs (infectious, mechanical, oncologic). Medications commonly cause SIADH by increasing ADH or its action. Some carcinomas, especially small cell lung carcinoma, can autonomously secrete ADH.

G. PSYCHOGENIC POLYDIPSIA AND BEER POTOMANIA—Marked free water intake (generally > 10 L/d) may produce hyponatremia. Euvolemia is maintained through renal excretion of sodium. Urine sodium is therefore generally elevated (> 20 mEq/L), and ADH levels are appropriately suppressed. As the increased free water is excreted, the urine osmolality approaches the minimum of 50 mosm/kg. Polydipsia occurs in psychiatric patients. Psychiatric medications may interfere with water excretion or increase thirst through anticholinergic side effects, further increasing water intake. The hyponatremia of beer potomania occurs in patients who consume large amounts of beer. Free water excretion is decreased because of decreased solute consumption and production; muscle wasting and malnutrition are contributing factors. Without enough solute, these patients have decreased free water excretory capacity even if they maximally dilute the urine.

H. RESET OSMOSTAT—Reset osmostat is a rare cause of hyponatremia characterized by appropriate ADH regulation in response to water deprivation and fluid challenges. Patients with reset osmostat regulate serum sodium and serum osmolality around a lower set point, concentrating or diluting urine in response to hyperosmolality and hypo-osmolality. The mild hypo-osmolality of pregnancy is a form of reset osmostat.

3. Hypervolemic hypotonic hyponatremia—Hypervolemic hyponatremia occurs in the edematous states of cirrhosis, heart failure, nephrotic syndrome, and advanced kidney disease (Figure 21–1). In cirrhosis and heart failure, effective circulating volume is decreased due to peripheral vasodilation or decreased cardiac output. Increased renin-angiotensin-aldosterone system activity and ADH secretion result in water retention. Note the pathophysiological

Table 21–2. Causes of syndrome of inappropriate ADH secretion (SIADH).

Central nervous system disorders

ADH, antidiuretic hormone; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

similarity to hypovolemic hyponatremia—the body sacrifices osmolality in an attempt to restore effective circulating volume.

The pathophysiology of hyponatremia in nephrotic syndrome is not completely understood, but the primary disturbance may be renal sodium retention, resulting in overfilling of the intravascular space and secondary edema

formation as fluid enters the interstitial space. Previously, it was thought that the decreased oncotic pressure of hypoalbuminemia caused fluid shifts from the intravascular space to the interstitial compartment. Intravascular underfilling led to secondary renal sodium retention. However, patients receiving therapy for glomerular disease and nephrotic syndrome often have edema resolution prior to normalization of the serum albumin.

Patients with advanced kidney disease typically have sodium retention and decreased free water excretory capacity, resulting in hypervolemic hyponatremia.

► Clinical Findings

A. Symptoms and Signs

Whether hyponatremia is symptomatic depends on its severity and acuity. Chronic disease can be severe (sodium concentration < 110 mEq/L), yet remarkably asymptomatic because the brain has adapted by decreasing its tonicity over weeks to months. Acute disease that has developed over hours to days can be severely symptomatic with relatively modest hyponatremia. Mild hyponatremia (sodium concentrations of 130–135 mEq/L) is usually asymptomatic.

Mild symptoms of nausea and malaise progress to headache, lethargy, and disorientation as the sodium concentration drops. The most serious symptoms are respiratory arrest, seizure, coma, permanent brain damage, brainstem herniation, and death. Premenopausal women are much more likely than menopausal women to die or suffer permanent brain injury from hyponatremic encephalopathy, suggesting a hormonal role in the pathophysiology.

Evaluation starts with a careful history for new medications, changes in fluid intake (polydipsia, anorexia, intravenous fluid rates and composition), fluid output (nausea and vomiting, diarrhea, ostomy output, polyuria, oliguria, insensible losses). The physical examination should help categorize the patient's volume status into hypovolemia, euvolemia, or hypervolemia.

B. Laboratory Findings

Laboratory assessment should include serum electrolytes, serum creatinine, serum osmolality, and urine sodium. The etiology of most cases of hyponatremia will be apparent from the history, physical, and basic laboratory tests. Additional tests of thyroid and adrenal function will occasionally be necessary.

SIADH is a clinical diagnosis characterized by (1) hyponatremia; (2) decreased osmolality (< 280 mosm/kg); (3) absence of heart, kidney, or liver disease; (4) normal thyroid and adrenal function (see Chapter 26); and (5) urine sodium usually over 20 mEq/L. In clinical practice, ADH levels are not measured. Patients with SIADH may have low blood urea nitrogen (BUN) (< 10 mg/dL [or < 3.6 mmol/L]) and hypouricemia (< 4 mg/dL [or < 238 μmol/L]), which are not only dilutional but result from increased urea and uric acid clearances in response to the volume-expanded state. Azotemia may reflect volume contraction, ruling out SIADH, which is seen in euvolemic patients.

► Complications

The most serious complication of hyponatremia is iatrogenic cerebral osmotic demyelination from overly rapid sodium correction. Also called central pontine myelinolysis, cerebral osmotic demyelination may occur outside the brainstem. Demyelination may occur days after sodium correction or initial neurologic recovery from hyponatremia. Hypoxic episodes during hyponatremia may contribute to demyelination. The neurologic effects are generally catastrophic and irreversible.

► Treatment

Regardless of the patient's volume status, another common feature is to restrict free water and hypotonic fluid intake, since these solutions will exacerbate hyponatremia. Free water intake from oral intake and intravenous fluids should generally be < 1–1.5 L/d.

Hypovolemic patients require adequate fluid resuscitation from isotonic fluids (either normal saline or lactated Ringer solution) to suppress the hypovolemic stimulus for ADH release. Patients with **cerebral salt wasting** may require hypertonic saline to prevent circulatory collapse; some may respond to fludrocortisone. **Hypervolemic** patients may require loop diuretics or dialysis, or both, to correct increased total body water and sodium. **Euvolemic** patients may respond to free water restriction alone.

Pseudohyponatremia from hypertriglyceridemia or hyperproteinemia requires no therapy except confirmation with the clinical laboratory. **Translocational hyponatremia** from glucose or mannitol can be managed with glucose correction or mannitol discontinuation (if possible). No specific therapy is necessary in patients with **reset osmostat** since they successfully regulate their serum sodium with fluid challenges and water deprivation.

Symptomatic and severe hyponatremia generally require hospitalization for careful monitoring of fluid balance and weights, treatment, and frequent sodium checks. Inciting medications should be discontinued if possible.

There is no consensus about the optimal rate of sodium correction in symptomatic hyponatremic patients. A reasonable rate is 10–12 mEq/L/d in mildly to moderately symptomatic patients. A more aggressive rate of 1–1.5 mEq/L/h (to a maximum correction of 10–12 mEq/L) has been used in severely symptomatic patients. Sodium concentration should be monitored as frequently as every 1–2 hours. As symptoms improve or resolve, the correction rate should be reduced to roughly 0.5 mEq/L/h. To avoid overcorrection, the clinician should stabilize the sodium around 125 mEq/L to 130 mEq/L.

In severely symptomatic patients, the clinician should calculate the sodium deficit and deliver 3% **hypertonic saline**. The sodium deficit can be calculated by the following formula:

$$\text{Sodium deficit} = \text{Total body water (TBW)} \\ \times (\text{Desired serum Na} - \text{Actual serum Na})$$

where TBW is typically 50% of total mass in women and 55% of total mass in men. For example, a nonedematous, severely symptomatic 70 kg woman with a serum sodium

of 122 mEq/L should have her serum sodium corrected to approximately 132 mEq/L in the first 24 hours. Her sodium deficit is calculated as:

$$\begin{aligned}\text{Sodium deficit} &= 70 \text{ kg} \times 0.5 \times (132 \text{ mEq/L} - 122 \text{ mEq/L}) \\ &= 350 \text{ mEq}\end{aligned}$$

3% hypertonic saline has a sodium concentration of 514 mEq/1000 mL. The delivery rate for hypertonic saline can be calculated as:

$$\begin{aligned}\text{Delivery rate} &= \text{Sodium deficit} / 514 \text{ mEq} / 1000 \\ &\quad \text{mL} / 24 \text{ hours} \\ &= 350 \text{ mEq} / 514 \text{ mEq} / 1000 \text{ mL} / 24 \text{ hours} \\ &= 28 \text{ mL} / \text{hour}\end{aligned}$$

In general, the 3% hypertonic saline infusion rate should not exceed 0.5 mL/kg body weight/h; higher rates may represent a miscalculated sodium deficit or a mathematical error. The goal is not to correct the serum sodium by more than 10–12 mEq/L over the first 24 hours. Hypertonic saline in hypervolemic patients can be hazardous, resulting in worsening volume overload, pulmonary edema, and ascites.

For patients who cannot adequately restrict free water or have an inadequate response to conservative measures, demeclocycline (300–600 mg orally twice daily) inhibits the effect of ADH on the distal tubule. Onset of action may require 1 week, and urinary concentrating ability may be permanently impaired, resulting in nephrogenic diabetes insipidus (DI) and even hypernatremia. Cirrhosis may increase the nephrotoxicity of demeclocycline.

Vasopressin antagonists may revolutionize the treatment of euvolemic and hypervolemic hyponatremia, especially in heart failure. Lixivaptan, tolvaptan, and satavaptan are oral selective vasopressin-2 receptor antagonists. V₂ receptors mediate the diuretic effect of ADH. For hospitalized patients with euvolemic SIADH, conivaptan is given as an intravenous loading dose of 20 mg delivered over 30 minutes, then as 20 mg continuously over 24 hours. Subsequent infusions may be administered every 1–3 days at 20–40 mg/d by continuous infusion. Tolvaptan and conivaptan are available in the United States. (Lixivaptan and satavaptan are not yet approved by the Food and Drug Administration [FDA] for use in the United States.)

▶ When to Refer

- Nephrology or endocrinology consultation should be considered in severe, symptomatic, refractory, or complicated cases of hyponatremia.
- Aggressive therapies with hypertonic saline, demeclocycline, vasopressin antagonists, or dialysis mandate specialist consultation.
- Consultation may be necessary with end-stage liver or heart disease.

▶ When to Admit

Hospital admission is necessary for symptomatic patients or those requiring aggressive therapies for close monitoring and frequent laboratory testing.

HYPERNATREMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Increased thirst and water intake is the first defense against hypernatremia.
- ▶ Urine osmolality helps differentiate renal from nonrenal water loss.

▶ General Considerations

Hypernatremia is defined as a sodium concentration > 145 mEq/L. All patients with hypernatremia have hyperosmolality, unlike hyponatremic patients who can have a low, normal, or high serum osmolality. The hypernatremic patient is typically hypovolemic due to free water losses, although hypervolemia is frequently seen, often as an iatrogenic complication in hospitalized patients with impaired access to free water. Rarely, excessive sodium intake may cause hypernatremia. Hypernatremia in primary aldosteronism is mild and usually does not cause symptoms.

An intact thirst mechanism and access to water are the primary defense against hypernatremia. The hypothalamus can sense minimal changes in serum osmolality, triggering the thirst mechanism and increased water intake. Thus, whatever the underlying disorder (eg, dehydration, lactulose or mannitol therapy, central and nephrogenic DI), excess water loss can cause hypernatremia only when adequate water intake is not possible.

▶ Clinical Findings

A. Symptoms and Signs

When the patient is dehydrated, orthostatic hypotension and oliguria are typical findings. Because water shifts from the cells to the intravascular space to protect volume status, these symptoms may be delayed. Lethargy, irritability, and weakness are early signs. Hyperthermia, delirium, seizures, and coma may be seen with severe hypernatremia (ie, sodium > 158 mEq/L). Symptoms in the elderly may not be specific; a recent change in consciousness is associated with a poor prognosis. Osmotic demyelination is an uncommon but reported consequence of severe hypernatremia.

B. Laboratory Findings

1. Urine osmolality > 400 mosm/kg—Renal water-conserving ability is functioning.

A. NONRENAL LOSSES—Hypertremia will develop if water intake falls behind hypotonic fluid losses from excessive sweating, the respiratory tract, or bowel movements. Lactulose causes an osmotic diarrhea with loss of free water.

B. RENAL LOSSES—While severe hyperglycemia can cause translocational hyponatremia (see above), progressive volume depletion from glucosuria can result in hypertremia. Osmotic diuresis can occur with the use of mannitol or urea.

2. Urine osmolality < 250 mosm/kg—Hypertremia with a dilute urine (osmolality < 250 mosm/kg) is characteristic of DI. Central DI results from inadequate ADH release. Nephrogenic DI results from renal insensitivity to ADH; common causes include lithium, demeclocycline, relief of urinary obstruction, interstitial nephritis, hypercalcemia, and hypokalemia.

▶ Treatment

Treatment of hypertremia includes correcting the cause of the fluid loss, replacing water, and replacing electrolytes (as needed). In response to increases in plasma osmolality, brain cells synthesize solutes called idiogenic osmoles, which cause intracellular fluid shifts. Osmole production begins 4–6 hours after dehydration and takes several days to reach steady state. If hypertremia is rapidly corrected, the osmotic imbalance may cause cerebral edema and potentially severe neurologic impairment. Fluids should be administered over a 48-hour period, aiming for serum sodium correction of approximately 1 mEq/L/h (1 mmol/L/h). There is no consensus about the optimal rates of sodium correction in hypertremia and hyponatremia.

A. Choice of Type of Fluid for Replacement

1. Hypertremia with hypovolemia—Hypovolemic patients should receive isotonic 0.9% normal saline to restore euvolemia and to treat hyperosmolality, since isotonic 0.9% normal saline (308 mosm/kg) is often hypo-osmolar compared with plasma. After adequate volume resuscitation with normal saline, 0.45% saline or 5% dextrose (or both) can be used to replace any remaining free water deficit. Milder volume deficits may be treated with 0.45% saline and 5% dextrose.

2. Hypertremia with euvolemia—Water ingestion or intravenous 5% dextrose will result in the excretion of excess sodium in the urine. If the glomerular filtration rate (GFR) is decreased, diuretics will increase urinary sodium excretion but may impair renal concentrating ability, increasing the quantity of water that needs to be replaced.

3. Hypertremia with hypervolemia—Treatment includes 5% dextrose solution to reduce hyperosmolality. Loop diuretics may be necessary to promote natriuresis and lower total body sodium. In severe rare cases with kidney disease, hemodialysis may be necessary to correct the excess total body sodium and water.

B. Calculation of Water Deficit

Fluid replacement should include the free water deficit and additional maintenance fluid to replace ongoing and anticipated fluid losses.

1. Acute hypertremia—In acute dehydration without much solute loss, free water loss is similar to the weight loss. Initially, a 5% dextrose solution may be used. As correction of water deficit progresses, therapy should continue with 0.45% saline with dextrose.

2. Chronic hypertremia—The water deficit is calculated to restore normal sodium concentration, typically 140 mEq/L. Total body water (TBW) (Table 21–1) correlates with muscle mass and therefore decreases with advancing age, cachexia, and dehydration and is lower in women than in men. Current TBW equals 40–60% current body weight.

$$\text{Volume (in L) to be replaced} = \text{Current TBW} \times \frac{[\text{Na}^+] - 140}{140}$$

▶ When to Refer

Patients with refractory or unexplained hypertremia should be referred for subspecialist consultation.

▶ When to Admit

- Patients with symptomatic hypertremia require hospitalization for evaluation and treatment.
- Significant comorbidities or concomitant acute illnesses, especially if contributing to hypertremia, may necessitate hospitalization.

VOLUME OVERLOAD

ESSENTIALS OF DIAGNOSIS

- ▶ Disorder of excessive sodium retention in the setting of low arterial underfilling (eg, congestive heart failure or cirrhosis).
- ▶ Hyponatremia from water retention in edematous states is associated with sodium retention.

The hallmark of a volume overloaded state is sodium retention. Abnormally low arterial filling, such as from congestive heart failure or cirrhosis, activates the neurohumoral axis, which stimulates the renin-angiotensin-aldosterone system, the sympathetic nervous system, and ADH (vasopressin) release. Sodium retention with edema results. The stimulus for vasopressin release is nonosmotic. Released in response to baroreceptor activation, vasopressin stimulates renal V_2 receptors, resulting in water reabsorption, edema formation, and hyponatremia.

HYPEROSMOLAR DISORDERS & OSMOLAR GAPS

HYPEROSMOLALITY WITH TRANSIENT OR NO SIGNIFICANT SHIFT IN WATER

Urea and alcohol readily cross cell membranes and can produce hyperosmolality. Urea is an ineffective osmole with little effect on osmotic water movement across cell membranes. Alcohol quickly equilibrates between the intra-cellular and extracellular compartments, adding 22 mosm/L for every 100 mg/dL (or 21.7 mmol/L) of ethanol. Ethanol ingestion should be considered in any case of stupor or coma with an elevated osmol gap (measured osmolality – calculated osmolality > 10 mosm/kg). Other toxic alcohols such as methanol and ethylene glycol cause an osmol gap and a metabolic acidosis with an increased anion gap (see Chapter 38). The combination of an increased anion gap metabolic acidosis and an osmol gap exceeding 10 mosm/kg is not specific for toxic alcohol ingestion and may occur with alcoholic ketoacidosis or lactic acidosis (see Metabolic Acidosis).

HYPEROSMOLALITY ASSOCIATED WITH SIGNIFICANT SHIFTS IN WATER

Increased concentrations of solutes that do not readily enter cells cause a shift of water from intracellular to extracellular. Hyperosmolality of effective osmoles such as sodium and glucose causes symptoms, primarily neurologic. The severity of symptoms depends on the degree of hyperosmolality and rapidity of development. In acute hyperosmolality, somnolence and confusion can appear when the osmolality exceeds 320–330 mosm/kg; coma, respiratory arrest, and death can result when osmolality exceeds 340–350 mosm/kg.

DISORDERS OF POTASSIUM CONCENTRATION

HYPOKALEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Severe hypokalemia may induce dangerous arrhythmias and rhabdomyolysis.
- ▶ Transtubular potassium concentration gradient (TTKG) can distinguish renal from nonrenal loss of potassium.

▶ General Considerations

Hypokalemia can result from insufficient dietary potassium intake, intracellular shifting of potassium from the extracellular space, extrarenal potassium loss, or renal potassium loss (Table 21–3). Cellular uptake of potassium is increased by insulin and β -adrenergic stimulation

Table 21–3. Causes of hypokalemia.

Decreased potassium intake Potassium shift into the cell

- Increased postprandial secretion of insulin
- Alkalosis
- Trauma (via β -adrenergic stimulation?)
- Periodic paralysis (hypokalemic)
- Barium intoxication

Renal potassium loss

- Increased aldosterone (mineralocorticoid) effects
 - Primary hyperaldosteronism
 - Secondary aldosteronism (dehydration, heart failure)
- Renovascular hypertension
- Malignant hypertension
- Ectopic ACTH-producing tumor
- Gitelman syndrome
- Bartter syndrome
- Cushing syndrome
- Licorice (European)
- Renin-producing tumor
- Congenital abnormality of steroid metabolism (eg, adrenogenital syndrome, 17α -hydroxylase defect, apparent mineralocorticoid excess, 11β -hydroxylase deficiency)
- Increased flow to distal nephron
 - Diuretics (furosemide, thiazides)
 - Salt-losing nephropathy
- Hypomagnesemia
 - Unreabsorbable anion
 - Carbenicillin, penicillin
- Renal tubular acidosis (type I or II)
 - Fanconi syndrome
 - Interstitial nephritis
 - Metabolic alkalosis (bicarbonaturia)
- Congenital defect of distal nephron
 - Liddle syndrome

Extrarenal potassium loss

- Vomiting, diarrhea, laxative abuse
- Villous adenoma, Zollinger-Ellison syndrome

and blocked by α -adrenergic stimulation. Aldosterone is an important regulator of total body potassium, increasing potassium secretion in the distal renal tubule. The most common cause of hypokalemia, especially in developing countries, is gastrointestinal loss from infectious diarrhea. The potassium concentration in intestinal secretion is ten times higher (80 mEq/L) than in gastric secretions. Hypokalemia in the presence of acidosis suggests profound potassium depletion and requires urgent treatment. Self-limited hypokalemia occurs in 50–60% of trauma patients, perhaps related to enhanced release of epinephrine.

Hypokalemia increases the likelihood of digitalis toxicity. In patients with heart disease, hypokalemia induced by β_2 -adrenergic agonists and diuretics may substantially increase the risk of arrhythmias. Numerous genetic mutations affect fluid and electrolyte metabolism, including disorders of potassium metabolism (Table 21–4).

Magnesium is an important cofactor for potassium uptake and maintenance of intracellular potassium levels. Loop diuretics (eg, furosemide) cause substantial renal potassium and magnesium losses. Magnesium depletion should be considered in refractory hypokalemia.

► Clinical Findings

A. Symptoms and Signs

Muscular weakness, fatigue, and muscle cramps are frequent complaints in mild to moderate hypokalemia. Gastrointestinal smooth muscle involvement may result in constipation or ileus. Flaccid paralysis, hyporeflexia, hypercapnia, tetany, and rhabdomyolysis may be seen with severe hypokalemia (< 2.5 mEq/L). The presence of hypertension may be a clue to the diagnosis of hypokalemia from aldosterone or mineralocorticoid excess (Table 21–4). Renal manifestations include nephrogenic DI and interstitial nephritis.

B. Laboratory Findings

Urinary potassium concentration is low (< 20 mEq/L) as a result of extrarenal loss (eg, diarrhea, vomiting) and inappropriately high (> 40 mEq/L) with renal loss (eg, mineralocorticoid excess, Bartter syndrome, Liddle syndrome) (Table 21–3).

The transtubular $[K^+]$ gradient (TTKG) is a simple and rapid evaluation of net potassium secretion. TTKG is calculated as follows:

$$\text{TTKG} = \frac{\text{Urine } K^+ / \text{Plasma } K^+}{\text{Urine osm} / \text{Plasma osm}}$$

Hypokalemia with a TTKG > 4 suggests renal potassium loss with increased distal K^+ secretion. In such cases, plasma renin and aldosterone levels are helpful in differential diagnosis. The presence of nonabsorbed anions, such as bicarbonate, increases the TTKG.

Table 21–4. Genetic disorders associated with electrolyte metabolism disturbances.

Disease	Site of Mutation
Potassium	
Hypokalemia	
Hypokalemic periodic paralysis	Dihydropyridine-sensitive skeletal muscle voltage-gated calcium channel
Bartter syndrome	Na^+ - K^+ - $2Cl^-$ cotransporter, K^+ channel (ROMK), or Cl^- channel of thick ascending limb of Henle (hypofunction), barttin
Gitelman syndrome	Thiazide-sensitive Na^+ - Cl^- cotransporter
Liddle syndrome	β or γ subunit of amiloride-sensitive Na^+ channel (hyperfunction)
Apparent mineralocorticoid excess	11 β -hydroxysteroid dehydrogenase (failure to inactivate cortisol)
Glucocorticoid-remediable hyperaldosteronism	Regulatory sequence of 11 β -hydroxylase controls aldosterone synthase inappropriately
Hyperkalemia	
Hyperkalemic periodic paralysis	α subunit of calcium channel
Pseudohypoaldosteronism type I	β or γ subunit of amiloride-sensitive Na^+ channel (hypofunction)
Pseudohypoaldosteronism type II (Gordon syndrome)	HNK2, HNK4
Calcium	
Familial hypocalciuric hypercalcemia	Ca^{2+} -sensing protein (hypofunction)
Familial hypocalcemia	Ca^{2+} -sensing protein (hyperfunction)
Phosphate	
Hypophosphatemic rickets	PEX gene, FGF23
Magnesium	
Hypomagnesemia-hypercalciuria syndrome	Paracellin-1
Water	
Nephrogenic diabetes insipidus	Vasopressin receptor-2 (Type 1), aquaporin-2
Acid-base	
Proximal RTA	Na^+ HCO_3^- cotransporter
Distal RTA	Cl^- HCO_3^- exchanger H^+ -ATPase
Proximal and distal RTA	Carbonic anhydrase II

FGF23, fibroblast growth factor 23; RTA, renal tubular acidosis.

C. Electrocardiogram

The electrocardiogram (ECG) shows decreased amplitude and broadening of T waves, prominent U waves, premature ventricular contractions, and depressed ST segments.

▶ Treatment

Oral potassium supplementation is the safest and easiest treatment for mild to moderate deficiency. Dietary potassium is almost entirely coupled to phosphate—rather than chloride—and is therefore not effective in correcting potassium loss associated with chloride depletion from diuretics or vomiting. In the setting of abnormal kidney function and mild to moderate diuretic dosage, 20 mEq/d of oral potassium is generally sufficient to prevent hypokalemia, but 40–100 mEq/d over a period of days to weeks is needed to treat hypokalemia and fully replete potassium stores.

Intravenous potassium is indicated for patients with severe hypokalemia and for those who cannot take oral supplementation. For severe deficiency, potassium may be given through a peripheral intravenous line in a concentration up to 40 mEq/L and at rates up to 10 mEq/h. Concentrations of up to 20 mEq/h may be given through a central venous catheter. Continuous ECG monitoring is indicated, and the serum potassium level should be checked every 3–6 hours. Avoid glucose-containing fluid to prevent further shifts of potassium into the cells. Magnesium deficiency should be corrected, particularly in refractory hypokalemia.

▶ When to Refer

Patients with unexplained hypokalemia, refractory hyperkalemia, or clinical features suggesting alternative diagnoses (eg, aldosteronism or hypokalemic periodic paralysis) should be referred for endocrinology or nephrology consultation.

▶ When to Admit

Patients with symptomatic or severe hypokalemia, especially with cardiac manifestations, require cardiac monitoring, frequent laboratory testing, and potassium supplementation.

HYPERKALEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Serum potassium level > 5.0 mEq/L (> 5.0 mmol/L).
- ▶ Hyperkalemia may develop in patients taking ACE inhibitors, angiotensin-receptor blockers, potassium-sparing diuretics, or their combination, even with no or only mild kidney dysfunction.
- ▶ The ECG may show peaked T waves, widened QRS and biphasic QRS-T complexes, or may be normal despite life-threatening hyperkalemia.
- ▶ Measurement of plasma potassium level differentiates potassium leak from blood cells in cases of clotting, leukocytosis, and thrombocytosis from elevated serum potassium.
- ▶ Rule out extracellular potassium shift from the cells in acidosis and assess renal potassium excretion.

▶ General Considerations

Hyperkalemia usually occurs in patients with advanced kidney disease but can also develop with normal kidney function (Table 21–5). Acidosis causes intracellular potassium to shift extracellularly. Serum potassium concentration rises about 0.7 mEq/L for every decrease of 0.1 pH unit during acidosis. Fist clenching during venipuncture may raise the potassium concentration by 1–2 mEq/L by causing acidosis and potassium shift from cells. In the absence of acidosis, serum potassium concentration rises about 1 mEq/L when there is a total body potassium excess of 1–4 mEq/kg. However, the higher the serum potassium concentration, the smaller the excess necessary to raise the potassium levels further.

Mineralocorticoid deficiency from Addison disease or chronic kidney disease (CKD) is another cause of hyperkalemia with decreased renal excretion of potassium. Mineralocorticoid resistance due to genetic disorders, interstitial kidney disease, or urinary tract obstruction also leads to hyperkalemia.

ACE inhibitors or angiotensin-receptor blockers (ARBs), commonly used in patients with congestive heart failure or CKD, may cause hyperkalemia. The concomitant use of spironolactone, eplerenone, or β -blockers further increases the risk of hyperkalemia. Thiazide or loop diuretics and sodium bicarbonate may minimize hyperkalemia. Persistent mild hyperkalemia in the absence of ACE inhibitor or ARB therapy is usually due to type IV renal tubular acidosis (RTA). Heparin inhibits aldosterone production in the adrenal glands, causing hyperkalemia.

Trimethoprim is structurally similar to amiloride and triamterene, and all three drugs inhibit renal potassium excretion through suppression of sodium channels in the distal nephron.

Cyclosporine and tacrolimus can induce hyperkalemia in organ transplant recipients, especially kidney transplant patients, partly due to suppression of the basolateral $\text{Na}^+ - \text{K}^+$ -ATPase in

Table 21-5. Causes of hyperkalemia.**Spurious/Pseudohyperkalemia**

Leakage from erythrocytes when separation of serum from clot is delayed (plasma K⁺ normal)
 Marked thrombocytosis or leukocytosis with release of intracellular K⁺ (plasma K⁺ normal)
 Repeated fist clenching during phlebotomy, with release of K⁺ from forearm muscles
 Specimen drawn from arm with intravenous K⁺ infusion

Decreased K⁺ excretion

Kidney disease, acute and chronic
 Renal secretory defects (may or may not have reduced kidney function): kidney transplant, interstitial nephritis, systemic lupus erythematosus, sickle cell disease, amyloidosis, obstructive nephropathy
 Hyporeninemic hypoaldosteronism (often in diabetic patients with mild to moderate nephropathy) or selective hypoaldosteronism (eg, AIDS patients)
 Drugs that inhibit potassium excretion: spironolactone, eplerenone, drosipironone, NSAIDs, ACE inhibitors, angiotensin II receptor blockers, triamterene, amiloride, trimethoprim, pentamidine, cyclosporine, tacrolimus)

Shift of K⁺ from within the cell

Massive release of intracellular K⁺ in burns, rhabdomyolysis, hemolysis, severe infection, internal bleeding, vigorous exercise
 Metabolic acidosis (in the case of organic acid accumulation—eg, lactic acidosis—a shift of K⁺ does not occur since organic acid can easily move across the cell membrane)
 Hypertonicity (solvent drag)
 Insulin deficiency (metabolic acidosis may not be apparent)
 Hyperkalemic periodic paralysis
 Drugs: succinylcholine, arginine, digitalis toxicity, β-adrenergic antagonists
 α-Adrenergic stimulation?

Excessive intake of K⁺

Especially in patients taking medications that decrease potassium secretion (see above)

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

principal cells. Hyperkalemia is commonly seen in HIV patients and has been attributed to impaired renal excretion of potassium due to pentamidine or trimethoprim-sulfamethoxazole or to hyporeninemic hypoaldosteronism.

▶ Clinical Findings

Hyperkalemia impairs neuromuscular transmission, causing muscle weakness, flaccid paralysis, and ileus. Electrocardiography is not a sensitive method for detecting hyperkalemia, since nearly half of patients with a serum potassium level > 6.5 mEq/L will not manifest ECG changes. ECG changes in hyperkalemia include bradycardia, PR interval prolongation, peaked T waves, QRS widening, and biphasic QRS-T complexes. Conduction disturbances, such as bundle branch block and atrioventricular block, may occur. Ventricular fibrillation and cardiac arrest are terminal events.

▶ Prevention

Inhibitors of the renin-angiotensin-aldosterone axis (ie, ACE inhibitors, ARBs, and spironolactone) and potassium-sparing

diuretics (eplerenone, triamterene) should be used cautiously in patients with heart failure, liver failure, and kidney disease. Laboratory monitoring should be performed within 1 week of drug initiation or dosage increase.

▶ Treatment

The diagnosis should be confirmed by repeat laboratory testing to rule out spurious hyperkalemia, especially in the absence of medications that cause hyperkalemia or in patients without kidney disease or a previous history of hyperkalemia. Plasma potassium concentration can be measured to avoid hyperkalemia due to potassium leakage out of red cells, white cells, and platelets. Kidney dysfunction should be ruled out at the initial assessment.

Treatment consists of withholding exogenous potassium, identifying the cause, reviewing the patient's medications and dietary potassium intake, and correcting the hyperkalemia. Emergent treatment is indicated when cardiac toxicity, muscle paralysis, or severe hyperkalemia (potassium > 6.5 mEq/L) is present, even in the absence of ECG changes. Insulin, bicarbonate, and β-agonists shift potassium intracellularly within minutes of administration (Table 21-6). Intravenous calcium may be given to antagonize the cell membrane effects of potassium, but its use should be restricted to life-threatening hyperkalemia in patients taking digitalis because hypercalcemia may cause digitalis toxicity. Hemodialysis may be required to remove potassium in patients with acute or chronic kidney injury.

▶ When to Refer

- Patients with hyperkalemia from kidney disease and reduced renal potassium excretion should see a nephrologist.
- Transplant patients may need adjustment of their immunosuppression regimen by transplant specialists.

▶ When to Admit

Patients with severe hyperkalemia > 6 mEq/L, any degree of hyperkalemia associated with ECG changes, or concomitant illness (eg, tumor lysis, rhabdomyolysis, metabolic acidosis) should be sent to the emergency department for immediate treatment.

Table 21-6. Treatment of hyperkalemia.

IMMEDIATE					
Modality	Mechanism of Action	Onset	Duration	Prescription	K ⁺ Removed from Body
Calcium	Antagonizes cardiac conduction abnormalities	0-5 minutes	1 hour	Calcium gluconate 10%, 5-30 mL intravenously; or calcium chloride 5%, 5-30 mL intravenously	0
Bicarbonate	Distributes K ⁺ into cells	15-30 minutes	1-2 hours	NaHCO ₃ , 44-88 mEq (1-2 ampules) intravenously Note: Sodium bicarbonate may not be effective in end-stage renal disease patients; dialysis is more expedient and effective. Some patients may not tolerate the additional sodium load of bicarbonate therapy.	0
Insulin	Distributes K ⁺ into cells	15-60 minutes	4-6 hours	Regular insulin, 5-10 units intravenously, plus glucose 50%, 25 g intravenously	0
Albuterol	Distributes K ⁺ into cells	15-30 minutes	2-4 hours	Nebulized albuterol, 10-20 mg in 4 mL normal saline, inhaled over 10 minutes Note: Much higher doses are necessary for hyperkalemia therapy (10-20 mg) than for airway disease (2.5 mg).	0
URGENT					
Modality	Mechanism of Action	Onset of Action		Prescription	K ⁺ Removed from Body
Loop diuretic	Renal K ⁺ excretion	0.5-2 hours		Furosemide, 40-160 mg intravenously Note: Diuretics may not be effective in patients with acute and chronic kidney diseases.	Variable
Sodium polystyrene sulfonate (Kayexalate)	Ion-exchange resin binds K ⁺	1-3 hours		Oral: 15-60 g in 20% sorbitol (60-240 mL) Rectal: 30-60 g in 20% sorbitol Note: Resins with sorbitol may cause bowel necrosis and intestinal perforation, especially in postoperative patients.	0.5-1 mEq/g resin
Hemodialysis ¹	Extracorporeal K ⁺ removal	1-8 hours		Dialysate [K ⁺] 0-1 mEq/L Note: A fast and effective therapy for hyperkalemia, hemodialysis can be delayed by vascular access placement and equipment and/or staffing availability. Serum K can be rapidly corrected within minutes, but post-dialysis rebound can occur.	25-50 mEq/h
Peritoneal dialysis	Peritoneal K ⁺ removal	1-4 hours		Frequent exchanges	200-300 mEq

¹Can be both acute immediate and urgent treatment of hyperkalemia.

Modified and reproduced, with permission, from Cogan MG. *Fluid and Electrolytes: Physiology and Pathophysiology*. McGraw-Hill, 1991.

DISORDERS OF CALCIUM CONCENTRATION

The normal total plasma (or serum) calcium concentration is 8.5-10.5 mg/dL (or 2.1-2.6 mmol/L). Ionized calcium (normal: 4.6-5.3 mg/dL [or 1.15-1.32 mmol/L]) is physiologically active and necessary for muscle contraction and nerve function.

The calcium-sensing receptor, a transmembrane protein that detects the extracellular calcium concentration, has been identified in the parathyroid gland and the kidney. Functional defects in this protein are associated with diseases of abnormal calcium metabolism such as familial hypocalcemia and familial hypocalciuric hypercalcemia (Table 21-4).

HYPOCALCEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Often mistaken as a neurologic disorder.
- ▶ Check for decreased parathyroid hormone (PTH), vitamin D, or magnesium depletion.
- ▶ If the ionized calcium level is normal despite a low total serum calcium, calcium metabolism is usually normal.

▶ General Considerations

The most common cause of low total serum calcium is hypoalbuminemia. When serum albumin concentration is lower than 4 g/dL (40 g/L), serum Ca^{2+} concentration is reduced by 0.8–1 mg/dL (0.20–0.25 mmol/L) for every 1 g/dL (10 g/L) of albumin.

The most accurate measurement of serum calcium is the ionized calcium concentration. True hypocalcemia (decreased ionized calcium) implies insufficient action of PTH or active vitamin D. Important causes of hypocalcemia are listed in Table 21–7.

The most common cause of hypocalcemia is advanced CKD, in which decreased production of active vitamin D_3 (1,25 dihydroxyvitamin D_3) and hyperphosphatemia both play a role (see Chapter 22). Some cases of primary hypoparathyroidism are due to mutations of the calcium-sensing

Table 21–7. Causes of hypocalcemia.

Decreased intake or absorption

- Malabsorption
- Small bowel bypass, short bowel
- Vitamin D deficit (decreased absorption, decreased production of 25-hydroxyvitamin D or 1,25-dihydroxyvitamin D)

Increased loss

- Alcoholism
- Chronic kidney disease
- Diuretic therapy

Endocrine disease

- Hypoparathyroidism (genetic, acquired; including hypomagnesemia and hypermagnesemia)
- Post-parathyroidectomy (hungry bone syndrome)
- Pseudohypoparathyroidism
- Calcitonin secretion with medullary carcinoma of the thyroid
- Familial hypocalcemia

Associated diseases

- Pancreatitis
- Rhabdomyolysis
- Septic shock

Physiologic causes

- Associated with decreased serum albumin¹
- Decreased end-organ response to vitamin D
- Hyperphosphatemia
- Induced by aminoglycoside antibiotics, plicamycin, loop diuretics, foscarnet

¹Ionized calcium concentration is normal.

receptor in which inappropriate suppression of PTH release leads to hypocalcemia (see Chapter 26). Magnesium depletion reduces both PTH release and tissue responsiveness to PTH, causing hypocalcemia. Hypocalcemia in pancreatitis is a marker of severe disease. Elderly hospitalized patients with hypocalcemia and hypophosphatemia, with or without an elevated PTH level, are likely vitamin D deficient.

▶ Clinical Findings

A. Symptoms and Signs

Hypocalcemia increases excitation of nerve and muscle cells, primarily affecting the neuromuscular and cardiovascular systems. Spasm of skeletal muscle causes cramps and tetany. Laryngospasm with stridor can obstruct the airway. Convulsions, perioral and peripheral paresthesias, and abdominal pain can develop. Classic physical findings include Chvostek sign (contraction of the facial muscle in response to tapping the facial nerve) and Trousseau sign (carpal spasm occurring with occlusion of the brachial artery by a blood pressure cuff). QT prolongation predisposes to ventricular arrhythmias. In chronic hypoparathyroidism, cataracts and calcification of basal ganglia may appear (see Chapter 26).

B. Laboratory Findings

Serum calcium concentration is low (< 8.5 mg/dL [or < 2.1 mmol/L]). In true hypocalcemia, the ionized serum calcium concentration is also low (< 4.6 mg/dL [or < 1.15 mmol/L]). Serum phosphate is usually elevated in hypoparathyroidism or in advanced CKD, whereas it is suppressed in early CKD or vitamin D deficiency.

Serum magnesium concentration is commonly low. In respiratory alkalosis, total serum calcium is normal but ionized calcium is low. The ECG shows a prolonged QT interval.

▶ Treatment¹

A. Severe, Symptomatic Hypocalcemia

In the presence of tetany, arrhythmias, or seizures, intravenous calcium gluconate is indicated. Because of the short duration of action, continuous calcium infusion is usually required. Ten to 15 milligrams of calcium per kilogram body weight, or six to eight 10-mL vials of 10% calcium gluconate (558–744 mg of calcium), is added to 1 L of D_5W and infused over 4–6 hours. By monitoring the serum calcium level frequently (every 4–6 hours), the infusion rate is adjusted to maintain the serum calcium level at 7–8.5 mg/dL.

B. Asymptomatic Hypocalcemia

Oral calcium (1–2 g) and vitamin D preparations, including active vitamin D sterols, are used. Calcium carbonate is well tolerated and less expensive than many other calcium tablets. A check of urinary calcium excretion is recommended after the initiation of therapy because hypercalciuria (urine calcium excretion > 300 mg or > 7.5 mmol per day)

¹See also Chapter 26 for discussion of the treatment of hypoparathyroidism.

or urine calcium:creatinine ratio > 0.3 may impair kidney function in these patients. The low serum calcium associated with hypoalbuminemia does not require replacement therapy. If serum Mg^{2+} is low, therapy must include magnesium replacement, which by itself will usually correct hypocalcemia.

▶ When to Refer

Patients with complicated hypocalcemia from hypoparathyroidism, familial hypocalcemia, or CKD require referral to an endocrinologist or nephrologist.

▶ When to Admit

Patients with tetany, arrhythmias, seizures, or other symptoms of hypocalcemia require immediate evaluation and therapy.

HYPERCALCEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Primary hyperparathyroidism and malignancy-associated hypercalcemia are the most common causes.
- ▶ Hypercalciuria usually precedes hypercalcemia.
- ▶ Most often, asymptomatic, mild hypercalcemia (≥ 10.5 mg/dL [or 2.6 mmol/L]) is due to primary hyperparathyroidism, whereas the symptomatic, severe hypercalcemia (≥ 14 mg/dL [or 3.5 mmol/L]) is due to hypercalcemia of malignancy.

▶ General Considerations

Important causes of hypercalcemia are listed in Table 21–8. Primary hyperparathyroidism and malignancy account for 90% of cases. Primary hyperparathyroidism is the most common cause of hypercalcemia (usually mild) in ambulatory patients. Chronic hypercalcemia (over 6 months) or some manifestation such as nephrolithiasis also suggests a benign cause. Tumor production of PTH-related proteins (PTHrP) is the most common paraneoplastic endocrine syndrome, accounting for most cases of hypercalcemia in inpatients (see Table 39–2). The neoplasm is clinically apparent in nearly all cases when the hypercalcemia is detected, and the prognosis

Table 21–8. Causes of hypercalcemia.

Increased intake or absorption

Milk-alkali syndrome

Vitamin D or vitamin A excess

Endocrine disorders

Primary hyperparathyroidism

Secondary or tertiary hyperparathyroidism (usually associated with hypocalcemia)

Acromegaly

Adrenal insufficiency

Pheochromocytoma

Thyrotoxicosis

Neoplastic diseases

Tumors producing PTH-related proteins (ovary, kidney, lung)

Multiple myeloma (elaboration of osteoclast-activating factor)

Lymphoma (occasionally from production of calcitriol)

Miscellaneous causes

Thiazide diuretic use

Granulomatous diseases (production of calcitriol)

Paget disease of bone

Hypophosphatasia

Immobilization

Familial hypocalciuric hypercalcemia

Complications of kidney transplantation

Lithium intake

PTH, parathyroid hormone.

is poor. Granulomatous diseases, such as sarcoidosis and tuberculosis, cause hypercalcemia via overproduction of active vitamin D_3 (1,25 dihydroxyvitamin D_3).

Milk-alkali syndrome has had a resurgence due to calcium ingestion for prevention of osteoporosis. Heavy calcium carbonate intake causes hypercalcemic acute kidney injury, likely from renal vasoconstriction. The decreased GFR impairs bicarbonate excretion, while hypercalcemia stimulates proton secretion and bicarbonate reabsorption. Metabolic alkalosis decreases calcium excretion, maintaining hypercalcemia.

Hypercalcemia causes nephrogenic DI through activation of calcium-sensing receptors in collecting ducts, which reduces ADH-induced water permeability. Volume depletion further worsens hypercalcemia.

▶ Clinical Findings

A. Symptoms and Signs

The history and physical examination should focus on the duration of hypercalcemia and evidence for a neoplasm. Hypercalcemia may affect gastrointestinal, kidney, and neurologic function. Mild hypercalcemia is often asymptomatic. Symptoms usually occur if the serum calcium is > 12 mg/dL (or > 3 mmol/L) and tend to be more severe if hypercalcemia develops acutely. Symptoms include constipation and polyuria, except in hypocalciuric hypercalcemia, in which polyuria is absent. Other symptoms include nausea, vomiting, anorexia, peptic ulcer disease, renal colic, and hematuria from nephrolithiasis. Polyuria from hypercalciuria-induced nephrogenic DI can result in volume depletion and acute kidney injury. Neurologic manifestations range from mild drowsiness to weakness, depression, lethargy, stupor, and coma in severe

hypercalcemia. Ventricular ectopy and idioventricular rhythm occur and can be accentuated by digitalis.

B. Laboratory Findings

The ionized calcium exceeds 1.32 mmol/L. A high serum chloride concentration and a low serum phosphate concentration in a ratio $> 33:1$ (or > 102 if SI units are utilized) suggests primary hyperparathyroidism where PTH decreases proximal tubular phosphate reabsorption. A low serum chloride concentration with a high serum bicarbonate concentration, along with elevated BUN and creatinine, suggests milk-alkali syndrome. Severe hypercalcemia (> 15 mg/dL [or > 3.75 mmol/L]) generally occurs in malignancy. More than 300 mg (or > 7.5 mmol) per day of urinary calcium excretion suggests hypercalciuria; < 100 mg (or < 2.5 mmol) per day suggests hypocalciuria. Hypercalciuric patients—such as those with malignancy or those receiving oral active vitamin D therapy—may easily develop hypercalcemia in case of volume depletion. Serum phosphate may or may not be low, depending on the cause. Hypocalciuric hypercalcemia occurs in milk-alkali syndrome, thiazide diuretic use, and familial hypocalciuric hypercalcemia.

The chest radiograph may reveal malignancy or granulomatous disease. The ECG shows a shortened QT interval. Measurements of PTH and PTHrP help distinguish between hyperparathyroidism (elevated PTH) and malignancy-associated hypercalcemia (suppressed PTH, elevated PTHrP).

▶ Treatment

Until the primary cause can be identified and treated, renal excretion of calcium is promoted through aggressive hydration and forced calciuresis. The tendency in hypercalcemia is hypovolemia from nephrogenic DI. In dehydrated patients with normal cardiac and kidney function, 0.45% saline or 0.9% saline can be given rapidly (250–500 mL/h). A meta-analysis questioned the efficacy and safety profile of intravenous furosemide for hypercalcemia. Thiazides can worsen hypercalcemia.

Bisphosphonates are the treatment of choice for hypercalcemia of malignancy. Although they are safe, effective, and normalize calcium in $> 70\%$ of patients, bisphosphonates may require up to 48–72 hours before reaching full therapeutic effect. Calcitonin may be helpful in the short-term until bisphosphonates reach therapeutic levels. In emergency cases, dialysis with low calcium dialysate may be needed. The calcimimetic agent cinacalcet hydrochloride suppresses PTH secretion and decreases serum calcium concentration and holds promise as a treatment option. See Chapter 39 for a discussion of the treatment of hypercalcemia of malignancy and Chapter 26 for a discussion of the treatment of hypercalcemia of hyperparathyroidism.

Typically, if dialysis patients do not receive proper supplementation of calcium and active vitamin D, hypocalcemia and hyperphosphatemia develop. On the other hand, hypercalcemia can sometimes develop, particularly in the setting of severe secondary hyperparathyroidism,

characterized by high PTH levels and subsequent release of calcium from bone. Therapy may include intravenous vitamin D, which further increases the serum calcium concentration. Another type of hypercalcemia occurs when PTH levels are low. Bone turnover is decreased, which results in a low buffering capacity for calcium. When calcium is administered in calcium-containing phosphate binders or dialysate, or when vitamin D is administered, hypercalcemia results. Hypercalcemia in dialysis patients usually occurs in the presence of hyperphosphatemia, and metastatic calcification may occur. Malignancy should be considered as a cause of the hypercalcemia.

▶ When to Refer

- Patients may require referral to an oncologist or endocrinologist depending on the underlying cause of hypercalcemia.
- Patients with granulomatous diseases (eg, tuberculosis and other chronic infections, granulomatosis with polyangiitis [formerly Wegener granulomatosis], sarcoidosis) may require assistance from infectious disease specialists, rheumatologists, or pulmonologists.

▶ When to Admit

- Patients with symptomatic or severe hypercalcemia require immediate treatment.
- Unexplained hypercalcemia with associated conditions, such as acute kidney injury or suspected malignancy, may require urgent treatment and expedited evaluation.

DISORDERS OF PHOSPHORUS CONCENTRATION

Plasma phosphorus is mainly inorganic phosphate and represents a small fraction ($< 0.2\%$) of total body phosphate.

Important determinants of plasma inorganic phosphate are renal excretion, intestinal absorption, and shift between the intracellular and extracellular spaces. The kidney is the most important regulator of the serum phosphate level. PTH decreases reabsorption of phosphate in the proximal tubule while 1,25-dihydroxyvitamin D₃ increases reabsorption. Renal proximal tubular reabsorption of phosphate is decreased by volume expansion, corticosteroids, and proximal tubular dysfunction (as in Fanconi syndrome). Fibroblast growth factor 23 (FGF23) is a potent phosphaturic hormone. Intestinal absorption

of phosphate is facilitated by active vitamin D. PTH stimulates phosphate release from bone and renal phosphate excretion; primary hyperparathyroidism can lead to hypophosphatemia and depletion of bone phosphate stores. By contrast, growth hormone augments proximal tubular reabsorption of phosphate. Cellular phosphate uptake is stimulated by various factors and conditions, including alkalemia, insulin, epinephrine, feeding, hungry bone syndrome, and accelerated cell proliferation.

Phosphorus metabolism and homeostasis are intimately related to calcium metabolism. See sections on metabolic bone disease in Chapter 26.

HYPOPHOSPHATEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Severe hypophosphatemia may cause tissue hypoxia and rhabdomyolysis.
- ▶ Renal loss of phosphate can be diagnosed by measuring urinary phosphate excretion and by calculating maximal tubular phosphate reabsorption rate (TmP/GFR).
- ▶ PTH and FGF23 are the major factors that decrease TmP/GFR, leading to renal loss of phosphate.

▶ General Considerations

The leading causes of hypophosphatemia are listed in Table 21–9. Hypophosphatemia may occur in the presence of normal phosphate stores. Serious depletion of body phosphate stores may exist with low, normal, or high serum phosphate concentrations.

Serum phosphate levels decrease transiently after food intake, thus fasting samples are recommended for accuracy. **Moderate hypophosphatemia** (1.0–2.4 mg/dL [or 0.32–0.79 mmol/L]) occurs commonly in hospitalized patients and may not reflect decreased phosphate stores.

In **severe hypophosphatemia** (< 1 mg/dL [or < 0.32 mmol/L]), the affinity of hemoglobin for oxygen increases through a decrease in the erythrocyte 2,3-diphosphoglycerate concentration, impairing tissue oxygenation and cell metabolism and resulting in muscle weakness or even rhabdomyolysis. Severe hypophosphatemia is common and multifactorial in alcoholic patients. In acute alcohol withdrawal, increased plasma insulin and epinephrine along with respiratory alkalosis promote intracellular shift of phosphate. Vomiting, diarrhea, and poor dietary intake contribute to hypophosphatemia. Chronic alcohol use results in a decrease in the renal threshold of phosphate excretion. This renal tubular dysfunction reverses after a month of abstinence. Patients with chronic obstructive pulmonary disease and asthma commonly have hypophosphatemia, attributed to xanthine derivatives causing shifts of phosphate intracellularly and the phosphaturic effects of β -adrenergic agonists, loop diuretics, xanthine derivatives, and corticosteroids. The metabolic syndrome, a major

Table 21–9. Causes of hypophosphatemia.

Diminished supply or absorption

Starvation
 Parenteral alimentation with inadequate phosphate content
 Malabsorption syndrome, small bowel bypass
 Absorption blocked by oral antacids with aluminum or magnesium
 Vitamin D–deficient and vitamin D–resistant osteomalacia

Increased loss

Phosphaturic drugs: theophylline, diuretics, bronchodilators, corticosteroids
 Hyperparathyroidism (primary or secondary)
 Hyperthyroidism
 Renal tubular defects with excessive phosphaturia (congenital, induced by monoclonal gammopathy, heavy metal poisoning), alcoholism
 Hypokalemic nephropathy
 Inadequately controlled diabetes mellitus
 Hypophosphatemic rickets
 Phosphatonins of oncogenic osteomalacia (eg, FGF23 production)

Intracellular shift of phosphorus

Administration of glucose
 Anabolic steroids, estrogen, oral contraceptives, β -adrenergic agonists, xanthine derivatives
 Hungry bone syndrome
 Respiratory alkalosis
 Salicylate poisoning

Electrolyte abnormalities

Hypercalcemia
 Hypomagnesemia
 Metabolic alkalosis

Abnormal losses followed by inadequate repletion

Diabetes mellitus with acidosis, particularly during aggressive therapy
 Recovery from starvation or prolonged catabolic state
 Chronic alcoholism, particularly during restoration of nutrition; associated with hypomagnesemia
 Recovery from severe burns

FGF23, fibroblast growth factor 23.

contributor to coronary heart disease risk, is associated with low phosphate (and magnesium) levels but the clinical significance of these disturbances is unclear. Refeeding or glucose administration to phosphate-depleted patients may cause fatal hypophosphatemia.

▶ Clinical Findings

A. Symptoms and Signs

Acute, severe hypophosphatemia (< 1.0 mg/dL [or < 0.32 mmol/L]) can lead to rhabdomyolysis, paresthesias, and encephalopathy (irritability, confusion, dysarthria, seizures, and coma). Respiratory failure or failure to wean from mechanical ventilation may occur as a result of diaphragmatic weakness. Arrhythmias and heart failure are uncommon but serious manifestations. Hematologic manifestations include acute hemolytic anemia from erythrocyte fragility, platelet dysfunction with petechial hemorrhages, and impaired chemotaxis of leukocytes (leading to increased susceptibility to gram-negative sepsis).

Chronic severe depletion may cause anorexia, pain in muscles and bones, and fractures.

B. Laboratory Findings

Urine phosphate excretion is a useful clue in the evaluation of hypophosphatemia. The normal renal response to hypophosphatemia is decreased urinary phosphate excretion to < 100 mg/day. The fractional excretion of phosphate ($F_E\text{PO}_4$) should be < 5%. The main factors regulating $F_E\text{PO}_4$ are PTH and phosphate intake. Increased PTH or phosphate intake decreases $F_E\text{PO}_4$ (ie, more phosphate is excreted into the urine).

Measurement of plasma PTH or PTHrP levels may be helpful. The clinical utility of serum FGF levels is undetermined except in uncommon diseases.

Other clinical features may be suggestive of hypophosphatemia, such as hemolytic anemia and rhabdomyolysis. Fanconi syndrome may present with any combination of uricosuria, aminoaciduria, normoglycemic glucosuria, normal anion gap metabolic acidosis, and phosphaturia. In chronic hypophosphatemia, radiographs and bone biopsies show changes resembling osteomalacia.

▶ Treatment

Hypophosphatemia can be prevented by including phosphate in repletion and maintenance fluids. A rapid decline in calcium levels can occur with parenteral administration of phosphate; oral replacement of phosphate is preferable. Moderate hypophosphatemia (1.0–2.5 mg/dL [or 0.32–0.79 mmol/L]) is usually asymptomatic and does not require treatment. The hypophosphatemia in patients with diabetic ketoacidosis (DKA) will usually correct with normal dietary intake. Chronic hypophosphatemia can be treated with oral phosphate repletion. Mixtures of sodium and potassium phosphate salts may be given to provide 0.5–1 g (16–32 mmol) of phosphate per day. For severe, symptomatic hypo-phosphatemia (< 1 mg/dL [or < 0.32 mmol/L]), an infusion should provide 279–310 mg/12 h (or 9–10 mmol/12 h) until the serum phosphorus exceeds 1 mg/dL and the patient can be switched to oral therapy. The infusion rate should be decreased if hypotension occurs. Monitoring of plasma phosphate, calcium, and potassium every 6 hours is necessary because the response to phosphate supplementation is not predictable. Magnesium deficiency often coexists and should be treated.

Contraindications to phosphate replacement include hypoparathyroidism, advanced CKD, tissue damage and necrosis, and hypercalcemia. When an associated hyperglycemia is treated, phosphate accompanies glucose into cells, and hypophosphatemia may ensue.

▶ When to Refer

- Patients with refractory hypophosphatemia with increased urinary phosphate excretion may require evaluation by an endocrinologist (for such conditions as hyperparathyroidism and vitamin D disorders) or a nephrologist (for such conditions as renal tubular defects).
- Patients with decreased gastrointestinal absorption may require referral to a gastroenterologist.

▶ When to Admit

Patients with severe or refractory hypophosphatemia will require intravenous phosphate.

HYPERPHOSPHATEMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Advanced CKD is the most common cause.
- ▶ Hyperphosphatemia in the presence of hypercalcemia imposes a high risk of metastatic calcification

▶ General Considerations

Advanced CKD with decreased urinary excretion of phosphate is the most common cause of hyperphosphatemia. Other causes are listed in Table 21–10.

Table 21–10. Causes of hyperphosphatemia.

Massive load of phosphate into the extracellular fluid

- Exogenous sources
 - Hypervitaminosis D
 - Laxatives or enemas containing phosphate
 - Intravenous phosphate supplement
- Endogenous sources
 - Rhabdomyolysis (especially if chronic kidney disease coexists)
 - Cell lysis by chemotherapy of malignancy, particularly lymphoproliferative diseases
 - Metabolic acidosis (lactic acidosis, ketoacidosis)
 - Respiratory acidosis (phosphate incorporation into cells is disturbed)

Decreased excretion into urine

- Chronic kidney disease
- Acute kidney injury
- Hypoparathyroidism
- Pseudohypoparathyroidism
- Acromegaly

Pseudohyperphosphatemia

- Multiple myeloma
- Hyperbilirubinemia
- Hypertriglyceridemia
- Hemolysis in vitro

► Clinical Findings

A. Symptoms and Signs

The clinical manifestations are those of the underlying disorder or associated condition.

B. Laboratory Findings

In addition to elevated phosphate, blood chemistry abnormalities are those of the underlying disease.

► Treatment

Treatment is directed at the underlying cause. Exogenous sources of phosphate, including enteral or parenteral nutrition and medications, should be reduced or eliminated. Dietary phosphate absorption can be reduced by oral phosphate binders, such as calcium carbonate, calcium acetate, sevelamer carbonate, lanthanum carbonate, and aluminum hydroxide. Sevelamer, lanthanum, and aluminum may be used in patients with hypercalcemia, although aluminum use should be limited to a few days because of the risk of aluminum accumulation and neurotoxicity. In acute kidney injury and advanced CKD, dialysis will reduce serum phosphate.

► When to Admit

Patients with acute severe hyperphosphatemia require hospitalization for emergent therapy, possibly including dialysis. Concomitant illnesses, such as acute kidney injury or cell lysis, may necessitate admission.

DISORDERS OF MAGNESIUM CONCENTRATION

Normal plasma magnesium concentration is 1.8–3.0 mg/dL (or 0.75–1.25 mmol/L), with about one-third bound to protein and two-thirds existing as free cation. Magnesium excretion is via the kidney. Magnesium's physiologic effects on the nervous system resemble those of calcium.

Altered magnesium concentration usually provokes an associated alteration of Ca^{2+} . Both hypomagnesemia and hypermagnesemia can decrease PTH secretion or action. Severe hypermagnesemia (> 5 mg/dL [or 2.1 mmol/L]) suppresses PTH secretion with consequent hypocalcemia; this disorder is typically seen only in patients receiving magnesium therapy for preeclampsia. Severe hypomagnesemia causes PTH resistance in end-organs and eventually decreased PTH secretion in severe cases.

HYPOMAGNESEMIA

ESSENTIALS OF DIAGNOSIS

- Serum concentration of magnesium may not be decreased even in the presence of magnesium depletion. Check urinary magnesium excretion if renal magnesium wasting is suspected.
- Causes neurologic symptoms and arrhythmias.
- Impairs release of PTH.

► General Considerations

Causes of hypomagnesemia are listed in Table 21–11. Normomagnesemia does not exclude magnesium depletion because only 1% of total body magnesium is in the extracellular fluid (ECF). Hypomagnesemia and hypokalemia share many etiologies, including diuretics, diarrhea, alcoholism, aminoglycosides, and amphotericin. Renal potassium wasting also occurs from hypomagnesemia, and is refractory to potassium replacement until magnesium is repleted. Hypomagnesemia also suppresses PTH release and causes end-organ resistance to PTH and low 1,25-dihydroxyvitamin D_3 levels. The resultant hypocalcemia is refractory to calcium replacement until the magnesium is normalized. Molecular mechanisms of magnesium wasting have been revealed in some hereditary disorders. The FDA has issued a warning about hypomagnesemia for patients taking proton pump inhibitors. The presumed mechanism is decreased

Table 21–11. Causes of hypomagnesemia.

Diminished absorption or intake

- Malabsorption, chronic diarrhea, laxative abuse
- Proton pump inhibitors
- Prolonged gastrointestinal suction
- Small bowel bypass
- Malnutrition
- Alcoholism
- Total parenteral alimentation with inadequate Mg^{2+} content

Increased renal loss

- Diuretic therapy (loop diuretics, thiazide diuretics)
- Hyperaldosteronism, Gitelman syndrome (a variant of Bartter syndrome)
- Hyperparathyroidism, hyperthyroidism
- Hypercalcemia
- Volume expansion
- Tubulointerstitial diseases
- Transplant kidney
- Drugs (aminoglycoside, cetuximab, cisplatin, amphotericin B, pentamidine)

Others

- Diabetes mellitus
- Post-parathyroidectomy (hungry bone syndrome)
- Respiratory alkalosis
- Pregnancy

intestinal magnesium absorption, but it is not clear why this complication develops in only a small fraction of patients taking these medications.

► Clinical Findings

A. Symptoms and Signs

Common symptoms are those of hypokalemia and hypocalcemia, with weakness and muscle cramps. Marked neuromuscular and central nervous system hyperirritability may produce tremors, athetoid movements, jerking, nystagmus, a Babinski response, confusion, and disorientation. Cardiovascular manifestations include hypertension, tachycardia, and ventricular arrhythmias.

B. Laboratory Findings

Urinary excretion of magnesium exceeding 10–30 mg/day or a fractional excretion > 2% indicates renal magnesium wasting. Hypocalcemia and hypokalemia are often present. The ECG shows a prolonged QT interval, due to lengthening of the ST segment. PTH secretion is often suppressed (see Hypocalcemia, above).

► Treatment

Magnesium oxide, 250–500 mg orally once or twice daily, is useful for treating chronic hypomagnesemia. Symptomatic hypomagnesemia requires intravenous magnesium sulfate 1–2 g over 5–60 minutes mixed in either dextrose 5% or 0.9% normal saline. Torsades de pointes in the setting of hypomagnesemia can be treated with 1–2 g of magnesium sulfate in 10 mL of dextrose 5% solution pushed intravenously over 15 minutes. Severe, non-life-threatening deficiency can be treated at a rate to 1–2 g/h over 3–6 hours. Magnesium sulfate may also be given intramuscularly in a dosage of 200–800 mg/day (8–33 mmol/day) in four divided doses. Serum levels must be monitored daily and dosage adjusted to keep the concentration from rising above 3 mg/dL. Tendon reflexes may be checked for hyporeflexia of hypermagnesemia. K^+ and Ca^{2+} replacement may be required, but patients with hypokalemia and hypocalcemia of hypomagnesemia do not recover without magnesium supplementation.

Patients with normal kidney function can excrete excess magnesium; hypermagnesemia should not develop with replacement dosages. In patients with CKD, magnesium replacement should be done cautiously to avoid hypermagnesemia. Reduced doses (50–75% dose reduction) and more frequent monitoring (at least twice daily) are indicated.

HYPERMAGNESEMIA

ESSENTIALS OF DIAGNOSIS

- Often associated with advanced CKD and chronic intake of magnesium-containing drugs.

► General Considerations

Hypermagnesemia is almost always the result of advanced CKD and impaired magnesium excretion. Antacids and laxatives are underrecognized sources of magnesium. Pregnant patients may have severe hypermagnesemia from intravenous magnesium for preeclampsia and eclampsia. Magnesium replacement should be done cautiously in patients with CKD; dose reductions up to 75% may be necessary to avoid hypermagnesemia.

► Clinical Findings

A. Symptoms and Signs

Muscle weakness, decreased deep tendon reflexes, mental obtundation, and confusion are characteristic manifestations. Weakness, flaccid paralysis, ileus, urinary retention, and hypotension are noted. Serious findings include respiratory muscle paralysis and cardiac arrest.

B. Laboratory Findings

Serum Mg^{2+} is elevated. In the common setting of CKD, BUN, creatinine, potassium, phosphate, and uric acid may all be elevated. Serum Ca^{2+} is often low. The ECG shows increased PR interval, broadened QRS complexes, and peaked T waves, probably related to associated hyperkalemia.

► Treatment

Exogenous sources of magnesium should be discontinued. Calcium antagonizes Mg^{2+} and may be given intravenously as calcium chloride, 500 mg or more at a rate of 100 mg (4.1 mmol) per minute. Hemodialysis or peritoneal dialysis may be necessary to remove magnesium, particularly with severe kidney disease.

Long-term use of magnesium hydroxide and magnesium sulfate should be avoided in patients with advanced stages of CKD.

ACID–BASE DISORDERS

Assessment of a patient's acid–base status requires measurement of arterial pH, PCO_2 , and plasma bicarbonate (HCO_3^-). Blood gas analyzers directly measure pH and

PCO_2 . The HCO_3^- value is calculated from the Henderson-Hasselbalch equation:

$$\text{pH} = 6.1 + \log \frac{\text{HCO}_3^-}{0.03 \times \text{PCO}_2}$$

The total venous CO_2 measurement is a more direct determination of HCO_3^- . Because of the dissociation characteristics of carbonic acid (H_2CO_3) at body pH, dissolved CO_2 is almost exclusively in the form of HCO_3^- , and for clinical purposes the total carbon dioxide content is equivalent (± 3 mEq/L) to the HCO_3^- concentration:

Venous blood gases can provide useful information for acid-base assessment since the arteriovenous differences in pH and PCO_2 are small and relatively constant. Venous blood pH is usually 0.03–0.04 units lower than arterial blood pH, and venous blood PCO_2 is 7 or 8 mm Hg higher than arterial blood PCO_2 . Calculated HCO_3^- concentration in venous blood is at most 2 mEq/L higher than arterial blood HCO_3^- . Arterial and venous blood gases will not be equivalent during a cardiopulmonary arrest; arterial samples should be obtained for the most accurate measurements of pH and PCO_2 .

TYPES OF ACID-BASE DISORDERS

There are two types of acid-base disorders: acidosis and alkalosis. These disorders can be either metabolic (decreased or increased HCO_3^-) or respiratory (decreased or increased PCO_2). Primary respiratory disorders affect blood acidity by changes in PCO_2 , and primary metabolic disorders are disturbances in HCO_3^- concentration. A primary disturbance is usually accompanied by a compensatory response, but the compensation does not fully correct the pH disturbance of the primary disorder. If the pH is < 7.40 , the primary process is acidosis, either respiratory

STEP-BY-STEP ANALYSIS OF ACID-BASE STATUS

- Step 1:** Determine the primary (or main) disorder—whether it is metabolic or respiratory—from blood pH, HCO_3^- , and PCO_2 values.
- Step 2:** Determine the presence of mixed acid-base disorders by calculating the range of compensatory responses (Table 21-12).
- Step 3:** Calculate the anion gap (Table 21-13).
- Step 4:** Calculate the corrected HCO_3^- concentration if the anion gap is increased (see above).
- Step 5:** Examine the patient to determine whether the clinical signs are compatible with the acid-base analysis.

($\text{PCO}_2 > 40$ mm Hg) or metabolic ($\text{HCO}_3^- < 24$ mEq/L). If the pH is higher than 7.40, the primary process is alkalosis, either respiratory ($\text{PCO}_2 < 40$ mm Hg) or metabolic ($\text{HCO}_3^- > 24$ mEq/L). One respiratory or metabolic disorder with its appropriate compensatory response is a simple acid-base disorder.

MIXED ACID-BASE DISORDERS

Two or three simultaneous disorders can be present in a mixed acid-base disorder, but there can never be two primary respiratory disorders. Uncovering a mixed acid-base disorder is clinically important, but requires a methodical approach to acid-base analysis (see box, Step-by-Step Analysis of Acid-Base Status). Once the primary disturbance has been determined, the clinician should assess whether the compensatory response is appropriate (Table 21-12). An inadequate or an exaggerated response indicates the presence of another primary acid-base disturbance.

The anion gap should always be calculated for two reasons. First, it is possible to have an abnormal anion

Table 21-12. Primary acid-base disorders and expected compensation.

Disorder	Primary Defect	Compensatory Response	Magnitude of Compensation
Respiratory acidosis			
Acute	$\uparrow \text{PCO}_2$	$\uparrow \text{HCO}_3^-$	$\uparrow \text{HCO}_3^-$ 1 mEq/L per 10 mm Hg $\uparrow \text{PCO}_2$
Chronic	$\uparrow \text{PCO}_2$	$\uparrow \text{HCO}_3^-$	$\uparrow \text{HCO}_3^-$ 3.5 mEq/L per 10 mm Hg $\uparrow \text{PCO}_2$
Respiratory alkalosis			
Acute	$\downarrow \text{PCO}_2$	$\downarrow \text{HCO}_3^-$	$\downarrow \text{HCO}_3^-$ 2 mEq/L per 10 mm Hg $\downarrow \text{PCO}_2$
Chronic	$\downarrow \text{PCO}_2$	$\downarrow \text{HCO}_3^-$	$\downarrow \text{HCO}_3^-$ 5 mEq/L per 10 mm Hg $\downarrow \text{PCO}_2$
Metabolic acidosis	$\downarrow \text{HCO}_3^-$	$\downarrow \text{PCO}_2$	$\downarrow \text{PCO}_2$ 1.3 mm Hg per 1 mEq/L $\downarrow \text{HCO}_3^-$
Metabolic alkalosis	$\uparrow \text{HCO}_3^-$	$\uparrow \text{PCO}_2$	$\uparrow \text{PCO}_2$ 0.7 mm Hg per 1 mEq/L $\uparrow \text{HCO}_3^-$

gap even if the sodium, chloride, and bicarbonate levels are normal. Second, a large anion gap (> 20 mEq/L) suggests a primary metabolic acid-base disturbance regardless of the pH or serum bicarbonate level because a markedly abnormal anion gap is never a compensatory response to a respiratory disorder. In patients with an increased anion gap metabolic acidosis, clinicians should calculate the corrected bicarbonate. In increased anion gap acidoses, there should be a mole for mole decrease in HCO_3^- as the anion gap increases. A corrected HCO_3^- value higher or lower than normal (24 mEq/L) indicates the concomitant presence of metabolic alkalosis or normal anion gap metabolic acidosis, respectively.

METABOLIC ACIDOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Decreased HCO_3^- with acidemia.
- ▶ Classified into increased anion gap acidosis and normal anion gap acidosis.
- ▶ Lactic acidosis, ketoacidosis, and toxins produce metabolic acidoses with the largest anion gaps.
- ▶ Normal anion gap acidosis is mainly caused by gastrointestinal HCO_3^- loss or RTA. Urinary anion gap may help distinguish between these causes.

▶ General Considerations

The hallmark of metabolic acidosis is decreased HCO_3^- . Metabolic acidoses are classified by the anion gap, either normal or increased (Table 21–13). The anion gap is the difference between readily measured anions and cations.

In plasma,

$$[\text{Na}^+] + \frac{\text{Unmeasured cations}}{\text{anions}} = \text{HCO}_3^- + \text{Cl}^- + \frac{\text{Unmeasured anions}}{\text{anions}}$$

$$\text{Anion gap} = \text{Na}^+ - (\text{HCO}_3^- + \text{Cl}^-)$$

Major unmeasured cations are calcium (2 mEq/L), magnesium (2 mEq/L), γ -globulins, and potassium (4 mEq/L). Major unmeasured anions are albumin (2 mEq/L per g/dL), phosphate (2 mEq/L), sulfate (1 mEq/L), lactate (1–2 mEq/L), and other organic anions (3–4 mEq/L). Traditionally, the normal anion gap has been 12 ± 4 mEq/L. With current auto-analyzers, the reference range may be lower (6 ± 1 mEq/L), primarily from an increase in Cl^- values. Despite its usefulness, the anion gap can be misleading. Non-acid-base disorders may cause errors in

Table 21–13. Anion gap in metabolic acidosis.¹

Decreased (< 6 mEq)

Hypoalbuminemia (decreased unmeasured anion)
 Plasma cell dyscrasias
 Monoclonal protein (cationic paraprotein) (accompanied by chloride and bicarbonate)

Bromide intoxication

Increased (> 12 mEq)

Metabolic anion

Diabetic ketoacidosis

Alcoholic ketoacidosis

Lactic acidosis

Chronic kidney disease (advanced stages) (PO_4^{3-} , SO_4^{2-})

Starvation

Metabolic alkalosis (increased number of negative charges on protein)

Drug or chemical anion

Salicylate intoxication

Sodium carbenicillin therapy

Methanol (formic acid)

Ethylene glycol (oxalic acid)

Normal (6–12 mEq)

Loss of HCO_3^-

Diarrhea

Recovery from diabetic ketoacidosis

Pancreatic fluid loss ileostomy (unadapted)

Carbonic anhydrase inhibitors

Chloride retention

Renal tubular acidosis

Ileal loop bladder

Administration of HCl equivalent or NH_4Cl

Arginine and lysine in parenteral nutrition

¹Reference ranges for anion gap may vary based on differing laboratory methods.

anion gap interpretation; these disorders including hypoalbuminemia, hypernatremia, or hyponatremia; antibiotics (eg, carbenicillin is an unmeasured anion; polymyxin is an unmeasured cation) may also cause errors in anion gap interpretation. Although not usually associated with metabolic acidosis, a decreased anion gap can occur because of a reduction in unmeasured anions or an increase in unmeasured cations. In hypoalbuminemia, a 2 mEq/L decrease in anion gap will occur for every 1 g/dL decline in serum albumin.

INCREASED ANION GAP ACIDOSIS (Increased Unmeasured Anions)

Normochloremic metabolic acidosis generally results from addition of organic acids such as lactate, acetoacetate, β -hydroxybutyrate, and exogenous toxins. Other anions such as isocitrate, α -ketoglutarate, malate and D-lactate, may contribute to the anion gap of lactic acidosis, DKA, and acidosis of unknown etiology. Uremia causes an increased anion gap metabolic acidosis from unexcreted organic acids and anions.

A. Lactic Acidosis

Lactic acid is formed from pyruvate in anaerobic glycolysis, typically in tissues with high rates of glycolysis, such as gut (responsible for over 50% of lactate production), skeletal muscle, brain, skin, and erythrocytes. Normally, lactate levels

remain low (1 mEq/L) because of metabolism of lactate principally by the liver through gluconeogenesis or oxidation via the Krebs cycle. The kidneys metabolize about 30% of lactate.

In lactic acidosis, lactate levels are at least 4–5 mEq/L but commonly 10–30 mEq/L. There are two basic types of lactic acidosis.

Type A (hypoxic) lactic acidosis is more common, resulting from decreased tissue perfusion; cardiogenic, septic, or hemorrhagic shock; and carbon monoxide or cyanide poisoning. These conditions increase peripheral lactic acid production and decrease hepatic metabolism of lactate as liver perfusion declines.

Type B lactic acidosis may be due to metabolic causes (eg, diabetes, ketoacidosis, liver disease, kidney disease, infection, leukemia, or lymphoma) or toxins (eg, ethanol, methanol, salicylates, isoniazid, or metformin). Propylene glycol can cause lactic acidosis from decreased liver metabolism; it is used as a vehicle for intravenous drugs, such as nitroglycerin, etomidate, and diazepam. Parenteral nutrition without thiamine causes severe refractory lactic acidosis from deranged pyruvate metabolism. Patients with short bowel syndrome may develop D-lactic acidosis with encephalopathy due to carbohydrate malabsorption and subsequent fermentation by colonic bacteria.

Nucleoside analog reverse transcriptase inhibitors can cause type B lactic acidosis due to mitochondrial toxicity.

Idiopathic lactic acidosis, usually in debilitated patients, has an extremely high mortality rate. (For treatment of lactic acidosis, see below and Chapter 27.)

B. Diabetic Ketoacidosis (DKA)

DKA is characterized by hyperglycemia and metabolic acidosis with an increased anion gap:

where B^- is β -hydroxybutyrate or acetoacetate, the ketones responsible for the increased anion gap. The anion gap should be calculated from the measured serum electrolytes; correction of the serum sodium for the dilutional effect of hyperglycemia will exaggerate the anion gap. Diabetics with ketoacidosis may have lactic acidosis from tissue hypoperfusion and increased anaerobic metabolism.

During the recovery phase of DKA, a hyperchloremic non-anion gap acidosis can develop because saline resuscitation results in chloride retention, restoration of GFR, and ketoaciduria. Ketone salts (NaB) are formed as bicarbonate is consumed:

The kidney reabsorbs ketone anions poorly but can compensate for the loss of anions by increasing the reabsorption of Cl^- .

Patients with DKA and normal kidney function may have marked ketonuria and severe metabolic acidosis but only a mildly increased anion gap. Thus, the size of the anion gap correlates poorly with the severity of the DKA; the urinary loss of Na^+ or K^+ salts of β -hydroxybutyrate will lower the anion gap without altering the H^+ excretion or the severity of

the acidosis. Urine dipsticks for ketones test primarily for acetoacetate and, to a lesser degree, acetone but not the predominant ketoacid, β -hydroxybutyrate. Dipstick tests for ketones may become more positive even as the patient improves due to the metabolism of hydroxybutyrate. Thus, the patient's clinical status and pH are better markers of improvement than the anion gap or ketone levels.

C. Alcoholic Ketoacidosis

Chronically malnourished patients who consume large quantities of alcohol daily may develop alcoholic ketoacidosis. Most of these patients have mixed acid–base disorders (10% have a triple acid–base disorder). Although decreased HCO_3^- is usual, 50% of the patients may have normal or alkalemic pH. Three types of metabolic acidosis are seen in alcoholic ketoacidosis: (1) Ketoacidosis is due to β -hydroxybutyrate and acetoacetate excess. (2) Lactic acidosis: Alcohol metabolism increases the NADH:NAD ratio, causing increased production and decreased utilization of lactate. Accompanying thiamine deficiency, which inhibits pyruvate carboxylase, further enhances lactic acid production in many cases. Moderate to severe elevations of lactate (> 6 mmol/L) are seen with concomitant disorders such as sepsis, pancreatitis, or hypoglycemia. (3) Hyperchloremic acidosis from bicarbonate loss in the urine is associated with ketonuria (see above). Metabolic alkalosis occurs from volume contraction and vomiting. Respiratory alkalosis results from alcohol withdrawal, pain, or associated disorders such as sepsis or liver disease. Half of the patients have hypoglycemia or hyperglycemia. When serum glucose levels are > 250 mg/dL, the distinction from DKA is difficult. The absence of a diabetic history and normoglycemia after initial therapy support the diagnosis of alcoholic ketoacidosis.

D. Toxins

(See also Chapter 38.) Multiple toxins and drugs increase the anion gap by increasing endogenous acid production. Common examples include methanol (metabolized to formic acid), ethylene glycol (glycolic and oxalic acid), and salicylates (salicylic acid and lactic acid). The latter can cause a mixed disorder of metabolic acidosis with respiratory alkalosis. In toluene poisoning, a metabolite hippurate is rapidly excreted by the kidney and may present as a normal anion gap acidosis. Isopropanol, which is metabolized to acetone, increases the osmolar gap, but not the anion gap.

E. Uremic Acidosis

As the GFR drops below 15–30 mL/min, the kidneys are increasingly unable to excrete H^+ and organic acids, such as phosphate and sulfate, resulting in an increased anion gap acidosis. Hyperchloremic normal anion gap acidosis develops in earlier stages of CKD.

NORMAL ANION GAP ACIDOSIS (Table 21–14)

The two major causes are gastrointestinal HCO_3^- loss and defects in renal acidification (renal tubular acidoses). The urinary anion gap can differentiate between these causes (see below).

Table 21-14. Hyperchloremic, normal anion gap metabolic acidoses.

	Renal Defect	Serum [K ⁺]	Distal H ⁺ Secretion		Urinary Anion Gap	Treatment
			Urinary NH ₄ ⁺ Plus Minimal Urine pH	Titratable Acid		
Gastrointestinal HCO ₃ ⁻ loss	None	↓	< 5.5	↑↑	Negative	Na ⁺ , K ⁺ , and HCO ₃ ⁻ as required
Renal tubular acidosis						
I. Classic distal	Distal H ⁺ secretion	↓	> 5.5	↓	Positive	NaHCO ₃ (1-3 mEq/kg/d)
II. Proximal secretion	Proximal H ⁺	↓	< 5.5	Normal	Positive	NaHCO ₃ or KHCO ₃ (10-15 mEq/kg/d), thiazide
IV. Hyporeninemic hypoaldosteronism	Distal Na ⁺ reabsorption, K ⁺ secretion, and H ⁺ secretion	↑	< 5.5	↓	Positive	Fludrocortisone (0.1-0.5 mg/d), dietary K ⁺ restriction, furosemide (40-160 mg/d), NaHCO ₃ (1-3 mEq/kg/d)

Modified and reproduced, with permission, from Cogan MG. *Fluid and Electrolytes: Physiology and Pathophysiology*. McGraw-Hill, 1991.

A. Gastrointestinal HCO₃⁻ Loss

The gastrointestinal tract secretes bicarbonate at multiple sites. Small bowel and pancreatic secretions contain large amounts of HCO₃⁻; massive diarrhea or pancreatic drainage can result in HCO₃⁻ loss. Hyperchloremia occurs because the ileum and colon secrete HCO₃⁻ in exchange for Cl⁻ by countertransport. The resultant volume contraction causes increased Cl⁻ retention by the kidney in the setting of decreased HCO₃⁻. Patients with ureterosigmoidostomies can develop hyperchloremic metabolic acidosis because the colon secretes HCO₃⁻ in the urine in exchange for Cl⁻.

B. Renal Tubular Acidosis (RTA)

Hyperchloremic acidosis with a normal anion gap and normal (or near normal) GFR, and in the absence of diarrhea, defines RTA. The defect is either inability to excrete H⁺ (inadequate generation of new HCO₃⁻) or inappropriate reabsorption of HCO₃⁻. Three major types can be differentiated by the clinical setting, urinary pH, urinary anion gap (see below), and serum K⁺ level. The pathophysiologic mechanisms of RTA have been elucidated by identifying the responsible molecules and gene mutations.

1. Classic distal RTA (type I)—This disorder is characterized by selective deficiency in H⁺ secretion in α intercalated cells in the collecting tubule. Despite acidosis, urinary pH cannot be acidified and is above 5.5, which retards the binding of H⁺ to phosphate (H⁺ + HPO₄²⁻ → H₂PO₄) and inhibits titratable acid excretion. Furthermore, urinary excretion of NH₄⁺Cl⁻ is decreased, and the urinary anion gap is positive (see below). Enhanced K⁺ excretion occurs probably because there is less competition from H⁺ in the distal nephron transport system. Furthermore, hyperaldosteronism occurs in response to renal salt wasting, which will increase potassium excretion. Nephrocalcinosis and nephrolithiasis are often seen in patients with distal RTA since chronic acidosis decreases tubular calcium reabsorption. Hypercalciuria, alkaline urine,

and lowered level of urinary citrate cause calcium phosphate stones and nephrocalcinosis.

Distal RTA develops as a consequence of paraproteinemias, autoimmune disease, and drugs and toxins such as amphotericin.

2. Proximal RTA (type II)—Proximal RTA is due to a selective defect in the proximal tubule's ability to reabsorb filtered HCO₃⁻. Carbonic anhydrase inhibitors (acetazolamide) can cause proximal RTA. About 90% of filtered HCO₃⁻ is absorbed by the proximal tubule. A proximal defect in HCO₃⁻ reabsorption will overwhelm the distal tubule's limited capacity to reabsorb HCO₃⁻, resulting in bicarbonaturia and metabolic acidosis. Distal delivery of HCO₃⁻ declines as the plasma HCO₃⁻ level decreases. When the plasma HCO₃⁻ level drops to 15–18 mEq/L, the distal nephron can reabsorb the diminished filtered load of HCO₃⁻. Bicarbonaturia resolves, and the urinary pH can be acidic. Thiazide-induced volume contraction can be used to enhance proximal HCO₃⁻ reabsorption, leading to the decrease in distal HCO₃⁻ delivery and improvement of bicarbonaturia and renal acidification. The increased delivery of HCO₃⁻ to the distal nephron increases K⁺ secretion, and hypokalemia results if a patient is loaded with excess HCO₃⁻ and K⁺ is not adequately supplemented. Proximal RTA can exist with other proximal reabsorption defects, such as Fanconi syndrome, resulting in glucosuria, aminoaciduria, phosphaturia, and uricosuria. Causes include multiple myeloma and nephrotoxic drugs.

3. Hyporeninemic hypoaldosteronemic RTA (type IV)—Type IV is the most common RTA in clinical practice. The defect is aldosterone deficiency or antagonism, which impairs distal nephron Na⁺ reabsorption and K⁺ and H⁺ excretion. Renal salt wasting and hyperkalemia are frequently present. Common causes are diabetic nephropathy, tubulointerstitial renal diseases, hypertensive nephrosclerosis, and AIDS. In patients with these disorders, drugs, such as ACE inhibitors, spironolactone, and NSAIDs, can exacerbate the hyperkalemia.

C. Dilutional Acidosis

Rapid dilution of plasma volume by 0.9% NaCl may cause hyperchloremic acidosis.

D. Recovery from DKA

See earlier section, Increased Anion Gap Acidosis (Increased Unmeasured Anion).

E. Posthypocapnia

In prolonged respiratory alkalosis, HCO_3^- decreases and Cl^- increases from decreased renal NH_4^+Cl^- excretion. If the respiratory alkalosis is corrected quickly, HCO_3^- will remain low until the kidneys can generate new HCO_3^- , which generally takes several days. In the meantime, the increased Pco_2 with low HCO_3^- causes metabolic acidosis.

F. Hyeralimentation

Hyeralimentation fluids may contain amino acid solutions that acidify when metabolized, such as arginine hydrochloride and lysine hydrochloride.

► Assessment of Hyperchloremic Metabolic Acidosis by Urinary Anion Gap

Increased renal NH_4^+Cl^- excretion to enhance H^+ removal is the normal physiologic response to metabolic acidosis. The daily urinary excretion of NH_4Cl can be increased from 30 mEq to 200 mEq in response to acidosis.

The urinary anion gap ($\text{Na}^+ + \text{K}^+ - \text{Cl}^-$) reflects the ability of the kidney to excrete NH_4Cl . The urinary anion gap differentiates between gastrointestinal and renal causes of hyperchloremic acidosis. If the cause is gastrointestinal HCO_3^- loss (diarrhea), renal acidification remains normal and NH_4Cl excretion increases, and the urinary anion gap is negative. If the cause is distal RTA, the urinary anion gap is positive, since the basic lesion in the disorder is the inability of the kidney to excrete H^+ as NH_4Cl . In proximal (type II) RTA, the kidney has defective HCO_3^- reabsorption, leading to increased HCO_3^- excretion rather than decreased NH_4Cl excretion; the urinary anion gap is often negative.

Urinary pH may not readily differentiate between the two causes. Despite acidosis, if volume depletion from diarrhea causes inadequate Na^+ delivery to the distal nephron and therefore decreased exchange with H^+ , urinary pH may not be lower than 5.3. In the presence of this relatively high urinary pH, however, H^+ excretion continues due to buffering of NH_3 to NH_4^+ , since the pK of this reaction is as high as 9.1. Potassium depletion, which can accompany diarrhea (and surreptitious laxative abuse), may also impair renal acidification. Thus, when volume depletion is present, the urinary anion gap is a better measure of ability to acidify the urine than urinary pH.

When large amounts of other anions are present in the urine, the urinary anion gap may not be reliable. In such a situation, NH_4^+ excretion can be estimated using the urinary osmolar gap.

$$\text{NH}_4^+ \text{ excretion (mmol/L)} = 0.5 \times \text{Urinary osmolar gap} \\ = 0.5 [\text{U osm} - 2(\text{U Na}^+ + \text{U K}^+) + \text{U urea} + \text{U glucose}]$$

where urine concentrations and osmolality are in mmol/L.

► Clinical Findings

A. Symptoms and Signs

Symptoms of metabolic acidosis are mainly those of the underlying disorder. Compensatory hyperventilation is an important clinical sign and may be misinterpreted as a primary respiratory disorder; Kussmaul breathing (deep, regular, sighing respirations) may be seen with severe metabolic acidosis.

B. Laboratory Findings

Blood pH, serum HCO_3^- , and PCO_2 are decreased. Anion gap may be normal (hyperchloremic) or increased (normochloremic). Hyperkalemia may be seen (see above).

► Treatment

A. Increased Anion Gap Acidosis

Treatment is aimed at the underlying disorder, such as insulin and fluid therapy for diabetes and appropriate volume resuscitation to restore tissue perfusion. The metabolism of lactate will produce HCO_3^- and increase pH. Supplemental HCO_3^- is indicated for treatment of hyperkalemia (Table 21-6) and some forms of normal anion gap acidosis but has been controversial for treatment of increased anion gap metabolic acidosis with respect to efficacy and safety. Large amounts of HCO_3^- may have deleterious effects, including hypernatremia, hyperosmolality, volume overload, and worsening of intracellular acidosis.

In addition, alkali administration stimulates phosphofructokinase activity, thus exacerbating lactic acidosis via enhanced lactate production. Ketogenesis is also augmented by alkali therapy.

In salicylate intoxication, alkali therapy must be started unless blood pH is already alkalinized by respiratory alkalosis, since an increased pH converts salicylate to more impermeable salicylic acid, decreasing central nervous system damage. In alcoholic ketoacidosis, thiamine should be given with glucose to avoid Wernicke encephalopathy. The bicarbonate deficit can be calculated as follows:

$$\text{HCO}_3^- \text{ deficit} = 0.5 \times \text{body weight in kg} \times (24 - \text{HCO}_3^-)$$

Half of the calculated deficit should be administered within the first 3–4 hours to avoid overcorrection and volume overload. In methanol intoxication, ethanol had been used as a competitive substrate for alcohol dehydrogenase, which metabolizes methanol to formaldehyde. Inhibition of alcohol dehydrogenase by fomepizole is the standard of care.

B. Normal Anion Gap Acidosis

Treatment of RTA is mainly achieved by administration of alkali (either as bicarbonate or citrate) to correct metabolic abnormalities and prevent nephrocalcinosis and CKD.

Large amounts of oral alkali (10–15 mEq/kg/d) (Table 21–14) may be required to treat proximal RTA because most of the alkali is excreted into the urine, which exacerbates hypokalemia. Thus, a mixture of sodium and potassium salts is preferred. Thiazides may reduce the amount of alkali required, but hypokalemia may develop. Treatment of type 1 distal RTA requires less alkali (1–3 mEq/kg/d) than proximal RTA. Potassium supplementation may be necessary.

For type IV RTA, dietary potassium restriction may be necessary and potassium-retaining drugs should be withdrawn. Fludrocortisone may be effective in cases with hypoaldosteronism, but should be used with care, preferably in combination with loop diuretics. In some cases, oral alkali supplementation (1–3 mEq/kg/d) may be required.

▶ When to Refer

Most clinicians will refer patients with renal tubular acidoses to a nephrologist for evaluation and possible alkali therapy.

▶ When to Admit

Patients will require emergency department evaluation or hospital admission depending on the severity of the acidosis and underlying conditions.

METABOLIC ALKALOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ High HCO_3^- with alkalemia.
- ▶ Evaluate effective circulating volume by physical examination.
- ▶ Check urinary chloride concentration to differentiate saline-responsive alkalosis from saline-unresponsive alkalosis.

▶ Classification

Metabolic alkalosis is characterized by high HCO_3^- . Abnormalities that generate HCO_3^- are called “initiation factors,” whereas abnormalities that promote renal conservation of HCO_3^- are called “maintenance factors.” Metabolic alkalosis may remain even after the initiation factors have resolved.

The causes of metabolic alkalosis are classified into two groups based on “saline responsiveness” using the urine Cl^- as a marker for volume status (Table 21–15). Saline-responsive metabolic alkalosis is a sign of extracellular volume contraction, and saline-unresponsive alkalosis implies excessive total body bicarbonate with either euvolemia or hypervolemia. The compensatory increase in PCO_2 rarely exceeds 55 mm Hg; higher PCO_2 values imply a superimposed primary respiratory acidosis.

A. Saline-Responsive Metabolic Alkalosis

Much more common than saline-unresponsive alkalosis, saline-responsive alkalosis is characterized by normotensive extracellular volume contraction and hypokalemia.

Table 21–15. Metabolic alkalosis.

Saline-Responsive ($U_{\text{Cl}} < 25$ mEq/L)	Saline-Unresponsive ($U_{\text{Cl}} > 40$ mEq/L)
Excessive body bicarbonate content Renal alkalosis Diuretic therapy Poorly reabsorbable anion therapy: carbenicillin, penicillin, sulfate, phosphate Posthypercapnia Gastrointestinal alkalosis Loss of HCl from vomiting or nasogastric suction Intestinal alkalosis: chloride diarrhea NaHCO_3 (baking soda) Sodium citrate, lactate, gluconate, acetate Transfusions Antacids Normal body bicarbonate content “Contraction alkalosis”	Excessive body bicarbonate content Renal alkalosis Normotensive Bartter syndrome (renal salt wasting and secondary hyperaldosteronism) Severe potassium depletion Refeeding alkalosis Hypercalcemia and hypoparathyroidism Hypertensive Endogenous mineralocorticoids Primary aldosteronism Hyperreninism Adrenal enzyme deficiency: 11- and 17-hydroxylase Liddle syndrome Exogenous alkali Exogenous mineralocorticoids Licorice

Modified and reproduced, with permission, from Narins RG et al. Diagnostic strategies in disorders of fluid, electrolyte and acid-base homeostasis. *Am J Med.* 1982 Mar;72(3):496–520.

Hypotension and orthostasis may be seen. In vomiting or nasogastric suction, loss of acid (HCl) initiates the alkalosis, but volume contraction from Cl^- loss maintains the alkalosis because the kidney avidly reabsorbs Na^+ to restore the ECF. Increased sodium reabsorption necessitates increased HCO_3^- reabsorption proximally, and the urinary pH remains acidic despite alkalemia (paradoxical aciduria). Renal Cl^- reabsorption is high, and urine Cl^- is low ($< 10\text{--}20$ mEq/L). In alkalosis, bicarbonaturia may force Na^+ excretion as the accompanying cation even if volume depletion is present. Therefore, urine Cl^- is preferred to urine Na^+ as a measure of extracellular volume. Diuretics may limit the utility of urine chloride by increasing urine chloride and sodium excretion, even in the setting of volume contraction.

Metabolic alkalosis is generally associated with hypokalemia due to the direct effect of alkalosis on renal potassium excretion and secondary hyperaldosteronism from volume depletion. Hypokalemia exacerbates the metabolic alkalosis by increasing bicarbonate reabsorption in the proximal tubule and hydrogen ion secretion in the distal tubule. Administration of KCl will correct the disorder.

1. Contraction alkalosis—Diuretics decrease extracellular volume from urinary loss of NaCl and water. The plasma HCO_3^- concentration increases because the extracellular fluid volume contracts around a stable total body bicarbonate. Contraction alkalosis is the opposite of dilutional acidosis.

2. Posthypercapnia alkalosis—In chronic respiratory acidosis, the kidney decreases bicarbonate excretion, increasing plasma HCO_3^- concentration (Table 21–12). Hypercapnia directly affects the proximal tubule to decrease NaCl reabsorption, which can cause extracellular volume depletion. If PCO_2 is rapidly corrected, metabolic alkalosis will exist until the kidney excretes the retained bicarbonate. Many patients with chronic respiratory acidosis receive diuretics, which further exacerbates the metabolic alkalosis.

B. Saline-Unresponsive Alkalosis

1. Hyperaldosteronism—Primary hyperaldosteronism causes extracellular volume expansion and hypertension by increasing distal sodium reabsorption. Aldosterone increases H^+ and K^+ excretion, producing metabolic alkalosis and hypokalemia. In an attempt to decrease extracellular volume, high levels of NaCl are excreted with a high urine Cl^- (> 20 mEq/L). Therapy with NaCl will increase volume expansion and hypertension and will not treat the underlying problem of mineralocorticoid excess.

2. Alkali administration with decreased GFR—The normal kidney has a substantial capacity for bicarbonate excretion, protecting against metabolic alkalosis even with large HCO_3^- intake. However, urinary excretion of bicarbonate is inadequate in CKD. If large amounts of HCO_3^- are consumed, as with intensive antacid therapy, metabolic alkalosis will occur. Lactate, citrate, and gluconate can also cause metabolic alkalosis because they are metabolized to bicarbonate. In milk-alkali syndrome, sustained heavy ingestion of absorbable antacids and milk causes hypercalcemic

kidney injury and metabolic alkalosis. Volume contraction from renal hypercalcemic effects exacerbates the alkalosis.

► Clinical Findings

A. Symptoms and Signs

There are no characteristic symptoms or signs. Orthostatic hypotension may be encountered. Concomitant hypokalemia may cause weakness and hyporeflexia. Tetany and neuromuscular irritability occur rarely.

B. Laboratory Findings

The arterial blood pH and bicarbonate are elevated. With respiratory compensation, the arterial Pco_2 is increased. Serum potassium and chloride are decreased. There may be an increased anion gap. The urine chloride can differentiate between saline-responsive (< 25 mEq/L) and unresponsive (> 40 mEq/L) causes.

► Treatment

Mild alkalosis is generally well tolerated. Severe or symptomatic alkalosis (pH > 7.60) requires urgent treatment.

A. Saline-Responsive Metabolic Alkalosis

Therapy for saline-responsive metabolic alkalosis is correction of the extracellular volume deficit with isotonic saline. Diuretics should be discontinued. H_2 -blockers or proton pump inhibitors may be helpful in patients with alkalosis from nasogastric suctioning. If pulmonary or cardiovascular disease prohibits adequate resuscitation, acetazolamide will increase renal bicarbonate excretion. Hypokalemia may develop because bicarbonate excretion may induce kaliuresis. Severe cases, especially those with reduced kidney function, may require dialysis with low-bicarbonate dialysate.

B. Saline-Unresponsive Metabolic Alkalosis

Therapy for saline-unresponsive metabolic alkalosis includes surgical removal of a mineralocorticoid-producing tumor and blockage of aldosterone effect with an ACE inhibitor or with spironolactone. Metabolic alkalosis in primary aldosteronism can be treated only with potassium repletion.

RESPIRATORY ACIDOSIS (HYPERCAPNIA)

Respiratory acidosis results from hypoventilation and subsequent hypercapnia. Pulmonary and extrapulmonary disorders can cause hypoventilation.

Acute respiratory failure is associated with severe acidosis and only a small increase in the plasma bicarbonate. After 6–12 hours, the primary increase in PCO_2 evokes a renal compensation to excrete more acid and to generate more HCO_3^- ; complete metabolic compensation by the kidney takes several days.

Chronic respiratory acidosis is generally seen in patients with underlying lung disease, such as chronic obstructive pulmonary disease. Renal excretion of acid as NH_4Cl results in hypochloremia. When chronic respiratory acidosis is corrected suddenly, posthypercapnic metabolic alkalosis ensues until the kidneys excrete the excess bicarbonate over 2–3 days.

► Clinical Findings

A. Symptoms and Signs

With acute onset, somnolence, confusion, mental status changes, asterixis, and myoclonus may develop. Severe hypercapnia increases cerebral blood flow, cerebrospinal fluid pressure, and intracranial pressure; papilledema and pseudotumor cerebri may be seen.

B. Laboratory Findings

Arterial pH is low and PCO_2 is increased. Serum HCO_3^- is elevated but does not fully correct the pH. If the disorder is chronic, hypochloremia is seen.

► Treatment

If opioid overdose is a possible diagnosis or there is no other obvious cause for hypoventilation, the clinician should consider a diagnostic and therapeutic trial of intravenous naloxone (see Chapter 38). In all forms of respiratory acidosis, treatment is directed at the underlying disorder to improve ventilation.

RESPIRATORY ALKALOSIS (HYPOCAPNIA)

Respiratory alkalosis occurs when hyperventilation reduces the PCO_2 , increasing serum pH. The most common cause of respiratory alkalosis is hyperventilation syndrome (Table 21–16), but bacterial septicemia and cirrhosis are other common causes. In pregnancy, progesterone stimulates the respiratory center, producing an average PCO_2 of 30 mm Hg and respiratory alkalosis. Symptoms of acute respiratory alkalosis are related to decreased cerebral blood flow induced by the disorder.

Determination of appropriate metabolic compensation may reveal an associated metabolic disorder (see above under Mixed Acid–Base Disorders).

Table 21–16. Causes of respiratory alkalosis.

Hypoxia

- Decreased inspired oxygen tension
- High altitude
- Ventilation/perfusion inequality
- Hypotension
- Severe anemia

CNS-mediated disorders

- Voluntary hyperventilation
- Anxiety-hyperventilation syndrome
- Neurologic disease
- Cerebrovascular accident (infarction, hemorrhage)
- Infection
- Trauma
- Tumor
- Pharmacologic and hormonal stimulation
- Salicylates
- Nicotine
- Xanthines
- Pregnancy (progesterone)

- Hepatic failure
- Gram-negative septicemia
- Recovery from metabolic acidosis
- Heat exposure

Pulmonary disease

- Interstitial lung disease
- Pneumonia
- Pulmonary embolism
- Pulmonary edema

Mechanical overventilation

Adapted, with permission, from Gennari FJ. Respiratory acidosis and alkalosis. In: *Maxwell and Kleeman's Clinical Disorders of Fluid and Electrolyte Metabolism*, 5th ed. Narins RG (editor). McGraw-Hill, 1994.

As in respiratory acidosis, the metabolic compensation is greater if the respiratory alkalosis is chronic (Table 21–12). Although serum HCO_3^- is frequently < 15 mEq/L in metabolic acidosis, such a low level in respiratory alkalosis is unusual and may represent a concomitant primary metabolic acidosis.

► Clinical Findings

A. Symptoms and Signs

In acute cases (hyperventilation), there is light-headedness, anxiety, perioral numbness, and paresthesias. Tetany occurs from a low ionized calcium, since severe alkalosis increases calcium binding to albumin.

B. Laboratory Findings

Arterial blood pH is elevated, and PCO_2 is low. Serum bicarbonate is decreased in chronic respiratory alkalosis.

► Treatment

Treatment is directed toward the underlying cause. In acute hyperventilation syndrome from anxiety, the traditional treatment of breathing into a paper bag should be discouraged because it does not correct PCO_2 and may decrease PO_2 . Reassurance may be sufficient for the

Table 21-17. Replacement guidelines for sweat and gastrointestinal fluid losses.

	Average Electrolyte Composition				Replacement Guidelines per Liter Lost				
	Na ⁺ (mEq/L)	K ⁺ (mEq/L)	Cl ⁻ (mEq/L)	HCO ₃ ⁻ (mEq/L)	0.9% Saline (mL)	0.45% Saline (mL)	D ₃ W (mL)	KCl (mEq/L)	7.5% NaHCO ₃ (45 mEq HCO ₃ ⁻ /amp)
Sweat	30-50	5	50			500	500	5

Duodenal fluid	60	15	100	10		1000		15	0.25 amp
Ileal fluid	100	10	60	60		600	400	10	1 amp
Colonic diarrhea	140 ¹	10	85	60		1000		10	1 amp

¹In the absence of diarrhea, colonic fluid Na⁺ levels are low (40 mEq/L).

anxious patient, but sedation may be necessary if the process persists. Hyperventilation is usually self-limited since muscle weakness caused by the respiratory alkalemia will suppress ventilation. Rapid correction of chronic respiratory alkalosis may result in metabolic acidosis as PCO₂ is increased in the setting of a previous compensatory decrease in HCO₃⁻.

FLUID MANAGEMENT

Daily parenteral maintenance fluids and electrolytes for an average adult would include 2500–3000 mL of 5% dextrose in 0.2% saline solution (34 mEq Na⁺ plus 34 mEq Cl⁻/L)

with 30 mEq/L of KCl. Guidelines for gastrointestinal fluid losses are shown in Table 21-17.

Weight loss or gain is the best indication of water balance. Insensible water loss should be considered in febrile patients. Water loss increases by 100–150 mL/d for each degree of body temperature over 37°C.

In patients requiring maintenance and possibly replacement of fluid and electrolytes by parenteral infusion, the total daily ration should be administered continuously over 24 hours to ensure optimal utilization.

If intravenous fluids are the only source of water, electrolytes, and calories for longer than a week, parenteral nutrition containing amino acids, lipids, trace metals, and vitamins may be indicated. (See Chapter 29.)

For parenteral alimentation, 620 mg (20 mmol) of phosphorus is required for every 1000 nonprotein kcal to maintain phosphate balance and to ensure anabolic function. For prolonged parenteral fluid maintenance, a daily ration is 620–1240 mg (20–40 mmol) of phosphorus.

22

Kidney Disease

Suzanne Watnick, MD
Tonja Dirx, MD

Kidney disease can be discovered incidentally during a routine medical evaluation or with evidence of kidney dysfunction, such as hypertension, edema, nausea, or hematuria. The initial approach in both situations should be to assess the cause and severity of renal abnormalities. In all cases this evaluation includes (1) an estimation of disease duration, (2) a careful urinalysis, and (3) an assessment of the glomerular filtration rate (GFR). The history and physical examinations, though equally important, are variable among renal syndromes—thus, specific symptoms and signs are discussed under each disease entity.

ASSESSMENT OF KIDNEY DISEASE

Disease Duration

Kidney disease may be acute or chronic. Acute kidney injury, also known as acute renal failure, is worsening of kidney function over hours to days, resulting in the retention of nitrogenous wastes (such as urea nitrogen) and creatinine in the blood. Retention of these substances is called azotemia. Chronic kidney disease (CKD) results from an abnormal loss of kidney function over months to years. Differentiating between the two is important for diagnosis, treatment, and outcome. Oliguria is unusual in CKD. Anemia (from low kidney erythropoietin production) is rare in the initial period of acute kidney disease. Small kidneys are most consistent with CKD, whereas normal to large-size kidneys can be seen with both chronic and acute disease.

Urinalysis

A urinalysis can provide information similar to a renal biopsy in a way that is cost-effective and, of course, noninvasive. The urine is collected in midstream or, if that is not feasible, by bladder catheterization. The urine should be examined within 1 hour after collection to avoid destruction of formed elements. Urinalysis includes a dipstick examination followed by microscopic assessment if the dipstick has positive findings. The dipstick examination measures urinary pH, protein, hemoglobin, glucose,

ketones, bilirubin, nitrites, and leukocyte esterase. Urinary specific gravity is often reported, too. Microscopy searches for all formed elements—crystals, cells, casts, and infecting organisms.

Various findings on the urinalysis are indicative of certain patterns of kidney disease. A bland (normal) urinary sediment is common, especially in CKD and acute disorders that are not intrinsic to the kidney, such as limited effective blood flow to the kidney or obstruction of outflow of urine. Casts are composed of Tamm-Horsfall urinary mucoprotein in the shape of the nephron segment where they were formed. Heavy proteinuria and lipiduria are consistent with the nephrotic syndrome. The presence of hematuria with dysmorphic red blood cells, red blood cell casts, and proteinuria is indicative of glomerulonephritis. Dysmorphic red blood cells are misshapen during abnormal passage from the capillary through the glomerular basement membrane (GBM) into the urinary space of Bowman capsule. Pigmented granular casts and renal tubular epithelial cells alone or in casts suggest acute tubular necrosis. White blood cells, including neutrophils and eosinophils, white blood cell casts (Table 22–1), red blood cells, and small amounts of protein can be found in interstitial nephritis and pyelonephritis; Wright and Hansel stains can detect eosinophiluria. Pyuria alone can indicate a urinary tract infection. Hematuria and proteinuria are discussed more thoroughly below.

A. Proteinuria

Proteinuria is defined as excessive protein excretion in the urine, generally > 150–160 mg/24 h in adults. Significant proteinuria is a sign of an underlying kidney abnormality, usually glomerular in origin when > 1 g/d to < 2 g/d. Less than 1 g/d can be due to multiple causes along the nephron segment, as listed below. Proteinuria can be accompanied by other clinical abnormalities—elevated blood urea nitrogen (BUN) and serum creatinine levels, abnormal urinary sediment, or evidence of systemic illness (eg, fever, rash, vasculitis).

There are several reasons for development of proteinuria: (1) **Functional proteinuria** is a benign process stemming from stressors such as acute illness, exercise, and

Table 22-1. Significance of specific urinary casts.

Type	Significance
Hyaline casts	Concentrated urine, febrile disease, after strenuous exercise, in the course of diuretic therapy (not indicative of renal disease)
Red cell casts	Glomerulonephritis
White cell casts	Pyelonephritis, interstitial nephritis (indicative of infection or inflammation)
Renal tubular cell casts	Acute tubular necrosis, interstitial nephritis
Coarse, granular casts	Nonspecific; can represent acute tubular necrosis
Broad, waxy casts	Chronic kidney disease (indicative of stasis in enlarged collecting tubules)

“orthostatic proteinuria.” The latter condition, generally found in people under age 30 years, usually results in urinary protein excretion of < 1 g/d. The orthostatic nature of the proteinuria is confirmed by measuring an 8-hour overnight supine urinary protein excretion, which should be < 50 mg. (2) **Overload proteinuria** can result from overproduction of circulating, filterable plasma proteins (monoclonal gammopathies), such as Bence Jones proteins associated with multiple myeloma. Urinary protein electrophoresis will exhibit a discrete protein peak. Other examples of overload proteinuria include myoglobinuria in rhabdomyolysis and hemoglobinuria in hemolysis. (3) **Glomerular proteinuria** results from effacement of epithelial cell foot processes and altered glomerular permeability with an increased filtration fraction of normal plasma proteins. Glomerular diseases exhibit some degree of proteinuria. The urinary protein electrophoresis will have a pattern exhibiting a large albumin spike indicative of increased permeability of albumin across a damaged GBM. (4) **Tubular proteinuria** occurs as a result of faulty reabsorption of normally filtered proteins in the proximal tubule, such as β_2 -microglobulin and immunoglobulin light chains. Causes include acute tubular necrosis, toxic injury (lead, aminoglycosides), drug-induced interstitial nephritis, and hereditary metabolic disorders (Wilson disease and Fanconi syndrome).

Evaluation of proteinuria by urinary dipstick primarily detects albumin, while overlooking positively charged light chains of immunoglobulins. These proteins can be detected by the addition of sulfosalicylic acid to the urine specimen. Precipitation without dipstick detection of albumin indicates the presence of paraproteins.

The next step is an estimation of proteinuria from a 24-hour urine collection. A finding of > 150–160 mg/24 h is abnormal, and > 3.5 g/24 h is consistent with nephrotic-range proteinuria. The simplest method is to collect a random urine sample. The ratio of urinary protein concentration to urinary creatinine concentration ($[U_{\text{protein}}]/[U_{\text{creatinine}}]$) correlates with 24-hour urine protein collection (< 0.2 is normal and corresponds to excretion of < 200

mg/24 h). The benefit of a urine protein-to-creatinine ratio is the ease of collection and the lack of error from overcollection or undercollection of urine. If a patient has proteinuria with or without loss of kidney function, kidney biopsy may be indicated, particularly if the kidney disease is acute in onset. The clinical consequences of proteinuria are discussed in the section Nephrotic Spectrum Glomerular Diseases below.

B. Hematuria

Hematuria is significant if there are more than three red cells per high-power field on at least two occasions. It is usually detected incidentally by the urine dipstick examination or clinically following an episode of macroscopic hematuria. The diagnosis must be confirmed via microscopic examination, as false-positive dipstick tests can be caused by myoglobin, oxidizing agents, beets and rhubarb, hydrochloric acid, and bacteria. Transient hematuria is common, but in patients younger than 40 years, it is less often of clinical significance due to lower concern for malignancy.

Hematuria may be due to renal or extrarenal causes. Extrarenal causes are addressed in Chapters 23 and 39; most worrisome are urologic malignancies. Renal causes account for approximately 10% of cases and are best considered anatomically as glomerular or nonglomerular. The most common extraglomerular sources include cysts, calculi, interstitial nephritis, and renal neoplasia. Glomerular causes include immunoglobulin A (IgA) nephropathy, thin GBM disease, membranoproliferative glomerulonephritis (MPGN), other hereditary glomerular diseases (eg, Alport syndrome), and systemic nephritic syndromes.

Currently, the United States Health Preventive Services Task Force does not recommend screening for hematuria. See Chapter 23 for evaluation of hematuria.

▶ Estimation of GFR

The GFR provides a useful index of kidney function at the level of the glomerulus. Patients with kidney disease can have a decreased GFR from any process that causes loss of nephron (and thus glomerular) mass. However, they can also have a normal or increased GFR, either from hyperfiltration at the glomerulus or disease at a different segment of the nephron, interstitium, or vascular supply. The GFR measures the amount of plasma ultrafiltered across the glomerular capillaries and correlates with the ability of the kidneys to filter fluids and various substances. Daily GFR in normal individuals is variable, with a range of 150–250 L/24 h or 100–120 mL/min/1.73 m² of body surface area. GFR can be measured indirectly by determining the renal clearance of plasma substances that are not bound to plasma proteins, are freely filterable across the glomerulus, and are neither secreted nor reabsorbed along the renal tubules. The formula used to determine the renal clearance of a substance is

$$C = \frac{U \times \dot{V}}{P}$$

where C is the clearance, U and P are the urine and plasma concentrations of the substance (mg/dL), and \dot{V} is the urine

flow rate (mL/min). In clinical practice, the clearance rate of endogenous creatinine, the creatinine clearance, is one way of estimating GFR. Creatinine is a product of muscle metabolism produced at a relatively constant rate and cleared by renal excretion. It is freely filterable by the glomerulus and not reabsorbed by the renal tubules. With stable kidney function, creatinine production and excretion are equal; thus, plasma creatinine concentrations remain constant. However, it is not a perfect indicator of GFR for the following reasons: (1) A small amount is normally eliminated by tubular secretion, and the fraction secreted progressively increases as GFR declines (overestimating GFR); (2) with severe kidney failure, gut microorganisms degrade creatinine; (3) an individual's meat intake and muscle mass affect baseline plasma creatinine levels; (4) commonly used drugs such as aspirin, cimetidine, probenecid, and trimethoprim reduce tubular secretion of creatinine, increasing the plasma creatinine concentration and falsely indicating kidney dysfunction; and (5) the accuracy of the measurement necessitates a stable plasma creatinine concentration over a 24-hour period, so that during the development of and recovery from acute kidney injury, when the serum creatinine is changing, the creatinine clearance is of questionable value (Table 22–2). Of note, the creatinine clearance is the traditional estimation equation used for consideration of drug dosing in patients with kidney disease.

One way to measure creatinine clearance is to collect a timed urine sample and determine the plasma creatinine level midway through the collection. An incomplete or prolonged urine collection is a common source of error. One way of estimating the completeness of the collection is to calculate a 24-hour creatinine excretion; the amount should be constant:

$$U_{cr} \times \dot{V} = 15\text{--}20 \text{ mg/kg for healthy young women}$$

$$U_{cr} \times \dot{V} = 20\text{--}25 \text{ mg/kg for healthy young men}$$

The creatinine clearance (C_{cr}) is approximately 100 mL/min/1.73 m² in healthy young women and 120 mL/min/1.73 m² in healthy young men. The C_{cr} declines by an

average of 0.8 mL/min/yr after age 40 years as part of the aging process, but 35% of subjects in one study had no decline in kidney function over 10 years.

C_{cr} can be estimated from the formula of Cockcroft and Gault, which incorporates age, sex, and weight to estimate C_{cr} from plasma creatinine levels without any urinary measurements:

$$C_{cr} = \frac{(140 - \text{Age}) \times \text{Weight (kg)}}{P_{cr} \times 72}$$

For women, the creatinine clearance is multiplied by 0.85 because muscle mass is less. This formula overestimates GFR in patients who are obese or edematous and is most accurate when normalized for body surface area of 1.73 m².

BUN is another index used in assessing kidney function. It is synthesized mainly in the liver and is the end product of protein catabolism. Urea is freely filtered by the glomerulus, and about 30–70% is reabsorbed in the renal tubules. Unlike creatinine clearance, which overestimates GFR, urea clearance underestimates GFR. Urea reabsorption may be decreased in volume replete patients, whereas volume depletion causes increased urea reabsorption, in conjunction with increased sodium reabsorption, from the kidney, increasing BUN. A normal BUN:creatinine ratio is 10:1, although this can vary between individuals. With volume depletion, the ratio can increase to 20:1 or higher. Other causes of increased BUN include increased catabolism (gastrointestinal [GI] bleeding, cell lysis, and corticosteroid usage), increased dietary protein, and decreased renal perfusion (congestive heart failure, renal artery stenosis) (Table 22–3). Reduced BUN is seen in liver disease and in the syndrome of inappropriate antidiuretic hormone (SIADH) secretion.

As patients approach end-stage renal disease (ESRD), a more accurate measure of GFR than creatinine clearance is the average of the creatinine and urea clearances. The creatinine clearance overestimates GFR, as mentioned above, while the urea clearance underestimates GFR. Therefore, an average of the two more accurately approximates the true GFR.

The four-variable estimated GFR is a complex equation, including serum creatinine, age, weight, and race, that is often reported alongside serum creatinine measurements

Table 22–2. Conditions affecting serum creatinine independently of glomerular filtration rate.

Condition	Mechanism
Conditions elevating creatinine	
Ketoacidosis, cephalothin, cefoxitin, flucytosine	Noncreatinine chromogen
Other drugs: aspirin, cimetidine, probenecid, trimethoprim	Inhibition of tubular creatinine secretion
Conditions decreasing creatinine	
Advanced age	Physiologic decrease in muscle mass
Cachexia	Pathologic decrease in muscle mass
Liver disease	Decreased hepatic creatine synthesis and cachexia

Table 22–3. Conditions affecting BUN independently of GFR.

Increased BUN

Reduced effective circulating blood volume (prerenal azotemia)
Catabolic states (gastrointestinal bleeding, corticosteroid use)
High-protein diets
Tetracycline

Decreased BUN

Liver disease
Malnutrition
Sickle cell anemia
SIADH

BUN, blood urea nitrogen; GFR, glomerular filtration rate; SIADH, syndrome of inappropriate antidiuretic hormone.

and more accurate than creatinine or urea clearance. This was derived from data collected for the Modification of Diet and Renal Disease (MDRD) study and has been validated in several other populations. Many laboratories will report a value for the estimated GFR in addition to a serum creatinine. Several web-based calculators will calculate this; one location is www.nephron.com.

Other useful, well-validated estimators of GFR include the CKD-EPI formula. This is more accurate and precise than the MDRD equation at higher levels of true GFR, possibly decreasing false-positive results. This formula may perform better in elderly populations; however, this estimation equation did not include large numbers of nonwhite patients.

Cystatin C is another endogenous marker of GFR, filtered freely at the glomerulus and produced at a relatively constant rate, irrespective of muscle mass. It is reabsorbed and partially metabolized in the renal tubular epithelial cells. Studies show less variability with age, gender, or race for cystatin C versus serum creatinine.

RENAL BIOPSY

Indications for percutaneous needle biopsy include (1) unexplained acute kidney injury or CKD; (2) acute nephritic syndromes; (3) unexplained proteinuria and hematuria; (4) previously identified and treated lesions to plan future therapy; (5) systemic diseases associated with kidney dysfunction, such as systemic lupus erythematosus, Goodpasture syndrome, and granulomatosis with polyangiitis (formerly Wegener granulomatosis), to confirm the extent of renal involvement and to guide management; (6) suspected transplant rejection, to differentiate it from other causes of acute kidney injury; and (7) to guide treatment. If a patient is unwilling to accept therapy based on biopsy findings, the risk of biopsy may outweigh its benefit. Relative contraindications include a solitary or ectopic kidney (exception: transplant allografts), horseshoe kidney, ESRD, congenital anomalies, and multiple cysts. Absolute contraindications include an uncorrected bleeding disorder, severe uncontrolled hypertension, renal infection, renal neoplasm, hydronephrosis, or an uncooperative patient.

Prior to biopsy, patients should not use medications that prolong clotting times and should have well-controlled blood pressure. Blood work should include a hemoglobin, platelet count, prothrombin time, and partial thromboplastin time. After biopsy, hematuria occurs in nearly all patients. Less than 10% will have macroscopic hematuria. Patients should remain supine for 4–6 hours postbiopsy. A patient with a 6-hour postbiopsy hematocrit > 3% lower than baseline should be closely monitored.

Percutaneous kidney biopsies are generally safe. Approximately 1% of patients will experience significant bleeding requiring blood transfusions. More than half of patients will have at least a small hematoma. Risk of major bleeding persists up to 72 hours after the biopsy. Any type of anticoagulation therapy should be held for 5–7 days postbiopsy if possible. The risks of nephrectomy and mortality are about 0.06–0.08%. When a percutaneous needle biopsy is technically not feasible and

renal tissue is deemed clinically essential, a closed renal biopsy via interventional radiologic techniques or open renal biopsy under general anesthesia can be done.

ACUTE KIDNEY INJURY (ACUTE RENAL FAILURE)

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden increase in BUN or serum creatinine.
- ▶ Oliguria can be associated.
- ▶ Symptoms and signs depend on cause.

▶ General Considerations

Acute kidney injury, also known as acute renal failure, is defined as a sudden decrease in kidney function, resulting in an inability to maintain acid-base, fluid and electrolyte balance and to excrete nitrogenous wastes. Serum creatinine is a convenient marker. A clinically applicable definition of acute kidney injury has been developed. The RIFLE criteria describe three progressive levels of acute kidney injury (risk, injury, and failure) based on the elevation in serum creatinine or decline in urinary output with two outcome measures (loss and ESRD). Risk, injury, and failure are defined, respectively, as a 1.5-fold increase in serum creatinine, a twofold or threefold increase in serum creatinine, or a decline in urinary output to 0.5 mL/kg/h over 6, 12, or 24 hours. These definitions were created by an international consensus panel and correlate with prognosis. The AKIN criteria are also predictive of outcomes, and closely follow the RIFLE criteria, with the addition of a change in serum creatinine of ≥ 0.3 mg/day qualifying as a risk for injury. In the absence of functioning kidneys, serum creatinine concentration will typically increase by 1–1.5 mg/dL daily, although with certain conditions, such as rhabdomyolysis, serum creatinine can increase more rapidly. On average, 5% of hospital admissions and 30% of intensive care unit (ICU) admissions carry a diagnosis of acute kidney injury, and it will develop in 25% of hospitalized patients. Patients with

acute kidney injury of any type are at higher risk for all-cause mortality according to recent prospective cohorts, whether or not there is substantial renal recovery.

► Clinical Findings

A. Symptoms and Signs

The uremic milieu of acute kidney injury can cause nonspecific symptoms. When present, symptoms are often due to uremia or its underlying cause. Uremia can cause nausea, vomiting, malaise, and altered sensorium. Hypertension can occur, and fluid homeostasis is often altered. Hypovolemia can cause states of low blood flow to the kidneys, sometimes termed “prerenal” states, whereas hypervolemia can result from intrinsic or “postrenal” disease. Pericardial effusions can occur with uremia, and a pericardial friction rub can be present. Effusions may result in cardiac tamponade. Arrhythmias occur, especially with hyperkalemia. The lung examination may show rales in the presence of hypervolemia. Acute kidney failure can cause nonspecific diffuse abdominal pain and ileus as well as platelet dysfunction; thus, bleeding and clotting disorders are more common in these patients. The neurologic examination reveals encephalopathic changes with asterixis and confusion; seizures may ensue.

B. Laboratory Findings

Elevated BUN and serum creatinine levels are present, though these elevations do not distinguish acute kidney disease from CKD. Hyperkalemia can occur from impaired renal potassium excretion. With hyperkalemia, the ECG can reveal peaked T waves, PR prolongation, and QRS widening. A long QT segment can occur with hypocalcemia. Anion gap and non-gap metabolic acidosis (due to decreased organic and nonorganic acid clearance) is often noted. Hyperphosphatemia occurs when phosphorus

cannot be secreted by damaged tubules either with or without increased cell catabolism. Metastatic calcium phosphate deposition may be observed when the product of calcium and phosphorus is elevated (eg, exceeding $55\text{--}65\text{ mg}^2/\text{dL}^2$). Anemia can occur as a result of decreased erythropoietin production over weeks, and associated platelet dysfunction is typical.

► Classification & Etiology

Acute kidney injury can be divided into three categories: prerenal causes (renal hypoperfusion leading to lower GFR), intrinsic renal disease, and postrenal causes (obstructive uropathy). Identifying the cause is the first step toward treating the patient (Table 22–4).

A. Prerenal Causes

Prerenal causes are the most common reason for acute kidney insults and injury, accounting for 40–80% of cases, depending on the population studied. Prerenal azotemia is due to renal hypoperfusion, which is an appropriate physiologic change. If it can be immediately reversed with restoration of renal blood flow, renal parenchymal damage often does not occur. If hypoperfusion persists, ischemia can result, causing intrinsic kidney injury.

Decreased renal perfusion can occur in several ways, such as a decrease in intravascular volume, a change in vascular resistance, or low cardiac output. Causes of volume depletion include hemorrhage, GI losses, dehydration, excessive diuresis, extravascular space sequestration, pancreatitis, burns, trauma, and peritonitis.

Changes in vascular resistance can occur systemically with sepsis, anaphylaxis, anesthesia, and afterload-reducing drugs. Blockers of the renin-angiotensin-aldosterone system, such as angiotensin-converting enzyme (ACE) inhibitors, prevent efferent renal arteriolar constriction out of

Table 22–4. Classification and differential diagnosis of acute kidney injury.

	Prerenal Azotemia	Postrenal Azotemia	Intrinsic Renal Disease		
			Acute Tubular Necrosis (Oliguric or Polyuric)	Acute Glomerulonephritis	Acute Interstitial Nephritis
Etiology	Poor renal perfusion	Obstruction of the urinary tract	Ischemia, nephrotoxins	Immune complex-mediated, pauci-immune, anti-GBM related	Allergic reaction; drug reaction; infection, collagen vascular disease
Serum BUN:Cr ratio	> 20:1	> 20:1	< 20:1	> 20:1	< 20:1
Urinary indices					
U _{Na} (mEq/L)	< 20	Variable	> 20	< 20	Variable
FE _{Na} (%)	< 1	Variable	> 1 (when oliguric)	< 1	< 1; > 1
Urine osmolality (mosm/kg)	> 500	< 400	250–300	Variable	Variable
Urinary sediment	Benign or hyaline casts	Normal or red cells, white cells, or crystals	Granular (muddy brown) casts, renal tubular casts	Red cells, dysmorphic red cells and red cell casts	White cells, white cell casts, with or without eosinophils

BUN:Cr, blood urea nitrogen:creatinine ratio; FE_{Na}, fractional excretion of sodium; U_{Na}, urinary concentration of sodium.

proportion to the afferent arteriolar constriction; thus, GFR will decrease with these medications. Nonsteroidal anti-inflammatory drugs (NSAIDs) prevent afferent arteriolar vasodilation by inhibiting prostaglandin-mediated signals. Thus, in cirrhosis and congestive heart failure, when prostaglandins are recruited to increase renal blood flow, NSAIDs will have particularly deleterious effects. Epinephrine, norepinephrine, high-dose dopamine, anesthetic agents, and cyclosporine also can cause renal vasoconstriction. Renal artery stenosis causes increased resistance and decreased renal perfusion.

Low cardiac output is a state of low effective renal arterial blood flow. This occurs in states of cardiogenic shock, congestive heart failure, pulmonary embolism, and pericardial tamponade. Arrhythmias and valvular disorders can also reduce cardiac output. In the ICU setting, positive pressure ventilation will decrease venous return, also decreasing cardiac output.

When GFR falls acutely, it is important to determine whether acute kidney injury is due to prerenal or intrinsic renal causes. The history and physical examination are important, and urinalysis can be helpful. The BUN:creatinine ratio will typically exceed 20:1 due to increased urea reabsorption. In an oliguric patient, another useful index is the fractional excretion of sodium (FE_{NA}). With decreased GFR, the kidney will reabsorb salt and water avidly if there is no intrinsic tubular dysfunction. Thus, patients with prerenal causes should have a low fractional excretion percent of sodium (< 1%). Oliguric patients with intrinsic kidney dysfunction typically have a high fractional excretion of sodium (> 1–2%). The FE_{NA} is calculated as follows: FE_{NA} = clearance of Na^+ /GFR = clearance of Na^+ / C_{cr} :

$$FE_{NA} = \frac{\text{Urine}_{NA} \times \text{Serum}_{cr}}{\text{Urine}_{cr} \times \text{Serum}_{NA}} \times 100$$

Renal sodium handling is more accurately assessed by the FE_{NA} in oliguric states than in nonoliguric states because the FE_{NA} could be relatively low in nonoliguric acute tubular necrosis if sodium intake and excretion are relatively low. (Oliguria is defined as urinary output < 400–500 mL/d, or < 20 mL/h.) Diuretics can cause increased sodium excretion. Thus, if the FE_{NA} is high within 12–24 hours after diuretic administration, the cause of acute kidney injury may not be accurately predicted. Acute kidney injury due to glomerulonephritis can have a low FE_{NA} because sodium reabsorption and tubular function may not be compromised.

Treatment of prerenal insults depends entirely on the causes, but maintenance of euvolemia, attention to serum potassium, and avoidance of nephrotoxic drugs are benchmarks of therapy. This involves careful assessment of volume status, cardiac function, diet, and drug usage.

B. Postrenal Causes

Postrenal causes are the least common reason for acute kidney injury, accounting for approximately 5–10% of cases, but important to detect because of their reversibility. Postrenal azotemia occurs when urinary flow from both kidneys, or a single functioning kidney, is obstructed. Occasionally,

postrenal uropathies can occur when a single kidney is obstructed if the contralateral kidney cannot adjust for the loss in function, (eg, in a patient with advanced CKD). Obstruction leads to elevated intraluminal pressure, causing kidney parenchymal damage, with marked effects on renal blood flow and tubular function, and a decrease in GFR.

Postrenal causes include urethral obstruction, bladder dysfunction or obstruction, and obstruction of both ureters or renal pelvises. In men, benign prostatic hyperplasia is the most common cause. Patients taking anticholinergic drugs are particularly at risk. Obstruction can also be caused by bladder, prostate, and cervical cancers; retroperitoneal fibrosis and other processes; and neurogenic bladder. Less common causes are blood clots, bilateral ureteral stones, urethral stones or stricture, and bilateral papillary necrosis.

Patients may be anuric or polyuric and may complain of lower abdominal pain. Polyuria can occur in the setting of partial obstructions with resultant tubular dysfunction and an inability to appropriately reabsorb salt and water loads. Obstruction can be constant or intermittent and partial or complete. On examination, the patient may have an enlarged prostate, distended bladder, or mass detected on pelvic examination.

Laboratory examination may initially reveal high urine osmolality, low urine sodium, high BUN:creatinine ratio, and low FE_{NA} (as tubular function may not be compromised initially). These indices are similar to a prerenal picture because extensive intrinsic renal damage has not occurred. After several days, the urine sodium increases as the kidneys fail and are unable to concentrate the urine—thus, isosthenuria is present. The urine sediment is generally benign.

Patients with acute kidney injury and suspected postrenal insults should undergo bladder catheterization and ultrasonography to assess for hydronephrosis and hydronephrosis. After reversal of the underlying process, these patients often undergo a postobstructive saluresis and diuresis, and care should be taken to avoid volume depletion. Rarely, obstruction is not diagnosed by ultrasonography. For example, patients with retroperitoneal fibrosis from tumor or radiation may not show dilation of the urinary tract. If suspicion does exist, a CT scan or MRI can establish the diagnosis. Prompt treatment of obstruction within days by catheters, stents, or other surgical procedures can result in partial or complete reversal of the acute process.

C. Intrinsic Acute Kidney Injury

Intrinsic renal disorders account for up to 50% of all cases of acute kidney injury. Intrinsic dysfunction is considered after prerenal and postrenal causes have been excluded. The sites of injury are the tubules, interstitium, vasculature, and glomeruli.

▶ When to Refer

- If a patient has signs of acute kidney injury that have not reversed over 1–2 weeks, but no signs of acute uremia, the patient can usually be referred to a nephrologist rather than admitted.
- If a patient has signs of persistent urinary tract obstruction, the patient should be referred to a urologist.

▶ When to Admit

The patient should be admitted if there is sudden loss of kidney function resulting in abnormalities that cannot be handled expeditiously in an outpatient setting (eg, hyperkalemia, volume overload, uremia) or other requirements for acute intervention, such as emergent urologic intervention or dialysis.

ACUTE TUBULAR NECROSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Acute kidney injury.
- ▶ Ischemic or toxic insult.
- ▶ Urine sediment with pigmented granular casts and renal tubular epithelial cells is pathognomonic but not essential.

▶ General Considerations

Acute kidney injury due to tubular damage is termed “acute tubular necrosis” and accounts for approximately 85% of intrinsic acute kidney injury. The two major causes of acute tubular necrosis are ischemia and nephrotoxin exposure. Ischemia causes tubular damage from states of prolonged low kidney perfusion, often termed a “prerenal” state, with resultant tubular necrosis and apoptosis. Ischemic acute kidney injury is characterized not only by inadequate GFR but also by renal blood flow inadequate to maintain parenchymal cellular formation. This occurs in the setting of prolonged hypotension or hypoxemia, such as volume depletion, shock, and sepsis. Major surgical procedures can involve prolonged periods of hypoperfusion, which are exacerbated by vasodilating anesthetic agents. Aside from the serum creatinine, other urinary and serum biomarkers, including neutrophil gelatinase-associated lipocalin and cystatin C, are being investigated in order to diagnose and treat acute kidney injury earlier in its course, with the potential for better outcomes.

Exogenous nephrotoxins more commonly cause damage than endogenous nephrotoxins.

A. Exogenous Nephrotoxins

Aminoglycosides cause some degree of acute tubular necrosis in up to 25% of hospitalized patients receiving

therapeutic levels of the drugs. Nonoliguric kidney injury typically starts to occur after 5–10 days of exposure. Predisposing factors include underlying kidney damage, volume depletion, and advanced age. Aminoglycosides can remain in renal tissues for up to a month, so kidney function may not recover for some time after stopping the medication. Monitoring of peak and trough levels is important, but trough levels are more helpful in predicting renal toxicity. Gentamicin is as nephrotoxic as tobramycin; streptomycin is the least nephrotoxic of the aminoglycosides, likely due to the number of cationic amino side chains present on each molecule.

Amphotericin B is typically nephrotoxic after a dose of 2–3 g. This causes a type I renal tubular acidosis with severe vasoconstriction and distal tubular damage, which can lead to hypokalemia and nephrogenic diabetes insipidus. **Vancomycin**, intravenous **acyclovir**, and several **cephalosporins** have been known to cause acute tubular necrosis.

Radiographic contrast media may be directly nephrotoxic. Contrast nephropathy is the third leading cause of new acute kidney injury in hospitalized patients. It probably results from the synergistic combination of direct renal tubular epithelial cell toxicity and renal medullary ischemia. Predisposing factors include advanced age, preexisting kidney disease (serum creatinine >2 mg/dL), volume depletion, diabetic nephropathy, congestive heart failure, multiple myeloma, repeated doses of contrast, and recent exposure to other nephrotoxic agents, including NSAIDs and ACE inhibitors. The combination of preexisting diabetes mellitus and kidney dysfunction poses the greatest risk (15–50%) for contrast nephropathy. Lower volumes of contrast with lower osmolality are recommended in high-risk patients. Toxicity usually occurs within 24–48 hours after the radiocontrast study. Nonionic contrast media may be less toxic, but this has not been well proven. Prevention should be the goal when using these agents. The mainstay of therapy is a liter of intravenous 0.9% saline over 10–12 hours both before and after the contrast administration—cautiously in patients with preexisting cardiac dysfunction. Neither mannitol nor furosemide offers benefit over 0.9% (normal) saline administration. In fact, furosemide may lead to increased rates of renal dysfunction in this setting. In some but not all studies, *N*-acetylcysteine given before and after contrast decreases the incidence of dye-induced nephrotoxicity. Acetylcysteine is a thiol-containing antioxidant with little toxicity whose mechanism of action is unclear. It is rarely given unless a patient has a preexisting risk factor. With little harm and possible benefit, administering acetylcysteine 600 mg orally every 12 hours twice, before and after a dye load, for patients at risk for acute kidney injury, is a reasonable strategy. Intravenous *N*-acetylcysteine, 1200 mg prior to an emergent procedure, has shown benefit compared with placebo and may be a good option if a patient needs contrast dye urgently. One large prospective randomized controlled trial showed no benefit of *N*-acetylcysteine in over 2300 patients randomized to either 1200 mg orally twice versus placebo prior to and after angiographic procedures. The primary endpoint was a 25% increase in serum creatinine within 48–96 hours after the procedure. Some

investigators have shown a benefit using sodium bicarbonate (154 mEq/L, intravenously at 3 mL/kg/h for 1 hour before the procedure, then 1 mL/kg/h for 6 hours after the procedure) over a more conventional regimen of normal saline as the isotonic volume expander. However, others have shown sodium bicarbonate was not superior to sodium chloride when using similar administration regimens. Other nephrotoxic agents should be avoided during the day before and after dye administration.

Cyclosporine toxicity is usually dose dependent. It causes distal tubular dysfunction (a type 4 renal tubular acidosis) from severe vasoconstriction. Regular blood level monitoring is important to prevent both acute and chronic nephrotoxicity. With patients who are taking cyclosporine for renal transplant rejection, kidney biopsy is often necessary to distinguish transplant rejection from cyclosporine toxicity. Renal function usually improves after reducing the dose or stopping the drug.

Other exogenous nephrotoxins include antineoplastics, such as cisplatin and organic solvents, and heavy metals such as mercury, cadmium, and arsenic.

B. Endogenous Nephrotoxins

Endogenous nephrotoxins include heme-containing products, uric acid, and paraproteins. **Myoglobinuria** as a consequence of rhabdomyolysis leads to acute tubular necrosis. Necrotic muscle releases large amounts of myoglobin, which is freely filtered across the glomerulus. The myoglobin is reabsorbed by the renal tubules, and direct damage can occur. Distal tubular obstruction from pigmented casts and intrarenal vasoconstriction can also cause damage. This type of kidney injury occurs in the setting of crush injury, or muscle necrosis from prolonged unconsciousness, seizures, cocaine, and alcohol abuse. Dehydration and acidosis predispose to the development of myoglobinuric acute kidney injury. Patients may complain of muscular pain and often have signs of muscle injury. Rhabdomyolysis of clinical importance commonly occurs with a serum creatine kinase (CK) >20,000–50,000 international units/L. One study showed that 58% of patients with acute kidney injury from rhabdomyolysis had CK levels >16,000 international units/L. Only 11% of patients without kidney injury had CK values >16,000 international units/L. The globin moiety of myoglobin will cause the urine dipstick to read falsely positive for hemoglobin: the urine appears dark brown, but no red cells are present. With lysis of muscle cells, patients also become hyperkalemic, hyperphosphatemic, and hyperuricemic. Hypocalcemia may ensue due to phosphorus and calcium precipitation. The mainstay of treatment is volume repletion. Other adjunctive treatments include mannitol for free radical clearance and diuresis as well as alkalization of the urine. These modalities have not been proved to change outcomes in human trials. Hypocalcemia should not be treated unless the patient is symptomatic. As the patient recovers, calcium can move back from tissues to plasma, so early exogenous calcium administration is not recommended unless the patient has symptoms or the level becomes exceedingly low in an unconscious patient because

such repletion could result in hypercalcemia later in the course of the illness.

Hemoglobin can cause a similar form of acute tubular necrosis. Massive intravascular hemolysis is seen in transfusion reactions and in certain hemolytic anemias. Reversal of the underlying disorder and hydration are the mainstays of treatment.

Hyperuricemia can occur in the setting of rapid cell turnover and lysis. Chemotherapy for germ cell neoplasms and leukemia and lymphoma are the primary causes. Acute kidney injury occurs with intratubular deposition of uric acid crystals; serum uric acid levels are often >15–20 mg/dL and urine uric acid levels >600 mg/24 h. A urine uric acid to urine creatinine ratio >1.0 indicates risk of acute kidney injury.

Bence Jones protein seen in conjunction with multiple myeloma can cause direct tubular toxicity and tubular obstruction. Other renal complications from multiple myeloma include hypercalcemia and renal tubular dysfunction, including proximal renal tubular acidosis (see Multiple Myeloma, below).

► Clinical Findings

A. Symptoms and Signs

See Acute Kidney Injury.

B. Laboratory Findings

Hyperkalemia and hyperphosphatemia are commonly encountered. BUN:creatinine ratio is usually <20:1 because tubular function is not intact, per the mechanisms described in the general section on acute kidney injury (Table 22–4). Urinalysis may show evidence of acute tubular damage. The urine may be brown. Urinary output can be either oliguric or nonoliguric, with oliguria portending a worse prognosis. Urine sodium concentration is typically elevated, but the FE_{Na} is more indicative of tubular function, as discussed above. On microscopic examination, an active sediment may show pigmented granular casts or “muddy brown” casts. Renal tubular epithelial cells and epithelial cell casts can be present (see Table 22–1).

► Treatment

Treatment is aimed at hastening recovery and avoiding complications. Preventive measures should be taken to avoid volume overload and hyperkalemia. Loop diuretics have been used in large doses (eg, furosemide in doses ranging from 20 mg to 160 mg orally or intravenously twice daily, or as a continuous infusion) to affect adequate diuresis and may help convert oliguric to nonoliguric renal failure. Such a conversion has never been shown to affect outcomes such as mortality, though. One retrospective study has shown potentially worse outcomes in patients who receive doses of furosemide, including non-recovery of renal function and an increased risk of death. A prospective randomized controlled trial has shown no difference between the administration of large doses of diuretics versus placebo on either recovery from acute kidney injury or death. Widespread use of diuretics in

critically ill patients with acute kidney injury should thus be discouraged. Disabling side effects of supranormal dosing include hearing loss and cerebellar dysfunction. This is mainly due to peak furosemide levels; this risk can be minimized by the use of a furosemide drip. A starting dose of 0.1–0.3 mg/kg/h is appropriate, increasing to a maximum of 0.5–1 mg/kg/h. A bolus of 1–1.5 mg/kg should be administered at the beginning of each dose escalation. Intravenous thiazide diuretics can be used to augment urinary output; chlorothiazide, 250–500 mg intravenously every 8–12 hours, is a reasonable choice. Another good choice to augment diuresis is metolazone at doses of 2.5–5 mg given orally once to twice daily, 30 minutes prior to loop diuretics. It is less expensive than intravenous chlorothiazide and has reasonable bioavailability. Short-term effects of loop diuretics include activation of the renin–angiotensin system. One prospective randomized trial showed the long-term benefits of plasma ultrafiltration over the use of intravenous diuretics in patients with decompensated heart failure. This intervention can be considered in ICU patients with acute kidney injury in need of volume removal who are nonresponsive to diuretics. Nutritional support should maintain adequate intake while preventing excessive catabolism. Dietary protein restriction of 0.6 g/kg/d helps prevent metabolic acidosis. Hypocalcemia and hyperphosphatemia can be improved with diet and phosphate-binding agents, such as aluminum hydroxide (500 mg orally with meals) over the short term, and calcium carbonate (500–1500 mg orally three times daily), calcium acetate (667 mg, two or three tablets, orally before meals), sevelamer carbonate (800–1600 mg orally three times daily), and lanthanum carbonate (1000 mg orally with meals) over longer periods. Hypocalcemia should not be treated in patients with rhabdomyolysis unless they are symptomatic. Hypermagnesemia can occur because of reduced magnesium excretion by the renal tubules, so magnesium-containing antacids and laxatives should be avoided in these patients. Dosages of all medications must be adjusted according to the estimated degree of renal impairment for drugs eliminated by the kidney.

Indications for dialysis in acute kidney injury from acute tubular necrosis or other intrinsic disorders include life-threatening electrolyte disturbances (such as hyperkalemia), volume overload unresponsive to diuresis, worsening acidosis, and uremic complications (eg, encephalopathy, pericarditis, and seizures). In gravely ill patients, less severe but worsening abnormalities may also be indications for dialytic support. Two prospective randomized control trials, each with more than 1100 patients, showed that an intensive dialysis dose was not superior to a more conventional dose.

▶ Course & Prognosis

The clinical course of acute tubular necrosis is often divided into three phases: initial injury, maintenance, and recovery. The maintenance phase is expressed as either oliguric (urinary output < 500 mL/d) or nonoliguric. Nonoliguric acute tubular necrosis has a better outcome. Conversion from oliguric to nonoliguric states may be attempted but has not been shown to change the prognosis. Drugs such as dopamine and diuretics are sometimes used

for this purpose but have not been shown to improve outcomes. In numerous studies, dopamine use in this setting has no benefit. Average duration of the maintenance phase is 1–3 weeks but may be several months. Cellular repair and removal of tubular debris occur during this period. The recovery phase can be heralded by diuresis. GFR begins to rise; BUN and serum creatinine fall.

The mortality rate associated with acute kidney injury is 20–50% in hospitalized settings, and up to 70% with additional comorbid illnesses. Increased mortality is associated with advanced age, severe underlying disease, and multi-system organ failure. Leading causes of death are infections, fluid and electrolyte disturbances, and worsening of underlying disease. Mortality rates may be starting to improve slightly according to two retrospective cohort studies conducted within the last 10 years.

▶ When to Refer

- A patient with acute tubular necrosis should be referred to a nephrologist when the etiology is unclear or renal function continues to worsen despite intervention.
- Also, referral is appropriate if fluid, electrolyte, and acid-base abnormalities are recalcitrant to interventions.
- Studies have shown that nephrology referral improves outcome in acute kidney injury.

▶ When to Admit

Admission is appropriate when a patient has symptoms or signs of acute kidney injury that require immediate intervention, such as intravenous fluids, dialytic therapy, or that requires a team approach that cannot be coordinated as an outpatient.

INTERSTITIAL NEPHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Fever.
- ▶ Transient maculopapular rash.
- ▶ Acute or chronic kidney injury.
- ▶ Pyuria (including eosinophiluria), white blood cell casts, and hematuria.

▶ General Considerations

Acute interstitial nephritis accounts for 10–15% of cases of intrinsic renal failure. An interstitial inflammatory response with edema and possible tubular cell damage is the typical pathologic finding. Cell-mediated immune reactions prevail over humoral responses. T lymphocytes can cause direct cytotoxicity or release lymphokines that recruit monocytes and inflammatory cells.

Although drugs account for over 70% of cases, acute interstitial nephritis also occurs in infectious diseases, immunologic disorders, or as an idiopathic condition. The most common drugs are penicillins and cephalosporins,

sulfonamides and sulfonamide-containing diuretics, NSAIDs, rifampin, phenytoin, and allopurinol. Proton pump inhibitors have also been recognized as a cause of acute interstitial nephritis. Infectious causes include streptococcal infections, leptospirosis, cytomegalovirus, histoplasmosis, and Rocky Mountain spotted fever. Immunologic entities are more commonly associated with glomerulonephritis, but systemic lupus erythematosus, Sjögren syndrome, sarcoidosis, and cryoglobulinemia can cause interstitial nephritis.

► Clinical Findings

Clinical features can include fever (> 80%), rash (25–50%), arthralgias, and peripheral blood eosinophilia (80%). The classic triad of fever, rash, and arthralgias is present in only 10–15% of cases. The urine often contains red cells (95%), white cells, and white cell casts. Proteinuria can be a feature, particularly in NSAID-induced interstitial nephritis, but is usually modest (< 2 g/24 h). Eosinophiluria is neither very sensitive nor specific and can be detected by Wright or Hansel stain.

► Treatment & Prognosis

Acute interstitial nephritis often carries a good prognosis. Recovery occurs over weeks to months, but urgent dialytic therapy may be necessary in up to one-third of all referred patients before resolution. Patients rarely progress to ESRD. Those with prolonged courses of oliguric failure and advanced age have a worse prognosis. Treatment consists of supportive measures and removal of the inciting agent. If kidney injury persists after these steps, a short course of corticosteroids can be given, although the data to support use of corticosteroids are not substantial. Short-term, high-dose methylprednisolone (0.5–1 g/d intravenously for 1–4 days) or prednisone (60 mg/d orally for 1–2 weeks) followed by a prednisone taper can be used in these more severe cases of drug-induced interstitial nephritis.

GLOMERULONEPHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Hematuria, dysmorphic red cells, red cell casts, and mild proteinuria.
- ▶ Dependent edema and hypertension.
- ▶ Acute renal insufficiency.

► General Considerations

Acute glomerulonephritis is a relatively uncommon cause of acute kidney injury, accounting for about 5% of cases. Pathologically, inflammatory glomerular lesions are seen. These include mesangioproliferative, focal and diffuse proliferative, and crescentic lesions. The larger the percentage of glomeruli involved and the more severe the lesion, the more likely it is that the patient will have a poor clinical outcome.

Categorization of acute glomerulonephritis can be done by serologic analysis. Markers include anti-GBM antibodies, antineutrophil cytoplasmic antibodies (ANCA), and other immune markers of disease.

Immune complex deposition usually occurs when moderate antigen excess over antibody production occurs. Complexes formed with marked antigen excess tend to remain in the circulation. Antibody excess with large antigen–antibody aggregates usually results in phagocytosis and clearance of the precipitates by the mononuclear phagocytic system in the liver and spleen. Causes include IgA nephropathy (Berger disease), peri-infectious or post-infectious glomerulonephritis, endocarditis, lupus nephritis, cryoglobulinemic glomerulonephritis (often associated with hepatitis C virus), and MPGN.

Anti-GBM-associated acute glomerulonephritis is either confined to the kidney or associated with pulmonary hemorrhage. The latter is termed “Goodpasture syndrome.” Injury is related to autoantibodies aimed against type IV collagen in the GBM rather than to immune complex deposition.

Pauci-immune acute glomerulonephritis is a form of small-vessel vasculitis associated with ANCA, causing primary and secondary kidney diseases that do not have direct immune complex deposition or antibody binding. Tissue injury is believed to be due to cell-mediated immune processes. An example is granulomatosis with polyangiitis, a systemic necrotizing vasculitis of small arteries and veins associated with intravascular and extravascular granuloma formation. In addition to glomerulonephritis, these patients can have upper airway, pulmonary, and skin manifestations of disease. Cytoplasmic ANCA (c-ANCA) is a common pattern. Microscopic polyangiitis is another pauci-immune vasculitis causing acute glomerulonephritis. Perinuclear staining (p-ANCA) is the common pattern. ANCA-associated and anti-GBM-associated acute glomerulonephritis can evolve to crescentic glomerulonephritis and often have poor outcomes unless treatment is started early. Both are described more fully below.

Other vascular causes of acute glomerulonephritis include hypertensive emergencies and the thrombotic microangiopathies such as hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura (see Chapter 14).

► Clinical Findings

A. Symptoms and Signs

Patients with acute glomerulonephritis are often hypertensive and edematous, and have an abnormal urinary sediment. The edema is found first in body parts with low tissue tension, such as the periorbital and scrotal regions.

B. Laboratory Findings

Serum creatinine can rise over days to months, depending on the rapidity of the underlying process. The BUN:creatinine ratio is not a reliable marker of kidney function and is more reflective of the underlying volume status of the patient. Dipstick and microscopic evaluation will reveal evidence of hematuria, moderate proteinuria (usually < 3 g/d), and cellular elements such as red cells, red cell casts, and white cells. Red cell casts are specific for glomerulonephritis, and a

detailed search is warranted. Either spot urinary protein-creatinine ratios or 24-hour urine collections can quantify protein excretion; the latter can quantify creatinine clearance when renal function is stable. However, in cases of rapidly changing serum creatinine values, the urinary creatinine clearance is an unreliable marker of GFR. The FE_{NA} is usually low unless the renal tubulo-interstitial space is affected, and renal dysfunction is marked (see Table 22–4).

Further tests include complement levels (C3, C4, CH50), ASO titer, anti-GBM antibody levels, ANCAs, antinuclear antibody titers, cryoglobulins, hepatitis serologies, blood cultures, renal ultrasound, and occasionally renal biopsy.

► Treatment

Depending on the nature and severity of disease, treatment can consist of high-dose corticosteroids and cytotoxic agents such as cyclophosphamide. Plasma exchange can be used in Goodpasture disease and pauci-immune glomerulonephritis as a temporizing measure until chemotherapy can take effect. Treatment and prognosis for specific diseases are discussed more fully below.

CARDIORENAL SYNDROME

ESSENTIALS OF DIAGNOSIS

- Cardiac dysfunction: signs or symptoms of heart failure, ischemic injury or arrhythmias.
- Kidney disease: acute or chronic, depending on type of cardiorenal syndrome.

► General Considerations

Cardiorenal syndrome is a pathophysiologic disorder of the heart and kidneys wherein the acute or chronic deterioration of one organ results in the acute or chronic deterioration of the other. This syndrome has been classified into five types.

Type 1 consists of acute kidney injury stemming from acute cardiac disease. Type 2 is CKD due to chronic cardiac disease. Type 3 is acute cardiac disease as a result of acute

kidney injury. Type 4 is chronic cardiac decompensation from CKD. Type 5 consists of heart and kidney dysfunction due to other acute or chronic systemic disorders (such as sepsis). Identifying and defining this common syndrome may assist in the future with treatments to improve its morbidity and mortality.

CHRONIC KIDNEY DISEASE

ESSENTIALS OF DIAGNOSIS

- Decline in the GFR over months to years
- Persistent proteinuria or abnormal renal morphology.
- Symptoms and signs of uremia when nearing end-stage disease.
- Hypertension in most cases.
- Bilateral small kidneys on ultrasound in advanced disease.

► General Considerations

CKD affects more than 20 million Americans, or one in nine adults. Most are unaware of the condition because they remain asymptomatic until the disease has significantly progressed. The National Kidney Foundation's staging system helps clinicians formulate practice plans (Table 22–5). Over 70% of cases of late-stage CKD (stage 5 CKD and ESRD) in the United States are due to diabetes mellitus or hypertension. Glomerulonephritis, cystic diseases, and other urologic diseases account for another 12%, and 15% of patients have other or unknown causes (Table 22–6). Recently, genetic polymorphisms of the *APOL-1* gene has been shown to be associated with an increased risk of the development of CKD in African Americans.

CKD is rarely reversible and usually leads to a progressive decline in kidney function even after the inciting event has been removed. Destruction of nephrons (inciting event) leads to compensatory hypertrophy of the remaining nephrons, which must increase their individual GFRs to supranormal in order to maintain overall homeostasis. One consequence of this compensatory hyperfiltration is that the serum creatinine may remain relatively normal even in the face of significant loss of renal mass; therefore, it is a relatively insensitive marker for renal damage and scarring. In addition, compensatory hyperfiltration leads to overwork injury in the remaining nephrons, which in turn causes progressive glomerular sclerosis and interstitial fibrosis. Angiotensin receptor blockers (ARBs) and ACE inhibitors can help reduce hyperfiltration injury and are particularly helpful in slowing the progression of proteinuric CKD. Fortunately, an individual's decreased renal mass as a result of kidney donation is not associated with the development of CKD later in life.

CKD is an independent risk factor for cardiovascular disease; proteinuric CKD confers an even higher risk of cardiovascular mortality.

Table 22-5. Stages of chronic kidney disease: A clinical action plan.^{1,2}

Stage	Description	GFR (mL/min/1.73 m ²)	Action ³
1	Kidney damage with normal or ↑ GFR	≥ 90	Diagnosis and treatment. Treatment of comorbid conditions. Slowing of progression. Cardiovascular disease risk reduction.
2	Kidney damage with mildly ↓ GFR	60-89	Estimating progression.
3	Moderately ↓ GFR	30-59	Evaluating and treating complications.
4	Severely ↓ GFR	15-29	Preparation for kidney replacement therapy.
5	End-stage renal disease (ESRD)	< 15 (or dialysis)	Replacement (if uremia is present).

¹From National Kidney Foundation, KDOQI, Chronic Kidney Disease Guidelines.

²Chronic kidney disease is defined as either kidney damage or GFR < 60 mL/min/1.73 m² for 3 or more months. Kidney damage is defined as pathologic abnormalities or markers of damage, including abnormalities in blood or urine tests or imaging studies.

³Includes actions from preceding stages.

GFR, glomerular filtration rate.

Table 22-6. Major causes of chronic kidney disease.

Glomerular diseases
Primary glomerular diseases
Focal and segmental glomerulosclerosis
Membranoproliferative glomerulonephritis
IgA nephropathy
Membranous nephropathy
Alport syndrome (hereditary nephritis)
Secondary glomerular diseases
Diabetic nephropathy
Amyloidosis
Postinfectious glomerulonephritis
HIV-associated nephropathy
Collagen-vascular diseases (eg, SLE)
HCV-associated membranoproliferative glomerulonephritis
Tubulointerstitial nephritis
Drug hypersensitivity
Heavy metals
Analgesic nephropathy
Reflux/chronic pyelonephritis
Sickle cell nephropathy
Idiopathic
Cystic diseases
Polycystic kidney disease
Medullary cystic disease
Obstructive nephropathies
Prostatic disease
Nephrolithiasis
Retroperitoneal fibrosis/tumor
Congenital
Vascular diseases
Hypertensive nephrosclerosis
Renal artery stenosis

HCV, hepatitis C virus; SLE, systemic lupus erythematosus.

Clinical Findings

A. Symptoms and Signs

In the early stages, CKD is asymptomatic. Symptoms develop slowly with the progressive decline in GFR, are nonspecific, and do not manifest until kidney disease is far advanced (GFR < 10–15 mL/min/1.73 m²). At this point, the build-up of metabolic waste products, or uremic toxins, can result in the uremic syndrome (Table 22-7). General

Table 22-7. Symptoms and signs of uremia.

Organ System	Symptoms	Signs
General	Fatigue, weakness	Sallow-appearing, chronically ill
Skin	Pruritus, easy bruisability	Pallor, ecchymoses, excoriations, edema, xerosis
ENT	Metallic taste in mouth, epistaxis	Urinous breath
Eye		Pale conjunctiva
Pulmonary	Shortness of breath	Rales, pleural effusion
Cardiovascular	Dyspnea on exertion, retrosternal pain on inspiration (pericarditis)	Hypertension, cardiomegaly, friction rub
Gastrointestinal	Anorexia, nausea, vomiting, hiccups	
Genitourinary	Nocturia, erectile dysfunction	Isosthenuria
Neuromuscular	Restless legs, numbness and cramps in legs	
Neurologic	Generalized irritability and inability to concentrate, decreased libido	Stupor, asterixis, myoclonus, peripheral neuropathy

symptoms of uremia may include fatigue, weakness, and malaise. GI symptoms, such as anorexia, nausea, vomiting, and a metallic taste in the mouth, are common. Neurologic problems may include irritability, difficulty in concentrating, insomnia, subtle memory defects, restless legs, paresthesias, and twitching. Pruritus is common and difficult to treat. Alterations in sexual function, including decreased libido, and menstrual irregularities are common. Chest pain is rare but can occur with pericarditis. Drug toxicity can develop as renal clearance worsens; in particular, hypoglycemia may become problematic, and even life-threatening, in diabetics since insulin is eliminated by the kidneys.

The most common physical finding in CKD is hypertension. It is often present in early stages of CKD and may worsen with CKD progression. The uremic patient (CKD stage 5) appears chronically ill. The skin may be sallow, with easy bruisability. Rarely seen in the current era is uremic frost, a cutaneous reflection of ESRD. Uremic fetor is the characteristic fishy odor of the breath. Cardiopulmonary signs may include rales, cardiomegaly, jugular venous distention, edema, and a pericardial friction rub (rarely). Mental status can vary from decreased concentration to confusion, stupor, and coma. Myoclonus and asterixis may be signs of uremia.

Symptoms and signs of uremia warrant immediate hospital admission and nephrology consultation for initiation of dialysis. The uremic syndrome resolves or lessens significantly with dialytic therapy.

In any patient with kidney disease, it is important to identify and correct all possibly reversible insults or exacerbating factors (Table 22–8). Urinary tract infections, obstruction, extracellular fluid volume depletion, hypotension, nephrotoxins (such as NSAIDs), severe or emergent hypertension, and congestive heart failure should be excluded. Any of the above can worsen underlying CKD.

Table 22–8. Reversible causes of kidney injury.

Reversible Factors	Diagnostic Clues
Infection	Urine culture and sensitivity tests
Obstruction	Bladder catheterization, then renal ultrasound
Extracellular fluid volume depletion or significant hypotension relative to baseline	Blood pressure and pulse, including orthostatic pulse
Hypokalemia, hypercalcemia, and hyperuricemia (usually > 15 mg/dL)	Serum electrolytes, calcium, phosphate, uric acid
Nephrotoxic agents	Drug history
Severe/urgent hypertension	Blood pressure, chest radiograph
Congestive heart failure	Physical examination, chest radiograph

B. Laboratory Findings

The diagnosis of CKD is made by documenting elevations of the serum creatinine over at least 3 months. Persistent proteinuria or abnormalities on renal imaging (eg, polycystic kidneys) are also diagnostic of CKD, even when estimated GFR is normal. It is helpful to plot the inverse of serum creatinine ($1/S_{Cr}$) versus time or estimated GFR (if reported by the laboratory) versus time. If three or more prior measurements are available, the time to ESRD can thus be estimated (Figure 22–1). If the slope of the line acutely declines, new and potentially reversible renal insults should be excluded as outlined above. Anemia, hyperphosphatemia, hypocalcemia, hyperkalemia, and metabolic acidosis can occur with both acute kidney disease and CKD. The urinalysis shows isosthenuria if tubular concentrating and diluting ability are impaired. The urinary sediment can show broad waxy casts as a result of dilated, hypertrophic nephrons. Proteinuria may be present. If so, it should be quantified as described above. Quantification of urinary protein is important for several reasons. First, it helps narrow the differential diagnosis of the etiology of the CKD (Table 22–6); for example, glomerular diseases tend to present with protein excretion of > 1 g/d. Second, the presence of proteinuria is associated with more rapid progression of CKD and cardiovascular mortality.

¹ Value of serum creatinine level = 1.0 mg/dL

² Value of serum creatinine level = 2.0 mg/dL

³ Value of serum creatinine level = 5.0 mg/dL

▲ **Figure 22–1.** Decline in kidney function (expressed as the reciprocal of serum creatinine as shown here, or as estimated glomerular filtration rate [eGFR]) plotted against time to end-stage renal disease (ESRD). The solid line indicates the linear decline in kidney function over time. The dotted line indicates the approximate time to ESRD.

C. Imaging

The finding of small echogenic kidneys bilaterally (<9–10 cm) by ultrasonography supports a diagnosis of CKD, although normal or even large kidneys can be seen with adult polycystic kidney disease, diabetic nephropathy, HIV-associated nephropathy, multiple myeloma, amyloidosis, and obstructive uropathy.

► Complications

The complications of CKD tend to occur at relatively predictable stages of disease as noted in Figure 22–2.

A. Cardiovascular Complications

Patients with CKD experience greater morbidity and mortality from cardiovascular disease in comparison to the general population. Death from cardiovascular causes accounts for 45% of all deaths of patients receiving dialysis. Eighty to 90 percent of patients with CKD die, primarily of cardiovascular disease, before reaching need for dialysis. The precise biologic mechanisms for this enhanced mortality are unclear but may have to do with the uremic milieu including abnormal phosphorus and calcium homeostasis, increased burden of oxidative stress, increased vascular reactivity, increased left ventricular hypertrophy, and underlying coexistent comorbidities such as hypertension and diabetes mellitus.

1. Hypertension—Hypertension is the most common complication of CKD. As kidney disease progresses, hypertension due to salt and water retention usually develops. Hyperreninemic states and exogenous erythropoietin administration can also exacerbate hypertension.

As with other patient populations, control of hypertension should focus on both nonpharmacologic therapy (eg, diet, exercise, weight loss, treatment of obstructive sleep apnea) and pharmacologic therapy. CKD results in disturbed sodium homeostasis such that the ability of the

kidney to adjust to variations in sodium and water intake becomes limited as GFR declines. The clinician should recommend institution of a diet with mildly decreased salt intake (3 g/d), and salt intake should be reduced to 2 g/d if hypertension persists or signs of CHF develop. Diuretics are nearly always needed to help control hypertension. However, volume contraction as a result of very low sodium intake or over-diuresis in the presence of impaired sodium homeostasis can result in further impairment of the GFR. In addition to diuretics, initial drug therapy should include ACE inhibitors or ARBs as recommended by national guidelines (if serum potassium permits). When an ACE inhibitor or an ARB is initiated or uptitrated, patients should have serum creatinine and potassium checked within 5–14 days. Hyperkalemia or a rise in serum creatinine > 30% from baseline mandates reduction or cessation of the drug. Second-line antihypertensive agents include calcium channel-blocking agents and β -blocking agents. Because of the difficulty in controlling hypertension in CKD, additional agents from other classes are often needed. Current guidelines suggest a blood pressure goal of 130/80 mm Hg for patients with CKD; a goal of 125/75 mm Hg is recommended for patients with proteinuria. It should be noted that treatment of blood pressure significantly below these goals is not supported by current data and may be dangerous in some populations, such as the elderly. Ongoing randomized controlled trials are looking at the benefit of systolic blood pressure goals of < 120 mm Hg versus < 140 mm Hg regarding outcomes such as ESRD and cardiac death in high-risk populations.

2. Coronary artery disease—Patients with CKD are at higher risk for death from cardiovascular disease than the general population. Traditional modifiable risk factors for cardiovascular disease, such as hypertension, tobacco use, and hyperlipidemia, should be aggressively treated in patients with CKD. Uremic vascular calcification involving disordered phosphorus homeostasis and other mediators may also be a cardiovascular risk factor in these patients.

▲ **Figure 22–2.** Complications of chronic kidney disease (CKD) by stage and glomerular filtration rate (GFR). Complications arising from CKD tend to occur at the stages depicted, although there is considerable variability noted in clinical practice. HTN, hypertension; PTH, parathyroid hormone. (Adapted, with permission, from William Bennett, MD.)

3. Congestive heart failure—The complications of CKD result in increased cardiac workload via underlying hypertensive disease, volume overload, and anemia. Patients with CKD may also have accelerated rates of atherosclerosis, and vascular calcification resulting in vessel stiffness. All of these factors contribute to left ventricular hypertrophy and diastolic dysfunction, which are present in most patients starting dialysis. Over time, systolic dysfunction may also develop. Water and salt restriction is usually necessary. Diuretics are of value if they can affect an increased urine volume, although thiazides are ineffective by themselves when the GFR is $< 20\text{--}30$ mL/min/1.73 m². Loop diuretics are commonly used, potentially in combination with thiazide diuretics, and higher doses are required as renal function declines. Digoxin is excreted by the kidney, and its toxicity is exacerbated in the presence of electrolyte disturbances which are common in CKD. The proven efficacy of ACE inhibitors in congestive heart failure holds true for patients with CKD. Despite the risks of hyperkalemia and worsening renal function, ACE inhibitors and ARBs can be used for patients with a serum creatinine > 3 mg/dL with close supervision and laboratory test monitoring.

4. Pericarditis—Pericarditis may develop in uremic patients but is rare. Symptoms include chest pain and fever. Pulsus paradoxus can be present; a friction rub may be auscultated, but the lack of a rub does not rule out a significant pericardial effusion. The chest radiograph can show an enlarged cardiac silhouette, and the ECG, generalized ST and T wave changes, characteristically a progression from diffuse ST elevation followed by a return to baseline and then T wave inversion. If pericardial effusion occurs, the ECG often shows nonspecific T wave changes and low QRS voltage; electrical alternans is a pathognomonic finding. Cardiac tamponade can occur; patients with tamponade have signs of poor cardiac output, with jugular venous distention and lungs clear to auscultation. Uremic pericarditis is a mandatory indication for hospitalization and initiation of hemodialysis.

B. Disorders of Mineral Metabolism

The metabolic bone disease of CKD refers to the complex disturbances of calcium and phosphorus metabolism, parathyroid hormone (PTH), active vitamin D, and possibly fibroblast growth factor-23 (FGF-23) homeostasis (see Chapter 21 and Figure 22–3). A typical pattern seen as early as CKD stage 3 is hyperphosphatemia, hypocalcemia, hypovitaminosis D, and secondary hyperparathyroidism as a result of the first three abnormalities. Traditionally, the emphasis on treating these disturbances centered around concern for the consequential bone disease and increased fracture risk noted in CKD patients. Now it is recognized that such disturbances also lead to vascular calcification and may be partly responsible for the accelerated cardiovascular disease and excess mortality seen in the CKD population. Epidemiologic studies in humans show an association between elevated phosphorus levels and increased risk of cardiovascular mortality in early CKD through ESRD. As yet, there are no intervention trials suggesting the best course of treatment in these patients; control of mineral and PTH levels per current guidelines is discussed below.

▲ **Figure 22–3.** Mineral abnormalities of chronic kidney disease (CKD). Decline in glomerular filtration rate (GFR) and loss of renal mass lead directly to increased serum phosphorus and hypovitaminosis D. Both of these abnormalities result in hypocalcemia and hyperparathyroidism. Many CKD patients also have nutritional 25(OH) vitamin D deficiency. PTH, parathyroid hormone.

Bone disease, or **renal osteodystrophy**, in advanced CKD is common and there are several types of lesions. Renal osteodystrophy can only be diagnosed by bone biopsy, which is rarely done. The most common bone disease, **osteitis fibrosa cystica**, is a result of secondary hyperparathyroidism and the osteoclast-stimulating effects of PTH. This is a high-turnover disease with osteoclastic bone resorption and subperiosteal lesions. **Metastatic calcifications**, such as tumoral calcinosis, can occur. Radiographically, lesions are most prominent in the phalanges and lateral ends of the clavicles. Adynamic bone disease, or low-bone turnover, is becoming more common and results from relatively low PTH levels or activity; it may result iatrogenically from suppression of PTH or via spontaneously low PTH production. **Osteomalacia**, or lack of bone mineralization, is another lesion associated with CKD. In the past, osteomalacia was associated with aluminum toxicity—either as a result of chronic ingestion of prescribed aluminum-containing phosphorus binders or from high levels of aluminum in untreated dialysate. Currently, osteomalacia is more likely to result from hypovitaminosis D; there is also theoretical risk of osteomalacia associated with use of bisphosphonates in advanced CKD.

All of the above entities can cause bony pain, proximal muscle weakness, and higher risk for fractures. Treatment involves correction of calcium, phosphorus, and 25-OH vitamin D levels toward normal values, along with treatment of hyperparathyroidism. Understanding the interplay between these abnormalities can help target therapy (Figure 22–3). Declining GFR leads to phosphorus retention. This results in hypocalcemia as phosphorus complexes with calcium, deposits in soft tissues, and stimulates PTH. Loss of renal mass, and low 25-OH vitamin D levels often seen in CKD patients results in low 1,25(OH) vitamin D production by the kidney. Because 1,25(OH) vitamin D is a suppressor of PTH production, hypovitaminosis D also leads to secondary hyperparathyroidism.

The first step in treatment of metabolic bone disease is control of hyperphosphatemia (defined as a serum phosphorus of ≤ 4.5 mg/dL in pre-ESRD CKD, or ≤ 5.5 mg/dL in ESRD patients). This involves dietary phosphorus

restriction initially, followed by the administration of oral phosphorus binders if targets are not achieved (see below). Dietary phosphorus restriction to 1000 mg/d can be challenging as many phosphorus sources are also rich in protein; care must be taken to avoid protein malnutrition. Oral phosphorus binders, such as calcium carbonate (650 mg/tablet) or calcium acetate (667 mg/capsule), block absorption of dietary phosphorus in the gut and are given three or four times daily at the beginning of meals. These should be titrated to a serum phosphorus of < 4.6 mg/dL in stage 3–4 of CKD (GFR of 15–59 mL/min) and < 4.6–5.5 mg/dL in ESRD patients. National guidelines recommend maximal elemental calcium doses of 1500 mg/d (eg, nine tablets of calcium acetate); doses should be decreased if serum calcium rises above 10 mg/dL. Phosphorus-binding agents that do not contain calcium are sevelamer and lanthanum. Sevelamer, 800 mg orally, and lanthanum carbonate, 1000 mg orally, are given at the beginning of meals. Aluminum hydroxide is a highly effective phosphorus binder but can cause osteomalacia and neurologic complications when used long-term. While it can be used in the acute setting for serum phosphorus > 7 mg/dL or for short periods (eg, 3 weeks) in CKD patients, long-term use should be avoided.

Once serum phosphorus levels are controlled, active vitamin D (1,25[OH] vitamin D, or calcitriol) or active vitamin D analogs are recommended to treat secondary hyperparathyroidism in stage 3–5 CKD. Serum 25-OH vitamin D levels should be measured and brought to normal (see Chapter 26) prior to considering administration of active vitamin D. Active vitamin D (calcitriol) increases serum calcium and phosphorus levels; both need to be monitored closely during calcitriol therapy, and its dose should be decreased if hypercalcemia or hyperphosphatemia occurs. Typical calcitriol dosing is 0.25 or 0.5 mcg orally daily or every other day initially. Cinacalcet is a calcimimetic agent that targets the calcium-sensing receptor on the chief cells of the parathyroid gland and suppresses PTH production. Cinacalcet, 30–90 mg orally once a day, can be used if elevated serum phosphorus or calcium levels prohibit the use of vitamin D analogs; cinacalcet can cause hypocalcemia. Optimal PTH levels in CKD are not known, but because skeletal resistance to PTH develops with uremia, relatively high levels are targeted in advanced CKD to avoid adynamic bone disease. Expert guidelines generally suggest goal PTH levels near or just above the upper limit of normal for moderate CKD, and at least twofold and up to ninefold the upper limit of normal for ESRD.

C. Hematologic Complications

1. Anemia—The anemia of CKD is primarily due to decreased erythropoietin production, which often becomes clinically significant during stage 3 CKD. Many patients are iron deficient as well due to impaired GI iron absorption.

Erythropoiesis-stimulating agents (eg, recombinant erythropoietin [epoetin] and darbepoetin) are FDA-approved in CKD for a goal hemoglobin (Hgb) of 10–11 g/dL if no other treatable causes for anemia are present. One study in patients with CKD showed no benefit of starting erythropoietin-like agents before Hgb values were < 9 g/dL. The dose needed can vary; the starting dose of epoetin is

50 units/kg (3000–4000 units/dose) once or twice a week. Darbepoetin is started at 0.45 mcg/kg and can be administered every 2–4 weeks. These agents can be given intravenously (eg, to the hemodialysis patient) or subcutaneously (eg, to the predialysis or dialysis patient); subcutaneous dosing of erythropoietin is roughly 30% more effective than intravenous dosing. Erythropoiesis-stimulating agents should be titrated to a Hgb of 10–11 g/dL for optimal safety; studies show that targeting a higher Hgb increases risk of stroke and possibly other cardiovascular events. When titrating doses, Hgb levels should rise no more than 1 g/dL every 3–4 weeks. Hypertension is a complication of erythropoietin or darbepoetin therapy in about 20% of patients. The dosage may require adjustment, or antihypertensive drugs may need to be given.

Iron stores must be adequate to ensure response to erythropoiesis-stimulating agents. Patients with CKD tend to have progressively increasing level of hepcidin, a molecule that blocks GI iron absorption and mobilization of iron from body stores. Therefore, traditional measures of iron stores are measured in CKD patients but are considered abnormal at a higher reference level. In CKD, a serum ferritin < 100–200 ng/mL or iron saturation < 20% is suggestive of iron deficiency. Iron stores should be replenished with oral or parenteral iron prior to the initiation of erythropoietic agents. Iron therapy should be withheld if the serum ferritin is > 500–800 ng/mL, even if the iron saturation is < 20%. Oral therapy with ferrous sulfate, gluconate, or fumarate (the latter two tend to be better tolerated), 325 mg once to three times daily, is the initial therapy for patients who are not yet receiving dialysis. For those that do not respond due to poor GI absorption or lack of tolerance, intravenous iron may be necessary.

The preliminary investigation of anemia in any CKD patient should also include assessment of thyroid function tests, serum vitamin B₁₂, and red blood cell folate stores, and fecal occult blood testing prior to initiating erythropoiesis-stimulating agent therapy.

2. Coagulopathy—The coagulopathy of CKD is mainly caused by platelet dysfunction. Platelet counts may be mildly decreased, and the bleeding time is prolonged due to abnormal adhesiveness and aggregation. Clinically, patients can have petechiae, purpura, and an increased tendency for bleeding during surgery.

Treatment is required only in patients who are symptomatic. Raising the Hgb to 9–10 g/dL in anemic patients can reduce bleeding time via increased blood viscosity. Desmopressin (25 mcg intravenously every 8–12 hours for two doses) is a short-lived but effective treatment for platelet dysfunction and it is often used in preparation for surgery. Conjugated estrogens, 2.5–5 mg orally for 5–7 days, may have an effect for several weeks but is very seldom used. Dialysis improves the bleeding time but does not normalize it. Cryoprecipitate (10–15 bags) is rarely used and lasts < 24 hours.

D. Hyperkalemia

Potassium balance generally remains intact in CKD until stages 4–5. However, hyperkalemia may occur at earlier stages

when certain conditions are present, such as type 4 renal tubular acidosis (seen in patients with diabetes mellitus), high potassium diets, or medications that decrease renal potassium secretion (amiloride, triamterene, spironolactone, eplerenone, NSAIDs, ACE inhibitors, ARBs) or block cellular potassium uptake (β -blockers). Other causes include acidic states, and any type of cellular destruction causing release of intracellular contents (which are high in potassium), such as hemolysis and rhabdomyolysis.

Treatment of acute hyperkalemia is discussed in Chapter 21 (see Table 21–6). Cardiac monitoring is indicated for any ECG changes seen with hyperkalemia or a serum potassium level > 6.0 – 6.5 mEq/L. The ion exchange resin sodium polystyrene sulfonate exchanges sodium for potassium and results in GI potassium excretion and is often used to treat acute hyperkalemia in addition to β -agonists, insulin plus glucose, and calcium gluconate as indicated. Chronic hyperkalemia is best treated with dietary potassium restriction (2 g/d) and minimization or elimination of any medications that may impair renal potassium excretion, as noted above. Loop diuretics may also be administered for their kaliuretic effect as long as the patient is not volume-depleted.

E. Acid-Base Disorders

Damaged kidneys are unable to excrete the 1 mEq/kg/d of acid generated by metabolism of dietary animal proteins in the typical Western diet. The resultant metabolic acidosis is primarily due to loss of renal mass; distal tubular defects may contribute to or worsen the acidosis. Although patients with CKD are in positive hydrogen ion balance, the arterial blood pH is maintained at 7.33–7.37 and serum bicarbonate concentration rarely falls below 15 mEq/L. The excess hydrogen ions are buffered by the large calcium carbonate and calcium phosphate stores in bone. This results in leaching of calcium and phosphorus from the bone and contributes to the metabolic bone disease described above. To help mitigate damage to bone and encourage normal growth, the serum bicarbonate level should be maintained at > 21 mEq/L. The most commonly used alkali salt is sodium bicarbonate. Administration should begin with 20–30 mEq/d divided into two doses per day and titrated as needed. Citrate salts increase the absorption of dietary aluminum and should be avoided in CKD patients.

F. Neurologic Complications

Uremic encephalopathy, resulting from the aggregation of uremic toxins, does not occur until GFR falls below 5–10 mL/min/1.73 m². Symptoms begin with difficulty in concentrating and can progress to lethargy, confusion, and coma. Physical findings may include nystagmus, weakness, asterix, and hyperreflexia. These symptoms and signs improve after initiation of dialysis.

Neuropathy is found in 65% of CKD stage 5 and ESRD patients but can also be seen in patients with CKD stage 4. Peripheral neuropathies manifest themselves as sensorimotor polyneuropathies (stocking-glove distribution) and isolated or multiple isolated mononeuropathies; other

CKD-associated neuropathies result in erectile dysfunction and autonomic dysfunction. Patients may have restless leg syndrome, loss of deep tendon reflexes, and distal pain. The earlier initiation of dialysis may prevent peripheral neuropathies, although the response to dialysis is variable.

G. Endocrine Disorders

In advanced CKD, circulating insulin levels are higher because of decreased renal insulin clearance, and, in diabetics, there is risk of developing dangerous hypoglycemia if this phenomenon is not anticipated. Doses of oral hypoglycemics and insulin may need reduction. Metformin is associated with risk of lactic acidosis when estimated GFR is < 60 mL/min/1.73 m² and should be discontinued at this point.

Decreased libido and erectile dysfunction are common in advanced CKD. Men have decreased testosterone levels; women are often anovulatory. Women with serum creatinine < 1.4 mg/dL are not at increased risk for poor outcomes in pregnancy; however, those with serum creatinine > 1.4 mg/dL may experience faster progression of CKD with pregnancy. Fetal survival is not compromised, however, unless CKD is advanced. Despite a high degree of infertility in patients with ESRD, pregnancy can occur in this setting—particularly in women who are well dialyzed and well nourished. However, fetal mortality approaches 50%, and babies who survive are often premature. In female patients with ESRD, renal transplantation with a well-functioning allograft affords the best chances for a successful pregnancy.

► Treatment

A. Slowing Progression

Treatment of the underlying cause of CKD is vital. Control of diabetes should be aggressive in early CKD; risk of hypoglycemia increases in advanced CKD as described above, and glycemic targets may need to be relaxed to avoid this dangerous complication. Blood pressure control is vital to slow progression of all forms of CKD; agents that block the renin-angiotensin-aldosterone system are particularly important in proteinuric disease (see section on hypertension). Several small studies suggest a possible benefit of oral alkali therapy in slowing CKD progression when acidemia is present (see above); there is also theoretic value in lowering uric acid levels in those with concomitant hyperuricemia, but clinical data are lacking at this time. Management of traditional cardiovascular risk factors should also be emphasized.

B. Dietary Management

Every patient with CKD should be evaluated by a renal nutritionist. Specific recommendations should be made concerning protein, salt, water, potassium, and phosphorus intake to help manage CKD progression and complications.

1. Protein restriction—Experimental models have shown that protein restriction slows the progression to ESRD;

however, this has not been consistently proved in clinical trials. The questionable benefits of protein restriction in slowing the rate of decline of GFR must be weighed against the risk of cachexia upon the initiation of dialysis; low serum albumin at the start of dialysis is one of the strongest predictors of mortality in this population.

2. Salt and water restriction—In advanced CKD, the kidney is unable to adapt to large changes in sodium intake. Intake > 3–4 g/d can lead to edema, hypertension, and congestive heart failure, whereas intake of < 1 g/d can lead to volume depletion and hypotension. For the nondialysis patient approaching ESRD, 2 g/d of sodium is an initial recommendation. A daily intake of 2 L of fluid maintains water balance.

3. Potassium restriction—Restriction is needed once the GFR has fallen below 10–20 mL/min/1.73 m², or earlier if the patient is hyperkalemic. Patients should receive detailed lists concerning potassium content of foods and should limit their intake to < 50–60 mEq/d (2 g); this is about half of normal intake.

4. Phosphorus restriction—The phosphorus level should be kept in the ‘normal’ range (<4.5 mg/dL) predialysis, and between 3.5 and 5.5 mg/dL when on dialysis, with a dietary restriction of 800–1000 mg/d. Foods rich in phosphorus such as cola beverages, eggs, dairy products, nuts, beans, and meat should be limited, although care must be taken to avoid protein malnutrition. Below a GFR of 20–30 mL/min/1.73 m², dietary restriction is rarely sufficient to reach target levels, and phosphorus binders are usually required. The treatment of hyperphosphatemia is discussed above in the section on disorders of mineral metabolism.

C. Medication Management

Many drugs are excreted by the kidney; dosages should be adjusted for GFR. Insulin doses may need to be adjusted as noted above. Magnesium-containing medications, such as laxatives or antacids, should be avoided as should phosphorus-containing medicines, particularly cathartics. Morphine metabolites are active and can accrue in advanced CKD; this problem is not encountered with other opioid agents. Drugs with potential nephrotoxicity (NSAIDs, intravenous contrast, as well as others noted in the Acute Kidney Injury section) should be avoided.

D. Treatment of End-Stage Renal Disease

When GFR declines to 5–10 mL/min/1.73 m² (with or without overt uremic symptoms), renal replacement therapy (hemodialysis, peritoneal dialysis, or kidney transplantation) is required to sustain life. Select patients with limited life expectancy because of very advanced age or comorbid conditions may choose not to pursue dialysis therapy. Patient education is very important in understanding which mode of therapy is most suitable; timely preparation for treatment is also key. Referral to a nephrologist for consideration of ESRD treatment should take place in late stage 3 CKD, or when the GFR is declining rapidly.

1. Dialysis—Dialysis initiation should be considered when GFR is 10 mL/min/1.73 m². Recent studies suggest that the well-selected patient without overt uremic symptoms may wait to initiate dialysis until GFR is closer to 7 mL/min/1.73 m². Other indications for dialysis, which may occur when GFR is 10–15 mL/min/1.73 m² include (1) uremic symptoms, (2) fluid overload unresponsive to diuresis, (3) refractory hyperkalemia, and (4) severe metabolic acidosis (pH < 7.20). Preparation for dialysis requires a team approach. Dietitians and social workers should be involved as well as primary care clinicians and nephrologists. The patient and family need early counseling regarding the risks and benefits of therapy. For very elderly patients, or those with multiple debilitating or life-limiting comorbidities, dialysis therapy may not meaningfully prolong life, and the option of not starting dialysis with the development of ESRD should be discussed with the patient and family. Conversely, for patients who are otherwise relatively healthy, evaluation for possible kidney transplantation should be considered prior to initiation of dialysis.

A. HEMODIALYSIS—Hemodialysis requires a constant flow of blood along one side of a semipermeable membrane with a cleansing solution, or dialysate, along the other. Diffusion and convection allow the dialysate to remove unwanted substances from the blood while adding back needed components. Vascular access for hemodialysis can be accomplished by an arteriovenous fistula (the preferred method) or prosthetic graft; creation of dialysis access should be considered well before dialysis initiation. An indwelling catheter is used when there is no useable vascular access; because catheters confer a high risk of bloodstream infection, they should be considered a temporary measure. Native fistulas typically last longer than prosthetic grafts but require a longer time (6–8 weeks or more after surgical construction) for maturation. Infection, thrombosis, and aneurysm formation are complications seen more often in grafts than fistulas. *Staphylococcus* species are the most common cause of soft-tissue infections and bacteremia.

Dialysis at a hemodialysis center occurs three times a week. Sessions last 3–5 hours depending on patient size, type of dialyzer used, and other factors. Other hemodialysis schedules can be considered depending on available resources and patient preferences. Results from nocturnal dialysis trials have not been uniform but have shown improvements over thrice weekly dialysis for blood pressure control, mineral metabolism, and quality of life. Home hemodialysis is often performed more frequently (3–6 days per week for shorter sessions) and requires a trained helper, and large equipment. The availability of these quotidian modalities (nocturnal and frequent home hemodialysis) is becoming more widespread; results of trials comparing these to conventional in-center dialysis have not thus far shown significant mortality differences.

B. PERITONEAL DIALYSIS—With peritoneal dialysis, the peritoneal membrane is the “dialyzer.” Dialysate is instilled into the peritoneal cavity through an indwelling catheter; water and solutes move across the capillary bed that lies between the visceral and parietal layers of the membrane

into the dialysate during a “dwell.” After equilibration, the dialysate is drained, and fresh dialysate is instilled—this is an “exchange.”

There are three kinds of peritoneal dialysis: continuous ambulatory peritoneal dialysis (CAPD), in which the patient exchanges the dialysate four to six times a day manually; continuous cyclic peritoneal dialysis (CCPD), which utilizes a cyclor machine to automatically perform exchanges at night; and nocturnal intermittent peritoneal dialysis (NIPD), where patients use a cyclor machine at night without any fluid in the peritoneum during the day. As with hemodialysis, peritoneal dialysis prescriptions are guided by adequacy measurements (ie, dialytic clearance of urea).

Peritoneal dialysis permits significant patient autonomy. Its continuous nature minimizes the symptomatic volume and electrolyte shifts observed in hemodialysis patients, and poorly dialyzable compounds (such as phosphates) are better cleared, which permits less dietary restriction. However, peritoneal dialysate removes large amounts of albumin, and nutritional status must be closely watched.

The most common complication of peritoneal dialysis is peritonitis. Rates are improving (< 0.5 episodes per patient-year). Peritonitis may present with nausea and vomiting, abdominal pain, diarrhea or constipation, and fever. The dialysate is usually cloudy; and a diagnostic peritoneal fluid cell count is > 100 white blood cells/mCL of which over 50% are polymorphonuclear neutrophils. *Staphylococcus aureus* is the most common infecting organism, but streptococci and gram-negative species are also common.

2. Kidney transplantation—Up to 50% of all patients with ESRD are otherwise healthy enough to be suitable for transplantation. Older age is becoming less of a barrier, as long as reasonable life expectancy is anticipated. Two-thirds of kidney allografts come from deceased donors, with the remainder from living related or unrelated donors. There are over 90,000 patients on the active waiting list for a deceased donor transplant in the United States; the average wait is 2–6 years, depending on geographic location and recipient blood type.

The 1- and 3-year kidney graft survival rates are approximately 96% and 91%, respectively, for living donor transplants and 91% and 81%, respectively, for deceased donor transplants. Factors that determine outcome include antigenic disparity (ABO blood groups and major histocompatibility or HLA) between donor and recipient, the type of immunologic response mounted by the host, and the immunosuppressive regimen used to prevent graft rejection. Nonimmunologic factors that affect the risk of chronic rejection include age and race of recipient; donor age; length of time on dialysis; and coexisting hyperlipidemia, hypertension, or cytomegalovirus infection.

Immunosuppressive regimens to prevent allograft rejection generally include a combination of a corticosteroid, an antimetabolite (azathioprine or mycophenolate mofetil), and a calcineurin inhibitor (tacrolimus or cyclosporine) or mTOR inhibitor (sirolimus). Maintenance doses are lower than doses given at the time of transplant, with the aim of preventing recurrent rejection and chronic allograft

nephropathy, prolonging graft survival, and minimizing potentially serious medication side effects. Aside from medication use, the life of a transplant recipient can return to nearly normal, although these patients are at higher risk for certain cancers and infections.

3. Medical management of ESRD—As noted above, some patients are not candidates for transplantation and may not benefit from dialysis. Recent studies suggest that very elderly persons who do not die soon after dialysis initiation rapidly lose functional status in the first year of treatment. The decision to initiate dialysis in patients with limited life expectancy should be weighed against possible deleterious changes in quality of life. For patients with ESRD who elect not to undergo dialysis, death occurs within days to weeks. In general, uremia develops and patients lose consciousness prior to death. Arrhythmias can occur as a result of electrolyte imbalance. Volume overload and dyspnea can be managed by volume restriction and opioids as described in Chapter 5. Involvement of a palliative care team is essential.

► Prognosis in ESRD

Compared with kidney transplant recipients and age-matched controls, mortality is higher for patients undergoing dialysis. There is likely little difference in survival for well-matched peritoneal versus hemodialysis patients.

Survival rates on dialysis depend on the underlying disease process. Five-year Kaplan-Meier survival rates vary from 36% for patients with diabetes to 53% for patients with glomerulonephritis. Overall 5-year survival is currently estimated at 42%. Patients undergoing dialysis have an average life-expectancy of 3–5 years, but survival for as long as 25 years may be achieved depending on comorbidities. The most common cause of death is cardiac disease (50%). Other causes include infection (12%), cerebrovascular disease (15%), and malignancy (6%). Diabetes, advanced age, a low serum albumin, lower socioeconomic status, and inadequate dialysis are all significant predictors of mortality; high fibroblast growth factor (FGF)-23 levels have emerged as a novel marker for mortality in ESRD.

► When to Refer

- A patient with stage 3–5 CKD should be referred to a nephrologist for management in conjunction with the primary care provider.
- A patient with other forms of CKD such as those with significant proteinuria (>1 g/d) or polycystic kidney disease should be referred to a nephrologist at earlier stages.

► When to Admit

- Admission should be considered for patients with decompensation of problems related to CKD, such as worsening of acid-base status, electrolyte abnormalities, and volume status that cannot be appropriately treated in the outpatient setting.
- Admission is appropriate when a patient needs to start dialysis and is not stable for outpatient initiation.

RENAL ARTERY STENOSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Produced by atherosclerotic occlusive disease (80–90% of patients) or fibromuscular dysplasia (10–15%).
- ▶ Hypertension.
- ▶ Acute kidney injury in patients starting ACE inhibitor therapy.

▶ General Considerations

Atherosclerotic ischemic renal disease accounts for nearly all cases of renal artery stenosis. Fibromuscular dysplasia is a rare cause of renal artery stenosis. Approximately 5% of Americans with hypertension suffer from renal artery stenosis. It occurs most commonly in those over 45 years of age with a history of atherosclerotic disease. Other risk factors include CKD, diabetes mellitus, tobacco use, and hypertension.

▶ Clinical Findings

A. Symptoms and Signs

Patients with atherosclerotic ischemic renal disease may have refractory hypertension, new-onset hypertension (in an older patient), pulmonary edema with poorly controlled blood pressure, and acute kidney injury upon starting an ACE inhibitor. In addition to hypertension, physical examination may reveal an audible abdominal bruit on the affected side. Fibromuscular dysplasia primarily affects young women. Unexplained hypertension in a woman younger than 40 years is reason to screen for this disorder.

B. Laboratory Findings

Laboratory values can show elevated BUN and serum creatinine levels in the setting of significant renal ischemia.

C. Imaging

Abdominal ultrasound can reveal asymmetric kidney size when one renal artery is affected out of proportion to the other.

Three prevailing methods used for screening are Doppler ultrasonography, CT angiography, and magnetic resonance angiography (MRA). **Doppler ultrasonography** is highly sensitive and specific (> 90% with an experienced ultrasonographer) and relatively inexpensive. However, this method is extremely operator and patient dependent. Measurements of blood flow must be made at the aorta and along each third of the renal artery in order to assess the disease. This test is a poor choice for patients who are obese, unable to lie supine, or have interfering bowel gas patterns.

CT angiography consists of intravenous digital subtraction angiography with arteriography and is a noninvasive procedure. The procedure uses a spiral (helical) CT scan with intravenous contrast injection. The sensitivities from various studies range from 77% to 98%, with less varying specificities in a range of 90–94%.

MRA is an excellent but expensive way to screen for renal artery stenosis, particularly in those with atherosclerotic disease. Sensitivity is 77–100%, although one study with particular flaws showed a sensitivity of only 62%. Specificity ranges from 71% to 96%. Turbulent blood flow can cause false-positive results. The imaging agent for MRA (gadolinium) has been associated with nephrogenic systemic fibrosis, which occurs primarily in patients with a GFR of < 15 mL/min/1.73 m², and rarely in patients with a GFR of 15–30 mL/min/1.73 m². It has also been seen in those with acute kidney injury and kidney transplants.

Renal angiography is the gold standard for diagnosis. CO₂ subtraction angiography can be used in place of dye when the risk of dye nephropathy exists—eg, in diabetic patients with kidney injury. Lesions are most commonly found in the proximal third or ostial region of the renal artery. The risk of atheroembolic phenomena after angiography ranges from 5% to 10%. Fibromuscular dysplasia has a characteristic “beads-on-a-string” appearance on angiography.

▶ Treatment

Treatment of atherosclerotic ischemic renal disease is controversial. Options include medical management, angioplasty with or without stenting, and surgical bypass. A 2009 study has shown that intervention is no better than optimal medical management in typical patients in whom renal artery stenosis was diagnosed via gold-standard mechanisms. Angioplasty might reduce the number of antihypertensive medications but does not significantly change the progression of kidney dysfunction in comparison to patients medically managed. Stenting produces significantly better angioplastic results. However, blood pressure is equally improved, and serum creatinines are similar at

6 months of observation compared with both angioplasty and stents. Angioplasty is equally as effective as, and safer than, surgical revision. Treatment of **fibromuscular dysplasia** with percutaneous transluminal angioplasty is often curative.

GLOMERULAR DISEASES

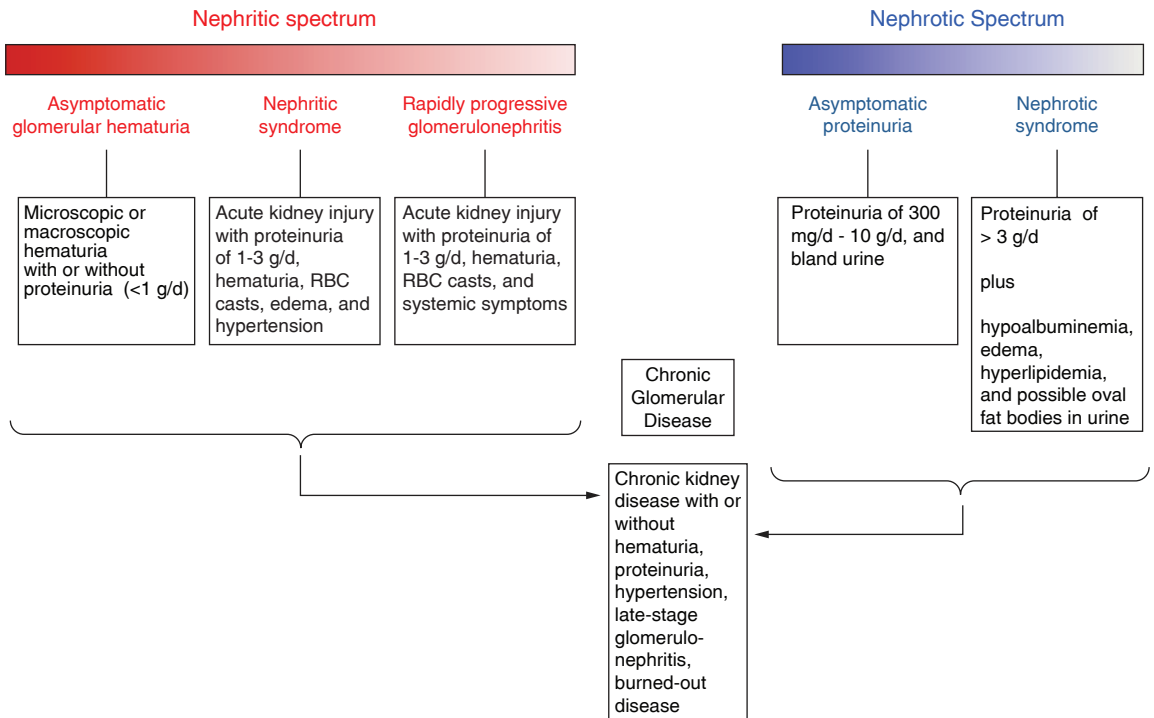

Abnormalities of glomerular function can be caused by damage to the major components of the glomerulus: the epithelium (podocytes), basement membrane, capillary endothelium, or mesangium. The damage may be caused by overwork injury, such as in CKD; by an inflammatory process, such as systemic lupus erythematosus; by a podocyte

protein mutation, such as in hereditary focal and segmental glomerulosclerosis; or a deposition disease, such as diabetes or amyloidosis. A specific histologic pattern of glomerular injury results from this damage and can be seen on renal biopsy.

Classification

Clinically, a glomerular disease can be classified as being in one of two spectra—either in the nephritic spectrum or the nephrotic spectrum (Figure 22–4). In the “least severe” end of the **nephritic spectrum**, the findings of glomerular hematuria (ie, dysmorphic red blood cells) are characteristic. The nephritic syndrome, comprising glomerular hematuria, subnephrotic proteinuria (<3 g/d), edema, and elevated creatinine, falls in the mid-portion of the spectrum. The rapidly progressive glomerulonephritides are at the “most severe” and clinically urgent end of the nephritic spectrum.

The **nephrotic spectrum** comprises diseases that present with primarily proteinuria of at least 0.5–1 g/d and a bland urine sediment (no cells or cellular casts). The more severe end of the nephrotic spectrum comprises the nephrotic syndrome, which is characterized by the constellation of nephrotic-range proteinuria of > 3 g/d, hypoalbuminuria, edema, and hyperlipidemia. Differentiating between a clinical presentation within the nephritic spectrum versus the

▲ Figure 22–4. Glomerular diseases present within one of the clinical spectra shown, the exact presentation is determined by the severity of the underlying disease and the pattern of injury. Nephritic diseases are characterized by the presence of an active urine sediment with glomerular hematuria and often with proteinuria. Nephrotic spectrum diseases are proteinuric with bland urine sediments (no cells or cellular casts). All glomerular diseases may progress to a chronic, scarred state. (Adapted, with permission, from Megan Troxell, MD, PhD.)

Table 22-9. Classification and findings in glomerulonephritis: Nephritic spectrum presentations.

	Typical presentation	Association/notes	Serology
Postinfectious glomerulonephritis	Children: abrupt onset of nephritic syndrome and acute kidney injury but can present anywhere in nephritic spectrum	Streptococci, other bacterial infections (eg, staphylococci, endocarditis, shunt infections)	Rising ASO titers, low complement levels
IgA nephropathy (Berger disease) and Henoch-Schönlein purpura, systemic IgA vasculitis	Classically: gross hematuria with upper respiratory tract infection; can present anywhere in nephritic spectrum; Henoch-Schönlein purpura with vasculitic rash and gastrointestinal hemorrhage	Abnormal IgA glycosylation in both primary (familial predisposition) and secondary disease (associated with cirrhosis, HIV, celiac disease) Henoch-Schönlein purpura in children after an inciting infection	No serologic tests helpful; complement levels are normal
Pauci-immune (granulomatosis with polyangiitis, Churg-Strauss, polyarteritis, idiopathic crescentic glomerulonephritis)	Classically as crescentic or RPGN, but can present anywhere in nephritic spectrum; may have respiratory tract/sinus symptoms in granulomatosis with polyangiitis	See Figure 22-5	ANCAs: MPO or PR3 titers high; complement levels normal
Anti-glomerular basement membrane glomerulonephritis; Goodpasture syndrome	Classically as crescentic or RPGN, but can present anywhere in nephritic spectrum; with pulmonary hemorrhage in Goodpasture syndrome	May develop as a result of respiratory irritant exposure (chemicals or tobacco use)	Anti-GBM antibody titers high; complement levels normal
Cryoglobulin-associated glomerulonephritis	Often acute nephritic syndrome; often with systemic vasculitis including rash and arthritis	Most commonly associated with chronic hepatitis C; may occur with other chronic infections or some connective tissue diseases	Cryoglobulins positive; rheumatoid factor may be elevated; complement levels low
Idiopathic MPGN	Classically presents with acute nephritic syndrome, but can see nephrotic syndrome features in addition	Most patients are < 30 years old Type I most common Type II (dense deposit disease) associated with C3 nephritic factor	Low complement levels
Hepatitis C infection	Anywhere in nephritic spectrum	Can cause MPGN pattern of injury or cryoglobulinemic glomerulonephritis; membranous nephropathy pattern of injury uncommon	Low complement levels; positive hepatitis C serology; rheumatoid factor may be elevated
Systemic lupus erythematosus	Anywhere in nephritic spectrum, depending on pattern/severity of injury	Treatment depends on clinical course and International Society of Nephrology and Renal Pathology Society (ISN/RPS) classification on biopsy	High ANA and anti-double-stranded DNA titers; low complement levels

ANA, antinuclear; ANCAs: antineutrophil cytoplasmic antibodies; GBM, glomerular basement membrane; MPGN, membranoproliferative glomerulonephritis; RPGN, rapidly progressive glomerulonephritis.

nephrotic spectrum is important because it helps narrow the differential diagnosis of the underlying glomerular disease (Tables 22-9 and 22-10).

Glomerular diseases can also be classified according to whether they cause only renal abnormalities (primary renal disease) or whether the renal abnormalities result from a systemic disease (secondary renal disease).

Further evaluation prior to renal biopsy may include serologic testing for systemic diseases that can result in glomerular damage (Figure 22-5).

Table 22-10. Classification and findings in glomerulonephritis: Nephrotic spectrum presentations.

Disease	Typical presentation	Association/notes
Minimal change disease (nil disease; lipid nephrosis)	Child with sudden onset of full nephrotic syndrome	Children: associated with allergy or viral infection Adults: associated with Hodgkin disease, NSAIDs
Membranous nephropathy	Anywhere in nephrotic spectrum, but nephrotic syndrome not uncommon; particular predisposition to hypercoagulable state	Primary (idiopathic) may be associated with antibodies to PLA ₂ R Associated with non-Hodgkin lymphoma, carcinoma (gastrointestinal, renal, bronchogenic, thyroid), gold therapy, penicillamine, SLE, chronic hepatitis B or C infection
Focal and segmental glomerulosclerosis	Anywhere in nephrotic spectrum; children with congenital disease have nephrotic syndrome	Children: congenital disease with podocyte gene mutation, or in spectrum of disease with minimal change disease Adults: Associated with heroin abuse, HIV infection, reflux nephropathy, obesity, pamidronate, podocyte protein mutations
Amyloidosis	Anywhere in nephrotic spectrum	AL: plasma cell dyscrasia with Ig light chain over-production and deposition; check SPEP and UPEP AA: serum amyloid protein A over-production and deposition in response to chronic inflammatory disease (rheumatoid arthritis, inflammatory bowel disease, chronic infection)
Diabetic nephropathy	High GFR (hyperfiltration) → microalbuminuria → frank proteinuria → decline in GFR	Diabetes diagnosis precedes diagnosis of nephropathy by years
HIV-associated nephropathy	Heavy proteinuria, often nephrotic syndrome, progresses to ESRD relatively quickly	Usually seen in antiviral treatment-naïve patients (rare in HAART era), predilection for those of African descent
Membranoproliferative glomerulonephropathy	Can present with nephrotic syndrome, but usually with nephritic features as well (glomerular hematuria)	See Table 22-9

ESRD, end-stage renal disease; GFR, glomerular filtration rate; HAART, highly active antiretroviral therapy; NSAIDs, nonsteroidal anti-inflammatory drugs; PLA₂R, phospholipase A₂ receptor; SLE, systemic lupus erythematosus; SPEP/UPEP: serum and urine protein electrophoresis.

NEPHRITIC SPECTRUM GLOMERULAR DISEASES

ESSENTIALS OF DIAGNOSIS

- ▶ Glomerular hematuria (dysmorphic red blood cells), possibly red blood cell urinary casts.
- ▶ Less than nephrotic range proteinuria (0.3–3 g/d).
- ▶ Hypertension is common.
- ▶ Entity classified into one of three groups: asymptomatic glomerular hematuria, acute nephritic syndrome, or rapidly progressive glomerulonephritis.
- ▶ Edema, if present, in dependent (eg, periorbital or scrotal) areas.

▶ General Considerations

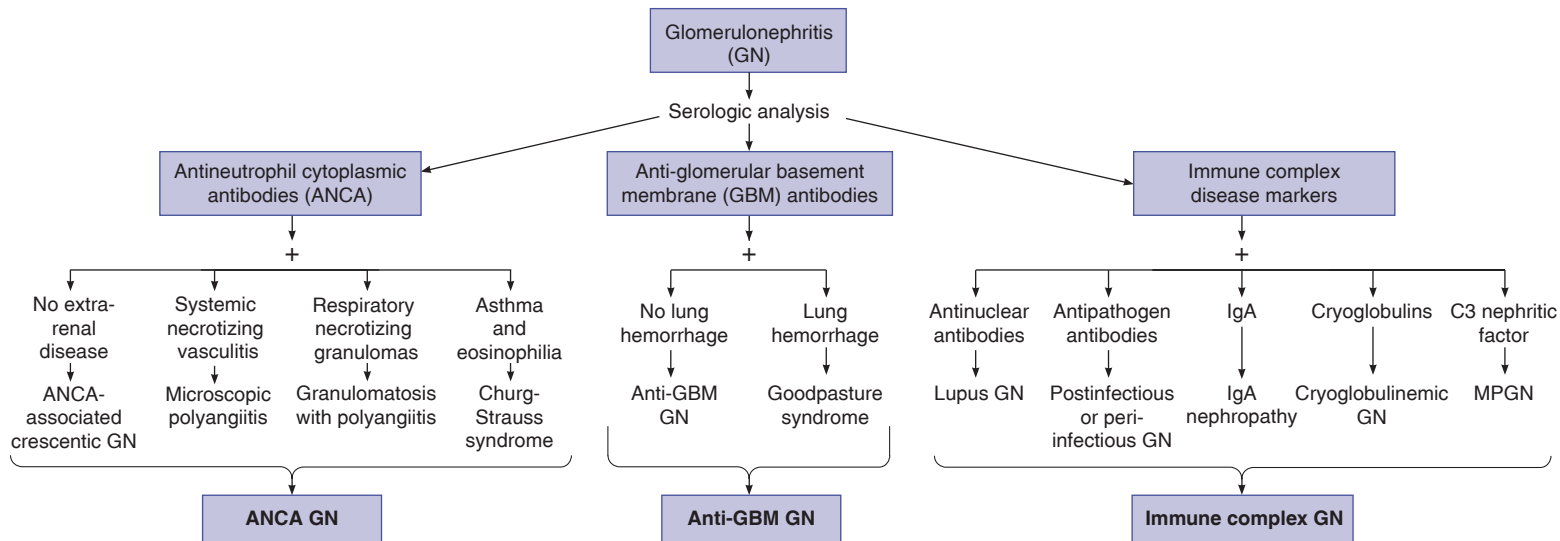

Glomerulonephritis is a term given to those diseases that present in the nephritic spectrum and usually signifies an

inflammatory process causing renal dysfunction. It can be acute, developing over days to weeks, with or without resolution, or may be more chronic and indolent with progressive scarring. As noted above, diseases that cause a nephritic spectrum presentation may present with glomerular hematuria with some proteinuria, with nephritic syndrome, or with rapidly progressive glomerulonephritis (Figure 22-4). The presentation depends on the severity of the underlying inflammation and the pattern of injury caused by the disease process.

▶ Clinical Findings

A. Symptoms and Signs

If the nephritic syndrome is present, edema is first seen in regions of low tissue pressure such as the periorbital and scrotal areas. Hypertension in the nephritic syndrome is due to sodium retention resulting from acute decrease in GFR. Heavy glomerular bleeding from inflammation may result in gross hematuria (smoky or cola-colored urine).

▲ **Figure 22-5.** Serologic analysis of patients with glomerulonephritis. MPGN, membranoproliferative glomerulonephritis. (Reproduced, with permission, from Greenberg A et al. *Primer on Kidney Diseases*. Academic Press, 1994 and Jennette JC, Falk RJ). Diagnosis and management of glomerulonephritis and vasculitis presenting as acute renal failure. *Med Clin North Am*. 1990;74(4):893-908. © Elsevier.)

B. Laboratory Findings

1. Serologic testing—Serologic tests, including complement levels, antinuclear antibodies, cryoglobulins, hepatitis serologies, ANCA, anti-GBM antibodies, and antistreptolysin O (ASO) titers (Figure 22–5), are done based on the history and physical examination to narrow the differential diagnosis of the nephritic spectrum disorder.

2. Urinalysis—The urinalysis shows protein and red blood cells. On microscopy, these cells are misshapen from traversing a damaged capillary membrane—so-called dysmorphic red blood cells. Red blood cell casts are seen with heavy glomerular bleeding and tubular stasis. When quantified, proteinuria is usually subnephrotic (<3 g/d).

3. Biopsy—Renal biopsy should be considered if there are no contraindications (eg, bleeding disorders, thrombocytopenia, uncontrolled hypertension). Light microscopy delineates the pattern of injury; underlying disease process can be further categorized according to the immunofluorescence pattern and appearance on electron microscopy.

► Treatment

General measures for all include aggressive treatment of hypertension and fluid overload if present. Dialysis may be needed as discussed in the acute kidney injury section. The inflammatory glomerular injury may require corticosteroids or cytotoxic agents, or both. (See specific diseases discussed below.)

► When to Refer

Any patient in whom a glomerulonephritis is suspected should be referred to a nephrologist.

► When to Admit

Any suspicion of acute nephritic syndrome or rapidly progressive glomerulonephritis warrants consideration of immediate hospitalization.

POSTINFECTIOUS GLOMERULONEPHRITIS

ESSENTIALS OF DIAGNOSIS

- ▶ Proteinuria.
- ▶ Glomerular hematuria.
- ▶ Symptoms 1–3 weeks after infection (often pharyngitis or impetigo).

► General Considerations

Postinfectious glomerulonephritis is most often due to infection with nephritogenic group A β -hemolytic streptococci. It can occur sporadically or in clusters and during epidemics. It commonly appears after pharyngitis or impetigo with onset 1–3 weeks after infection (average 7–10 days).

Other infections have been associated with postinfectious glomerulonephritis including bacteremic states

(especially with *S aureus*), bacterial pneumonias, deep-seated abscesses, gram-negative infections, infective endocarditis, and shunt infections. Viral, fungal, and parasitic causes of postinfectious glomerulonephritis pattern of glomerular injury include hepatitis B or C, HIV, cytomegalovirus infection, infectious mononucleosis, coccidioidomycosis, malaria, mycobacteria, syphilis, and toxoplasmosis.

► Clinical Findings

A. Symptoms and Signs

Disease presentation can vary widely across the nephritic spectrum from asymptomatic glomerular hematuria (especially in epidemic cases) to nephritic syndrome with hypertension, oliguria, edema, and perhaps cola-colored urine.

B. Laboratory Findings

Serum complement levels are low; in postinfectious glomerulonephritis due to group A streptococcal infection, antistreptolysin O (ASO) titers can be high unless the immune response has been blunted with previous antibiotic treatment. Glomerular hematuria and subnephrotic proteinuria are present; severe cases may demonstrate elevated serum creatinine and red cell casts in the urine. Renal biopsy shows a diffuse proliferative pattern of injury on light microscopy. Immunofluorescence shows IgG and C3 in a granular pattern in the mesangium and along the capillary basement membrane. Electron microscopy shows large, dense subepithelial deposits or “humps.”

► Treatment

The underlying infection should be identified and treated appropriately, but otherwise, treatment for postinfectious glomerulonephritis is supportive. Antihypertensives, salt restriction, and diuretics should be used if needed. Corticosteroids have not been shown to improve outcome. Prognosis depends on the severity of the glomerular injury and age of the patient. Children are more likely to fully recover; adults are more prone to the development of severe disease (rapidly progressive glomerulonephritis with crescent formation) and CKD.

IGA NEPHROPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Proteinuria: minimal to nephrotic range.
- ▶ Glomerular hematuria: microscopic is common; macroscopic (gross) after infection.
- ▶ Positive IgA staining on renal biopsy.

► General Considerations

IgA nephropathy (Berger disease) is a primary renal disease of IgA deposition in the glomerular mesangium. The inciting cause is unknown but is likely due to abnormal glycosylation of IgA subclass 1 molecules. IgA nephropathy can be a primary (renal-limited) disease, or it can be secondary to hepatic cirrhosis, celiac disease, and infections such as HIV and cytomegalovirus. Susceptibility to IgA nephropathy seems to be inheritable.

IgA nephropathy is the most common primary glomerular disease worldwide, particularly in Asia. It is most commonly seen in children and young adults, with males affected two to three times more commonly than females.

► Clinical Findings

An episode of gross hematuria is the most common presenting symptom. Frequently, this is associated with an upper respiratory infection (50%), GI symptoms (10%), or a flu-like illness (15%). The urine becomes red or cola-colored 1–2 days after illness onset. In contrast to postinfectious glomerulonephritis, this feature has been called “synpharyngitic hematuria” since there is no significant latent period. IgA nephropathy can present as any of the nephritic syndromes from asymptomatic microscopic hematuria to rapidly progressive glomerulonephritis. Rarely, it can present as a nephrotic syndrome.

There are no serologic tests that aid in the diagnosis of IgA nephropathy; serum IgA subclass 1 testing may be a possibility in the future. Serum complements are normal. The typical pattern of injury seen on renal biopsy is a focal glomerulonephritis with mesangial proliferation; immunofluorescence demonstrates diffuse mesangial IgA and C3 deposits.

► Treatment

The disease course of primary IgA nephropathy varies widely among patients; treatment approach needs to be tailored to risk for progression. Patients with low risk for progression (no hypertension, normal GFR, minimal proteinuria) can be monitored annually. Patients at medium to high risk (proteinuria > 0.5 g/d, decreased GFR, or hypertension, or any combination of these three conditions) should be given an initial course of conservative treatment, including ACE inhibitor or ARB therapy and blood pressure control to 130/80 mm Hg. For those in this risk category who have nephrotic syndrome or a rapid decline in GFR, or those in whom proteinuria is not suppressed to < 1 g/d but have relatively preserved GFR (stage 3 CKD or less), immunosuppressive therapy should be considered. In patients with proteinuria of 1.0–3.5 g/d and GFR > 70 mL/min/1.73 m², corticosteroid therapy has proven beneficial. One such regimen (methylprednisolone, 1 g/d intravenously for 3 days during months 1, 3, and 5, plus prednisone in a dosage of 0.5 mg/kg orally every other day for 6 months) showed a 2% doubling of creatinine after 6 years in the treatment group versus a 21% doubling of creatinine in the control group. For patients with a GFR < 70 mL/min/1.73 m² and a predicted progression to ESRD in < 5 years, some experts have suggested a trial of low-dose cyclophosphamide followed by maintenance azathioprine. Kidney transplantation is an

excellent option for patients with ESRD, but recurrent disease has been documented in 30% of patients 5–10 years post-transplant. Fortunately, recurrent disease rarely leads to failure of the allograft.

► Prognosis

Approximately one-third of patients experience spontaneous clinical remission. Progression to ESRD occurs in 20–30% of patients. The remaining patients show chronic microscopic hematuria and a stable serum creatinine. The most unfavorable prognostic indicator is proteinuria > 1 g/d; other unfavorable prognostic indicators include hypertension, persistent microscopic hematuria and proteinuria, glomerulosclerosis or glomerular crescents on biopsy, and abnormal GFR on presentation.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura is a small-vessel leukocytoclastic vasculitis associated with IgA subclass 1 deposition in vessel walls. It is most common in children and is often associated with an inciting infection, such as group A streptococcus or other exposure. There is a male predominance. It classically presents with palpable purpura in the lower extremities and buttock area; arthralgias; and abdominal symptoms, such as nausea, colic, and melena. A decrease in GFR is common with a nephritic presentation. The renal lesions are considered by most experts to be identical to those found in IgA nephropathy. Most patients with microscopic hematuria and minimal proteinuria recover fully over several weeks. Progressive CKD and possibly ESRD are more likely to develop in those with the nephrotic syndrome and the presence of both nephritic and nephrotic syndrome poses the worst renal prognosis. Histologic classification of the lesions in children may also provide prognostic information. To date, although several treatment regimens of various immunosuppressive agents have been clinically tested, none have been definitively proven to alter the course of severe Henoch-Schönlein purpura nephritis. Rituximab treatment and plasma exchange have been successful for severe disease according to several case reports, but clinical trials are lacking.

Further details about Henoch-Schönlein purpura are provided in Chapter 20.

PAUCI-IMMUNE GLOMERULONEPHRITIS (ANCA-Associated)

Pauci-immune necrotizing glomerulonephritis is caused by the following systemic ANCA-associated small-vessel vasculitides: granulomatosis with polyangiitis, microscopic polyangiitis, and Churg-Strauss disease (see Chapter 20). ANCA-associated glomerulonephritis can also present as a primary renal lesion without systemic involvement; this is termed “idiopathic crescentic glomerulonephritis.” The precise pathogenesis of these entities is unknown; it is likely that ANCAs are responsible for neutrophil activation and consequent vascular damage. Immunofluorescence of renal biopsy specimens do not reveal any evidence of immunoglobulin or complement deposition, hence the term “pauci-immune.” Renal involvement classically presents as a rapidly progressive glomerulonephritis.

► Clinical Findings

A. Symptoms and Signs

Symptoms of a systemic inflammatory disease, including fever, malaise, and weight loss may be present and usually precede initial presentation by several months. In addition to hematuria and proteinuria from glomerular inflammation, some patients exhibit purpura from dermal capillary involvement and mononeuritis multiplex from nerve arteriolar involvement. Ninety percent of patients with granulomatosis with polyangiitis have upper (especially sinus) or lower respiratory tract symptoms with nodular lesions that can cavitate and bleed. Hemoptysis is a concerning sign and usually warrants hospitalization.

B. Laboratory Findings

Serologically, ANCA subtype analysis is done. A c-ANCA is specific for antiproteinase-3 antibodies (PR3-ANCA), while a p-ANCA is specific for antimyeloperoxidase antibodies (MPO-ANCA). Most patients with granulomatosis with polyangiitis are c-ANCA positive; the remainder can have a p-ANCA pattern or rarely do not demonstrate ANCA serologically. Microscopic angiitis has either a p-ANCA or c-ANCA pattern about 80% of the time. As noted above, the small vessels and glomeruli lack immune deposits on immunofluorescence. Necrotizing lesions and crescents are the pattern of injury associated with this rapidly progressive glomerulonephritis.

► Treatment

Treatment should be instituted early. Induction therapy of high-dose corticosteroids (methylprednisolone, 1–2 g/d intravenously for 3 days, followed by prednisone, 1 mg/kg orally for 1 month, with a slow taper over the next 6 months) and cytotoxic agents (cyclophosphamide, 0.5–1 g/m² intravenously per month or 1.5–2 mg/kg orally for 3–6 months) is followed by long-term azathioprine or mycophenolate mofetil. Plasma exchange has been shown to be beneficial in conjunction with induction therapy; however, a recent meta-analysis calls into question the strength of this benefit. Rituximab has recently been shown to be noninferior to cyclophosphamide for induction.

► Prognosis

Without treatment, prognosis is extremely poor. However, with aggressive treatment, complete remission can be achieved in about 75% of patients. Prognosis depends on the extent of renal involvement before treatment is started. ANCA titers should be monitored to follow treatment efficacy; rising titers herald relapse. Patients receiving cyclophosphamide should receive prophylaxis for *Pneumocystis jiroveci*, such as trimethoprim-sulfamethoxazole double-strength orally 3 days per week.

ANTI-GLOMERULAR BASEMENT MEMBRANE GLOMERULONEPHRITIS & GOODPASTURE SYNDROME

Goodpasture syndrome is defined by the clinical constellation of glomerulonephritis and pulmonary hemorrhage; injury to both is mediated by antibodies to epitopes in the GBM (Figure 22–5). Up to one-third of patients with anti-GBM glomerulonephritis have no evidence of concomitant lung injury. Anti-GBM-associated glomerulonephritis accounts for 10–20% of patients with rapidly progressive acute glomerulonephritis. The incidence peaks in the second and third decades of life during which time males are predominantly affected and lung involvement is more common, and again in the sixth and seventh decades with less gender predominance. Lung involvement has been associated with pulmonary infection, tobacco use, and hydrocarbon solvent exposure; HLA-DR2 and -B7 antigens may predispose as well.

► Clinical Findings

A. Symptoms and Signs

The onset of disease is preceded by an upper respiratory tract infection in 20–60% of cases; hemoptysis, dyspnea, and possible respiratory failure may ensue. Other findings are consistent with a rapidly progressive acute glomerulonephritis, although some cases may present with much milder forms of the nephritic spectrum of disease (eg, glomerular hematuria and proteinuria with minimal renal dysfunction).

B. Laboratory Findings

Laboratory evaluation can show iron deficiency anemia if pulmonary hemorrhage has been prolonged. Serum

complement levels are normal. Sputum may contain hemosiderin-laden macrophages. Chest radiographs can show shifting pulmonary infiltrates due to pulmonary hemorrhage. The diffusion capacity of carbon monoxide is markedly increased. Diagnosis is confirmed by finding circulating anti-GBM antibodies, which are positive in over 90% of patients. About 15% of patients also have elevated ANCA titers; these patients should be treated with plasma exchange as for anti-GBM disease. Renal biopsy typically shows crescent formation on light microscopy, with linear IgG staining along the GBM on immunofluorescence.

▶ Treatment

The treatment of choice is a combination of plasma exchange therapy to remove circulating antibodies, and administration of immunosuppressive drugs to prevent formation of new antibodies and control the inflammatory response. Corticosteroids are typically given initially in pulse doses of methylprednisolone, 1–2 g/d for 3 days, then prednisone orally 1 mg/kg/d. Cyclophosphamide is administered intravenously at a dose of 0.5–1 g/m² per month or orally at a dosage of 2–3 mg/kg/d. Daily plasma exchange is performed for up to 2 weeks. A poorer prognosis exists in patients with oliguria and a serum creatinine > 6–7 mg/dL, or requiring dialysis upon presentation. Anti-GBM antibody titers should decrease as the clinical course improves.

CRYOGLOBULIN-ASSOCIATED GLOMERULONEPHRITIS

Essential (mixed) cryoglobulinemia is a disorder associated with cold-precipitable immunoglobulins (cryoglobulins). Glomerular disease results from the precipitation of cryoglobulins in glomerular capillaries (Figure 22–5). The cause is typically hepatitis C infection, but other infections (such as hepatitis B) or other occult or clinically apparent viral, bacterial, and fungal infections can be causative; it is also associated with some connective tissue diseases.

Patients exhibit purpuric and necrotizing skin lesions in dependent areas, arthralgias, fever, and hepatosplenomegaly. Serum complement levels are depressed. Rheumatoid factor is often elevated when cryoglobulins are present. Renal biopsy may show several different patterns of injury; there may be crescent formation, glomerular capillary thrombi, or MPGN (see below). Treatment consists of aggressively targeting the causative infection. Pulse corticosteroids, plasma exchange, and cytotoxic agents have been used when risk of exacerbating the underlying infection is resolved. Interferon- α (IFN- α) has been shown to benefit patients with hepatitis C–related cryoglobulinemia; in patients who do not respond to such treatment or for whom antiviral treatment is not indicated, there is some suggestion that rituximab may improve renal outcomes.

Colucci G et al. Cryoglobulinemic membranoproliferative glomerulonephritis: beyond conventional therapy. *Clin Nephrol.* 2011 Apr;75(4):374–9. [PMID: 21426893]

IDIOPATHIC MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

MPGN in its primary form is an idiopathic renal disease that usually presents with nephritic features ranging from asymptomatic glomerular hematuria and proteinuria, to episodes of gross hematuria, to the acute nephritic syndrome. MPGN may also present with the nephrotic syndrome. Most patients are under 30 years of age, and a recent history of upper respiratory tract infection is present in nearly half. At least two major subgroups are recognized: type I and type II. Both are characterized by hypocomplementemia; in type I MPGN, the classic complement pathway is activated, leading to low or normal C3 with low C4, whereas in type II disease, the alternative complement pathway is activated and C3 is low while C4 is normal. Prognosis is worse in type II disease.

Renal biopsy in **type I MPGN** demonstrates a thickened GBM due to immune complex deposition and abnormal mesangial cell proliferation between the GBM and the endothelial cells. This gives a characteristic “splitting” or “tram-track” appearance to the capillary wall. Immunofluorescence shows IgG, IgM, and granular deposits of C3, C1q, and C4. Subendothelial deposits are seen on electron microscopy.

Type II MPGN (dense deposit disease) is less common than type I and is associated with C3 nephritic factor, a circulating IgG antibody. Light microscopy is similar to type I. Electron microscopy shows a characteristic ribbon-like deposit of homogeneous material that replaces part of the GBM.

Treatment of idiopathic MPGN is controversial. After ruling out secondary or systemic causes, treatment of children with nephrotic syndrome consists of corticosteroids at 40 mg/m² every other day for a prolonged duration. Uncontrolled studies suggest that there may be some role for other immunosuppressive regimens, including cyclophosphamide, cyclosporine, and mycophenolate mofetil. ACE inhibitors and ARBs should be used to treat hypertension and proteinuria. Adults are less likely to respond to corticosteroid treatment. In the past, 50% of patients progressed to ESRD in 10 years; this rate may now be slightly lower with the introduction of more aggressive therapy. Less favorable prognostic findings include type II MPGN, early renal insufficiency, hypertension, and persistent nephrotic syndrome. Both types of MPGN will recur after renal transplantation; however, type II recurs more commonly. Plasma exchange has been used with mixed results to treat post-transplant recurrence of MPGN.

Yuan M et al. Combination therapy with mycophenolate mofetil and prednisone in steroid-resistant idiopathic membranoproliferative glomerulonephritis. *Clin Nephrol.* 2010 May; 73(5):354–9. [PMID: 20420795]

HEPATITIS C VIRUS INFECTION

Renal disease in the setting of hepatitis C viral infection was not well-recognized until 1993. Now it accounts for approximately 8% of patients with ESRD. The three patterns of renal injury associated with hepatitis C are secondary MPGN, cryoglobulinemic glomerulonephritis, and membranous nephropathy. A type I MPGN (see section above) is the most common lesion found on kidney biopsy. These patients typically have hematuria and proteinuria, hypertension, and anemia. Occasionally, they also exhibit features of the nephrotic syndrome. Many patients have elevated serum transaminases and an elevated rheumatoid factor. Hypocomplementemia is very common, with C4 typically more reduced than C3. Cryoglobulinemic disease is discussed above. Membranous glomerulopathy is the least common of the three and presents with a typical nephrotic picture; neither cryoglobulins nor rheumatoid factor is present.

▶ Treatment

In patients with hepatitis C virus–associated MPGN not receiving treatment for liver disease, the question arises whether to initiate therapy for kidney disease. The main indications for therapy are poor renal function, nephrotic syndrome, new or worsening hypertension, fibrosis or tubulointerstitial disease on biopsy, and progressive disease. IFN- α may result in suppression of viremia and improvement in hepatic function. Renal function rarely improves unless viral suppression occurs; however, renal function often worsens when therapy is abated. Ribavirin is relatively contraindicated in kidney disease because of the dose-related hemolysis that occurs with renal dysfunction. Despite this, some case series have shown benefit with combined IFN- α and ribavirin in closely monitored settings.

Perico N et al. Hepatitis C infection and chronic renal diseases. *Clin J Am Soc Nephrol.* 2009 Jan;4(1):207–20. [PMID: 19129320]

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus is an autoimmune disease in which renal involvement is common. In various series, renal involvement ranges from 35% to 90% (see Chapter 20), with the higher estimates encompassing subclinical disease.

Lupus nephritis may present as any entity in the spectrum of clinical glomerular disease, although most presentations are as glomerulonephritis. Nonglomerular syndromes include tubulointerstitial nephritis and vasculitis. All patients with systemic lupus erythematosus should have routine urinalyses to monitor for the appearance of hematuria or proteinuria. If urinary abnormalities are detected, renal biopsy is often performed. The 2003 International Society of Nephrology and Renal Pathology Society (ISN/RPS) classification of renal glomerular lesions is class I, minimal mesangial nephritis; class II, mesangial proliferative nephritis; class III, focal (< 50% of glomeruli affected with capillary involvement) proliferative nephritis;

class IV, diffuse (> 50% of glomeruli affected with capillary involvement) proliferative nephritis; class V, membranous nephropathy; and class VI, advanced sclerosis without residual disease activity. Classes III and IV, the most severe forms of lupus nephritis, are further classified as active or chronic, and global or segmental, which confers additional prognostic value.

▶ Treatment

Individuals with **class I** and **class II lesions** require no treatment. Transformation of these types to a more active lesion may occur and is usually accompanied by an increase in lupus serologic activity and evidence of deteriorating renal function (eg, rising serum creatinine, increasing proteinuria). Repeat biopsy to confirm the transformation in these patients is recommended. Patients with extensive **class III lesions** and all **class IV lesions** should receive aggressive immunosuppressive therapy. The features signifying the poorest prognosis in patients with class III or IV lesions include elevated serum creatinine, lower complement levels, male sex, presence of antiphospholipid antibodies, nephrotic-range proteinuria, black race, and poor response to therapy. Indications for treatment of **class V lesions** are unclear; however, if superimposed proliferative lesions exist, aggressive therapy should be instituted.

Treatment of **proliferative lupus nephritis** consists of induction therapy, followed by maintenance treatment. All induction therapy includes corticosteroids (eg, methylprednisolone 1 g intravenously daily for 3 days followed by prednisone, 1 mg/kg orally daily with subsequent taper over 4–6 weeks) in combination with either cyclophosphamide or mycophenolate mofetil. Current data suggest that blacks and Hispanics respond more favorably to mycophenolate mofetil rather than cyclophosphamide; in addition, mycophenolate mofetil has a more favorable side-effect profile than does cyclophosphamide. Cyclophosphamide induction regimens vary but usually involve monthly intravenous pulse doses (500–750 mg/m²) for 4–8 months. Induction is followed by daily oral mycophenolate mofetil or azathioprine maintenance therapy. A recent trial showed that mycophenolate mofetil was superior to azathioprine maintenance and caused few adverse effects. Mycophenolate mofetil induction is typically given at 2–3 g/d, then tapered to 1–2 g/d for maintenance. Tacrolimus or cyclosporine may also be considered, but the relapse rate is high upon discontinuation of these agents. Rituximab has also been used for induction therapy, but clinical trial data are lacking. Remission rates with induction vary from 80% for partial remission to 50–60% for full remission; it may take more than 6 months to see these effects. Relapse is common and rates of disease flare are higher in those who do not experience complete remission; similarly, progression to ESRD is more common in those who relapse more frequently, or in whom no remission has been achieved.

The normalization of various laboratory tests (double-stranded DNA antibodies, serum C3, C4, CH₅₀ levels) can be useful in monitoring treatment. Urinary protein levels and sediment activity are also helpful markers. Patients with systemic lupus erythematosus who undergo dialysis have a

favorable prospect for long-term survival; interestingly, systemic lupus symptoms may become quiescent with the development of ESRD. Patients with systemic lupus erythematosus undergoing kidney transplants have recurrent renal disease in 8% of cases.

NEPHROTIC SPECTRUM GLOMERULAR DISEASES

ESSENTIALS OF DIAGNOSIS

- ▶ Bland urine sediment (few if any cells or cellular casts).
- ▶ Full-blown nephrotic syndrome consists of the following:
 - -Urine protein excretion > 3 g per 24 hours.
 - -Hypoalbuminemia (albumin < 3 g/dL).
 - -Peripheral edema.
 - -Hyperlipidemia.
 - -Oval fat bodies in the urine.

▶ General Considerations

In adults, about one-third of patients with nephrotic syndrome have a systemic disease such as diabetes mellitus, amyloidosis, or systemic lupus erythematosus. With the current epidemic of type 2 diabetes mellitus, the proportion with diabetes is slowly increasing. The remainder have proteinuria due to primary renal disease. The most common causes are minimal change disease, focal segmental glomerulosclerosis, membranous nephropathy, and MPGN (see above). Any of these disease processes can present on the less severe end of the spectrum with a bland urinalysis and proteinuria, or with the full-blown nephrotic syndrome. Serum creatinine may or may not be abnormal at the time of presentation, depending on the severity, acuity and chronicity of the disease.

▶ Clinical Findings

A. Symptoms and Signs

Peripheral edema is a hallmark of the nephrotic syndrome, occurring when the serum albumin concentration is < 3 g/dL (30 g/L). Edema is most likely due to sodium retention and, at albumin levels < 2 g/dL (20 g/L), arterial underfilling from low plasma oncotic pressure. Initially, this presents in

the dependent areas of the body subject to gravity, such as the lower extremities; however, such edema can become generalized, including notable periorbital edema. Patients can experience dyspnea due to pulmonary edema, pleural effusions, and diaphragmatic compromise with ascites. Complaints of abdominal fullness may also be present in patients with ascites.

Patients with the nephrotic syndrome may also have an increase incidence of infection owing to loss of immunoglobulins and certain complement moieties in the urine; similarly, there can be increased risk of venous thrombosis secondary to loss of anticoagulant factors.

B. Laboratory Findings

1. Urinalysis—Proteinuria occurs as a result of effacement of podocytes (foot processes) and an alteration of the negative charge of the GBM. The screening test for proteinuria is the urinary dipstick analysis; however, this test indicates albumin only. The addition of sulfosalicylic acid to the urine sediment allows abnormal paraproteins to be detected. A spot urine protein to urine creatinine ratio gives a reasonable approximation of grams of protein excreted per day.

Microscopically, the urinary sediment has relatively few cellular elements or casts. However, if marked hyperlipidemia is present, the urine can have oval fat bodies resulting from lipid deposits in sloughed renal tubular epithelial cells. They appear as “grape clusters” under light microscopy and “Maltese crosses” under polarized light.

2. Blood chemistries—The nephrotic syndrome results in hypoalbuminemia (< 3 g/dL [30 g/L]) and hypoproteinemia (< 6 g/dL [60 g/L]). Hyperlipidemia occurs in over 50% of patients with early nephrotic syndrome, and becomes more frequent and worsens in degree as the severity of the nephritic syndrome increases. A fall in oncotic pressure triggers increased hepatic production of lipids (cholesterol and apolipoprotein B). There is also decreased clearance of very low-density lipoproteins, causing hypertriglyceridemia. Patients may also have an elevated erythrocyte sedimentation rate as a result of alterations in some plasma components such as increased levels of fibrinogen. Patients may become deficient in vitamin D, zinc, and copper from loss of binding proteins in the urine.

Laboratory testing to determine the underlying cause may include complement levels, serum and urine protein electrophoresis, antinuclear antibodies, and serologic tests for hepatitis.

3. Renal biopsy—Renal biopsy is often performed in adults with new-onset idiopathic nephrotic syndrome if a primary renal disease that may require drug therapy (eg, corticosteroids, cytotoxic agents) is suspected. Chronically and significantly elevated creatinine levels may indicate irreversible kidney disease mitigating the usefulness of kidney biopsy. In the setting of long-standing diabetes mellitus type 1 or 2, proteinuric renal disease is rarely biopsied unless atypical features (such as significant glomerular hematuria or cellular casts) are also present, or if there is other reason to suspect a second renal lesion.

► Treatment

A. Protein Loss

The daily total dietary protein intake should replace the daily urinary protein losses so as to avoid negative nitrogen balance. Protein malnutrition often occurs with urinary protein losses > 10 g/d. In the past, protein restriction was suggested for patients with kidney disease. The largest human trial to date (the MDRD Study) did not show a significant benefit, but two meta-analyses in 1999 and 2001 have shown a mild renal benefit. For this reason, the KDOQI recommends protein restriction to 0.6–0.8 g/kg/d in patients with a GFR < 25 mL/min/1.73 m² prior to starting dialysis. However, great care must be taken to avoid malnutrition in these patients.

In both diabetic and nondiabetic patients, therapy that is aimed at reducing proteinuria may also reduce progression of renal disease. ACE inhibitors and ARBs lower urine protein excretion by lowering efferent arteriolar resistance, thereby reducing glomerular capillary pressure; they also have antifibrotic effects. ACE inhibitors and ARBs can be used in patients with reduced GFR as long as significant hyperkalemia (potassium > 5.2–5.5 mEq/L) does not occur and serum creatinine rises < 30%; these patients should be monitored closely to avoid acute kidney injury and hyperkalemia. The combination of an ACE inhibitor and ARB versus ARB alone for slowing the progression of diabetic nephropathy is being tested in a multicenter, prospective randomized study.

B. Edema

Dietary salt restriction is essential for managing edema; most patients also require diuretic therapy. Commonly used diuretics include thiazide and loop diuretics (both are highly protein bound). With hypoalbuminemia and decreased GFR, diuretic delivery to the kidney is reduced, and patients often require larger doses. A combination of loop and thiazide diuretics can potentiate the diuretic effect. This may be needed for patients with refractory fluid retention.

C. Hyperlipidemia

Hypercholesterolemia and hypertriglyceridemia occur as noted above. Dietary modification and exercise should be advocated; however, effective lipid-lowering usually also requires pharmacologic treatment (see Chapter 28). Statins are hepatically cleared, so dosage is not altered for CKD. Rhabdomyolysis, however, is more common in patients with CKD who take gemfibrozil in combination with statins; combining fenofibrate or niacin with a statin poses less risk of rhabdomyolysis.

D. Hypercoagulable State

Patients with serum albumin < 2 g/dL can become hypercoagulable. Nephrotic patients have urinary losses of antithrombin, protein C, and protein S and increased platelet activation. Patients are prone to renal vein thrombosis and other venous thromboemboli, particularly with membranous glomerulopathy. Anticoagulation therapy is

warranted for at least 3–6 months in patients with evidence of thrombosis in any location. Patients with renal vein thrombosis or recurrent thromboemboli require indefinite anticoagulation.

► When to Refer

Any patient noted to have nephrotic syndrome should be referred immediately to a nephrologist for aggressive volume and blood pressure management, assessment for renal biopsy, and treatment of the underlying disease. Proteinuria of > 1 g/d without the nephrotic syndrome also merits nephrology referral, though with less urgency.

► When to Admit

Patients with edema refractory to outpatient therapy or rapidly worsening kidney function that may require inpatient interventions should be admitted.

NEPHROTIC SPECTRUM DISEASE IN PRIMARY RENAL DISORDERS

MINIMAL CHANGE DISEASE

ESSENTIALS OF DIAGNOSIS

- Nephrotic range proteinuria.
- Kidney biopsy shows no changes on light microscopy.
- Characteristic foot-process effacement on electron microscopy.

► General Considerations

Minimal change disease is the most common cause of proteinuric renal disease in children, accounting for about 80% of cases. It often remits upon treatment with a course of corticosteroids. Indeed, children with nephrotic syndrome are often treated for minimal change disease empirically without a biopsy diagnosis. Biopsy should be considered for children with nephrotic syndrome who exhibit unusual features (such as signs of other systemic illness), who are steroid-resistant (see below), or who relapse frequently upon withdrawal of corticosteroid therapy. Minimal change disease is less common in adults, accounting for 20–25% of cases of primary nephrotic syndrome in those over age 40 years. This entity can be idiopathic but also occurs following viral upper respiratory infections (especially in children), in association with tumors such as Hodgkin disease, with drugs (lithium), and with hypersensitivity reactions (especially to NSAIDs and bee stings).

► Clinical Findings

A. Symptoms and Signs

Patients often exhibit the manifestations of full-blown nephrotic syndrome. They are more susceptible to infection, especially with gram-positive organisms, have a tendency toward thromboembolic events, develop severe hyperlipidemia, and experience protein malnutrition. Minimal change disease can rarely cause acute kidney injury due to tubular changes and interstitial edema.

B. Histologic Findings

Glomeruli show no changes on light microscopy or immunofluorescence. On electron microscopy, there is a characteristic effacement of podocyte foot processes. A subgroup of patients also shows mesangial cell proliferation; such patients have more hematuria and hypertension and poor response to standard corticosteroid treatment.

► Treatment

Treatment is with prednisone, 60 mg/m²/d orally. Adults often require longer courses of therapy than children. It can take up to 16 weeks to achieve a response to corticosteroids. Treatment should be continued for several weeks after complete remission of proteinuria. A significant number of patients will relapse and require further corticosteroid treatment. Steroid-resistant nephrotic syndrome is defined as persistent proteinuria after a 4-week course of prednisone. Patients with frequent relapses or corticosteroid resistance may need cyclophosphamide or cyclosporine to induce subsequent remissions; tacrolimus or rituximab may also be considered, although controlled trials are lacking. Progression to ESRD is rare. Complications most often arise from prolonged corticosteroid use.

MEMBRANOUS NEPHROPATHY

ESSENTIALS OF DIAGNOSIS

- Nephrotic range proteinuria.
- Associated with coagulopathy, eg, renal vein thrombosis, if nephrotic syndrome present.
- “Spike and dome” pattern on kidney biopsy from subepithelial deposits.
- Secondary causes notably include hepatitis B virus and carcinomas.

► General Considerations

Membranous nephropathy is the most common cause of primary nephrotic syndrome in adults, usually presenting in the fifth and sixth decades. It is an immune-mediated disease characterized by immune complex deposition in the subepithelial portion of glomerular capillary walls. The antigen in the primary form of the disease appears to be a phospholipase A₂ receptor (PLA₂R) on the podocyte in 70–80% of patients. Secondary disease is associated with underlying carcinomas; infections, such as hepatitis B, endocarditis, and syphilis; autoimmune disease, such as systemic lupus erythematosus, mixed connective tissue disease, and thyroiditis; and certain drugs, such as penicillamine and captopril. The course of disease is variable, with about 50% of patients progressing to ESRD over 3–10 years. Poorer outcome is associated with concomitant tubulointerstitial fibrosis, male sex, elevated serum creatinine, hypertension, and heavy proteinuria (> 10 g/d).

► Clinical Findings

A. Symptoms and Signs

Patients with membranous nephropathy and nephrotic syndrome have a higher risk of hypercoagulable state than those with nephrosis from other etiologies; there is a particular predisposition to renal vein thrombosis in these patients. There may be symptoms or signs of an underlying infection or neoplasm (especially lung, stomach, breast, and colon cancers) in secondary membranous nephropathy.

B. Laboratory Findings

See above for laboratory findings in the nephrotic syndrome. Serum evaluation for circulating PLA₂R antibodies to assess for idiopathic membranous nephropathy may be available in the future. By light microscopy, capillary wall thickness is increased without inflammatory changes or cellular proliferation; when stained with silver methenamine, a “spike and dome” pattern may be observed owing to projections of excess GBM between the subepithelial deposits. Immunofluorescence shows IgG and C3 uniformly along capillary loops. Electron microscopy shows a discontinuous pattern of dense deposits along the subepithelial surface of the basement membrane.

► Treatment

Treatment is controversial. After underlying causes are excluded, treatment depends on the risk of renal disease progression. One algorithm is based on the degree of proteinuria. In patients with proteinuria < 3.5 g/d, the risk of progression is low. These individuals should be closely monitored with a low-salt diet, strict blood pressure control, and an ACE inhibitor or ARB for reduction of proteinuria. Patients with proteinuria of 3.5–8 g/d but normal renal function are at moderate risk. They should follow the above suggestions and can elect immunosuppressive regimens with corticosteroids and chlorambucil or cyclophosphamide for 6 months, although only 65% of these patients experience partial or complete remission within 3–4 years.

Cyclosporine is a second choice. The highest-risk patients—those with > 8 g/d of proteinuria and possible renal dysfunction—might receive corticosteroids with a cytotoxic agent as first-line immunosuppressant therapy, though the choice of cyclosporine is also reasonable. Mycophenolate mofetil and rituximab are becoming more widely accepted as possible first-line agents of treatment or for patients who relapse or do not tolerate other immunosuppressive agents. Patients with primary membranous nephropathy are excellent candidates for transplant.

Cravedi P et al. Efficacy and safety of rituximab second-line therapy for membranous nephropathy: a prospective, matched-cohort study. *Am J Nephrol.* 2011;33(5):461–8. [PMID: 21508634]

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

This lesion can present as idiopathic disease or secondary to such conditions as heroin use, morbid obesity, chronic urinary reflux, and HIV infection. Idiopathic disease may be related to heritable abnormalities of any of several podocyte proteins. Clinically, patients with nephrotic spectrum findings may have overt nephrotic syndrome. Decreased kidney function is present in 25–50% at time of diagnosis. Patients with focal segmental glomerulosclerosis and nephrotic syndrome typically progress to ESRD in 6–8 years.

Diagnosis requires renal biopsy. Light microscopy shows sclerosis of portions (or segments) of some, but not all glomeruli (thus, focal and not diffuse disease). IgM and C3 are seen in the sclerotic lesions on immunofluorescence, although it is presumed that these immune components are simply trapped in the sclerotic glomeruli and are not participating in the pathogenesis of the disease. Electron microscopy shows fusion of epithelial foot processes as seen in minimal change disease.

Treatment for primary focal segmental glomerulosclerosis is controversial, although supportive care for nephrotic patients is indicated (diuretics for edema, ACE inhibitors or ARBs to target proteinuria and hypertension, statins or niacin for hyperlipidemia). High-dose oral prednisone (1–1.5 mg/kg/d) for 2–3 months followed by a slow taper can induce remission within 5–9 months in over half of patients. Other cytotoxic drug therapy can be considered for steroid-resistant patients, including calcineurin inhibitors and mycophenolate mofetil. For those patients with primary focal segmental glomerulosclerosis who progress to ESRD and undergo renal transplantation, relapse rate and graft loss is relatively high; plasma exchange therapy just prior to transplant and with early signs of relapse appear to be beneficial in lowering risk of these outcomes.

NEPHROTIC SPECTRUM DISEASE FROM SYSTEMIC DISORDERS

AMYLOIDOSIS

Amyloidosis is caused by extracellular deposition of the fibrous protein amyloid in one or more sites in the body. The amyloid fibrils are composed of proteins that have formed characteristic β -pleated sheets. Primary renal amyloidosis (AL amyloidosis) may occur in the absence of systemic disease or associated with multiple myeloma; indeed, both are plasma cell dyscrasias, which overproduce immunoglobulin light chain (the amyloid protein). Serum and urine protein electrophoresis can be helpful in delineating the light chain present in such cases. Secondary amyloidosis (AA amyloidosis) is due to a chronic inflammatory disease, such as rheumatoid arthritis, inflammatory bowel disease, or chronic infection. In these cases, acute phase reactant serum amyloid A is synthesized in the liver and deposited in the tissues. Amyloid-affected kidneys can be enlarged as a result of this deposition disease. Pathologically, glomeruli are filled with amorphous deposits that stain positive with Congo red and show green birefringence.

Treatment options are few. Remissions can occur in secondary amyloidosis if the inciting agent is removed. Primary amyloidosis of the kidney progresses to ESRD in an average of 2–3 years. Five-year overall survival is <20%, with death occurring from ESRD and heart disease. The use of alkylating agents and corticosteroids—eg, melphalan and prednisone—can reduce proteinuria and improve renal function in a small percentage of patients. Significant reduction in free light chain burden (>90%) has been shown to correlate with improved renal outcomes. Melphalan and stem cell transplantation are associated with high toxicity (45% mortality) but induce remission in 80% of the remaining patients. Renal transplant is an option in patients with secondary amyloid.

Qu Z et al. Clinical and pathological features of renal amyloidosis: an analysis of 32 patients in a single Chinese centre. *Nephrology (Carlton).* 2010 Feb;15(1):102–7. [PMID: 20377777]

DIABETIC NEPHROPATHY

ESSENTIALS OF DIAGNOSIS

- ▶ Prior evidence of diabetes mellitus, typically over 10 years.
- ▶ Albuminuria (microscopic or macroscopic) precedes decline in GFR.
- ▶ Signs of diabetic nephropathy on renal biopsy, if done.
- ▶ Other end-organ damage, such as retinopathy, is common.

▶ General Considerations

Diabetic nephropathy is the most common cause of ESRD in the United States (about 4000 cases a year). Type 1 diabetes mellitus carries a 30–40% risk of nephropathy after 20 years, whereas type 2 has a 15–20% risk after 20 years. ESRD is much more likely to develop in persons with type 1 diabetes mellitus, in part due to fewer comorbidities and deaths before ESRD ensues. With the current epidemic of obesity and type 2 diabetes mellitus, rates of diabetic nephropathy are projected to continue to increase. Patients at higher risk include males, African Americans, and Native Americans.

▶ Clinical Findings

The first stage of diabetic nephropathy is hyperfiltration, with an increase in GFR, followed by the development of microalbuminuria (30–300 mg/d). As the nephropathy progresses, (macro)albuminuria (> 300 mg/d, or enough to be detected on regular dipstick) is seen, and the GFR returns to normal and then goes on to decrease. Yearly screening for the development of microalbuminuria is recommended for all diabetic patients. In patients prone to nephropathy, microalbuminuria develops within 10–15 years after onset of diabetes and progresses over the next 3–7 years to overt proteinuria (> 300 mg of albuminuria per day).

The most common lesion in diabetic nephropathy is diffuse glomerulosclerosis, but nodular glomerulosclerosis (Kimmelstiel-Wilson nodules) is pathognomonic. The kidneys in these patients are usually enlarged as a result of cellular hypertrophy and proliferation.

Patients with diabetes are prone to other renal disease. These include papillary necrosis, chronic interstitial nephritis, and type 4 (hyporeninemic hypoaldosteronemic) renal tubular acidosis. Patients are more susceptible to acute kidney injury from many insults, including intravenous contrast material and concomitant use of renin-angiotensin blockers (eg, ACE inhibitors) and NSAIDs. In diabetic patients with consequent comorbidities, there is a poor prognosis once dialysis is begun.

▶ Treatment

With the onset of microalbuminuria, aggressive treatment is necessary. Strict glycemic control and treatment of

hypertension have been proven to slow progression of disease; current guidelines support a goal blood pressure of 130/80 mm Hg in most patients, and possibly 120/75 mm Hg in overtly proteinuric patients. In particular, ACE inhibitors and ARBs lower the rate of progression to clinical proteinuria and slow progression to ESRD by reducing intraglomerular pressure as well as by treating hypertension; they may also have antifibrotic effects. Even in the subset of patients with markedly diminished GFR, these agents seem to provide renal benefit if patients can avoid hyperkalemia and as long as GFR does not decline more than 30% with the initiation of this therapy. Some experts have advocated for combination ACE inhibitor and ARB therapy as a way to maximally target proteinuria; however, the ONTARGET trial suggested great caution in using combination therapy because of the development of hyperkalemia and worsening kidney function in the group given both telmisartan and ramipril.

HIV-ASSOCIATED NEPHROPATHY

HIV-associated nephropathy can present as the nephrotic syndrome in patients with HIV infection. Decline in GFR can progress rapidly. Most patients are black, possibly because of a genetic predisposition. Often, patients have low CD4 counts and have advanced HIV disease, but HIV-associated nephropathy can also be the initial presentation of disease.

Light microscopy shows focal segmental glomerulosclerosis as described above. Lesions are often of the collapsing variety, and renal biopsy specimens also exhibit severe tubulointerstitial damage.

Small, uncontrolled studies have shown that highly active antiretroviral therapy (HAART) for a prolonged course can slow progression of disease. Despite this minimal evidence, HAART has been recommended for use in these patients given the therapy's other beneficial effects and reasonable toxicity profile. Either ACE inhibitors or ARBs can be used to control blood pressure and slow disease progression. Corticosteroid treatment has been used with variable success at a dosage of 1 mg/kg/d, along with cyclosporine.

TUBULOINTERSTITIAL DISEASES

Tubulointerstitial disease may be acute or chronic. Acute disease is most commonly associated with medications, infectious agents, and systemic rheumatologic disorders. Interstitial edema, infiltration with polymorphonuclear neutrophils, and tubular cell necrosis can be seen. (See Acute Kidney Injury, above, and Table 22–11.) Chronic disease is associated with insults from an acute factor or progressive insults without any obvious acute cause. Interstitial fibrosis and tubular atrophy are present, with a mononuclear cell predominance. The chronic disorders are described below.

CHRONIC TUBULOINTERSTITIAL DISEASES

ESSENTIALS OF DIAGNOSIS

- ▶ Kidney size is small and contracted.
- ▶ Decreased urinary concentrating ability.
- ▶ Hyperchloremic metabolic acidosis.
- ▶ Reduced GFR.

Table 22–11. Causes of acute tubulointerstitial nephritis (abbreviated list).

Tubulointerstitial nephritis-uveitis (TIN-U)	

▶ General Considerations

The primary causes of chronic tubulointerstitial disease are discussed below. Other causes include multiple myeloma and gout, which are discussed in the section on multisystem disease with variable kidney involvement.

A. Obstructive Uropathy

The most common cause of chronic tubulointerstitial disease is prolonged obstruction of the urinary tract. In partial obstruction, patients can exhibit polyuria (possibly due to vasopressin insensitivity and poor ability to concentrate the urine) or oliguria (due to decreased GFR). Azotemia and hypertension (due to increased renin-angiotensin production) are usually present. The major causes are prostatic disease in men; ureteral calculus in a single functioning kidney; bilateral ureteral calculi; carcinoma of the cervix, colon, or bladder; and retroperitoneal tumors or fibrosis.

Abdominal, rectal, and genitourinary examinations are helpful. Urinalysis can show hematuria, pyuria, and bacteriuria but is often benign. Abdominal ultrasound may detect mass lesions, hydronephrosis, and hydronephrosis. CT scanning and MRI provide more detailed information.

B. Vesicoureteral Reflux

Reflux nephropathy is primarily a disorder of childhood and occurs when urine passes retrograde from the bladder to the kidneys during voiding. It is the second most common cause of chronic tubulointerstitial disease. It occurs as a result of an incompetent vesicoureteral sphincter. Urine can extravasate into the interstitium; an inflammatory response develops, and fibrosis occurs. The inflammatory response is due to either bacteria or normal urinary components.

Patients are typically diagnosed as young children with a history of recurrent urinary tract infections. This entity can be detected before birth via screening fetal ultrasonography. After birth, a voiding cystourethrogram can be done. Less commonly, this entity is not diagnosed until adolescence or young adulthood when patients present with hypertension and substantial proteinuria, unusual in most tubular diseases. At this point, renal ultrasound or IVP can show renal scarring and hydronephrosis. IVP is relatively contraindicated in patients with kidney dysfunction who are at higher risk for contrast nephropathy. On renal biopsy, focal glomerulosclerosis can be seen in those with kidney damage. Although most damage occurs before age 5 years, progressive renal deterioration to ESRD continues as a result of the early insults.

C. Analgesics

Analgesic nephropathy is most commonly seen in patients who ingest large quantities of analgesic combinations. The drugs of concern are phenacetin, paracetamol, aspirin, and NSAIDs, with acetaminophen a possible but less certain culprit. Ingestion of at least 1 g/d for 3 years of these

analgesics is considered necessary for kidney dysfunction to develop. This disorder occurs most frequently in individuals who are using analgesics for chronic headaches, muscular pains, and arthritis. Most patients grossly underestimate their analgesic use.

Tubulointerstitial inflammation and papillary necrosis are seen on pathologic examination. Papillary tip and inner medullary concentrations of some analgesics are tenfold higher than in the renal cortex. Phenacetin—once a common cause of this disorder and now rarely available—is metabolized in the papillae by the prostaglandin hydroperoxidase pathway to reactive intermediates that bind covalently to interstitial cell macromolecules, causing necrosis. Aspirin and other NSAIDs can cause damage by their metabolism to active intermediates which can result in cell necrosis. These drugs also decrease medullary blood flow (via inhibition of prostaglandin synthesis) and decrease glutathione levels, which are necessary for detoxification.

Patients can exhibit hematuria, mild proteinuria, polyuria (from tubular damage), anemia (from GI bleeding or erythropoietin deficiency), and sterile pyuria. As a result of papillary necrosis, sloughed papillae can be found in the urine. An IVP may be helpful for detecting these—contrast will fill the area of the sloughed papillae, leaving a “ring shadow” sign at the papillary tip. However, IVP is rarely used in patients with significant kidney dysfunction, given the need for dye and associated acute kidney injury.

D. Heavy Metals

Environmental exposure to heavy metals—such as lead and cadmium—is seen infrequently now in the United States. Chronic lead exposure can lead to tubulointerstitial disease. Individuals at risk are those with occupational exposure (eg, welders who work with lead-based paint) and drinkers of alcohol distilled in automobile radiators (“moonshine” whiskey users). Lead is filtered by the glomerulus and is transported across the proximal convoluted tubules, where it accumulates and causes cell damage. Fibrosed arterioles and cortical scarring also lead to damaged kidneys. Proximal tubular damage leads to decreased secretion of uric acid, resulting in hyperuricemia and saturnine gout. Patients commonly are hypertensive. Diagnosis is most reliably performed with a calcium disodium edetate (EDTA) chelation test. Urinary excretion of > 600 mg of lead in 24 hours following 1 g of EDTA indicates excessive lead exposure.

Occupational exposure to cadmium also causes proximal tubular dysfunction. Hypercalciuria and nephrolithiasis can be seen. Other heavy metals that can cause tubulointerstitial disease include mercury and bismuth.

▶ Clinical Findings

A. Symptoms and Signs

Polyuria is common because tubular damage leads to inability to concentrate the urine. Volume depletion can also occur as a result of a salt-wasting defect in some individuals.

B. Laboratory Findings

Patients can become hyperkalemic both because the GFR is lower and the distal tubules become aldosterone resistant. A hyperchloremic renal tubular acidosis is characteristic from a component of type 4 or type 1 renal tubular acidosis. Less commonly, a proximal renal tubular acidosis is seen due to direct proximal tubular damage. The cause of the renal tubular acidosis is threefold: (1) reduced ammonia production, (2) inability to acidify the distal tubules, and (3) proximal tubular bicarbonate wasting. The urinalysis is nonspecific, as opposed to that seen in acute interstitial nephritis. Proteinuria is typically < 2 g/d (owing to inability of the proximal tubule to reabsorb freely filterable proteins); a few cells may be seen; and broad waxy casts are often present.

▶ Treatment

Treatment depends first on identifying the disorder responsible for kidney dysfunction. The degree of interstitial fibrosis that has developed can help predict recovery of renal function. Once there is evidence for loss of parenchyma (small shrunken kidneys or interstitial fibrosis on biopsy), little can prevent the progression toward ESRD. Treatment is then directed at medical management. Tubular dysfunction may require potassium and phosphorus restriction and sodium, calcium, or bicarbonate supplements.

If hydronephrosis is present, relief of obstruction should be accomplished promptly. Prolonged obstruction leads to further tubular damage—particularly in the distal nephron—which may be irreversible despite relief of obstruction. Neither surgical correction of reflux nor medical therapy with antibiotics can prevent deterioration toward ESRD once renal scarring has occurred.

Patients in whom lead nephropathy is suspected should continue chelation therapy with EDTA if there is no evidence of irreversible renal damage (eg, renal scarring or small kidneys). Continued exposure should be avoided.

Treatment of analgesic nephropathy requires withdrawal of all analgesics. Stabilization or improvement of renal function may occur if significant interstitial fibrosis is not present. Hydration during exposure to analgesics may also have some beneficial effects.

▶ When to Refer

- Patients with stage 3–5 CKD should be referred to a nephrologist when tubulointerstitial diseases are suspected. Other select cases of stage 1–2 CKD should also be referred.
- Patients with urologic abnormalities should be referred to a urologist.

Gooch K et al. NSAID use and progression of chronic kidney disease. *Am J Med.* 2007 Mar;120(3):280.e1–7. [PMID: 17349452]

CYSTIC DISEASES OF THE KIDNEY

Renal cysts are epithelium-lined cavities filled with fluid or semisolid material. They develop primarily from renal

Table 22-12. Clinical features of renal cystic disease.

	Simple Renal Cysts	Acquired Renal Cysts	Autosomal Dominant Polycystic Kidney Disease	Medullary Sponge Kidney	Medullary Cystic Kidney
Prevalence	Common	Dialysis patients	1:1000	1:5000	Rare

Hypertension	None	Variable	Common	None	None
Associated complications	None	Adenocarcinoma in cysts	Urinary tract infections, renal calculi, cerebral aneurysms 10-15%, hepatic cysts 40-60%	Renal calculi, urinary tract infections	Polyuria, salt wasting
Kidney failure	Never	Always	Frequently	Never	Always

tubular elements. One or more simple cysts are found in 50% of individuals over the age of 50 years. They are rarely symptomatic and have little clinical significance. In contrast, generalized cystic diseases are associated with cysts scattered throughout the cortex and medulla of both kidneys and can progress to ESRD (Table 22-12).

SIMPLE OR SOLITARY CYSTS

Simple cysts account for 65-70% of all renal masses. They are generally found at the outer cortex and contain fluid that is consistent with an ultrafiltrate of plasma. Most are found incidentally on ultrasonographic examination. Simple cysts are typically asymptomatic but can become infected.

The main concern with simple cysts is to differentiate them from malignancy, abscess, or polycystic kidney disease. Renal cystic disease can develop in dialysis patients. These cysts have a potential for progression to malignancy. Ultrasound and CT scanning are the recommended procedures for evaluating these masses. Simple cysts must meet three sonographic criteria to be considered benign: (1) echo free, (2) sharply demarcated mass with smooth walls, and (3) an enhanced back wall (indicating good transmission through the cyst). Complex cysts can have thick walls, calcifications, solid components, and mixed echogenicity. On CT scan, the simple cyst should have a smooth thin wall that is sharply demarcated. It should not enhance with contrast media. A renal cell carcinoma will enhance but typically is of lower density than the rest of the parenchyma. Arteriography can also be used to evaluate a mass preoperatively. A renal cell carcinoma is hypervascular in 80%, hypovascular in 15%, and avascular in 5% of cases.

If a cyst meets the criteria for being benign, periodic reevaluation is the standard of care. If the lesion is not consistent with a simple cyst, follow-up with a urologic consultant and possible surgical exploration is recommended.

Terada N et al. Risk factors for renal cysts. *BJU Int.* 2004 Jun;93(9):1300-2. [PMID: 15180627]

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ESSENTIALS OF DIAGNOSIS

- ▶ Multiple cysts in bilateral kidneys; total number depends on age.
- ▶ Large, palpable kidneys on examination.
- ▶ Combination of hypertension and abdominal mass suggestive of disease.
- ▶ Family history is compelling but not necessary.
- ▶ Chromosomal abnormalities present in some patients.

▶ General Considerations

This disorder is among the most common hereditary diseases in the United States, affecting 500,000 individuals, or 1 in 800 live births. Fifty percent of patients will have ESRD by age 60 years. The disease has variable penetrance but accounts for 10% of dialysis patients in the United States. At least two genes account for this disorder: *ADPKD1* on the short arm of chromosome 16 (85-90% of patients) and *ADPKD2* on chromosome 4 (10-15%). Patients with the *PKD2* mutation have slower progression of disease and longer life expectancy than those with *PKD1*. Other sporadic cases without these mutations have also been recognized.

▶ Clinical Findings

Abdominal or flank pain and microscopic or gross hematuria are present in most patients. A history of urinary tract

infections and nephrolithiasis is common. A family history is positive in 75% of cases, and > 50% of patients have hypertension (see below) that may antedate the clinical manifestations of the disease. Patients have large kidneys that may be palpable on abdominal examination. The combination of hypertension and an abdominal mass should suggest the disease. Forty to 50 percent have concurrent hepatic cysts. Pancreatic and splenic cysts occur also. Hemoglobin and hematocrit tend to be maintained as a result of erythropoietin production by the cysts. The urinalysis may show hematuria and mild proteinuria. In patients with *PKD1*, ultrasonography confirms the diagnosis—two or more cysts in patients under age 30 years (sensitivity of 88.5%), two or more cysts in each kidney in patients age 30–59 years (sensitivity of 100%), and four or more cysts in each kidney in patients age 60 years or older are diagnostic for autosomal dominant polycystic kidney disease. If sonographic results are unclear, CT scan is recommended and highly sensitive.

► Complications & Treatment

A. Pain

Abdominal or flank pain is caused by infection, bleeding into cysts, and nephrolithiasis. Bed rest and analgesics are recommended. Cyst decompression can help with chronic pain.

B. Hematuria

Gross hematuria is most commonly due to rupture of a cyst into the renal pelvis, but it can also be caused by a kidney stone or urinary tract infection. Hematuria typically resolves within 7 days with bed rest and hydration. Recurrent bleeding should suggest the possibility of underlying renal cell carcinoma, particularly in men over age 50 years.

C. Renal Infection

An infected renal cyst should be suspected in patients who have flank pain, fever, and leukocytosis. Blood cultures may be positive, and urinalysis may be normal because the cyst does not communicate directly with the urinary tract. CT scans can be helpful because an infected cyst may have an increased wall thickness. Bacterial cyst infections are difficult to treat. Antibiotics with cystic penetration should be used, eg, fluoroquinolones or trimethoprim-sulfamethoxazole and chloramphenicol. Treatment may require 2 weeks of parenteral therapy followed by long-term oral therapy.

D. Nephrolithiasis

Up to 20% of patients have kidney stones, primarily calcium oxalate. Hydration (2–3 L/d) is recommended.

E. Hypertension

Fifty percent of patients have hypertension at time of presentation, and it will develop in most patients during the course of the disease. Cyst-induced ischemia appears to cause activation of the renin-angiotensin system, and cyst decompression can lower blood pressure temporarily. Hypertension should be treated aggressively, as this may prolong the time to ESRD. (Diuretics should be used cautiously since the effect on renal cyst formation is unknown.)

F. Cerebral Aneurysms

About 10–15% of these patients have arterial aneurysms in the circle of Willis. Screening arteriography is not recommended unless the patient has a family history of aneurysms or is undergoing elective surgery with a high risk of developing moderate to severe hypertension.

G. Other Complications

Vascular problems include mitral valve prolapse in up to 25% of patients, aortic aneurysms, and aortic valve abnormalities. Colonic diverticula are more common in patients with polycystic kidneys.

► Prognosis

Significant research is ongoing regarding therapy. Vasopressin receptor antagonists have been successful in animal models but have not yet been shown to be helpful in slowing down progression of disease in humans. These agents lower renal epithelial cell intracellular cyclic AMP (cAMP) levels, and in vitro evidence suggests that intracellular cAMP plays a significant role in cystogenesis in polycystic kidney disease. Other agents, octreotide and sirolimus, have shown a decreased rate of cyst growth but no decrease in the rate of decline in kidney function. Avoidance of caffeine may prevent cyst formation due to effects on G-coupled proteins. Treatment of hypertension and a low-protein diet may slow the progression of disease, although this is not well proven.

MEDULLARY SPONGE KIDNEY

This disease is a relatively common and benign disorder that is present at birth and not usually diagnosed until the fourth or fifth decade. It is caused by autosomal dominant mutations in the *MCKD1* or *MCKD2* genes on chromosomes 1 and 16, respectively. Kidneys have a marked irregular enlargement of the medullary and interpapillary collecting ducts. This is associated with medullary cysts that are diffuse, giving a “Swiss cheese” appearance in these regions.

► Clinical Findings

Medullary sponge kidney presents with gross or microscopic hematuria, recurrent urinary tract infections, or nephrolithiasis. Common abnormalities are a decreased urinary concentrating ability and nephrocalcinosis; less common is incomplete type I distal renal tubular acidosis. The diagnosis can be made by CT, which shows cystic dilatation of the

distal collecting tubules, a striated appearance in this area, and calcifications in the renal collecting system.

► Treatment

There is no known therapy. Adequate fluid intake (2 L/d) helps prevent stone formation. If hypercalciuria is present, thiazide diuretics are recommended because they decrease calcium excretion. Alkali therapy is recommended if renal tubular acidosis is present.

► Prognosis

Renal function is well maintained unless there are complications from recurrent urinary tract infections and nephrolithiasis.

MULTISYSTEM DISEASES WITH VARIABLE KIDNEY INVOLVEMENT¹

MULTIPLE MYELOMA

Multiple myeloma is a malignancy of plasma cells (see Chapter 13). Renal involvement occurs in about 25% of all patients. “Myeloma kidney” is the presence of light chain immunoglobulins (Bence Jones protein) in the urine causing renal toxicity. Bence Jones protein causes direct renal tubular toxicity and results in tubular obstruction by precipitating in the tubules. The earliest tubular damage results in Fanconi syndrome (a type II proximal renal tubular acidosis). The proteinuria seen with multiple myeloma is primarily due to light chains that are not detected on urine dipstick, which mainly detects albumin. Hypercalcemia and hyperuricemia are frequently seen. Glomerular amyloidosis can develop in patients with multiple myeloma; in these patients, dipstick protein determinations are positive due to glomerular epithelial cell foot process effacement and albumin “spilling” into Bowman capsule with resultant albuminuria. Other conditions resulting in renal dysfunction include plasma cell infiltration of the renal parenchyma and a hyperviscosity syndrome compromising renal blood flow. Therapy for acute kidney injury attributed to multiple myeloma includes correction of hypercalcemia, volume repletion, and chemotherapy for the underlying malignancy. Plasmapheresis had been considered appropriate to decrease the burden of existing monoclonal proteins while awaiting chemotherapeutic regimens to take effect. However, in the largest randomized prospective trial to date, plasmapheresis did not provide any renal benefit to these patients. Pheresis therapy still remains controversial.

Roussou M et al. Reversibility of renal failure in newly diagnosed patients with multiple myeloma and the role of novel agents. *Leuk Res.* 2010 Oct;34(10):1395–7. [PMID: 20510452]

¹Other diseases with variable involvement described elsewhere in this chapter include systemic lupus erythematosus, diabetes mellitus, and the vasculitides such as granulomatosis with polyangiitis and Goodpasture disease.

SICKLE CELL DISEASE

Renal dysfunction associated with sickle cell disease is most commonly due to sickling of red blood cells in the renal medulla because of low oxygen tension and hypertonicity. Congestion and stasis lead to hemorrhage, interstitial inflammation, and papillary infarcts. Clinically, hematuria is common. Damage to renal capillaries also leads to diminished concentrating ability. Isosthenuria (urine osmolality equal to that of serum) is routine, and patients can easily become dehydrated. Papillary necrosis occurs as well. These abnormalities are commonly encountered in sickle cell trait. Sickle cell glomerulopathy is less common but will inexorably progress to ESRD. Its primary clinical manifestation is proteinuria. Optimal treatment requires adequate hydration and control of the sickle cell disease.

Maigne G et al. Glomerular lesions in patients with sickle cell disease. *Medicine (Baltimore).* 2010 Jan;89(1):18–27. [PMID: 20075701]

TUBERCULOSIS

The classic renal manifestation of tuberculosis is the presence of microscopic pyuria with a sterile urine culture—or “sterile pyuria.” More often, other bacteria are also present. Microscopic hematuria is often present with pyuria. Urine cultures are the gold standard for diagnosis. Three to six first morning midstream specimens should be performed to improve sensitivity. Papillary necrosis and cavitation of the renal parenchyma occur less frequently, as do ureteral strictures and calcifications. Adequate drug therapy can result in resolution of renal involvement.

Chapagain A et al. Presentation, diagnosis, and treatment outcome of tuberculous-mediated tubulointerstitial nephritis. *Kidney Int.* 2011 Mar;79(6):671–7. [PMID: 21160461]

Figueiredo AA et al. Epidemiology of urogenital tuberculosis worldwide. *Int J Urol.* 2008 Sep;15(9):827–32. [PMID: 18637157]

GOUT & THE KIDNEY

The kidney is the primary organ for excretion of uric acid. Patients with proximal tubular dysfunction have decreased excretion of uric acid and are more prone to gouty attacks. Depending on the pH and uric acid concentration, deposition can occur in the tubules, the interstitium, or the urinary tract. The more alkaline pH of the interstitium causes urate salt deposition, whereas the acidic environment of the tubules and urinary tract causes uric acid crystal deposition at high concentrations.

Three disorders are commonly seen: (1) uric acid nephrolithiasis, (2) acute uric acid nephropathy, and (3) chronic urate nephropathy. Kidney dysfunction with uric acid nephrolithiasis stems from obstructive nephropathy. Acute uric acid nephropathy presents similarly to acute tubulointerstitial nephritis with direct toxicity

from uric acid crystals. Chronic urate nephropathy is caused by deposition of urate crystals in the alkaline medium of the interstitium; this can lead to fibrosis and atrophy. Epidemiologically, hyperuricemia and gout have been associated with worsening cardiovascular outcomes.

Treatment between gouty attacks involves avoidance of food and drugs causing hyperuricemia, aggressive hydration, and pharmacotherapy aimed at reducing serum uric acid levels. These disorders are seen in both “overproducers” and “underexcretors” of uric acid. The latter situation may seem counterintuitive; however, these patients have hyperacidic urine, which explains the deposition of relatively insoluble uric acid crystals. For those with uric acid nephrolithiasis, fluid intake should exceed 3 L/d, and use of a urinary alkalinizing agent can be considered.

Goicoechea M et al. Effect of allopurinol in chronic kidney disease progression and cardiovascular risk. *Clin J Am Soc Nephrol*. 2010 Aug;5(8):1388–93. [PMID: 20538833]

NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis is a multisystem disorder seen only in patients with CKD (primarily with a GFR < 15 mL/min/1.73 m², but rarely with a GFR of 15–29 mL/min/1.73 m²), acute kidney injury, and after kidney transplantation. Histopathologically, there is an increase in dermal

spindle cells positive for CD34 and procollagen I. Collagen bundles with mucin and elastic fibers are also noted.

Nephrogenic systemic fibrosis was first recognized in hemodialysis patients in 1997 and has been strongly linked to use of contrast agents containing gadolinium. Incidence is projected to be 1–4% in the highest risk (ESRD) population that has received gadolinium, and lower in patients with less severe kidney dysfunction. The FDA has issued a warning regarding avoidance of exposure to this agent for patients with GFR < 30 mL/min/1.73 m².

▶ Clinical Findings

Nephrogenic systemic fibrosis affects several organ systems, including the skin, muscles, lungs, and cardiovascular system. The most common manifestation is a debilitating fibrosing skin disorder that can range from skin-colored to erythematous papules, which coalesce to brawny patches. The skin can be thick and woody in areas and is painful out-of-proportion to findings on examination.

▶ Treatment

Several case reports and series have described benefit for patients after treatment with corticosteroids, photopheresis, plasmapheresis, and sodium thiosulfate. The true effectiveness of these interventions is still unclear. Alternative or no imaging agents should be used for patients requiring MR with contrast at risk for nephrogenic systemic fibrosis.

Agarwal R et al. Gadolinium-based contrast agents and nephrogenic systemic fibrosis: a systematic review and meta-analysis. *Nephrol Dial Transplant*. 2009 Mar;24(3):856–63. [PMID: 18952698]

Marshall L. Stoller, MD

Thomas J. Walsh, MD, MS

HEMATURIA

ESSENTIALS OF DIAGNOSIS

- ▶ Both gross and microscopic hematuria require evaluation.
- ▶ The upper urinary tract should be imaged, and cystoscopy should be performed if there is hematuria in the absence of infection.

▶ General Considerations

An **upper tract source** (kidneys and ureters) can be identified in 10% of patients with gross or microscopic hematuria. For upper tract sources, stone disease accounts for 40%, medical kidney disease (medullary sponge kidney, glomerulonephritis, papillary necrosis) for 20%, renal cell carcinoma for 10%, and urothelial cell carcinoma of the ureter or renal pelvis for 5%. Drug ingestion and associated medical problems may provide diagnostic clues. Analgesic use (papillary necrosis), cyclophosphamide (chemical cystitis), antibiotics (interstitial nephritis), diabetes mellitus, sickle cell trait or disease (papillary necrosis), a history of stone disease, or malignancy should all be investigated. The **lower tract source** of gross hematuria (in the absence of infection) is most commonly from urothelial cell carcinoma of the bladder. Microscopic hematuria in the male is most commonly from benign prostatic hyperplasia. The presence of hematuria in patients receiving anticoagulation therapy cannot be ascribed to the anticoagulation; a complete evaluation is warranted consisting of upper tract imaging, cystoscopy, and urine cytology (see Chapter 39 for Bladder Cancer, Cancers of the Ureter and Renal Pelvis, Renal Cell Carcinoma, and Kidney and Testis Tumors).

▶ Clinical Findings

A. Symptoms and Signs

If gross hematuria occurs, a description of the timing (initial, terminal, total) may provide a clue to the localization

of disease. Associated symptoms (ie, renal colic, irritative voiding symptoms, constitutional symptoms) should be investigated. Physical examination should emphasize signs of systemic disease (fever, rash, lymphadenopathy, abdominal or pelvic masses) as well as signs of medical kidney disease (hypertension, volume overload). Urologic evaluation may demonstrate an enlarged prostate, flank mass, or urethral disease.

B. Laboratory Findings

Initial laboratory investigations include a urinalysis and urine culture. Proteinuria and casts suggest renal origin. Irritative voiding symptoms, bacteriuria, and a positive urine culture in the female suggest urinary tract infection, but follow-up urinalysis is important after treatment to ensure resolution of the hematuria.

Further evaluation may include urinary cytology to assist in the diagnosis of bladder neoplasm.

C. Imaging

Upper tract imaging (usually abdominal and pelvic CT scanning without and with contrast) may identify neoplasms of the kidney or ureter as well as benign conditions such as urolithiasis, obstructive uropathy, papillary necrosis, medullary sponge kidney, or polycystic kidney disease. CT urography and MRI have replaced intravenous urography when imaging the upper tracts for sources of hematuria. The role of ultrasonographic evaluation of the urinary tract for hematuria is unclear. Although it may provide adequate information for the kidney, its sensitivity in detecting ureteral disease is lower. In addition, its higher degree of operator dependence may further confound the issue.

D. Cystoscopy

Cystoscopy can be used to assess for bladder or urethral neoplasm, benign prostatic enlargement, and radiation or chemical cystitis. For gross hematuria, cystoscopy is ideally performed while the patient is actively bleeding to allow better localization (ie, lateralize to one side of the upper tracts, bladder, or urethra).

▶ Follow-up

In patients with negative evaluations, repeat evaluations may be warranted to avoid a missed malignancy; however, the ideal frequency of such evaluations is not defined. Urinary cytology can be repeated in 3–6 months, and cystoscopy and upper tract imaging after a year.

▶ When to Refer

In the absence of infection, hematuria (either gross or microscopic) requires evaluation.

Grossfeld G et al. Evaluation of asymptomatic microscopic hematuria in adults: the American Urological Association best practice policy—part I: definition, detection, prevalence, and etiology. *Urology*. 2001 Apr;57(4):599–603. [PMID: 11306356]

GENITOURINARY TRACT INFECTIONS

1. Acute Cystitis

ESSENTIALS OF DIAGNOSIS

- ▶ Irritative voiding symptoms.
- ▶ Patient usually afebrile.
- ▶ Positive urine culture; blood cultures may also be positive.

▶ General Considerations

Acute cystitis is an infection of the bladder most commonly due to the coliform bacteria (especially *Escherichia coli*) and occasionally gram-positive bacteria (enterococci). The route of infection is typically ascending from the urethra. Viral cystitis due to adenovirus is sometimes seen in children but is rare in adults. Cystitis in men is rare and implies a pathologic process such as infected stones, prostatitis, or chronic urinary retention requiring further investigation.

▶ Clinical Findings

A. Symptoms and Signs

Irritative voiding symptoms (frequency, urgency, dysuria) and suprapubic discomfort are common. Women may

experience gross hematuria, and symptoms may often appear following sexual intercourse. Physical examination may elicit suprapubic tenderness, but examination is often unremarkable. Systemic toxicity is absent.

B. Laboratory Findings

Urinalysis shows pyuria and bacteriuria and varying degrees of hematuria. The degree of pyuria and bacteriuria does not necessarily correlate with the severity of symptoms. Urine culture is positive for the offending organism, but colony counts exceeding 10^5 /mL are not essential for the diagnosis.

C. Imaging

Because uncomplicated cystitis is rare in men, elucidation of the underlying problem with appropriate investigations, such as abdominal ultrasonography or cystoscopy (or both), is warranted. Follow-up imaging using CT scanning is warranted if pyelonephritis, recurrent infections, or anatomic abnormalities are suspected.

▶ Differential Diagnosis

In women, infectious processes such as vulvovaginitis and pelvic inflammatory disease can usually be distinguished by pelvic examination and urinalysis. In men, urethritis and prostatitis may be distinguished by physical examination (urethral discharge or prostatic tenderness).

Noninfectious causes of cystitis-like symptoms include pelvic irradiation, chemotherapy (cyclophosphamide), bladder carcinoma, interstitial cystitis, voiding dysfunction disorders, and psychosomatic disorders.

▶ Prevention

Women who have more than three episodes of cystitis per year are considered candidates for prophylactic antibiotic therapy to prevent recurrence after treatment of urinary tract infection. Prior to institution of therapy, a thorough urologic evaluation is warranted to exclude any anatomic abnormality (eg, stones, reflux, fistula). The three most commonly used oral agents for prophylaxis are trimethoprim-sulfamethoxazole (40 mg/200 mg), nitrofurantoin (100 mg), and cephalexin (250 mg). Single dosing at bedtime or at the time of intercourse is the recommended schedule.

The risk of acquiring a catheter-associated urinary tract infection in hospitalized patients can be minimized by using indwelling catheters only when necessary, implementing systems to ensure removal of catheters when no longer needed, using antimicrobial catheters in high-risk patients, using external collection devices in select men, identifying significant postvoid residuals by ultrasound, maintaining proper insertion techniques, and utilizing alternatives such as intermittent catheterization. The cost of treating a catheter-associated urinary tract infection acquired by a hospitalized patient is one of the complications that is not reimbursed by the Centers for Medicare & Medicaid Services.

► Treatment

Uncomplicated cystitis in women can be treated with short-term antimicrobial therapy, which consists of single-dose therapy or 1–3 days of therapy. Fluoroquinolones and nitrofurantoin are the drugs of choice for uncomplicated cystitis (Table 23–1). Trimethoprim-sulfamethoxazole can be ineffective because of the emergence of resistant organisms. In men, uncomplicated urinary tract infection is rare, and thus, the duration of antibiotic therapy depends on the underlying etiology. Hot sitz baths or urinary analgesics (phenazopyridine, 200 mg orally three times daily) may provide symptomatic relief.

► Prognosis

Infections typically respond rapidly to therapy, and failure to respond suggests resistance to the selected drug or anatomic abnormalities requiring further investigation.

► When to Refer

- Suspicion or radiographic evidence of anatomic abnormality.
- Evidence of urolithiasis.
- Recurrent cystitis due to bacterial persistence.

Table 23–1. Empiric therapy for urinary tract infections.

Diagnosis	Antibiotic	Route	Duration	Cost per Duration Noted ¹
Acute pyelonephritis	Ampicillin, 1 g every 6 hours, and gentamicin, 1 mg/kg every 8 hours	Intravenous	21 days	\$567.00 not including intravenous supplies
	Ciprofloxacin, 750 mg every 12 hours	Oral	21 days	\$236.50
	Ofloxacin, 200–300 mg every 12 hours	Oral	21 days	\$239.00 (300 mg)
	Trimethoprim-sulfamethoxazole, 160/800 mg every 12 hours ²	Oral	21 days	\$45.80
Chronic pyelonephritis	Same as for acute pyelonephritis, but duration of therapy is 3–6 months			
Acute cystitis	Cephalexin, 250–500 mg every 6 hours	Oral	1–3 days	\$16.60/3 days (500 mg)
	Ciprofloxacin, 250–500 mg every 12 hours	Oral	1–3 days	\$32.00/3 days (500 mg)
	Nitrofurantoin (macrocrystals), 100 mg every 12 hours	Oral	7 days	\$26.00
	Norfloxacin, 400 mg every 12 hours	Oral	1–3 days	\$26.40/3 days
	Ofloxacin, 200 mg every 12 hours	Oral	1–3 days	\$28.70/3 days
	Trimethoprim-sulfamethoxazole, 160/800 mg, two tablets ²	Oral	Single dose	\$2.20
Acute bacterial prostatitis	Same as for acute pyelonephritis		21 days	
Chronic bacterial prostatitis	Ciprofloxacin, 250–500 mg every 12 hours	Oral	1–3 months	\$322.00/1 month (500 mg)
	Ofloxacin, 200–400 mg every 12 hours	Oral	1–3 months	\$360.00/1 month (400 mg)
	Trimethoprim-sulfamethoxazole, 160/800 mg every 12 hours ²	Oral	1–3 months	\$65.40/1 month
Acute epididymitis	Ceftriaxone, 250 mg as single dose, plus Doxycycline, 100 mg every 12 hours	Intramuscular	Once	\$2.00/250 mg
		Oral	10 days	\$10.40
Non-sexually transmitted	Same as for chronic bacterial prostatitis	Oral	3 weeks

²Increasing resistance noted (up to 20%).

2. Acute Pyelonephritis

ESSENTIALS OF DIAGNOSIS

- ▶ Fever.
- ▶ Flank pain.
- ▶ Irritative voiding symptoms.
- ▶ Positive urine culture.

▶ General Considerations

Acute pyelonephritis is an infectious inflammatory disease involving the kidney parenchyma and renal pelvis. Gram-negative bacteria are the most common causative agents including *E coli*, *Proteus*, *Klebsiella*, *Enterobacter*, and *Pseudomonas*. Gram-positive bacteria are less commonly seen but include *Enterococcus faecalis* and *Staphylococcus aureus*. The infection usually ascends from the lower urinary tract—with the exception of *S aureus*, which usually is spread by a hematogenous route.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms include fever, flank pain, shaking chills, and irritative voiding symptoms (urgency, frequency, dysuria). Associated nausea and vomiting, and diarrhea are common. Signs include fever and tachycardia. Costovertebral angle tenderness is usually pronounced.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. White cell casts may be seen. Urine culture demonstrates heavy growth of the offending agent, and blood culture may also be positive.

C. Imaging

In complicated pyelonephritis, renal ultrasound may show hydronephrosis from a stone or other source of obstruction.

▶ Differential Diagnosis

Acute intra-abdominal disease such as appendicitis, cholecystitis, pancreatitis, or diverticulitis must be distinguished from pyelonephritis. A normal urinalysis is usually seen in gastrointestinal disorders; however, on occasion, inflammation from adjacent bowel (appendicitis or diverticulitis) may result in hematuria or sterile pyuria. Abnormal liver function tests or elevated amylase levels may assist in the differentiation. Lower lobe pneumonia is distinguishable by the abnormal chest radiograph.

In males, the main differential diagnosis for acute pyelonephritis includes acute epididymitis, acute prostatitis, and acute cystitis. Physical examination and the location of the pain should permit this distinction.

▶ Complications

Sepsis with shock can occur with acute pyelonephritis. In diabetic patients, emphysematous pyelonephritis resulting from gas-producing organisms may be life threatening if not adequately treated. Healthy adults usually recover complete kidney function, yet if coexistent kidney disease is present, scarring or chronic pyelonephritis may result. Inadequate therapy could result in abscess formation.

▶ Treatment

Urine and blood cultures are obtained to identify the causative agent and to determine antimicrobial sensitivity. In the inpatient setting, intravenous ampicillin and an aminoglycoside are initiated prior to obtaining sensitivity results (Table 23–1). In the outpatient setting, quinolones may be initiated (Table 23–1). Antibiotics are adjusted according to sensitivities. Fevers may persist for up to 72 hours; failure to respond warrants imaging (CT or ultrasound) to exclude complicating factors that may require intervention. Catheter drainage may be necessary in the face of urinary retention and nephrostomy drainage if there is ureteral obstruction. In inpatients, intravenous antibiotics are continued for 24 hours after the fever resolves, and oral antibiotics are then given to complete a 14-day course of therapy. Follow-up urine cultures are mandatory following the completion of treatment.

▶ Prognosis

With prompt diagnosis and appropriate treatment, acute pyelonephritis carries a good prognosis. Complicating factors, underlying kidney disease, and increasing patient age may lead to a less favorable outcome.

▶ When to Refer

- Evidence of complicating factors (urolithiasis, obstruction).
- Absence of clinical improvement in 48 hours.

▶ When to Admit

- Severe infections or complicating factors, evidence of sepsis or need for parenteral antibiotics.
- Need for radiographic imaging or drainage of urinary tract obstruction.

Gupta K et al. International clinical practice guidelines for the treatment of acute uncomplicated cystitis and pyelonephritis in women: a 2010 update by the Infectious Disease Society of America and the European Society for Microbiology and Infectious Diseases. *Clin Infect Dis*. 2011 Mar 1;52(5):e103–20. [PMID: 21292654]

Meng MV. Infection of the upper urinary tract. In: Wessells H (editor). *Urological Emergencies: A Practical Guide*. New York: Humana Press, 2012.

3. Acute Bacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- ▶ Fever.
- ▶ Irritative voiding symptoms.
- ▶ Perineal or suprapubic pain; exquisite tenderness common on rectal examination.
- ▶ Positive urine culture.

▶ General Considerations

Acute bacterial prostatitis is usually caused by gram-negative rods, especially *E coli* and *Pseudomonas* species and less commonly by gram-positive organisms (eg, enterococci). The most likely routes of infection include ascent up the urethra and reflux of infected urine into the prostatic ducts. Lymphatic and hematogenous routes are probably rare.

▶ Clinical Findings

A. Symptoms and Signs

Perineal, sacral, or suprapubic pain, fever, and irritative voiding complaints are common. Varying degrees of obstructive symptoms may occur as the acutely inflamed prostate swells, which may lead to urinary retention. High fevers and a warm and often exquisitely tender prostate are detected on examination. Care should be taken to perform a gentle rectal examination, since vigorous manipulations may result in septicemia. Prostatic massage is contraindicated.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. Urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen (Table 23–2).

▶ Differential Diagnosis

Acute pyelonephritis or acute epididymitis should be distinguishable by the location of pain as well as by physical examination. Acute diverticulitis is occasionally confused

with acute prostatitis; however, the history and urinalysis should permit clear distinction. Urinary retention from benign or malignant prostatic enlargement is distinguishable by initial or follow-up rectal examination.

▶ Treatment

Hospitalization may be required, and parenteral antibiotics (ampicillin and aminoglycoside) should be initiated until organism sensitivities are available (Table 23–1). After the patient is afebrile for 24–48 hours, oral antibiotics (eg, quinolones) are used to complete 4–6 weeks of therapy. If urinary retention develops, urethral catheterization or instrumentation is contraindicated, and a percutaneous suprapubic tube is required. Follow-up urine culture and examination of prostatic secretions should be performed after the completion of therapy to ensure eradication.

▶ Prognosis

With effective treatment, chronic bacterial prostatitis is rare.

▶ When to Refer

- Evidence of urinary retention.
- Evidence of chronic prostatitis.

▶ When to Admit

- Signs of sepsis.
- Need for surgical drainage of bladder or prostatic abscess.

Benway BM et al. Bacterial prostatitis. *Urol Clin North Am*. 2008 Feb;35(1):23–32. [PMID: 18061021]

4. Chronic Bacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- ▶ Irritative voiding symptoms.
- ▶ Perineal or suprapubic discomfort, often dull and poorly localized.
- ▶ Positive expressed prostatic secretions and culture.

Table 23–2. Clinical characteristics of prostatitis and prostaticodynia syndromes.

Findings	Acute Bacterial Prostatitis	Chronic Bacterial Prostatitis	Nonbacterial Prostatitis	Prostaticodynia
Fever	+	–	–	–
Urinalysis	+	–	–	–
Expressed prostate secretions	Contraindicated	+	+	–
Bacterial culture	+	+	–	–

► General Considerations

Although chronic bacterial prostatitis may evolve from acute bacterial prostatitis, many men have no history of acute infection. Gram-negative rods are the most common etiologic agents, but only one gram-positive organism (*Enterococcus*) is associated with chronic infection. Routes of infection are the same as discussed for acute infection.

► Clinical Findings

A. Symptoms and Signs

Clinical manifestations are variable. Some patients are asymptomatic, but most have varying degrees of irritative voiding symptoms. Low back and perineal pain are not uncommon. Many patients report a history of urinary tract infections. Physical examination is often unremarkable, although the prostate may feel normal, boggy, or indurated.

B. Laboratory Findings

Urinalysis is normal unless a secondary cystitis is present. Expressed prostatic secretions demonstrate increased numbers of leukocytes (>10 per high-power field), especially lipid-laden macrophages. However, this finding is consistent with inflammation and is not diagnostic of bacterial prostatitis (Table 23–2). Leukocyte and bacterial counts from expressed prostatic secretions do not correlate with severity of symptoms. Culture of the secretions or the post-prostatic massage urine specimen is necessary to make the diagnosis.

C. Imaging

Imaging tests are not necessary, although pelvic radiographs or transrectal ultrasound may demonstrate prostatic calculi.

► Differential Diagnosis

Chronic urethritis may mimic chronic prostatitis, though cultures of the fractionated urine may localize the source of infection to the initial specimen, which would come from the urethra. Cystitis may be secondary to prostatitis, but urine samples after prostatic massage may localize the infection to the prostate. Anal disease may share some of the symptoms of prostatitis, but physical examination should permit a distinction between the two.

► Treatment

Few antimicrobial agents attain therapeutic intraprostatic levels in the absence of acute inflammation. Trimethoprim does diffuse into the prostate, and trimethoprim-sulfamethoxazole is associated with the best cure rates (Table 23–1). However, increasing resistance up to 20% has been noted. Other effective agents include carbenicillin, erythromycin, cephalexin, and the quinolones. The optimal duration of therapy remains controversial, ranging from 6 to 12 weeks. Symptomatic relief may be provided by anti-inflammatory agents (indomethacin, ibuprofen) and hot sitz baths.

► Prognosis

Chronic bacterial prostatitis is difficult to cure, but its symptoms and tendency to cause recurrent urinary tract infections can be controlled by suppressive antibiotic therapy.

► When to Refer

- Persistent symptoms.
- Consideration of enrollment in clinical trials.

5. Nonbacterial Prostatitis

ESSENTIALS OF DIAGNOSIS

- Irritative voiding symptoms.
- Perineal or suprapubic discomfort, similar to that of chronic bacterial prostatitis.
- Positive expressed prostatic secretions, but culture is negative.

► General Considerations

Nonbacterial prostatitis is the most common of the prostatitis syndromes, and its cause is unknown. Speculation implicates chlamydiae, mycoplasmas, ureaplasmas, and viruses, but no substantial proof exists. In some cases, nonbacterial prostatitis may represent a noninfectious inflammatory or autoimmune disorder. Because the cause of nonbacterial prostatitis remains unknown, the diagnosis is usually one of exclusion.

► Clinical Findings

A. Symptoms and Signs

The clinical presentation is identical to that of chronic bacterial prostatitis; however, no history of urinary tract infections is present. The National Institutes of Health Chronic Prostatitis Symptom Index (NIH-CPSI) (<http://www2.nidk.nih.gov/NR/rdonlyres/93B6388F-B429-4603-9C3C-6765BDEB49A1/0/NIHCPSIEnglish.pdf>) has been validated to quantify symptoms of chronic nonbacterial prostatitis or chronic pelvic pain syndrome.

B. Laboratory Findings

Increased numbers of leukocytes are seen on expressed prostatic secretions, but all cultures are negative.

► Differential Diagnosis

The major distinction is from chronic bacterial prostatitis. The absence of a history of urinary tract infection and of positive cultures makes the distinction (Table 23–2). In older men with irritative voiding symptoms and negative cultures, the possibility of bladder cancer must be excluded. Urinary cytologic examination and cystoscopy are warranted.

► Treatment

Because of the uncertainty regarding the etiology of non-bacterial prostatitis, a trial of antimicrobial therapy directed against *Ureaplasma*, *Mycoplasma*, or *Chlamydia* is warranted. Erythromycin (250 mg orally four times daily) can be initiated for 14 days yet should be continued for 3–6 weeks only if a favorable clinical response ensues. Some symptomatic relief may be obtained with nonsteroidal anti-inflammatory agents or sitz baths. Dietary restrictions are not necessary unless the patient relates a history of symptom exacerbation by certain substances such as alcohol, caffeine, and perhaps certain foods.

► Prognosis

Annoying, recurrent symptoms are common, but serious sequelae have not been identified.

Nickel JC et al. Phenotypic approach to the management of chronic prostatitis/chronic pelvic pain syndrome. *Curr Urol Rep.* 2009 Jul;10(4):307–12. [PMID: 19570493]

6. Prostatodynia

Prostatodynia is a noninflammatory disorder that affects young and middle-aged men and has variable causes, including voiding dysfunction and pelvic floor musculature dysfunction. The term “prostatodynia” is a misnomer, as the prostate is actually normal.

► Clinical Findings

A. Symptoms and Signs

Symptoms are the same as those seen with chronic prostatitis, yet there is no history of urinary tract infection. Additional symptoms may include hesitancy and interruption of flow. Patients may relate a lifelong history of voiding difficulty. Physical examination is unremarkable, but increased anal sphincter tone and periprostatic tenderness may be observed.

B. Laboratory Findings

Urinalysis is normal. Expressed prostatic secretions show normal numbers of leukocytes (Table 23–2). Urodynamic testing may show signs of dysfunctional voiding (detrusor contraction without urethral relaxation, high urethral pressures, spasms of the urinary sphincter) and is indicated in patients failing empiric trials of α -blockers or anticholinergics.

► Differential Diagnosis

Normal urinalysis will distinguish it from acute infectious processes. Examination of expressed prostatic secretions will distinguish this entity from prostatitis syndromes (Table 23–2).

► Treatment

Bladder neck and urethral spasms can be treated by α -blocking agents (terazosin, 1–10 mg orally once a day, or doxazosin, 1–8 mg orally once a day). Pelvic floor muscle dysfunction may respond to diazepam and biofeedback techniques. Sitz baths may contribute to symptomatic relief.

► Prognosis

Prognosis is variable depending on the specific cause.

7. Acute Epididymitis

- Fever.
- Irritative voiding symptoms.
- Painful enlargement of epididymis.

► General Considerations

Most cases of acute epididymitis are infectious and can be divided into one of two categories that have different age distributions and etiologic agents. **Sexually transmitted forms** typically occur in men under age 40 years, are associated with urethritis, and result from *Chlamydia trachomatis* or *Neisseria gonorrhoeae*. **Non-sexually transmitted forms** typically occur in older men, are associated with urinary tract infections and prostatitis, and are caused by gram-negative rods. The route of infection is probably via the urethra to the ejaculatory duct and then down the vas deferens to the epididymis. Amiodarone has been associated with self-limited epididymitis, which is a dose-dependent phenomenon.

► Clinical Findings

A. Symptoms and Signs

Symptoms may follow acute physical strain (heavy lifting), trauma, or sexual activity. Associated symptoms of urethritis (pain at the tip of the penis and urethral discharge) or cystitis (irritative voiding symptoms) may occur. Pain develops in the scrotum and may radiate along the spermatic cord or to the flank. Fever and scrotal swelling are usually apparent. Early in the course, the epididymis may be distinguishable from the testis; however, later the two

may appear as one enlarged, tender mass. The prostate may be tender on rectal examination.

B. Laboratory Findings

Complete blood count shows leukocytosis and a left shift. In the sexually transmitted variety, Gram staining of a smear of urethral discharge may be diagnostic of gram-negative intracellular diplococci (*N gonorrhoeae*). White cells without visible organisms on urethral smear represent non-gonococcal urethritis, and *C trachomatis* is the most likely pathogen. In the non-sexually transmitted variety, urinalysis shows pyuria, bacteriuria, and varying degrees of hematuria. Urine cultures will demonstrate the offending pathogen.

C. Imaging

Scrotal ultrasound may aid in the diagnosis if examination is difficult because of the presence of a large hydrocele or because questions exist regarding the diagnosis.

► Differential Diagnosis

Tumors generally cause painless enlargement of the testis. Urinalysis is negative, and examination reveals a normal epididymis. Scrotal ultrasound is helpful to define the pathology. Testicular torsion usually occurs in prepubertal males but is occasionally seen in young adults. Acute onset of symptoms and a negative urinalysis favor testicular torsion or torsion of one of the testicular or epididymal appendages. Prehn sign (elevation of the scrotum above the pubic symphysis improves pain from epididymitis) may be helpful but is not reliable.

► Treatment

Bed rest with scrotal elevation is important in the acute phase. Treatment is directed toward the identified pathogen (Table 23–1). The sexually transmitted variety is treated with 10–21 days of antibiotics, and the sexual partner must be treated as well. Non-sexually transmitted forms are treated for 21–28 days with appropriate antibiotics, at which time evaluation of the urinary tract is warranted to identify underlying disease.

► Prognosis

Prompt treatment usually results in a favorable outcome. Delayed or inadequate treatment may result in epididymo-orchitis, decreased fertility, or abscess formation.

► When to Refer

- Persistent symptoms and infection despite antibiotic therapy.
- Signs of sepsis or abscess formation.

Tracy CR et al. Diagnosis and management of epididymitis. *Urol Clin North Am.* 2008 Feb;35(1):101–8. [PMID: 18061028]

INTERSTITIAL CYSTITIS

ESSENTIALS OF DIAGNOSIS

- Pain with a full bladder or urinary urgency.
- Submucosal petechiae or ulcers on cystoscopic examination.
- Diagnosis of exclusion.

► General Considerations

Interstitial cystitis (painful bladder syndrome) is characterized by pain with bladder filling that is relieved by emptying and is often associated with urgency and frequency. This is a diagnosis of exclusion, and patients must have a negative urine culture and cytology and no other obvious cause such as radiation cystitis, chemical cystitis (cyclophosphamide), vaginitis, urethral diverticulum, or genital herpes. Up to 40% of patients referred to urologists for interstitial cystitis may actually be found to have a different diagnosis after careful evaluation.

Population-based studies have demonstrated a prevalence of between 18 and 40 per 100,000 people. Both sexes are involved, but most patients are women, with a mean age of 40 years at onset. Patients with interstitial cystitis are more likely to report bladder problems in childhood, and there appears to be a higher prevalence in women. Up to 50% of patients may experience spontaneous remission of symptoms, with a mean duration of 8 months without treatment.

The etiology of interstitial cystitis is unknown, and it is most likely not a single disease but rather several diseases with similar symptoms. Associated diseases include severe allergies, irritable bowel syndrome, or inflammatory bowel disease. Theories regarding the cause of interstitial cystitis include increased epithelial permeability, neurogenic causes (sensory nervous system abnormalities), and autoimmunity.

► Clinical Findings

A. Symptoms and Signs

Pain with bladder filling that is relieved with urination or urgency, frequency, and nocturia are the most common symptoms. Patients should be asked about exposure to pelvic radiation or treatment with cyclophosphamide. Examination should exclude genital herpes, vaginitis, or a urethral diverticulum.

B. Laboratory Findings

Urinalysis, urine culture, and urinary cytologies are obtained to examine for infectious causes and bladder malignancy. Urodynamic testing assesses bladder sensation and compliance and excludes detrusor instability.

C. Cystoscopy

The bladder is distended with fluid (hydrodistention) to detect glomerulations (submucosal hemorrhage), which

may or may not be present. Biopsy should be performed to exclude other causes such as carcinoma, eosinophilic cystitis, and tuberculous cystitis. The presence of submucosal mast cells is not needed to make the diagnosis of interstitial cystitis.

► Differential Diagnosis

Exposures to radiation or cyclophosphamide are obtained by the history. Bacterial cystitis, genital herpes, or vaginitis can be excluded by urinalysis, culture, and physical examination. A urethral diverticulum may be suspected if palpation of the urethra demonstrates an indurated mass that results in the expression of pus from the urethral meatus. Urethral carcinoma presents as a firm mass on palpation.

► Treatment

There is no cure for interstitial cystitis, but most patients achieve symptomatic relief from one of several approaches, including hydrodistention, which is usually done as part of the diagnostic evaluation. Approximately 20–30% of patients notice symptomatic improvement following this maneuver. Also of importance is the measurement of bladder capacity during hydrodistention, since patients with very small bladder capacities (< 200 mL) are unlikely to respond to medical therapy.

Amitriptyline (10–75 mg/d orally) is often used as first-line medical therapy in patients with interstitial cystitis. Both central and peripheral mechanisms may contribute to its activity. Nifedipine (30–60 mg/d orally) and other calcium channel blockers have also demonstrated some activity in patients with interstitial cystitis. Pentosan polysulfate sodium (Elmiron) is an oral synthetic sulfated polysaccharide that helps restore integrity to the epithelium of the bladder in a subset of patients and has been evaluated in a placebo-controlled trial. Other options include intravesical instillation of dimethyl sulfoxide (DMSO) and heparin. Intravesical bacillus Calmette-Guérin (BCG) is not beneficial.

Further treatment modalities include transcutaneous electric nerve stimulation (TENS) and acupuncture. Surgical therapy for interstitial cystitis should be considered only as a last resort and may require cystourethrectomy with urinary diversion.

URINARY STONE DISEASE

ESSENTIALS OF DIAGNOSIS

- Severe flank pain.
- Nausea and vomiting.
- Identification on noncontrast CT or ultrasonography.

► General Considerations

Urinary stone disease is exceeded in frequency as a urinary tract disorder only by infections and prostatic disease and is estimated to afflict 240,000–720,000 Americans per year. Men are more frequently affected by urolithiasis than women, with a ratio of 2.5:1. Initial presentation predominates in the third and fourth decades. The ratio of men to women approaches parity in the sixth and seventh decades.

Urinary calculi are polycrystalline aggregates composed of varying amounts of crystalloid and a small amount of organic matrix. Stone formation requires saturated urine that is dependent on pH, ionic strength, solute concentration, and complexation. There are five major types of urinary stones: calcium oxalate, calcium phosphate, struvite (magnesium ammonium phosphate), uric acid, and cystine. The most common types are composed of calcium, and for that reason most urinary stones (85%) are radiopaque (as seen on plain abdominal radiographs). Uric acid stones can be radiolucent yet frequently are composed of a combination of uric acid and calcium oxalate and thus are frequently radiopaque. Cystine stones frequently have a smooth-edged ground-glass appearance.

Geographic factors contribute to the development of stones. Areas of high humidity and elevated temperatures appear to be contributing factors, and the incidence of symptomatic ureteral stones is greatest during hot summer months. Persons in sedentary occupations have a higher incidence of stones than manual laborers. Increasing evidence is revealing that urinary stone disease may be a precursor to subsequent cardiovascular disease.

High protein and high salt intake may be important factors in the development of urinary stones while carbohydrates and fats have not been proven to have an impact on urinary stone disease.

Genetic factors may contribute to urinary stone formation. Cystinuria is an autosomal recessive disorder. Homozygous individuals have markedly increased excretion of cystine and frequently have numerous recurrent episodes of urinary stones despite attempts to optimize medical treatment. Distal renal tubular acidosis may be

transmitted as a hereditary trait, and urolithiasis occurs in up to 75% of patients affected with this disorder.

► Clinical Findings

A. Symptoms and Signs

Obstructing urinary stones usually present with acute and severe colic. Pain usually occurs suddenly and may awaken patients from sleep. It is localized to the flank, is usually severe, and may be associated with nausea and vomiting. Patients are constantly moving trying to find a comfortable position—in sharp contrast to those with an acute abdomen. The pain may occur episodically and may radiate anteriorly over the abdomen. As the stone progresses down the ureter, the pain may be referred into the ipsilateral testis or labium. If the stone becomes lodged at the ureterovesicular junction, patients will complain of marked urinary urgency and frequency and in men, pain may radiate to the tip of the penis. After the stone passes into the bladder, there typically is minimal pain with passage through the urethra. Stone size does not correlate with the severity of the symptoms.

B. Laboratory Findings

Urinalysis usually reveals microscopic or gross hematuria (~90%). However, the absence of microhematuria does not exclude urinary stones. Infection must be excluded, because the combination of infection and urinary tract obstruction requires prompt intervention as described below. Urinary pH is a valuable clue to the cause of the possible stone. Normal urine pH is 5.8–5.9. There is a normal postprandial urinary alkaline tide. Numerous dipstick measurements are valuable in the complete workup of a patient in whom urinary stones are suspected. Persistent urinary pH below 5.5 is suggestive of uric acid or cystine stones, both relatively radiolucent as seen on plain abdominal radiographs. In contrast, a persistent urinary pH > 7.2 is suggestive of a struvite infection stone, which is radiopaque on

plain radiographs. Patients with calcium-based stones typically have a urinary pH between 5.5 and 6.8.

C. Metabolic Evaluation

Patients should strain their urine through cheesecloth or a urine strainer. Stone analysis should be performed on recovered stones. Controversy exists in deciding which patients need a thorough metabolic evaluation for stone disease. Patients with uncomplicated first-time stones should probably undergo blood screening for abnormalities of serum calcium, electrolytes, and uric acid as a baseline.

More extensive evaluation is required in patients who have recurrent stones or those with a family history of nephrolithiasis. Patients are encouraged to change their diet to reduce sodium intake, reduce their animal protein intake during individual meals, and to ingest adequate fluid intake to achieve a voided volume of 1.5–2.0 L of urine. After these dietary changes have been initiated, a 24-hour urine collection should be obtained to ascertain urinary volume, pH, calcium, uric acid, oxalate, phosphate, sodium, and citrate excretion. Serum parathyroid hormone (PTH) and calcium can be obtained if the 24-hour urine collection reveals hypercalciuria. Table 23–3 demonstrates the diagnostic criteria for the hypercalciuric states. (See discussion below.)

D. Imaging

A plain abdominal radiograph (KUB, kidney-ureter-bladder) and renal ultrasound examination will diagnose most stones. More than 60% of patients with acute renal colic will have with a stone in the distal 4 cm of the ureter; attention should be directed to that region when examining plain radiographs and abdominal ultrasonographic studies. Spiral CT is frequently the first-line tool in evaluating flank pain. Repeated CT scans should be avoided due to the substantial radiation exposure to these patients who have recurrent stones at a young age. CT scans should be obtained in the prone position to help differentiate distal

Table 23–3. Diagnostic criteria of different types of hypercalciuria.

	Absorptive Type I	Absorptive Type II	Absorptive Type III	Resorptive	Renal

PTH, parathyroid hormone; ↑, elevated; ↓, low; N, normal.

ureterovesicular stones from those that have already passed into the urinary bladder. Stone density can be estimated with Hounsfield units (HU) on CT scans to help determine stone type. Stones with low HU (< 450) are typically composed of uric acid, while those with high HU (> 1200) are typically composed of calcium oxalate monohydrate. All stones whether radiopaque or radiolucent on plain abdominal radiographs will be visible on noncontrast CT except the rare calculi due to the protease inhibitor indinavir.

► Medical Treatment & Prevention

To reduce the recurrence rate of urinary stones, one must attempt to achieve a stone-free status. Small stone fragments may serve as a nidus for future stone development. Selected patients must be thoroughly evaluated to reduce stone recurrence rates. Patients who have formed uric acid stones may have recurrences within months if appropriate therapy is not initiated. If no medical treatment is provided after surgical stone removal, stones will generally recur in 50% of patients within 5 years. Of greatest importance in reducing stone recurrence is an increased fluid intake. Absolute volumes are not established, but increasing fluid intake to ensure a voided volume of 1.5–2.0 L/d is recommended (average voided volume is 1.6 L/d). Patients are encouraged to ingest fluids during meals, 2 hours after each meal (when the body is most dehydrated), and prior to going to sleep in the evening—enough to awaken the patient to void—and to ingest additional fluids during the night. Increasing fluids only during daylight hours may not dilute a supersaturated urine overnight and thus initiate a new stone.

A. Diet

Sodium intake should be restricted to keep urinary sodium levels < 150 mEq/d. Increased sodium intake will increase sodium and calcium excretion, increase monosodium urates (that can act as a nidus for stone growth), increase the relative saturation of calcium phosphate, and decrease urinary citrate excretion. All of these factors encourage stone growth. Animal protein intake should be spread out through the day and not consumed during any individual meal and is best limited to 1 g/kg/d. An increased protein load during an individual meal can also increase calcium, oxalate, and uric acid excretion and decrease urinary citrate excretion.

Bran can significantly decrease urinary calcium excretion by increasing bowel transit time and mechanically binding to calcium. Excess intake of oxalate and purines can increase the incidence of stones in predisposed individuals. Dietary calcium or calcium supplements should not be routinely decreased. In fact, decreased calcium consumption has been found to increase stone recurrence. Only type II absorptive hypercalciuric patients (see below) benefit from a low calcium diet.

B. Calcium Nephrolithiasis

1. Hypercalciuric—Hypercalciuric calcium nephrolithiasis (>250 mg/24 h; >4 mg/kg/24 h) can be caused by absorptive, resorptive, and renal disorders.

Absorptive hypercalciuria is secondary to increased absorption of calcium at the level of the small bowel, predominantly in the jejunum, and can be further subdivided into types I, II, and III. Type I absorptive hypercalciuria is independent of calcium intake. There is increased urinary calcium on a regular or even a calcium-restricted diet. Treatment is centered on decreasing bowel absorption of calcium. Cellulose phosphate, a chelating agent, is an effective form of therapy. An average dose is 10–15 g in three divided doses. It binds to the calcium and impedes small bowel absorption due to its increased bulk. Cellulose phosphate does not change the intestinal transport mechanism. It should be given with meals so it will be available to bind to the dietary calcium. Taking this chelating agent prior to bedtime is ineffective. Postmenopausal women should be treated with caution. It is interesting, however, that there is no enhanced decline in bone density after long-term use. Inappropriate use may result in a negative calcium balance and a secondary parathyroid stimulation. Long-term use without follow-up metabolic surveillance may result in hypomagnesuria and secondary hyperoxaluria and recurrent calculi. Routine follow-up every 6–8 months will help encourage medical compliance and permit adjustments in medical therapy based on repeat metabolic studies.

Thiazide therapy is more commonly used and is an alternative to cellulose phosphate in the treatment of type I absorptive hypercalciuria. Thiazides decrease renal calcium excretion but have no impact on intestinal absorption. This therapy results in increased bone density of approximately 1% per year. Thiazides have limited long-term utility (< 5 years) since they may lose their hypocalciuric effect with continued therapy.

Type II absorptive hypercalciuria is diet dependent and fortunately rare. Decreasing calcium intake by 50% (approximately 400 mg/d) will decrease the hypercalciuria to normal values (150–200 mg/24 h). There is no specific medical therapy.

Type III absorptive hypercalciuria is secondary to a renal phosphate leak. This results in increased vitamin D synthesis and secondarily increased small bowel absorption of calcium. This can be readily reversed by orthophosphates (250 mg orally three to four times per day), presently available without need for a prescription. Orthophosphates do not change intestinal absorption but rather inhibit vitamin D synthesis.

Resorptive hypercalciuria is secondary to hyperparathyroidism. Hypercalcemia, hypophosphatemia, hypercalciuria, and an elevated serum PTH value are found. Appropriate surgical resection of the parathyroid adenoma cures the disease and recurrent urinary stones are decreased by > 90%. Medical management is invariably a failure.

Renal hypercalciuria occurs when the renal tubules are unable to efficiently reabsorb filtered calcium, and hypercalciuria results. Spilling calcium in the urine results in secondary hyperparathyroidism. Serum calcium typically is normal. Thiazides are effective long-term therapy in patients with this disorder.

2. Hyperuricosuric—Hyperuricosuric calcium nephrolithiasis is secondary to dietary purine excess or endogenous uric acid metabolic defects. Most cases (85%) can be

treated with purine dietary restrictions; those that are not reversed with dietary modification are successfully treated with allopurinol. In contrast to uric acid nephrolithiasis, patients with hyperuricosuric calcium stones typically maintain a urinary pH > 5.5. Monosodium urates adsorb and adsorb inhibitors and promote heterogeneous nucleation. Hyperuricosuric calcium nephrolithiasis is initiated with epitaxy, or heterogeneous nucleation. In such situations, similar crystal structures (ie, uric acid and calcium oxalate) can grow together with the aid of a protein matrix infrastructure.

3. Hyperoxaluric—Hyperoxaluric calcium nephrolithiasis (> 40 mg oxalate/24h urine) is usually due to primary intestinal disorders. Patients usually have a history of chronic diarrhea frequently associated with inflammatory bowel disease. In these situations, increased bowel fat or bile (or both) combine with intraluminal calcium to form a soap-like product. Calcium is therefore unavailable to bind to oxalate, which is then freely and rapidly absorbed. A small increase in oxalate absorption will significantly increase stone formation. If the diarrhea or steatorrhea cannot be effectively curtailed, oral calcium should be taken with meals; the calcium can be obtained by either ingesting milk products or taking calcium carbonate supplements (250–500 mg). Excess ascorbic acid (> 2 g/d) will substantially increase urinary oxalate levels. Rare enzymatic liver defects can lead to primary hyperoxaluria that is routinely fatal without a combined liver and kidney transplantation.

4. Hypocitraturic—Hypocitraturic calcium nephrolithiasis may be secondary to chronic diarrhea, type I (distal) renal tubular acidosis, chronic hydrochlorothiazide treatment, or in any other condition that results in a metabolic acidosis. The metabolic acidosis will encourage citrate transport into the proximal tubular cells and be consumed by the citric acid cycle in their mitochondria and result in hypocitraturia (< 450 mg/24h). Hypocitraturia is frequently associated with most forms of calcium stone formation. Urinary citrate binds to calcium in solution, thereby decreasing available calcium for precipitation and subsequent stone formation. Potassium citrate supplements are usually effective treatment in these situations. Urinary citrate is decreased in acidosis and is increased during alkalosis. The potassium will supplement the frequently associated hypokalemic states, and citrate will help correct the acidosis. A typical dose is 20 mEq three times a day (available in 10-mEq waxed tablets or in solution), or 30 mEq of crystal formulations twice a day. Alternatively, oral lemonade has been shown to increase urinary citrate by about 150 mg/24h.

C. Uric Acid Calculi

The average normal urinary pH is 5.8–5.9. Urinary pH is consistently < 5.5 in persons who form uric acid stones. The pK of uric acid is 5.75, at which point half of the uric acid is ionized as a urate salt and is soluble, while the other half is insoluble. Increasing the urinary pH above 6.2 dramatically increases uric acid solubility and can effectively

dissolve large calculi at a rate of 1 cm per month as seen on plain abdominal radiographs, and effectively prevents future uric acid stone formation. Urinary alkalization is the key to stone dissolution and prophylaxis. Potassium citrate is the most frequently used medication to increase urinary pH. It can be given in liquid preparation, as crystals that need to be taken with fluids, or as tablets (10 mEq), two by mouth three or four times daily. Patients with uric acid calculi should be given nitrazine pH paper with which to monitor the effectiveness of their urinary alkalization; the goal is a urinary pH > 6.2 and < 6.5 (to avoid calcium phosphate precipitation). Other contributing factors include hyperuricemia, myeloproliferative disorders, malignancy with increased uric acid production, abrupt and dramatic weight loss, and uricosuric medications. If hyperuricemia is present, allopurinol (300 mg/d orally) may be given. Although pure uric acid stones are relatively radiolucent, most have some calcium components and can be visualized on plain abdominal radiographs. Renal ultrasonography is a helpful adjunct for appropriate diagnosis and long-term management.

D. Struvite Calculi

Struvite stones are synonymous with magnesium-ammonium-phosphate or infection stones. They are most commonly seen in women with recurrent urinary tract infections recalcitrant to appropriate antibiotics. They rarely present as ureteral stones with colic without prior upper tract endourologic intervention. Frequently, a struvite stone is discovered as a large staghorn configured calculus forming a cast of the renal collecting system. Struvite stones are radiodense. Urinary pH is high, routinely above 7.2. These stones are formed secondary to urease-producing organisms, including *Proteus*, *Pseudomonas*, *Providencia* and, less commonly, *Klebsiella*, *Staphylococcus*, and *Mycoplasma*. An *E coli* urinary tract infection is not consistent with an infectious reservoir originating from a struvite calculus. These frequently large stones are relatively soft and amenable to percutaneous nephrolithotomy. Appropriate perioperative antibiotics are required. They can recur rapidly, and efforts should be taken to render the patient stone-free. Postoperative irrigation through nephrostomy tubes can eliminate small fragments. Acetohydroxamic acid is an effective urease inhibitor, but it is poorly tolerated by most patients because of its gastrointestinal toxicity.

E. Cystine Calculi

Cystine stones are a result of abnormal excretion of cystine, ornithine, lysine, and arginine. Cystine is the only amino acid that becomes insoluble in urine. These stones are particularly difficult to manage medically. Prevention is centered around marked increased fluid intake during the day and evening to achieve a urinary volume of 3–4 L/d, urinary alkalization with a urinary pH > 7.0 (monitored with Nitrazine pH paper), and disulfide inhibitors such as tiopronin (α -mercaptopyrionylglycine) or penicillamine. There are no known inhibitors of cystine calculi.

► Surgical Treatment

Forced intravenous fluids will not push stones down the ureter. Effective peristalsis directing a bolus of urine down the ureter requires opposing ureteral walls to approach each other and touch, which large dilated systems cannot do. In fact, forced diuresis is counterproductive and will exacerbate the pain; a euvolemic state should be achieved. Associated fever may represent infection, a medical emergency requiring prompt drainage by a ureteral catheter or a percutaneous nephrostomy tube. Antibiotics alone are inadequate unless the obstruction is drained.

A. Ureteral Stones

Impediment to urine flow by ureteral stones usually occurs at two sites: at the ureteropelvic junction and at the ureterovesicular junction as the ureter enters the bladder. Prediction of spontaneous stone passage is difficult. Stones < 5–6 mm in diameter as seen on a plain abdominal radiograph usually pass spontaneously. Medical expulsive therapy with α -blockers (such as tamsulosin, 0.4 mg orally once daily) in combination with a nonsteroidal anti-inflammatory agent (such as ibuprofen 600 mg orally three times per day with a full stomach), with or without a short course of a low-dose oral corticosteroid dramatically increases the rate of spontaneous stone passage. Active medical expulsive therapy with appropriate pain medications is appropriate for the first few weeks. If stone passage fails, with or without medical expulsive therapy, or the patient has intolerable pain or persistent nausea or vomiting, therapeutic intervention is indicated. Distal ureteral stones are best managed with ureteroscopic stone extraction or in situ extracorporeal shock wave lithotripsy (SWL). Ureteroscopic stone extraction involves placement of a small endoscope through the urethra and into the ureter. Under direct vision, basket extraction or stone laser fragmentation followed by extraction is performed. Complications during endoscopic retrieval increase as the duration of attempted medical expulsive therapy increases beyond 6 weeks. Indications for earlier intervention include severe pain unresponsive to medications, fever, persistent nausea and vomiting requiring intravenous hydration, social requirements requiring return to work, or anticipated travel. Most upper tract stones that enter the bladder can exit the urethra with minimal discomfort.

In situ SWL, an alternative, utilizes an external energy source that is focused on the stone. This focused energy is additive, resulting in minimal tissue insult except at the focus where the stone is positioned with the aid of fluoroscopy or ultrasonography. This can be performed under anesthesia as an outpatient procedure and has a high stone fragmentation rate. Most stone fragments will pass uneventfully within 2 weeks, but those that have not passed within 6 weeks are unlikely to pass without intervention. Women of childbearing age are best not treated with SWL for a stone in the lower ureter because the impact on the ovary is unknown.

Proximal and midureteral stones—those above the inferior margin of the sacroiliac joint—can be treated with SWL or ureteroscopy. SWL is delivered directly to the stone

(in situ) without the need to push the stone back into the renal pelvis. To help ensure adequate drainage after SWL, a double J ureteral stent may be placed, but it does not ensure passage of stone fragments. Occasionally, stone fragments will obstruct the ureter after SWL. Conservative management will usually result in spontaneous resolution with eventual passage of the stone fragments. If this is unsuccessful, adequate proximal drainage through a percutaneous nephrostomy tube will facilitate passage. In rare instances, ureteroscopic extraction will be required.

B. Renal Calculi

Patients with renal calculi presenting without pain, urinary tract infections, or obstruction need not be treated. They should be monitored with serial abdominal radiographs or renal ultrasonographic examinations. If calculi are growing or become symptomatic, intervention should be undertaken. Renal calculi < 1.5 cm in diameter are best treated with SWL. Calculi located in the inferior calyx frequently result in suboptimal stone-free rates as measured at 3 months by x-ray. Such calculi and others of larger diameter are best treated via percutaneous nephrolithotomy. Percutaneous nephrolithotomy is performed by inserting a needle into the appropriate renal calyx and dilating a tract large enough to allow a nephroscope to pass and inspect, fragment, and remove stone and stone fragments. Perioperative antibiotic coverage should be given on the basis of preoperative urine cultures.

► When to Refer

- Evidence of urinary obstruction.
- Urinary stone with fever.
- Anatomic abnormalities or solitary kidney.
- Concomitant pyelonephritis.

► When to Admit

- Intractable nausea and vomiting or pain.
- Fever.

MALE ERECTILE DYSFUNCTION & SEXUAL DYSFUNCTION

ESSENTIALS OF DIAGNOSIS

- ▶ Erectile dysfunction can have organic and psychogenic etiologies.
- ▶ Organic erectile dysfunction may be an early sign of cardiovascular disease and requires evaluation.
- ▶ Peyronie disease is a common fibrotic disorder of the penile erectile bodies that causes penile deformity and sexual dysfunction.

▶ General Considerations

Erectile dysfunction is the consistent inability to attain or maintain a sufficiently rigid penile erection for sexual performance. The condition affects nearly 30 million American men, and its incidence is age related. Approximately 52% of men aged 40–70 years experience erectile dysfunction. Most cases of erectile dysfunction have an organic rather than a psychogenic cause. Normal male erection is a neurovascular event relying on an intact autonomic and somatic nerve supply to the penis, smooth and striated musculature of the corpora cavernosa and pelvic floor, and arterial blood flow supplied by the paired pudendal arteries. Erection is caused and maintained by an increase in arterial flow, active relaxation of the smooth muscle within the sinusoids of the paired corpora cavernosa of the penis, and an increase in venous resistance. Contraction of the bulbocavernosus and ischiocavernosus muscles results in further rigidity of the penis with intracavernosal pressures far exceeding systolic blood pressure. Nitric oxide is a pivotal neurotransmitter that initiates and sustains erections; however, other molecules contribute, including acetylcholine, prostaglandins, and vasoactive intestinal peptide.

Male sexual dysfunction may be manifested in a variety of ways, and patient history is critical to the proper classification and treatment. Androgens have a strong influence on the sexual desire of men. A **loss of libido** may indicate androgen deficiency on the basis of either hypothalamic, pituitary, or testicular disease. **Loss of erections** may result from arterial, venous, neurogenic, or psychogenic causes. Concurrent medical problems may damage one or more of the mechanisms. Of particular concern is endothelial dysfunction, defined as the decreased bioavailability of nitric oxide with subsequent impairment of arterial vasodilation. Erectile dysfunction may be an early manifestation of endothelial dysfunction, which precedes more severe, systemic atherosclerotic, cardiovascular disease. In addition, many medications, especially antihypertensive and antidepressant agents, are associated with erectile dysfunction. **Peyronie disease** is a fibrotic disorder of the tunica albuginea of the penis resulting in varying degrees of penile curvature or deformity and sexual dysfunction. Peyronie disease develops in approximately 5% of men older than 50 years, but this may be an underestimate related to embarrassment in seeking care. After onset of the disease, 10% of men improve

spontaneously. If left untreated, the disease progresses in half of the remainder and the rest stabilize. Deformity of the penis can be severe enough to impair normal sexual function. The etiology of Peyronie disease is not fully understood and is likely multifactorial. The most promising hypothesis is that subtle penile trauma is followed by abnormal wound healing, although other potential disease modulators may include vascular disease and hypogonadism.

Priapism is the occurrence of penile erection unrelated to sexual stimulation, generally lasting longer than 4 hours, and potentially leading to irreversible damage to the erectile mechanisms. Priapism can be due to unregulated high blood flow, but more commonly, it is due to trapping of blood within the erectile bodies resulting in penile ischemia and infarction of the sinusoidal tissue. Priapism may be caused by any of the treatments for erectile dysfunction, drug use, and red blood cell dyscrasias.

Anejaculation is the loss of seminal emission and may result from androgen deficiency by decreasing prostate and seminal vesicle secretions as well as sympathetic denervation as a result of diabetes mellitus or pelvic or retroperitoneal surgery or radiation. **Retrograde ejaculation** may occur as a result of mechanical disruption of the bladder neck, especially following transurethral resection of the prostate, pelvic radiation, treatment with α -blockers, or due to sympathetic denervation. If libido and erection are intact, the **loss of orgasm** is usually of psychological origin. **Premature ejaculation** is the persistent or recurrent ejaculation with minimal stimulation before a person desires (associated with distress) and may be primary or secondary. The former is usually psychogenic in origin and additional history may elucidate the presence of a new partner, unreasonable expectations about performance, or emotional disorders. The latter is caused by erectile dysfunction and may be corrected with erectile dysfunction treatment.

▶ Clinical Findings

A. Symptoms and Signs

Erectile dysfunction should be distinguished from problems of penile deformity, ejaculation, libido, and orgasm. The severity of the dysfunction (maintaining vs attaining; chronic, occasional, or situational) as well as its timing should be noted. The history should include inquiries about dyslipidemia, hypertension, depression, neurologic disease, diabetes mellitus, chronic kidney disease, and endocrine disorders as well as cardiac or peripheral vascular disease. Pelvic trauma, surgery, or irradiation identifies patients at increased risk for erectile dysfunction. Penile deformity or curvature that prevents normal intercourse should be noted because this may indicate the presence of Peyronie disease, which may complicate treatment. The history should clarify the severity of curvature, loss of penile length, and other deformities that may prevent normal, painless sexual intercourse. It is important to determine whether the patient has any normal erections in the early morning or during sleep. If normal erections occur, an organic cause is less likely. The ability to attain but not maintain an erection may be the first sign of **endothelial dysfunction**, which is the decreased responsiveness of the

penile vasculature to nitric oxide released from pelvic parasympathetic nerves. The gradual loss of erections over time is more suggestive of an organic cause with the exception of erectile dysfunction that immediately follows pelvic surgery or trauma. Medication use should be noted, since 25% of all cases of sexual dysfunction may be drug related. The use of alcohol, tobacco, and recreational drugs should be recorded, since each is associated with an increased risk of sexual dysfunction.

During the physical examination, secondary sexual characteristics should be assessed. Motor and sensory examination should be performed as well as palpation and quantification of lower extremity vascular pulsations. The genitalia should be examined, noting the presence of penile scarring or plaque formation (Peyronie disease) and any abnormalities in size or consistency of either testicle.

B. Laboratory Findings

Laboratory evaluation should consist of a fasting lipid profile and glucose, testosterone, and prolactin. Patients with abnormalities of testosterone or prolactin require further evaluation with measurement of free testosterone and luteinizing hormone (LH) to distinguish hypothalamic-pituitary dysfunction from testes failure.

C. Special Tests

Further testing is based on the patient's history and is performed when etiology is unclear. Organic and psychogenic erectile dysfunction frequently occur in tandem, given that erectile dysfunction can contribute to emotional stress. Erectile dysfunction that is primarily psychogenic can generally be differentiated by patient history, whereby men will describe normal nocturnal or morning erections, or situational erectile dysfunction. If the distinction remains unclear, clarity may be gained with the use of nocturnal penile tumescence testing, where the frequency and rigidity of erections are recorded by a tension meter attached to the penis before sleep. Patients with psychogenic erectile dysfunction will have nocturnal erections of adequate frequency and rigidity.

Treatment of patients with oral medications (sildenafil, vardenafil, and tadalafil) provides insight into the etiology and severity of erectile dysfunction. Patients with inadequate response to oral medications may undergo further evaluation with direct injection of vasoactive medications into the penis. These medications (prostaglandin E_1 , papaverine, phentolamine or a combination of drugs) induce erections in men with intact vascular systems. Patients who respond with a rigid erection require no further vascular evaluation.

Additional vascular testing is indicated in select patients who do not achieve an erection after penile injection and who are candidates for vascular reconstructive surgery. Duplex ultrasound, penile cavernosography, and pudendal arteriography can distinguish arterial from venous erectile dysfunction and help predict which patients may benefit from vascular surgery.

► Treatment

Treatment of men suffering from sexual dysfunction should be patient centered and goal oriented, since the

disease is generally not life-threatening. Most men can be treated successfully with one of the approaches outlined below. Men who have psychogenic erectile dysfunction will probably benefit from behaviorally oriented sex therapy.

A. Hormonal Replacement

Testosterone replacement therapy may be offered to men with documented biochemical hypogonadism who have undergone endocrinologic evaluation and in whom there is no evidence of prostate cancer or other contraindication to treatment. Restoration of normal testosterone levels may improve libido and effectiveness of oral erectile medications.

B. Vasoactive Therapy

Sexual stimulation with subsequent nitric oxide release from the parasympathetic nerves and endothelium initiates penile erection. Nitric oxide enters smooth muscle cells, increases cyclic guanosine monophosphate (cGMP) production, which mediates calcium sequestration and cellular hyperpolarization. Phosphodiesterase-5 (PDE-5) degrades cGMP and fosters penile detumescence. Activation of pelvic sympathetic nerves causes ejaculation, contraction of the smooth muscle within the corpora cavernosa and complete penile detumescence.

1. Oral agents—Sildenafil, vardenafil, and tadalafil inhibit PDE-5, preventing the degradation of cGMP, thereby sustaining inflow of blood into the erect penis. The drugs are similarly effective; some patients who do not respond to one PDE-5 inhibitor may respond to one of the other agents. Because of differences in receptor binding affinity and pharmacokinetics, the drugs have variable durations of activity and side effects. Each drug should be initiated at the lowest dose and titrated to effect. There is no effect on libido, and priapism is exceedingly rare. The additive effect of nitrate medications may lead to exaggerated cardiac preload reduction and hypotension; therefore, these drugs are contraindicated in patients taking nitroglycerin or nitrates. The greatest risk for this effect is within the first hour after taking sildenafil but this risk period may be longer for tadalafil due to increased drug half-life. All patients being evaluated for acute chest pain should be asked if they are taking a PDE-5 inhibitor before administering nitroglycerin and close monitoring of blood pressure is warranted if there is concern regarding drug overlap. Fixed atherosclerotic disease in the aortoiliac system is associated with diminished efficacy.

The combination of PDE-5 inhibitors and α -receptor blockers (which may be prescribed for lower urinary tract symptoms) may cause a larger reduction in systemic blood pressure than when PDE-5 inhibitors are used alone. However, these two classes of medication may be safely used in combination if they are started in a stepwise fashion, with escalation of dose when there is no evidence of syncope. In select men, combined treatment with PDE-5 inhibitors and testosterone replacement may be warranted, since adequate androgen levels may be required for the penile vasculature to be fully responsive to vasoactive drugs.

2. Injectable agents—Direct injection of vasoactive prostaglandins with or without papaverine or phentolamine into the penis is an acceptable form of treatment for many men

with erectile dysfunction. Injections are performed using a tuberculin syringe or a metered-dose injection device. The base and lateral aspect of the penis is used as the injection site to avoid injury to the superficial blood supply located anteriorly. Complications are rare and include bruising, dizziness, local pain, fibrosis, priapism, and infection. Vasoactive prostaglandins (alprostadil) can also be delivered via a urethral suppository with slightly less effectiveness.

The presence of a prolonged erection (priapism) requires immediate medical attention to prevent erectile dysfunction and fibrosis of the cavernosal tissues. Initial management may include aspiration of blood from the penis or injection of sympathomimetic drugs (epinephrine or phenylephrine); if these maneuvers fail, surgical shunts may need to be performed to drain blood from the corpora cavernosa.

C. Vacuum Erection Device

The vacuum erection device causes erection by creating a vacuum chamber around the penis, whereby blood is drawn into the corpora cavernosa. Once adequate tumescence has been achieved, an elastic constriction band is placed around the proximal penile shaft to prevent loss of erection, and the vacuum cylinder is removed. Such devices are highly effective, regardless of the cause of erectile dysfunction; however, the devices are cumbersome with a high rate of discontinued use. Complications are rare.

D. Penile Prostheses

Prosthetic devices may be implanted directly into the paired corporal bodies. Penile prostheses may be semi-rigid (malleable) or inflatable. Each is manufactured in a variety of sizes and is custom-fit to the individual. Even for men with normal erectile function, the penis is flaccid 90% of time; therefore, inflatable devices may result in a more natural appearance and better functionality. Complications are rare but include mechanical failure, infection, and injury to adjacent anatomic structures during surgery. For men who elect this treatment, personal and partner satisfaction rates exceed 90%.

E. Vascular Reconstruction

Patients with disorders of the arterial system are candidates for various forms of arterial reconstruction, including endarterectomy and balloon dilation for proximal arterial occlusion and arterial bypass procedures utilizing arterial (epigastric) or venous (deep dorsal vein) segments for distal occlusion. Patients with venous disorders may be managed with ligation of certain veins (deep dorsal or emissary veins) or the crura of the corpora cavernosa. Experience with vascular reconstructive procedures is limited, and many patients so treated still fail to achieve a rigid erection.

F. Medical and Surgical Therapy for Peyronie Disease

A wide range of medical and surgical treatments have been used to treat the disorder. There are no oral therapies for Peyronie disease that are approved by the FDA; however, evidence from randomized controlled trials supports the use of pentoxifylline, coenzyme Q10, colchicine, potassium

aminobenzoate (Potaba), and L-carnitine. The intraplaque injection of verapamil or interferon improves penile deformity in some patients. Surgical treatment is an alternative for men with compromised sexual function due to severe curvature or lesions causing penile instability. The choice of corrective procedure should be tailored to each patient after a detailed evaluation of disease severity and sexual function.

▶ When to Refer

- Patients with inadequate response to oral medications or who are unable to tolerate side effects.
- Patients with Peyronie disease (penile curvature) or other penile deformity.
- Patients with a history of pelvic or perineal trauma, surgery, or radiation.
- Young patients or those with lifelong erectile dysfunction.
- Ischemic priapism is a medical emergency and requires immediate referral to a urologist or the emergency department for intervention to allow restoration of penile blood perfusion.

MALE INFERTILITY

ESSENTIALS OF DIAGNOSIS

- ▶ Couple infertility is related to the male partner in 50% of cases.
- ▶ Causes include decreased or absent sperm production or function, or obstruction of the male genital tract.
- ▶ Detailed history, physical examination, and repeated semen analysis are the cornerstones of diagnosis and treatment.
- ▶ In select men, abnormal semen quality may indicate poor somatic health and increased risk for certain health conditions.

► General Considerations

Infertility, the inability of a couple to conceive a child after 1 year of sexual intercourse without contraceptive use, affects 15–20% of US couples. Approximately one-third of cases result from male factors, one-third from female factors, and one-third from combined factors; therefore, evaluation of both partners is critical. Clinical evaluation is warranted following 6 months of unprotected intercourse in select couples. Following a detailed history and physical examination, a semen analysis is essential for diagnosis and should be performed at least twice, on two separate occasions (Figure 23–1). Because spermatogenesis takes approximately 74 days, it is important to review events from the past 3 months. Some types of male infertility put men at higher risk for the later development of testicular germ cell cancer; thus, they should be counseled appropriately and taught self testicular exam.

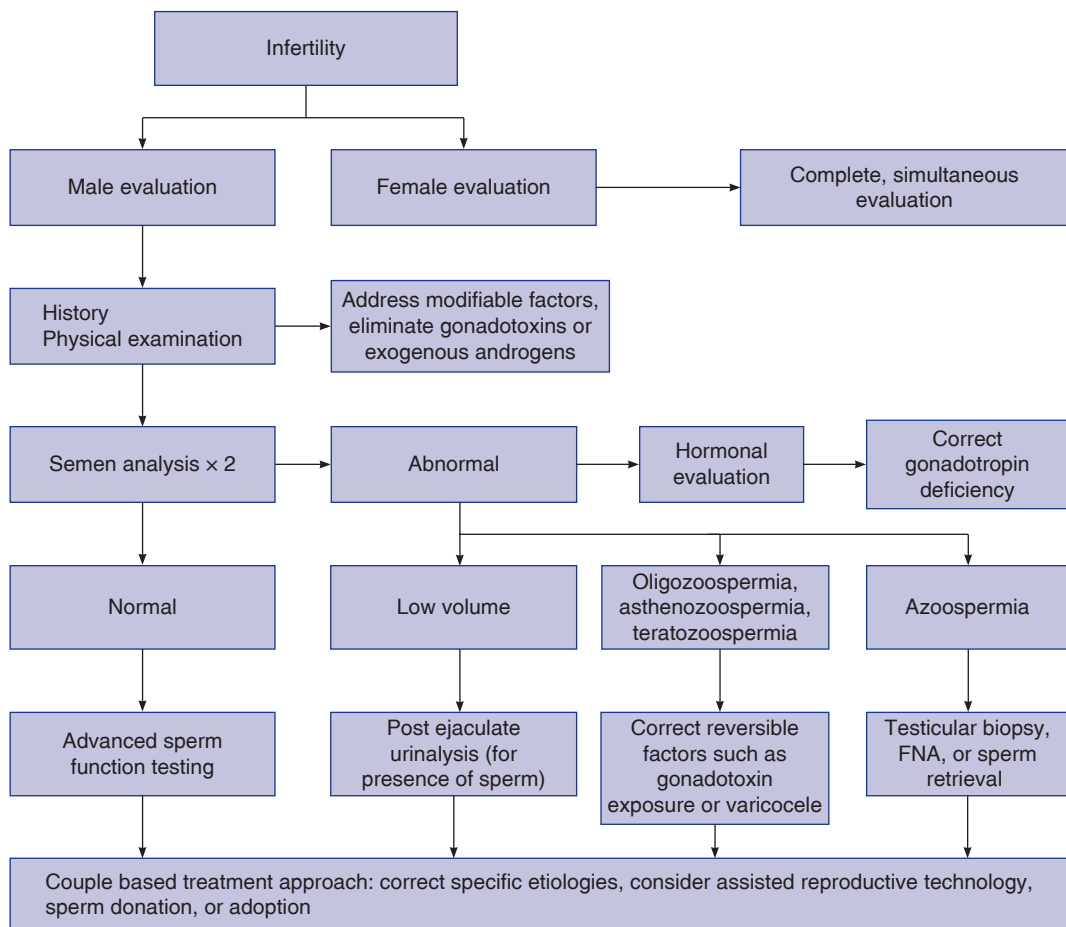

► Clinical Findings

A. Symptoms and Signs

The history should include prior testicular insults (torsion, cryptorchidism, trauma), infections (mumps orchitis,

epididymitis), environmental factors (excessive heat, radiation, chemotherapy, prolonged pesticide exposure), medications (anabolic steroids, cimetidine, and spironolactone may affect spermatogenesis; phenytoin may lower FSH; sulfasalazine and nitrofurantoin affect sperm motility), and drugs (alcohol, tobacco, marijuana). Sexual habits, frequency and timing of intercourse, use of lubricants, and each partner's previous fertility experiences are important. Loss of libido and headaches, visual disturbances, or galactorrhea may indicate a pituitary tumor. The past medical or surgical history may reveal thyroid or liver disease (abnormalities of spermatogenesis), diabetic neuropathy (retrograde or anejaculation), radical pelvic or retroperitoneal surgery (absent seminal emission secondary to sympathetic nerve injury), or hernia repair (damage to the vas deferens or testicular blood supply).

Physical examination should pay particular attention to features of hypogonadism: underdeveloped secondary sexual characteristics, diminished male pattern hair distribution (axillary, body, facial, pubic), body habitus, and gynecomastia. The scrotal contents should be carefully evaluated. Testicular size should be noted (normal size approximately 4.5 × 2.5 cm, volume 18 mL). **Varicoceles**

▲ **Figure 23-1.** Couple based approach to evaluation and treatment of male factor infertility. FNA, fine-needle aspiration.

are abnormally dilated and refluxing veins of the pampiniform plexus that can be identified in the standing position by gentle palpation of the spermatic cord and, on occasion, may only be appreciated with the Valsalva maneuver. The vas deferens, epididymis, and prostate should be palpated (absence of all or part of the vas deferens may indicate the presence a cystic fibrosis variant, congenital bilateral or unilateral absence of the vas deferens).

B. Laboratory Findings

Semen analysis should be performed after 2 to 3 days of ejaculatory abstinence. The specimen should be analyzed within 1 hour after collection. Abnormal sperm concentrations are <15 million/mL (**oligozoospermia** is the presence of <15 million sperm/mL in the ejaculate; **azoospermia** is the absence of sperm). Normal semen volumes range between 1.5 mL and 5 mL (volumes <1.5 mL may result in inadequate buffering of the vaginal acidity and may be due to retrograde ejaculation, ejaculatory duct obstruction, or androgen insufficiency). Normal sperm motility and morphology demonstrate $>45\%$ motile cells and $>4\%$ normal morphology (World Health Organization). Abnormal motility may result from varicocele, antisperm antibodies, infection, abnormalities of the sperm flagella, or partial ejaculatory duct obstruction. Abnormal morphology may result from a varicocele, infection, or exposure to gonadotoxins (eg, tobacco smoke).

Endocrine evaluation is warranted if sperm counts are low (<15 million/mL) or if there is a basis from the history and physical examination for suspecting an endocrinologic origin. Initial testing should include serum FSH and testosterone. Specific abnormalities in these hormones should prompt additional testing, including LH and prolactin. Elevated FSH and LH levels and low testosterone levels (hypergonadotropic hypogonadism) are associated with primary testicular failure. Low FSH and LH associated with low testosterone occur in secondary testicular failure (hypogonadotropic hypogonadism) and may be of hypothalamic or pituitary origin. Elevation of serum prolactin may indicate the presence of pituitary prolactinoma.

C. Genetic Testing

Men with sperm concentrations <10 million/mL should undergo testing for Y chromosome microdeletions and karyotypic abnormalities. Gene deletions from the long arm of the Y chromosome may cause azoospermia or oligozoospermia with age-related decline in spermatogenesis that is transmissible to male offspring. Karyotyping may reveal Klinefelter syndrome. Partial or complete absence of the vas deferens should prompt testing for cystic fibrosis mutations.

D. Imaging

Scrotal ultrasound may detect a subclinical varicocele. Vasography may be required in patients with suspected genital duct obstruction. Men with low ejaculate volume and no evidence of retrograde ejaculation should undergo transrectal ultrasound to evaluate the prostate and seminal vesicles. MRI of the sella turcica should be performed in

men with markedly elevated prolactin or hypogonadotropic hypogonadism to evaluate the anterior pituitary gland. MRI of the pelvis and scrotum should be considered in men for whom the testes cannot be identified in the scrotum by physical examination or ultrasound.

E. Special Tests

Patients with low volume ejaculate should have post-ejaculation urine samples centrifuged and analyzed for sperm to evaluate for retrograde ejaculation. In cases of disproportionately low motility, sperm vitality and the presence of autoantibodies should be assessed. Rounds cells in concentrations >1 million/mL should prompt leukocyte esterase or peroxidase staining (immature germ cells are found normally, but inflammatory cells may require treatment).

▶ Treatment

A. General Measures

Education about the proper timing for intercourse in relation to the woman's ovulatory cycle as well as the avoidance of spermicidal lubricants should be discussed. In cases of gonadotoxic exposure or medication-related factors, the offending agent should be removed. Patients with active genitourinary tract infections should be treated with appropriate antibiotics. Healthy lifestyle habits, including healthy diet, moderate exercise, and avoidance of gonadotoxins (such as tobacco smoke) should be reinforced.

B. Varicocele

Varicocelectomy is performed by stopping retrograde blood flow in spermatic cord veins. Surgical ligation may be accomplished via subinguinal, inguinal, retroperitoneal, or laparoscopic approaches. Percutaneous venographic embolization of varicoceles is feasible but may have a higher recurrence rate.

C. Endocrine Therapy

Hypogonadotropic hypogonadism may be treated with chorionic gonadotropin once primary pituitary disease has been excluded or treated. Dosage is usually 2000 international units intramuscularly three times a week. If sperm counts fail to rise after 12 months, FSH therapy should be initiated.

D. Ejaculatory Dysfunction Therapy

Patients with retrograde ejaculation may benefit from α -adrenergic agonists (pseudoephedrine, 60 mg orally three times a day) or imipramine (25 mg orally three times a day). Medical failures may require the collection of post-ejaculation urine for intrauterine insemination. Anejaculation can be treated with vibratory stimulation or electroejaculation in select cases.

E. Ductal Obstruction

Obstruction of the ejaculatory ducts may be corrected by transurethral resection of the ducts in the prostatic urethra.

If obstruction of the vas deferens or epididymis is suspected, the level of obstruction must be determined via a vasogram prior to operative treatment, with the exception of prior vasectomy. Obstruction of the vas deferens is best managed by microsurgical vasovasostomy or vasoe-pididymostomy.

F. Assisted Reproductive Techniques

Intrauterine insemination, in vitro fertilization, and intracytoplasmic sperm injection (ICSI) are alternatives for patients in whom other means of treating reduced sperm concentration, motility, or functionality has failed. With the use of ICSI, azoospermic men can father their genetic progeny by surgical retrieval of sperm from the testicle, epididymis, or vas deferens.

▶ When to Refer

- Couples with clinical infertility or concern about fertility potential.
- Men with known genital insults, genetic diagnoses, or syndromes that preclude natural fertility.
- Reproductive-aged men with newly diagnosed cancer or other disease that may require cytotoxic therapies with interest in fertility preservation.

BENIGN PROSTATIC HYPERPLASIA

ESSENTIALS OF DIAGNOSIS

- ▶ Obstructive or irritative voiding symptoms.
- ▶ May have enlarged prostate on rectal examination.
- ▶ Absence of urinary tract infection, neurologic disorder, stricture disease, prostatic or bladder malignancy.

▶ General Considerations

Benign prostatic hyperplasia is the most common benign tumor in men, and its incidence is age related. The prevalence of histologic benign prostatic hyperplasia in autopsy studies rises from approximately 20% in men aged 41–50 years, to 50% in men aged 51–60, and to over 90% in men

over 80 years of age. Although clinical evidence of disease occurs less commonly, symptoms of prostatic obstruction are also age related. At age 55 years, approximately 25% of men report obstructive voiding symptoms. At age 75 years, 50% of men report a decrease in the force and caliber of the urinary stream.

Risk factors for the development of benign prostatic hyperplasia are poorly understood. Some studies have suggested a genetic predisposition and some have noted racial differences. Approximately 50% of men under age 60 years who undergo surgery for benign prostatic hyperplasia may have a heritable form of the disease. This form is most likely an autosomal dominant trait, and first-degree male relatives of such patients carry an increased relative risk of approximately fourfold.

▶ Clinical Findings

A. Symptoms

The symptoms of benign prostatic hyperplasia can be divided into obstructive and irritative complaints. **Obstructive symptoms** include hesitancy, decreased force and caliber of the stream, sensation of incomplete bladder emptying, double voiding (urinating a second time within 2 hours), straining to urinate, and postvoid dribbling. **Irritative symptoms** include urgency, frequency, and nocturia.

The American Urological Association (AUA) symptom index (Table 23–4) is perhaps the single most important tool used in the evaluation of patients with this disorder and should be calculated for all patients before starting therapy. The answers to seven questions quantitate the severity of obstructive or irritative complaints on a scale of 0–5. Thus, the score can range from 0 to 35, in increasing severity of symptoms.

A detailed history focusing on the urinary tract should be obtained to exclude other possible causes of symptoms such as prostate cancer or disorders unrelated to the prostate such as urinary tract infection, neurogenic bladder, or urethral stricture.

B. Signs

A physical examination, digital rectal examination (DRE), and a focused neurologic examination should be performed on all patients. The size and consistency of the prostate should be noted, but prostate size does not correlate with the severity of symptoms or the degree of obstruction. Benign prostatic hyperplasia usually results in a smooth, firm, elastic enlargement of the prostate. Induration, if detected, must alert the clinician to the possibility of cancer, and further evaluation is needed (ie, prostate-specific antigen [PSA] testing, transrectal ultrasound, and biopsy). Examination of the lower abdomen should be performed to assess for a distended bladder.

C. Laboratory Findings

Urinalysis should be performed to exclude infection or hematuria. A serum PSA is considered optional, yet most clinicians will include it in the initial evaluation, particularly if life expectancy is > 10 years. PSA certainly increases

Table 23-4. American Urological Association symptom index for benign prostatic hyperplasia.¹

Questions to Be Answered	Not at All	Less Than One Time in Five	Less Than Half the Time	About Half the Time	More Than Half the Time	Almost Always
1. Over the past month, how often have you had a sensation of not emptying your bladder completely after you finish urinating?	0	1	2	3	4	5
2. Over the past month, how often have you had to urinate again less than 2 hours after you finished urinating?	0	1	2	3	4	5
3. Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
4. Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
5. Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
6. Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1	2	3	4	5

¹Sum of seven circled numbers equals the symptom score. See text for explanation.

the ability to detect prostate cancer over DRE alone; however, because there is much overlap between levels seen in benign prostatic hyperplasia and prostate cancer, its use remains controversial (see below in the section on screening for prostate cancer).

D. Imaging

Upper tract imaging (CT or renal ultrasound) is recommended only in the presence of concomitant urinary tract disease or complications from benign prostatic hyperplasia (ie, hematuria, urinary tract infection, chronic kidney disease, history of stone disease).

E. Cystoscopy

Cystoscopy is not recommended to determine the need for treatment but may assist in determining the surgical approach in patients opting for invasive therapy.

F. Additional Tests

Cystometrograms and urodynamic profiles should be reserved for patients with suspected neurologic disease or those who have failed prostate surgery. Flow rates, postvoid residual urine determination, and pressure-flow studies are considered optional.

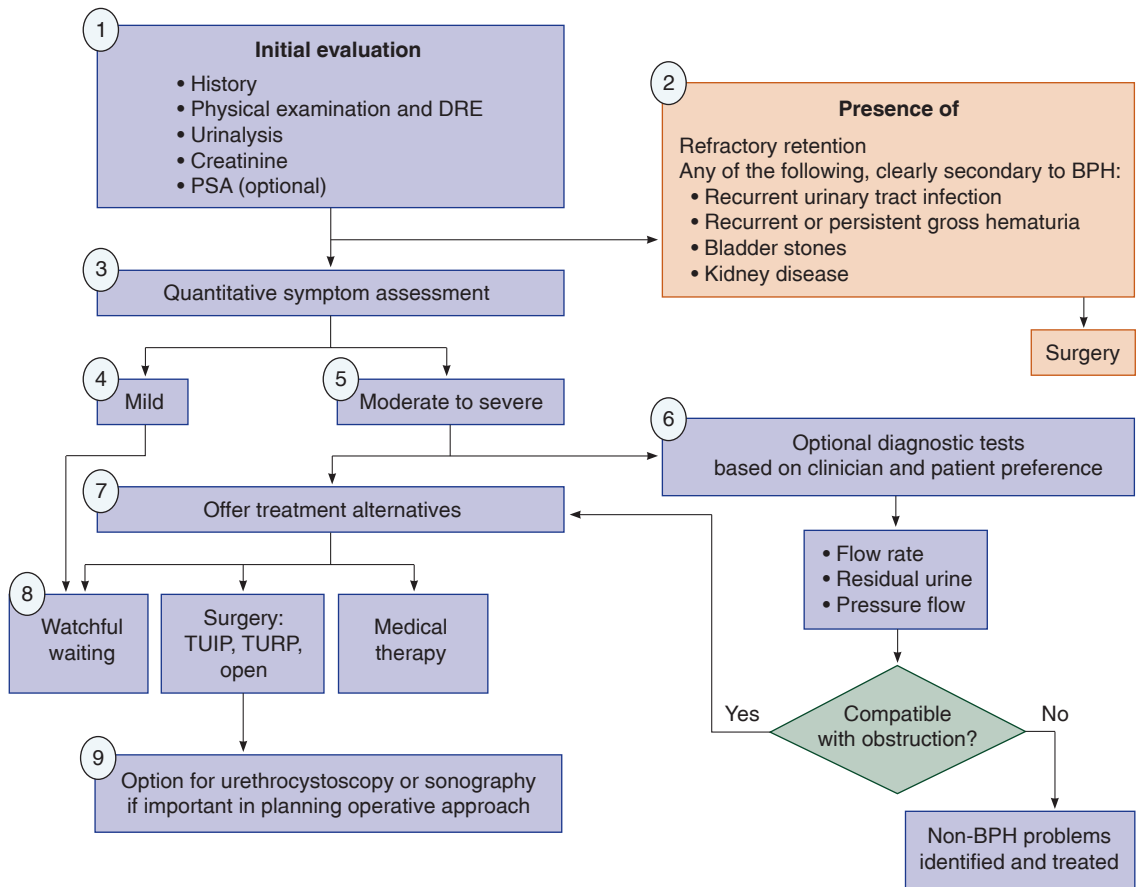

► Differential Diagnosis

A history of prior urethral instrumentation, urethritis, or trauma should be elucidated to exclude urethral stricture or bladder neck contracture. Hematuria and pain are

commonly associated with bladder stones. Carcinoma of the prostate may be detected by abnormalities on the DRE or an elevated PSA (see Chapter 39 for Prostate Cancer). A urinary tract infection can mimic the irritative symptoms of benign prostatic hyperplasia and can be readily identified by urinalysis and culture; however, a urinary tract infection can also be a complication of benign prostatic hyperplasia. Carcinoma of the bladder, especially carcinoma in situ, may also present with irritative voiding complaints; however, urinalysis usually shows evidence of hematuria (see Chapter 39 for Bladder Cancer). Patients with a neurogenic bladder may also have many of the same symptoms and signs as those with benign prostatic hyperplasia; however, a history of neurologic disease, stroke, diabetes mellitus, or back injury may be obtained, and diminished perineal or lower extremity sensation or alterations in rectal sphincter tone or the bulbocavernosus reflex might be observed on examination. Simultaneous alterations in bowel function (constipation) might also suggest the possibility of a neurologic disorder.

► Treatment

Clinical practice guidelines exist for the evaluation and treatment of patients with benign prostatic hyperplasia (Figure 23-2). Following evaluation as outlined above, patients should be offered various forms of therapy for benign prostatic hyperplasia. Patients are advised to consult with their primary care clinicians and make an educated decision on the basis of the relative efficacy and side effects of the treatment options (Table 23-5).

Table 23-5. Summary of benign prostatic hyperplasia treatment outcomes.¹

Outcome	TUIP	Open Surgery	TURP	Watchful Waiting	α -Blockers	Finasteride ²
Chance for improvement ¹	78–83%	94–99.8%	75–96%	31–55%	59–86%	54–78%
Degree of symptom improvement (% reduction in symptom score)	73%	79%	85%	Unknown	51%	31%
Morbidity and complications ¹	2.2–33.3%	7–42.7%	5.2–30.7%	1–5%	2.9–43.3%	13.6–8.8%
Death within 30–90 days ¹	0.2–1.5%	1–4.6%	0.5–3.3%	0.8%	0.8%	0.8%
Total incontinence ¹	0.1–1.1%	0.3–0.7%	0.7–1.4%	2%	2%	2%
Need for operative treatment for surgical complications ¹	1.3–2.7%	0.6–14.1%	0.7–10.1%	0	0	0
Erectile dysfunction ¹	3.9–24.5%	4.7–39.2%	3.3–34.8%	3%	3%	2.5–5.3%
Retrograde ejaculation	6–55%	36–95%	25–99%	0	4–11%	0
Loss of work in days	7–21	21–28	7–21	1	3.5	1.5%
Hospital stay in days	1–3	5–10	3–5	0	0	0

¹90% confidence interval.

²Most of the data reviewed for finasteride are derived from three trials that have required an enlarged prostate for entry. The chance of improvement in men with symptoms yet minimally enlarged prostates may be much less, as noted from the VA Cooperative Trial.

TUIP, transurethral incision of the prostate; TURP, transurethral resection of the prostate.

Patients with mild symptoms (AUA scores 0–7) should be managed by watchful waiting only. Absolute surgical indications are refractory urinary retention (failing at least one attempt at catheter removal), large bladder diverticula, or any of the following sequelae of benign prostatic hyperplasia: recurrent urinary tract infection, recurrent gross hematuria, bladder stones, or chronic kidney disease.

A. Watchful Waiting

The risk of progression or complications is uncertain. However, in men with symptomatic disease, it is clear that progression is not inevitable and that some men undergo spontaneous improvement or resolution of their symptoms.

Retrospective studies on the natural history of benign prostatic hyperplasia are inherently subject to bias, relating in part to patient selection and also to the type and extent of follow-up. Very few prospective studies addressing the natural history have been reported. One small series demonstrated that approximately 10% of symptomatic men may progress to urinary retention while 50% of patients demonstrate marked improvement or resolution of symptoms. A large randomized study compared finasteride with placebo in men with moderate to severely symptomatic disease and enlarged prostates on DRE. Patients in the placebo arm demonstrated a 7% risk of developing urinary retention over 4 years.

Men with moderate or severe symptoms can also be observed if they so choose. The optimal interval for follow-up is not defined, nor are the specific end points for intervention.

B. Medical Therapy

1. α -Blockers— α -Blockers can be classified according to their receptor selectivity as well as their half-life (Table 23–6).

Prazosin is effective; however, it requires dose titration and twice daily dosing. Typical side effects include orthostatic hypotension, dizziness, tiredness, retrograde ejaculation, rhinitis, and headache.

Long-acting α -blockers allow for once-a-day dosing, but dose titration is still necessary because side effects similar to those seen with prazosin may occur. Terazosin improves symptoms and in numerous studies is superior to placebo or finasteride. Terazosin is started at a dosage of 1 mg orally daily for 3 days, increased to 2 mg orally daily for 11 days, then 5 mg orally daily. Additional dose escalation to 10 mg orally daily can be performed if necessary. Doxazosin is started at a dosage of 1 mg orally daily for 7 days, increased to 2 mg orally daily for 7 days, then 4 mg orally daily. Additional dose escalation to 8 mg orally daily can be performed if necessary. Alfuzosin is a long-acting α -blocker; its dose is 10 mg orally once daily and does not require titration.

α_{1a} -Receptors are localized to the prostate and bladder neck. Selective blockade of these receptors results in fewer systemic side effects than α -blocker therapy (orthostatic hypotension, dizziness, tiredness, rhinitis, and headache), thus obviating the need for dose titration. The typical dose of tamsulosin is 0.4 mg orally daily taken 30 minutes after a meal. Several randomized, double-blind, placebo-controlled trials have been performed comparing terazosin, doxazosin, tamsulosin, and alfuzosin with placebo. All agents have demonstrated safety and efficacy. However, floppy eye syndrome, a complication of cataract surgery, can occur in patients taking α -blockers and α_{1a} -blockers.

2. 5α -Reductase inhibitors—Finasteride is a 5α -reductase inhibitor that blocks the conversion of testosterone to dihydrotestosterone. This drug impacts upon the epithelial component of the prostate, resulting in reduction in size of the gland and improvement in symptoms. Six months of therapy is required for maximum effects on prostate size (20% reduction) and symptomatic improvement.

Several randomized, double-blind, placebo-controlled trials have been performed comparing finasteride with placebo. Efficacy, safety, and durability are well established. However, symptomatic improvement is seen only in men with enlarged prostates (> 40 mL by ultrasonographic examination). Side effects include decreased libido, decrease in volume of ejaculate, and erectile dysfunction. Serum PSA is reduced by approximately 50% in patients receiving finasteride therapy. Therefore, in order to compare with pre-finasteride levels, the serum PSA of a patient taking finasteride should be doubled.

A report suggests that finasteride therapy may decrease the incidence of urinary retention and the need for operative treatment in men with enlarged prostates and moderate to severe symptoms. The larger the prostate over 40 mL, the greater the relative-risk reduction. However, optimal identification of appropriate patients for prophylactic therapy remains to be determined. Dutasteride is a dual 5α -reductase inhibitor that appears to be similar to finasteride in its effectiveness; its dose is 0.5 mg orally daily.

Both finasteride and dutasteride have been shown to be effective chemopreventive agents for prostate cancer in large, randomized clinical trials. The 25% risk reduction was observed in men with both low and high risk for prostate cancer. However, despite the strength of the evidence for 5α -reductase inhibitors in reducing the risk of prostate

Table 23–6. α -Blockade for benign prostatic hyperplasia.

Agent	Action	Oral Dose
Alfuzosin	α_1 -Blockade	10 mg daily
Doxazosin	α_1 -Blockade	1–8 mg daily
Phenoxybenzamine	α_1 - and α_2 -Blockade	5–10 mg twice daily
Prazosin	α_1 -Blockade	1–5 mg twice daily
Silodosin	α_{1a} -Blockade	4 or 8 mg daily
Tadalafil	Phosphodiesterase type 5 inhibitor	5 mg daily
Tamsulosin	α_{1a} -Blockade	0.4 or 0.8 mg daily
Terazosin	α_1 -Blockade	1–10 mg daily

cancer, an FDA advisory committee recommended against labeling these agents for prostate cancer chemoprevention, citing the potential increased risk of high-grade tumors in these studies, isolated risk reduction in low-grade tumors, and inability to apply the findings to the general population. Moreover, the FDA has included the increased risk of being diagnosed with high-grade prostate cancer in the labels of all 5 α -reductase inhibitors.

3. Phosphodiesterase-5 inhibitor—The FDA approved the use of tadalafil to treat the signs and symptoms of benign prostatic hyperplasia in 2011; it is also approved for use in men with both urinary symptoms and erectile dysfunction. The data from two randomized, double-blind, placebo-controlled trials demonstrated significant improvements in standardized measurements of urinary function between 2 and 4 weeks after initiating treatment at 5 mg, with minimal adverse effects.

4. Combination therapy—The four-arm Veterans Administration Cooperative Trial compared placebo, finasteride alone, terazosin alone, and combination of finasteride and terazosin. Over 1200 patients participated, and significant decreases in symptom scores and increases in urinary flow rates were seen only in the arms containing terazosin. However, enlarged prostates were not an entry criterion; in fact, prostate size in this study was much smaller than in previous controlled trials using finasteride (32 versus 52 mL). Other randomized, placebo-controlled trials comparing finasteride with placebo in men with lower urinary tract symptoms and large prostates showed finasteride to be beneficial for reducing symptoms, increasing urinary flow rate, and reducing the risk of complications due to benign prostatic hyperplasia as well as reducing the number of men who required surgery for benign prostatic hyperplasia. The Medical Therapy of Prostatic Symptoms (MTOPs) trial is a large, randomized, placebo-controlled trial comparing finasteride, doxazosin, the combination of the two, and placebo in 3047 men observed for a mean of 4.5 years. Long-term combination therapy with doxazosin and finasteride was safe and reduced the risk of overall clinical progression of benign prostatic hyperplasia significantly more than did treatment with either drug alone. Combination therapy and finasteride alone reduced the long-term risk of acute urinary retention and the need for invasive therapy. Combination therapy had the risks of additional side effects and the cost of two medications.

5. Phytotherapy—Phytotherapy is the use of plants or plant extracts for medicinal purposes. Its use in benign prostatic hyperplasia has been popularized by patient-driven enthusiasm. Several plant extracts have been popularized, including the saw palmetto berry, the bark of *Pygeum africanum*, the roots of *Echinacea purpurea* and *Hypoxis rooperi*, pollen extract, and the leaves of the trembling poplar. The mechanisms of action of these agents are unknown. A 2006 prospective, randomized, double-blind, placebo-controlled trial revealed no improvement in symptoms, urinary flow rate, or quality of life for men with benign prostatic hyperplasia with saw palmetto treatment compared with placebo.

C. Conventional Surgical Therapy

1. Transurethral resection of the prostate (TURP)

Ninety-five percent of simple prostatectomies can be performed endoscopically (TURP). Most of these procedures are performed under a spinal anesthetic and require a 1- to 2-day hospital stay. Symptom scores and flow rate improvement are superior following TURP relative to any minimally invasive therapy; however, the length of the hospital stay is greater. Much controversy revolves around possible higher rates of morbidity and mortality associated with TURP in comparison with open surgery, but the higher rates observed in one study probably related to more significant comorbidities in the TURP patients compared with the patients who received open surgical treatment. Several other studies could not confirm the difference in mortality when controlling for age and comorbidities. The risks of TURP include retrograde ejaculation (75%), erectile dysfunction (5–10%), and urinary incontinence (< 1%). Complications include bleeding, urethral stricture or bladder neck contracture, perforation of the prostate capsule with extravasation, and, if severe, transurethral resection syndrome, a hypervolemic, hyponatremic state resulting from absorption of the hypotonic irrigating solution. Clinical manifestations of the syndrome include nausea, vomiting, confusion, hypertension, bradycardia, and visual disturbances. The risk of transurethral resection syndrome increases with resection times over 90 minutes. Treatment includes diuresis and, in severe cases, hypertonic saline administration (see Hyponatremia, Chapter 21).

2. Transurethral incision of the prostate (TUIP)

Men with moderate to severe symptoms and small prostates often have posterior commissure hyperplasia or an “elevated bladder neck.” These patients will often benefit from incision of the prostate. The procedure is more rapid and less morbid than TURP. Outcomes in well-selected patients are comparable, though a lower rate of retrograde ejaculation has been reported (25%).

3. Open simple prostatectomy—When the prostate is too large to remove endoscopically, open enucleation is necessary. What size is “too large” depends upon the surgeon's experience with TURP. Glands over 100 g are usually considered for open enucleation. In addition to size, other relative indications for open prostatectomy include concomitant bladder diverticulum or bladder stone and whether dorsal lithotomy positioning is or is not possible.

Open prostatectomies can be performed with either a suprapubic or retropubic approach. Simple suprapubic prostatectomy is performed transvesically and is the operation of choice if there is concomitant bladder pathology. After the adenoma is removed, both a urethral and a suprapubic catheter are inserted prior to closure.

In simple retropubic prostatectomy, the bladder is not entered but rather a transverse incision is made in the surgical capsule of the prostate and the adenoma is enucleated as described above; only a urethral catheter is needed at the end of the case.

D. Minimally Invasive Therapy

1. Laser therapy—Several coagulation necrosis techniques have been utilized. Transurethral laser-induced prostatectomy (TULIP) is performed under transrectal ultrasound guidance. The instrument is placed in the urethra and transrectal ultrasound is used to direct the device as it is slowly pulled from the bladder neck to the apex. The depth of treatment is monitored with ultrasound.

Most urologists prefer to use visually directed laser techniques. Visual coagulative necrosis is performed under cystoscopic control, and the laser fiber is pulled through the prostate at several designated areas depending upon the size and configuration of the gland. Four-quadrant and sextant approaches have been described for lateral lobes, with additional treatments directed at enlarged median lobes. Coagulative techniques do not create an immediate visual defect in the prostatic urethra—tissue is sloughed over the course of several weeks up to 3 months following the procedure.

Visual contact ablative techniques take longer in the operating room because the fiber is placed in direct contact with the prostate tissue, which is vaporized. Photovaporization of the prostate (PVP), an alternative laser technique, uses a high-power KTP laser. An immediate defect is obtained in the prostatic urethra, similar to that seen during TURP.

Interstitial laser therapy places fibers directly into the prostate, usually under cystoscopic control. Irritative voiding symptoms may be less in these patients as the urethral mucosa is spared and prostate tissue is resorbed by the body rather than sloughed.

Advantages to laser surgery include minimal blood loss, rare occurrence of transurethral resection syndrome, the ability to treat patients while on anticoagulation therapy, and outpatient surgery. Disadvantages are the lack of tissue for pathologic examination, the longer postoperative catheterization time, the more frequent irritative voiding complaints, and the expense of laser fibers and generators.

Large multicenter, randomized studies with long-term follow-up are needed in comparing laser prostate surgery with TURP and other forms of minimally invasive surgery.

2. Transurethral needle ablation of the prostate (TUNA)—This procedure uses a specially designed urethral catheter that is passed into the urethra. Interstitial radiofrequency needles are then deployed from the tip of the catheter, piercing the mucosa of the prostatic urethra. Radiofrequencies are then used to heat the tissue, resulting in coagulative necrosis. Bladder neck and median lobe enlargement are not well treated by TUNA. Subjective and

objective improvement in voiding occurs. In randomized trials comparing TUNA to TURP, similar improvement was seen when comparing life scores, peak urinary flow rates, and postvoid residual urine.

3. Transurethral electrovaporization of the prostate—This technique uses the standard resectoscope. High current densities result in heat vaporization of tissue, creating a cavity in the prostatic urethra. Because the device requires slower sweeping speeds over the prostatic urethra and the depth of vaporization is approximately one-third of a standard loop, this procedure usually takes longer than a standard TURP. Long-term comparative data are needed.

4. Hyperthermia—Microwave hyperthermia is most commonly delivered with a transurethral catheter. Some devices cool the urethral mucosa to decrease the risk of injury. However, if temperatures do not go above 45 °C, cooling is unnecessary. Symptom score and flow rate improvement are obtained, but (as with laser surgery) large randomized studies with long-term follow-up are needed to assess durability and cost-effectiveness.

▶ When to Refer

- Progression to urinary retention.
- Patient dissatisfaction with medical therapy.
- Need for surgical intervention or further evaluation (cystoscopy).

Nervous System Disorders

Michael J. Aminoff, MD, DSc, FRCP

Geoffrey A. Kerchner, MD, PhD

HEADACHE

Headache is such a common complaint and can occur for so many different reasons that its proper evaluation may be difficult. New, severe, or acute headaches are more likely than chronic headaches to relate to an intracranial disorder; the approach to such headaches is discussed in Chapter 2. Chronic headaches may be primary or secondary to another disorder. Common primary headache syndromes include migraine, tension-type headache, and cluster headache. Important secondary causes to consider include intracranial lesions, head injury, cervical spondylosis, dental or ocular disease, temporomandibular joint dysfunction, sinusitis, hypertension, depression, and a wide variety of general medical disorders. Although underlying structural lesions are not present in most patients presenting with headache, it is nevertheless important to bear this possibility in mind. About one-third of patients with brain tumors, for example, present with a primary complaint of headache.

The intensity, quality, and site of pain—and especially the duration of the headache and the presence of associated neurologic symptoms—may provide clues to the underlying cause. Migraine headaches are often described as pulsating or throbbing; a sense of tightness or pressure is common with tension headache. Sharp lancinating pain suggests a neuritic cause; ocular or periorbital icpick-like pains occur with migraine or cluster headache; and a dull or steady headache is typical of an intracranial mass lesion. Ocular or periocular pain suggests an ophthalmologic disorder; band-like pain is common with tension headaches; and lateralized headache is common with migraine or cluster headache. In patients with sinusitis, there may be tenderness of overlying skin and bone. With intracranial mass lesions, headache may be focal or generalized; in patients with trigeminal or glossopharyngeal neuralgia, the pain is localized to one of the divisions of the trigeminal nerve or to the pharynx and external auditory meatus, respectively.

Inquiry should be made of precipitating factors. Recent sinusitis, dental surgery, head injury, or symptoms suggestive of a systemic viral infection may suggest the underlying cause. Migraine may be exacerbated by emotional stress, fatigue, foods containing nitrite or tyramine, or the menstrual period. Alcohol may precipitate cluster headache.

Temporomandibular joint dysfunction causes headache or facial pain that comes on with chewing; trigeminal or glossopharyngeal neuralgia may also be precipitated by chewing, and masticatory claudication sometimes occurs with giant cell arteritis. Cough-induced headache occurs with structural lesions of the posterior fossa, but in many instances no specific cause can be found.

The timing of symptoms is important. Headaches are typically worse on awakening in patients with an intracranial mass or sleep apnea. Cluster headaches tend to occur at the same time each day or night. Tension headaches are worse with stress or at the end of the day.

Associated symptoms may also be helpful. Nausea; sensitivity to light, sound, and exertion; and a proclivity to retreat to a dark, quiet room typify migraine. Anxiety, agitation, and even suicidality may accompany cluster headache. Other accompanying symptoms may point to specific disorders.

A progressive headache disorder, new onset of headache in middle or later life, headaches that disturb sleep or are related to exertion, and headaches that are associated with neurologic symptoms or a focal neurologic deficit usually require cranial MRI or CT scan to exclude an intracranial mass lesion. Signs of meningeal irritation and impairment of consciousness also indicate the need for further investigation (cranial CT scan or MRI and examination of the cerebrospinal fluid) to exclude subarachnoid hemorrhage or meningeal infection. The diagnosis and treatment of primary neurologic disorders associated with headache are considered separately under these disorders.

1. Migraine

ESSENTIALS OF DIAGNOSIS

- ▶ Headache, usually pulsatile.
- ▶ Pain is typically, but not always, unilateral.
- ▶ Nausea, vomiting, photophobia, and phonophobia are common accompaniments.
- ▶ An aura of transient neurologic symptoms (commonly visual) may precede head pain.
- ▶ Commonly, head pain occurs with no aura.

► General Considerations

The pathophysiology of migraine probably relates to neurovascular dysfunction. Headache results from the dilatation of blood vessels innervated by the trigeminal nerve caused by release of neuropeptides from parasympathetic nerve fibers approximating these vessels. The probable underlying mechanism is activation of the trigeminal nucleus caudalis, nucleus tractus solitarius, and dorsal raphe nucleus. Imaging studies have revealed changes in brainstem regions involved in sensory modulation, suggesting that migraine relates to a failure of normal sensory processing. Before or simultaneous with symptom onset, regional cerebral blood flow is decreased in the cortex corresponding to the clinically affected area; after one to several hours, hyperemia occurs in this same region. Cortical spreading depression of Leão has been implicated.

► Clinical Findings

Classic migrainous headache is a lateralized throbbing headache that occurs episodically following its onset in adolescence or early adult life. In many cases, however, the headaches do not conform to this pattern, although their associated features and response to antimigrainous preparations nevertheless suggest that they have a similar basis. In this broader sense, migrainous headaches may be lateralized or generalized, may be dull or throbbing, and are sometimes associated with anorexia, nausea, vomiting, photophobia, phonophobia, osmophobia, cognitive impairment, and blurring of vision. They usually build up gradually and may last for several hours or longer. Focal disturbances of neurologic function may precede or accompany the headaches and have been attributed to constriction of branches of the internal carotid artery. Visual disturbances occur commonly and may consist of field defects; of luminous visual hallucinations such as stars, sparks, unformed light flashes (photopsia), geometric patterns, or zigzags of light; or of some combination of field defects and luminous hallucinations (scintillating scotomas). Other focal disturbances such as aphasia or numbness, paresthesias, clumsiness, dysarthria, dysequilibrium, or weakness in a circumscribed distribution may also occur.

In rare instances, the neurologic or somatic disturbance accompanying typical migrainous headaches becomes the sole manifestation of an attack (“migraine equivalent”). Very rarely, the patient may be left with a permanent neurologic deficit following a migrainous attack, and migraine with aura may be a risk factor for stroke.

Patients often give a family history of migraine. Attacks may be triggered by emotional or physical stress, lack or excess of sleep, missed meals, specific foods (eg, chocolate), alcoholic beverages, bright lights, loud noise, menstruation, or use of oral contraceptives.

An uncommon variant is **basilar artery migraine**, in which blindness or visual disturbances throughout both visual fields are initially accompanied or followed by dysarthria, dysequilibrium, tinnitus, and perioral and distal paresthesias and are sometimes followed by transient loss or impairment of consciousness or by a confusional state.

This, in turn, is followed by a throbbing (usually occipital) headache, often with nausea and vomiting.

In **ophthalmoplegic migraine**, lateralized pain—often about the eye—is accompanied by nausea, vomiting, and diplopia due to transient external ophthalmoplegia. The ophthalmoplegia is due to third nerve palsy, sometimes with accompanying sixth nerve involvement, and may outlast the orbital pain by several days or even weeks. The ophthalmic division of the fifth nerve has also been affected in some patients. Ophthalmoplegic migraine is rare; more common causes of a painful ophthalmoplegia are internal carotid artery aneurysms and diabetes.

Migraine often exhibits a complex, polygenic pattern of inheritance. Sometimes, an autosomal dominant inheritance pattern is apparent, as in **familial hemiplegic migraine** (FHM), in which attacks of lateralized weakness represent the aura. Mutations in three associated genes—*ATP1A2*, *CACNA1A*, and *SCN1A*—account for about three-quarters of cases.

► Treatment

Management of migraine consists of avoidance of any precipitating factors, together with prophylactic or symptomatic pharmacologic treatment if necessary.

A. Symptomatic Therapy

During acute attacks, many patients find it helpful to rest in a quiet, darkened room until symptoms subside. A simple analgesic (eg, aspirin, acetaminophen, ibuprofen, or naproxen) taken right away often provides relief, but treatment with prescription therapy is sometimes necessary. To prevent medication overuse, use of simple analgesics should be limited to 15 days or less per month, and combination analgesics should be limited to no more than 10 days per month.

Cafergot, a combination of ergotamine tartrate (1 mg) and caffeine (100 mg), is often particularly helpful; one or two tablets are taken at the onset of headache or warning symptoms, followed by one tablet every 30 minutes, if necessary, up to six tablets per attack and no more than 10 days per month. Because of impaired absorption or vomiting during acute attacks, oral medication sometimes fails to help. Cafergot given rectally as suppositories (one-half to one suppository containing 2 mg of ergotamine) or dihydroergotamine mesylate (0.5–1 mg intravenously or 1–2 mg subcutaneously or intramuscularly) may be useful in such cases. Ergotamine-containing preparations should be avoided in pregnancy and when cardiovascular disease or risk factors are present. Prochlorperazine, administered rectally (25 mg suppository) or intravenously or orally (5–10 mg) can be an effective alternative, as can the various butalbital-containing combination analgesics available.

Sumatriptan, which has a high affinity for 5-HT₁ receptors, is a rapidly effective agent for aborting attacks when given subcutaneously by an autoinjection device (4–6 mg once subcutaneously, may repeat once after 2 hours if needed; maximum dose 12 mg/24 h). Nasal and oral preparations are available but may be less effective due to slower absorption. Zolmitriptan, another selective 5-HT₁ receptor

agonist, has high bioavailability after oral administration and is also effective for the immediate treatment of migraine. The optimal initial oral dose is 5 mg, and relief usually occurs within 1 hour; may repeat once after 2 hours. It is also available in a nasal formulation, which has a rapid onset of action; the dose is 5 mg in one nostril once and it may be repeated once after 2 hours. The maximum dose for both formulations is 10 mg/24 h. A number of other triptans are available, including rizatriptan (5–10 mg orally at onset, may repeat every 2 hours twice [maximum dose 30 mg/24 h]); naratriptan (1–2.5 mg orally at onset, may repeat once after 4 hours [maximum dose 5 mg/24 h]); almotriptan (6.25–12.5 mg orally at onset, may repeat dose once after 2 hours [maximum dose 25 mg/24 h]); frovatriptan (2.5 mg orally at onset, may repeat after 2 hours once [maximum dose 7.5 mg/24]); and eletriptan (20–40 mg orally at onset; may repeat after 2 hours once [maximum dose 80 mg/24 h]). Eletriptan is useful for immediate therapy and frovatriptan, which has a longer half-life, may be worthwhile for patients with prolonged attacks or attacks provoked by menstrual periods.

Triptans may cause nausea and vomiting. They should probably be avoided in women who are pregnant, in patients with hemiplegic or basilar migraine, and in patients with risk factors for stroke (such as hypertension, prior stroke or transient ischemic attack, diabetes mellitus, hypercholesterolemia, obesity). Triptans are contraindicated in

patients with coronary or peripheral vascular disease. Patients often experience greater benefit when the triptan is combined with naproxen (500 mg).

Several non-triptan abortive therapies, including telcagepant (a calcitonin gene-related peptide antagonist) and lasmiditan (a serotonin 1F receptor agonist), are currently in clinical trials and may be better tolerated than triptans.

The neuroleptic droperidol is also helpful in aborting acute attacks, particularly in an emergency setting in opioid-tolerant patients. Intravenous metoclopramide and prochlorperazine are effective. Opioid analgesics are sometimes required when other therapies fail. Intravenous propofol in subanesthetic doses may help in intractable cases.

B. Preventive Therapy

Preventive treatment may be necessary if migraine headaches occur more frequently than two or three times a month or significant disability is associated with attacks. Some of the more common drugs used for this purpose are listed in Table 24–1. Their mode of action is unclear but may involve alteration of central neurotransmission. Several drugs may have to be tried in turn before the headaches are brought under control. Once a drug has been found to help, it should be continued for several months. If

Table 24–1. Prophylactic treatment of migraine.

Drug	Usual Adult Oral Daily Dose	Common Side Effects
Antiepileptic¹		
Topiramate	100 mg (divided twice daily)	Somnolence, nausea, dyspepsia, irritability, dizziness, ataxia, nystagmus, diplopia, glaucoma, renal calculi, weight loss, hypohidrosis, hyperthermia.
Valproic acid ^{2,3}	500–1000 mg (divided twice daily)	Nausea, vomiting, diarrhea, drowsiness, alopecia, weight gain, hepatotoxicity, thrombocytopenia, tremor, pancreatitis.
Cardiovascular		
Candesartan ³	8–32 mg	Dizziness, cough, diarrhea, fatigue.
Propranolol	80–240 mg (divided twice to four times daily)	Fatigue, dizziness, hypotension, bradycardia, depression, insomnia, nausea, vomiting, constipation.
Timolol	10–30 mg	Similar to propranolol.
Verapamil ⁴	80–240 mg (divided three times daily)	Headache, hypotension, flushing, edema, constipation. May aggravate atrioventricular nodal heart block and congestive heart failure.
Antidepressant⁵		
Amitriptyline ⁶	10–150 mg	Sedation, dry mouth, constipation, weight gain, blurred vision, edema, hypotension, urinary retention.
Other		
Botulinum toxin A	Intramuscular injection by trained clinician	Injection site reaction, hypersensitivity, muscle weakness.

¹Gabapentin and possibly other antiepileptics have also been used successfully.

²Avoid during pregnancy.

³Not FDA-approved for this indication.

⁴Other calcium channel antagonists (eg, nimodipine, nicardipine, and diltiazem) may also help.

⁵Depression is commonly comorbid with migraine disorder and may warrant separate treatment.

⁶Other tricyclic antidepressants (eg, nortriptyline and imipramine) may similarly help.

the patient remains headache-free, the dose may be tapered and the drug eventually withdrawn. Botulinum toxin type A was approved by the US Food and Drug Administration (FDA) for migraine prevention in late 2010, despite conflicting results regarding its efficacy among randomized, placebo-controlled trials. Although acupuncture has been widely used in the prophylaxis of migraine, a randomized controlled trial failed to show any difference between it and sham acupuncture. Some neurostimulation techniques look promising, including occipital nerve stimulation.

2. Tension-type Headache

This is the most common type of primary headache disorder. Patients frequently complain of pericranial tenderness, poor concentration, and other nonspecific symptoms, in addition to constant daily headaches that are often vise-like or tight in quality but are not pulsatile. Headaches may be exacerbated by emotional stress, fatigue, noise, or glare. The headaches are usually generalized, may be most intense about the neck or back of the head, and are not associated with focal neurologic symptoms. There is diagnostic overlap with migraine.

The therapeutic approach is similar to that in migraine, except that triptan drugs are not indicated. Treatment of comorbid anxiety or depression is important. Techniques to induce relaxation are sometimes useful and include massage, hot baths, and biofeedback.

3. Cluster Headache

Cluster headache affects predominantly middle-aged men. The pathophysiology is unclear but may relate to activation of cells in the ipsilateral hypothalamus, triggering the trigeminal autonomic vascular system. There is often no family history of headache or migraine. Episodes of severe unilateral periorbital pain occur daily for several weeks and are often accompanied by one or more of the following: ipsilateral nasal congestion, rhinorrhea, lacrimation, redness of the eye, and Horner syndrome (ptosis of the eyelid, meiosis or constriction of the pupil, and anhidrosis or reduced sweat secretion). During attacks, patients are often restless and agitated. Episodes often occur at night, awaken the patient, and last for between 15 minutes and 3 hours. Spontaneous remission then occurs, and the patient remains well for weeks or months before another bout of closely spaced attacks occurs. Bouts may last for 4 to 8 weeks and may occur up to several times per year. During a bout, many patients report that alcohol triggers an attack; others report that stress, glare, or ingestion of specific foods occasionally precipitates attacks. In occasional patients, remission does not occur. This variant has been referred to as chronic cluster headache. **Hemicrania continua** is a separate primary headache syndrome with unilateral head pain and associated autonomic symptoms; unlike cluster headache, the pain is continuous without pain-free periods, and it completely resolves with indomethacin.

Examination reveals no abnormality apart from Horner syndrome that either occurs transiently during an attack or, in longstanding cases, remains as a residual deficit between attacks.

Treatment of an individual attack with oral drugs is generally unsatisfactory, but subcutaneous (6 mg dose) or intranasal (20-mg/spray) sumatriptan or inhalation of 100% oxygen (12–15 L/min for 15 minutes via a non-rebreather mask) may be effective. Zolmitriptan (5- and 10-mg nasal spray) is also effective. Dihydroergotamine (0.5–1 mg intramuscularly or intravenously) is sometimes used. Viscous lidocaine (1 mg of 4–6% solution) intranasally is sometimes effective.

Various prophylactic agents that have been found to be effective in individual patients include civamide (not available in the United States), lithium carbonate (monitored by plasma lithium determination), verapamil (240–960 mg daily), topiramate (100–400 mg daily), valproate (750–1500 mg daily), and suboccipital corticosteroid injection about the greater occipital nerve. As there is often a delay before these medications are effective, transitional therapy is often used. Ergotamine tartrate is effective and can be given as rectal suppositories (0.5–1 mg at night or twice daily), by mouth (2 mg daily), or by subcutaneous injection (0.25 mg three times daily for 5 days per week). Other options include prednisone (60 mg daily for 5 days followed by gradual withdrawal), or dihydroergotamine (9.25 mg intravenously over several days or 0.5 mg intramuscularly twice daily). Stimulation of the occipital nerve may be helpful.

4. Posttraumatic Headache

A variety of nonspecific symptoms may follow closed head injury, regardless of whether consciousness is lost. Headache is often a conspicuous feature.

The headache itself usually appears within a day or so following injury, may worsen over the ensuing weeks, and then gradually subsides. It is usually a constant dull ache, with superimposed throbbing that may be localized, lateralized, or generalized. It is sometimes accompanied by nausea, vomiting, or scintillating scotomas. Headaches occurring more than 1–2 weeks after the inciting event are probably not directly attributable to the head injury.

Dysequilibrium, sometimes with a rotatory component, may also occur and is often enhanced by postural change or head movement. Impaired memory, poor concentration, emotional instability, and increased irritability are other common complaints and occasionally are the sole manifestations of the syndrome. The duration of symptoms relates in part to the severity of the original injury, but even trivial injuries are sometimes followed by symptoms that persist for months.

Special investigations are usually not helpful. The electroencephalogram may show minor nonspecific changes, while the electronystagmogram sometimes suggests either peripheral or central vestibulopathy. CT scans or MRI of the head usually show no abnormal findings.

Treatment is difficult, but optimistic encouragement and graduated rehabilitation, depending on the occupational circumstances, are advised as symptoms often resolve spontaneously within several months. Headaches often respond to simple analgesics, but severe headaches may necessitate preventive treatment as outlined for migraine.

5. Primary Cough Headache

Severe head pain may be produced by coughing (and by straining, sneezing, and laughing) but, fortunately, usually lasts for only a few minutes or less. The pathophysiologic basis of the complaint is not known, and often there is no underlying structural lesion. However, intracranial lesions, usually in the posterior fossa (eg, Arnold-Chiari malformation), are present in about 10% of cases, and brain tumors or other space-occupying lesions may present in this way. Accordingly, CT scanning or MRI should be undertaken in all patients and repeated annually for several years, since a small structural lesion may not show up initially.

The disorder is usually self-limited, although it may persist for several years. For unknown reasons, symptoms sometimes clear completely after lumbar puncture. Indomethacin (75–150 mg daily orally) may provide relief. Similar activity-triggered headache syndromes include **primary exertional headache** and **primary headache associated with sexual activity**.

6. Headache Due to Giant Cell (Temporal or Cranial) Arteritis

The superficial temporal, vertebral, ophthalmic, and posterior ciliary arteries are often the most severely affected pathologically. Most patients are elderly. The major symptom is lateralized headache, often associated with or preceded by myalgia, malaise, anorexia, weight loss, and other nonspecific complaints. Loss of vision is the most feared manifestation and occurs quite commonly. Clinical examination often reveals tenderness of the scalp and over the temporal arteries. Further details, including approaches to treatment, are given in Chapter 20.

7. Headache Due to Intracranial Mass Lesions

Intracranial mass lesions of all types may cause headache owing to displacement of vascular structures and other pain-sensitive tissues. Posterior fossa tumors often cause occipital pain, and supratentorial lesions lead to bifrontal headache, but such findings are too inconsistent to be of value in attempts at localizing a pathologic process. The headaches are nonspecific in character and may vary in severity from mild to severe. They may be worsened by exertion or postural change and may be associated with nausea and vomiting, but this is true of migraine also. Headaches are also a feature of pseudotumor cerebri (idiopathic intracranial hypertension) (see below). Signs of focal or diffuse cerebral dysfunction or of increased intracranial pressure will indicate the need for further investigation. Similarly, a progressive headache disorder or the new onset of headaches in middle or later life merits investigation if no cause is apparent.

8. Medication Overuse (Analgesic Rebound) Headache

In approximately half of all patients with chronic daily headaches, medication overuse is responsible. They present with chronic pain or with complaints of severe headache

unresponsive to medication. Early initiation of a migraine preventive therapy (see above) permits withdrawal of analgesics and eventual relief of headache.

9. Headache Due to Other Neurologic Causes

Cerebrovascular disease may be associated with headache, but the mechanism is unclear. Headache may occur with internal carotid artery occlusion or carotid dissection and after carotid endarterectomy. Diagnosis is facilitated by the clinical accompaniments and the circumstances in which the headache developed.

Acute severe headache accompanies subarachnoid hemorrhage and meningeal infections; accompanying signs of impairment of consciousness and sign of meningeal irritation indicate the need for further investigations.

Dull or throbbing headache is a frequent sequela of lumbar puncture and may last for several days. It is aggravated by the erect posture and alleviated by recumbency. The exact mechanism is unclear, but it is commonly attributed to leakage of cerebrospinal fluid through the dural puncture site. Its incidence may be reduced if a small-diameter needle is used for the spinal tap, and perhaps also if the patient lies prone or supine after the procedure.

▶ When to Refer

- Acute onset of “worst headache in my life.”
- Increasing headache unresponsive to simple measures.
- History of trauma, hypertension, fever, visual changes.
- Presence of neurologic signs or of scalp tenderness.

▶ When to Admit

- Suspected subarachnoid hemorrhage or structural intracranial lesion.
- Depends on underlying cause.

FACIAL PAIN

1. Trigeminal Neuralgia

ESSENTIALS OF DIAGNOSIS

- ▶ Brief episodes of stabbing facial pain.
- ▶ Pain is in the territory of the second and third division of the trigeminal nerve.
- ▶ Pain exacerbated by touch.

▶ General Considerations

Trigeminal neuralgia (“tic douloureux”) is most common in middle and later life. It affects women more frequently than men.

▶ Clinical Findings

Momentary episodes of sudden lancinating facial pain occur and commonly arise near one side of the mouth and shoot toward the ear, eye, or nostril on that side. The pain may be triggered or precipitated by such factors as touch, movement, drafts, and eating. Indeed, in order to lessen the likelihood of triggering further attacks, many patients try to hold the face still while talking. Spontaneous remissions for several months or longer may occur. As the disorder progresses, however, the episodes of pain become more frequent, remissions become shorter and less common, and a dull ache may persist between the episodes of stabbing pain. Symptoms remain confined to the distribution of the trigeminal nerve (usually the second or third division) on one side only.

▶ Differential Diagnosis

The characteristic features of the pain in trigeminal neuralgia usually distinguish it from other causes of facial pain. Neurologic examination shows no abnormality except in a few patients in whom trigeminal neuralgia is symptomatic of some underlying lesion, such as multiple sclerosis or a brainstem neoplasm, in which case the finding will depend on the nature and site of the lesion. Similarly, CT scans and radiologic contrast studies are often normal in patients with classic trigeminal neuralgia.

In a young patient presenting with trigeminal neuralgia, multiple sclerosis must be suspected even if there are no

other neurologic signs. In such circumstances, findings on evoked potential testing and examination of cerebrospinal fluid may be corroborative. When the facial pain is due to a posterior fossa tumor, CT scanning and MRI generally reveal the lesion.

▶ Treatment

The drugs most helpful for treatment are oxcarbazepine (although not approved by the FDA for this indication) or carbamazepine, with monitoring by serial blood counts and liver function tests. If these medications are ineffective or cannot be tolerated, phenytoin should be tried. (Doses and side effects of these drugs are shown in Table 24–3). Baclofen (10–20 mg three or four times daily) or lamotrigine (400 mg orally daily) may also be helpful, either alone or in combination with one of these other agents. Gabapentin may also relieve pain, especially in patients who do not respond to conventional medical therapy and those with multiple sclerosis. Depending on response and tolerance, up to 2400 mg daily orally is given in divided doses.

In the past, alcohol injection of the affected nerve, rhizotomy, or tractotomy was recommended if pharmacologic treatment was unsuccessful. More recently, however, posterior fossa exploration has frequently revealed some structural cause for the neuralgia (despite normal findings on CT scans, MRI, or arteriograms), such as an anomalous artery or vein impinging on the trigeminal nerve root. In such cases, simple decompression and separation of the anomalous vessel from the nerve root produce lasting relief of symptoms. In elderly patients with a limited life expectancy, radiofrequency rhizotomy is sometimes preferred because it is easy to perform, has few complications, and provides symptomatic relief for a period of time. Gamma radiosurgery to the trigeminal root is another noninvasive approach that appears to be successful in most patients, with essentially no side effects other than facial paresthesias in a few instances; up to one-third of patients achieved a pain-free state without need for medication after the procedure. Surgical exploration generally reveals no abnormality and is inappropriate in patients with trigeminal neuralgia due to multiple sclerosis.

Gronseth G et al. Practice Parameter: the diagnostic evaluation and treatment of trigeminal neuralgia (an evidence-based review). 2. Atypical Facial Pain

Facial pain without the typical features of trigeminal neuralgia is generally a constant, often burning pain that may have a restricted distribution at its onset but soon spreads to the rest of the face on the affected side and sometimes

involves the other side, the neck, or the back of the head as well. The disorder is especially common in middle-aged women, many of them depressed, but it is not clear whether depression is the cause of or a reaction to the pain. Simple analgesics should be given a trial, as should tricyclic antidepressants, carbamazepine, oxcarbazepine, and phenytoin; the response is often disappointing. Opioid analgesics pose a danger of addiction in patients with this disorder. Attempts at surgical treatment are not indicated.

Cornelissen P et al. Evidence-based interventional pain medicine according to clinical diagnoses. 3. Persistent idiopathic facial pain. *Pain Pract.* 2009 Nov–Dec;9(6):443–8. [PMID: 19874535]

3. Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia is an uncommon disorder in which pain similar in quality to that in trigeminal neuralgia occurs in the throat, about the tonsillar fossa, and sometimes deep in the ear and at the back of the tongue. The pain may be precipitated by swallowing, chewing, talking, or yawning and is sometimes accompanied by syncope. In most instances, no underlying structural abnormality is present; multiple sclerosis is sometimes responsible. Oxcarbazepine and carbamazepine (see Table 24–3) are the treatments of choice and should be tried before any surgical procedures are considered. Microvascular decompression is generally preferred over destructive surgical procedures such as partial rhizotomy in medically refractory cases and is often effective without causing severe complications.

4. Postherpetic Neuralgia

Herpes zoster (shingles) is due to reactivation of a latent varicella-zoster virus infection in a sensory nerve ganglion. Postherpetic neuralgia develops in about 15% of patients who have shingles. This complication seems especially likely to occur in elderly or immunocompromised persons, when the rash is severe, and when the first division of the trigeminal nerve is affected. It also relates to the duration of the rash before medical consultation. A history of shingles and the presence of cutaneous scarring resulting from shingles aid in the diagnosis. Severe pain with shingles correlates with the intensity of postherpetic symptoms.

The incidence of postherpetic neuralgia may be reduced by the treatment of shingles with oral acyclovir or famciclovir, but this is disputed; systemic corticosteroids do not help. Management of the established complication is essentially medical. If simple analgesics fail to help, a trial of a tricyclic antidepressant (eg, amitriptyline, up to 100–150 mg daily orally) is often effective. Other patients respond to carbamazepine (up to 1200 mg daily orally), phenytoin (300 mg daily orally), gabapentin (up to 3600 mg daily orally), or pregabalin (up to 600 mg/daily orally). A combination of gabapentin and morphine taken orally may provide better analgesia at lower doses of each agent than either taken alone. Topical application of capsaicin cream (eg, Zostrix, 0.025%) may be helpful, but a transdermal patch (8%) had no effect. Topical lidocaine (5%) is also worthy of trial. The administration of live-attenuated

zoster vaccine to patients over the age of 60 years is important in preventing the occurrence of herpes zoster, although it does not reduce the incidence of postherpetic neuralgia.

5. Facial Pain Due to Other Causes

Facial pain may be caused by temporomandibular joint dysfunction in patients with malocclusion, abnormal bite, or faulty dentures. There may be tenderness of the masticatory muscles, and an association between pain onset and jaw movement is sometimes noted. This pattern differs from that of jaw (masticatory) claudication, a symptom of giant cell arteritis, in which pain develops progressively with mastication. Treatment of the underlying joint dysfunction relieves symptoms.

A relationship of facial pain to chewing or temperature changes may suggest a dental disturbance. The cause is sometimes not obvious, and diagnosis requires careful dental examination and radiographs. Sinusitis and ear infections causing facial pain are usually recognized by the history of respiratory tract infection, fever and, in some instances, nasal or aural discharge. There may be localized tenderness. Radiologic evidence of sinus infection or mastoiditis is confirmatory.

Glaucoma is an important ocular cause of facial pain, usually localized to the periorbital region.

On occasion, pain in the jaw may be the principal manifestation of angina pectoris. Precipitation by exertion and radiation to more typical areas establish the cardiac origin.

▶ When to Refer

- Worsening pain unresponsive to simple measures.
- Continuing pain of uncertain cause.
- For consideration of surgical treatment (trigeminal or glossopharyngeal neuralgia).

EPILEPSY

ESSENTIALS OF DIAGNOSIS

- ▶ Recurrent seizures.
- ▶ Characteristic electroencephalographic changes accompany seizures.
- ▶ Mental status abnormalities or focal neurologic symptoms may persist for hours postictally.

► General Considerations

The term “epilepsy” denotes any disorder characterized by recurrent unprovoked seizures. A seizure is a transient disturbance of cerebral function due to an abnormal paroxysmal neuronal discharge in the brain. Epilepsy is common, affecting approximately 0.5% of the population in the United States.

► Etiology

According to the International League Against Epilepsy classification system, the many etiologies of seizures can be grouped into three categories.

A. Genetic Epilepsy

This category encompasses a broad range of disorders, for which the age at onset ranges from the neonatal period to adolescence or even later in life. Monogenic disorders tend to exhibit an autosomal dominant pattern of inheritance, and where the mutation is known, the responsible gene often encodes a neuronal ion channel.

B. Structural/Metabolic Epilepsy

There are many causes for recurrent seizures.

1. Pediatric age groups—Congenital abnormalities and perinatal injuries may result in seizures presenting in infancy or childhood.

2. Metabolic disorders—Withdrawal from alcohol or drugs is a common cause of recurrent seizures, and other metabolic disorders (such as uremia and hypoglycemia or hyperglycemia) may also be responsible. Since these seizures are provoked by a readily reversible cause, this would not be considered epilepsy.

3. Trauma—Trauma is an important cause of seizures at any age, but especially in young adults. Posttraumatic epilepsy is more likely to develop if the dura mater was penetrated and generally becomes manifest within 2 years following the injury. However, seizures developing in the first week after head injury do not necessarily imply that future attacks will occur. There is no clear evidence that prophylactic anticonvulsant drug treatment reduces the incidence of posttraumatic epilepsy.

4. Tumors and other space-occupying lesions—Neoplasms may lead to seizures at any age, but they are an especially important cause of seizures in middle and later life, when the incidence of neoplastic disease increases. The seizures are commonly the initial symptoms of the tumor and often are focal in character. They are most likely to occur with structural lesions involving the frontal, parietal, or temporal regions. Tumors must be excluded by imaging studies (MRI preferred over CT) in all patients with onset of seizures after 30 years of age, focal seizures or signs, or a progressive seizure disorder.

5. Vascular diseases—Vascular diseases become increasingly frequent causes of seizures with advancing age and are the most common cause of seizures with onset at age 60 years or older.

6. Degenerative disorders—Alzheimer disease and other degenerative disorders are a cause of seizures in later life.

7. Infectious diseases—Infectious diseases must be considered in all age groups as potentially reversible causes of seizures. Seizures may occur with an acute infective or inflammatory illness, such as bacterial meningitis or herpes encephalitis, or in patients with more longstanding or chronic disorders, such as neurosyphilis or cerebral cysticercosis. In patients with AIDS, they may result from central nervous system toxoplasmosis, cryptococcal meningitis, secondary viral encephalitis, or other infective complications. Seizures are a common sequela of supra-tentorial brain abscess, developing most frequently in the first year after treatment.

C. Unknown

In many cases, the cause of epilepsy cannot be determined.

► Classification of Seizures

The International League Against Epilepsy distinguishes seizures affecting only part of the brain (focal seizures) from those that are generalized (Table 24–2).

A. Focal Seizures

The initial clinical and electroencephalographic manifestations of partial seizures indicate that only a restricted part of one cerebral hemisphere has been activated. The ictal manifestations depend on the area of the brain involved. Focal seizures sometimes involve impairment of consciousness and may evolve to convulsive seizures, in a process previously called secondary generalization.

1. Without impairment of consciousness—Seizures may be manifested by focal motor symptoms (convulsive jerking) or somatosensory symptoms (eg, paresthesias or tingling) that spread (or “march”) to different parts of the limb or body depending on their cortical representation; such seizures were previously described as “simple partial” seizures. In other instances, special sensory symptoms (eg, light flashes or buzzing) indicate involvement of visual, auditory, olfactory, or gustatory regions of the brain, or there may be autonomic symptoms or signs (eg, abnormal epigastric sensations, sweating, flushing, pupillary dilation). The sole manifestations of some seizures are phenomena such as dysphasia, dysmnestic symptoms (eg, déjà vu, jamais vu), affective disturbances, illusions, or structured hallucinations, but such symptoms are usually accompanied by impairment of consciousness.

2. With impairment of consciousness—Impaired consciousness or responsiveness may be preceded, accompanied, or followed by the various symptoms mentioned above, and automatisms may occur. Such seizures were previously called “complex partial” seizures.

B. Generalized Seizures

There are several different varieties of generalized seizures, as outlined below. In some circumstances, seizures cannot be classified because of incomplete information or because they do not fit into any category.

Table 24-2. Seizure classification.

Seizure Type	Key Features	Other Associated Features
Focal seizures	Involvement of only a restricted part of brain; may evolve to a bilateral, convulsive seizure	
Without impairment of consciousness		Observable focal motor or autonomic symptoms, or subjective sensory or psychic symptoms may occur
With impairment of consciousness		Above symptoms may precede, accompany, or follow the period of altered responsiveness
Generalized seizures	Diffuse involvement of brain at onset	
Absence (petit mal)	Consciousness impaired briefly; patient often unaware of attacks	May have clonic, tonic, or atonic (ie, loss of postural tone) components; autonomic components (eg, enuresis); or accompanying automatisms Almost always begin in childhood and frequently cease by age 20
Atypical absences	May be more gradual in onset and termination than typical absence	More marked changes in tone may occur
Myoclonic	Single or multiple myoclonic jerks	
Tonic-clonic (grand mal)	Tonic phase: Sudden loss of consciousness, with rigidity and arrest of respiration, lasting < 1 minute Clonic phase: Jerking occurs, usually for < 2-3 minutes Flaccid coma: Variable duration	May be accompanied by tongue biting, incontinence, or aspiration; commonly followed by postictal confusion variable in duration
Status epilepticus	Repeated seizures without recovery between them; a fixed and enduring epileptic condition lasting ≥ 30 minutes	

1. Absence seizures—These are characterized by impairment of consciousness, sometimes with mild clonic, tonic, or atonic components (ie, reduction or loss of postural tone), autonomic components (eg, enuresis), or accompanying automatisms. Onset and termination of attacks are abrupt. If attacks occur during conversation, the patient may miss a few words or may break off in midsentence for a few seconds. The impairment of external awareness is so brief that the patient is unaware of it. Absence (“petit mal”) seizures almost always begin in childhood and frequently cease by the age of 20 years, although occasionally they are then replaced by other forms of generalized seizure. Electroencephalographically, such attacks are associated with bursts of bilaterally synchronous and symmetric 3-Hz spike-and-wave activity. A normal background in the electroencephalogram and normal or above-normal intelligence imply a good prognosis for the ultimate cessation of these seizures.

2. Atypical absence seizures—There may be more marked changes in tone, or attacks may have a more gradual onset and termination than in typical absence seizures. They commonly occur in patients with multiple seizure types, may be accompanied by developmental delay or mental retardation, and are associated with slower spike-wave discharges than those in typical absence attacks.

3. Myoclonic seizures—Myoclonic seizures consist of single or multiple myoclonic jerks.

4. Tonic-clonic (“grand mal”) seizures—In these seizures, which are characterized by sudden loss of

consciousness, the patient becomes rigid and falls to the ground, and respiration is arrested. This tonic phase, which usually lasts for < 1 minute, is followed by a clonic phase in which there is jerking of the body musculature that may last for 2 or 3 minutes and is then followed by a stage of flaccid coma. During the seizure, the tongue or lips may be bitten, urinary or fecal incontinence may occur, and the patient may be injured. Immediately after the seizure, the patient may recover consciousness, drift into sleep, have a further convulsion without recovery of consciousness between the attacks (**status epilepticus**), or after recovering consciousness have a further convulsion (**serial seizures**). In other cases, patients will behave in an abnormal fashion in the immediate postictal period, without subsequent awareness or memory of events (**postepileptic automatism**). Headache, disorientation, confusion, drowsiness, nausea, soreness of the muscles, or some combination of these symptoms commonly occurs postictally.

5. Tonic, clonic, or atonic seizures—Loss of consciousness may occur with either the tonic or clonic accompaniments described above, especially in children. Atonic seizures (**epileptic drop attacks**) have also been described.

▶ Clinical Findings

A. Symptoms and Signs

Nonspecific changes such as headache, mood alterations, lethargy, and myoclonic jerking alert some patients to an impending seizure hours before it occurs. These prodromal

symptoms are distinct from the aura; the aura that may precede a generalized seizure by a few seconds or minutes is itself a part of the attack and it arises locally from a restricted part of the brain.

In most patients, seizures occur unpredictably at any time and without any relationship to posture or ongoing activities. Occasionally, however, they occur at a particular time (eg, during sleep) or in relation to external precipitants such as lack of sleep, missed meals, emotional stress, menstruation, alcohol ingestion (or alcohol withdrawal; see below), or use of certain drugs. Fever and nonspecific infections may also precipitate seizures in epileptic patients. In a few patients, seizures are provoked by specific stimuli such as flashing lights or a flickering television set (**photosensitive epilepsy**), music, or reading.

Clinical examination between seizures shows no abnormality in patients with idiopathic epilepsy, but in the immediate postictal period, extensor plantar responses may be seen. The presence of lateralized or focal signs postictally suggests that seizures may have a focal origin. In patients with symptomatic epilepsy, the findings on examination will reflect the underlying cause.

B. Imaging

MRI is indicated for patients with focal neurologic symptoms or signs, focal seizures, or electroencephalographic findings of a focal disturbance; some clinicians routinely order MRI for all patients with new-onset seizure disorders. CT is generally less sensitive than MRI to small structural brain abnormalities but may be used when MRI is contraindicated (eg, in a patient with a metallic implant). Such studies should be performed in patients with clinical evidence of a progressive disorder and in those with new onset of seizures after the age of 20 years because of the possibility of an underlying neoplasm.

C. Laboratory and Other Studies

Initial investigations should include hematologic and biochemical screening tests (eg, complete blood count, serum glucose, electrolytes, creatinine, calcium, magnesium, and liver function tests). The hematologic and biochemical screening tests are important both to exclude various causes of seizures and to provide a baseline for subsequent monitoring of long-term effects of treatment. A lumbar puncture may be necessary when any sign of infection is present or in the evaluation of new-onset seizures in the acute setting.

Electroencephalography may support the clinical diagnosis of epilepsy (by demonstrating paroxysmal abnormalities containing spikes or sharp waves), may provide a guide to prognosis, and may help classify the seizure disorder. Classification of the disorder is important for determining the most appropriate anticonvulsant drug with which to start treatment. For example, absence and focal seizures with impairment of consciousness may be difficult to distinguish clinically, but the electroencephalographic findings and treatment of choice differ in these two conditions. Finally, by localizing the epileptogenic source, the electroencephalographic findings are important in evaluating candidates for surgical treatment.

► Differential Diagnosis

The distinction between the various disorders likely to be confused with generalized seizures is usually made on the basis of the history. The importance of obtaining an eyewitness account of the attacks cannot be overemphasized.

A. Differential Diagnosis of Focal Seizures

1. Transient ischemic attacks—These attacks are distinguished from seizures by their longer duration, lack of spread, and symptoms. Level of consciousness, which is unaltered, does not distinguish them. There is a loss of motor or sensory function (eg, weakness or numbness) with transient ischemic attacks, whereas positive symptoms (eg, convulsive jerking or paresthesias) characterize seizures.

2. Rage attacks—Rage attacks are usually situational and lead to goal-directed aggressive behavior.

3. Panic attacks—These may be hard to distinguish from focal seizures unless there is evidence of an anxiety disorder between attacks and the attacks have a clear relationship to external circumstances.

B. Differential Diagnosis of Generalized Seizures

1. Syncope—Syncope episodes usually occur in relation to postural change, emotional stress, instrumentation, pain, or straining. They are typically preceded by pallor, sweating, nausea, and malaise and lead to loss of consciousness accompanied by flaccidity; recovery occurs rapidly with recumbency, and there is no postictal headache or confusion. In some instances, however, motor accompaniments may simulate a seizure. Serum creatine kinase measured about 3 hours after the event is generally normal after syncopal episodes but markedly elevated after tonic-clonic seizures.

2. Cardiac disease—Cerebral hypoperfusion due to a disturbance of cardiac rhythm should be suspected in patients with known cardiac or vascular disease or in elderly patients who present with episodic loss of consciousness. Prodromal symptoms are typically absent. Repeated Holter monitoring may be necessary to establish the diagnosis; monitoring initiated by the patient (“event monitor”) may be valuable if the disturbances of consciousness are rare. A relationship of attacks to physical activity and the finding of a systolic murmur are suggestive of aortic stenosis.

3. Brainstem ischemia—Loss of consciousness is preceded or accompanied by other brainstem signs. Basilar artery migraine and vertebrobasilar vascular disease are discussed elsewhere in this chapter.

4. Psychogenic nonepileptic seizure (PNES)—Simulating an epileptic seizure, a PNES may occur due to a conversion disorder or malingering. Many patients also have true seizures or a family history of epilepsy. Although a PNES tends to occur at times of emotional stress, this may also be the case with true seizures.

Clinically, the attacks superficially resemble tonic-clonic seizures, but there may be obvious preparation before a PNES occurs. Moreover, there is usually no tonic phase; instead, there may be an asynchronous thrashing of the limbs, which increases if restraints are imposed and rarely leads to injury. Consciousness may be normal or “lost,” but in the latter context the occurrence of goal-directed behavior or of shouting, swearing, etc, indicates that it is feigned. Postictally, there are no changes in behavior or neurologic findings.

Often, clinical observation is insufficient to discriminate epileptic from nonepileptic seizures. Video electroencephalographic monitoring may be quite helpful: epileptic seizures, especially those involving altered consciousness, commonly involve scalp electroencephalographic signs that coincide with a behavioral spell, whereas a PNES does not. The serum level of prolactin has been found to increase dramatically between 15 and 30 minutes after a tonic-clonic convulsion in most patients, whereas it is unchanged after a PNES. Serum creatine kinase levels also increase after a convulsion but not a PNES.

► Treatment

A. General Measures

For patients with epilepsy, drug treatment is prescribed with the goal of preventing further attacks and is usually continued until there have been no seizures for at least 3 years. Epileptic patients should be advised to avoid situations that could be dangerous or life-threatening if further seizures should occur. Legislation may require clinicians to report to the state authorities any patients with seizures or other episodic disturbances of consciousness; driving cessation for 6 months or as legislated is appropriate following an unprovoked seizure.

1. Choice of medication—Drug selection depends on seizure type (Table 24–3). The dose of the selected drug is gradually increased until seizures are controlled or side effects prevent further increases. If seizures continue despite treatment at the maximal tolerated dose, a second drug is added and the dose increased depending on tolerance; the first drug is then gradually withdrawn. In treatment of focal seizures, the success rate is higher with carbamazepine, phenytoin, or valproic acid than with phenobarbital or primidone. Gabapentin, topiramate, lamotrigine, oxcarbazepine, levetiracetam, zonisamide, lacosamide, ezogabine, and tiagabine are newer antiepileptic drugs used to treat focal seizures. Felbamate is also effective for such seizures but, because it may cause aplastic anemia or fulminant hepatic failure, should be used only in selected patients unresponsive to other measures. Rufinamide is currently approved only for seizures in patients with Lennox-Gastaut syndrome, but it may be effective against seizures in a broader range of refractory patients. For generalized or unclassified seizures, valproate is better tolerated than topiramate and more efficacious than lamotrigine and is thus preferred for many patients; however, the teratogenic potential of valproate makes its use undesirable in women of childbearing age. All antiepileptics are potentially teratogenic, although the

teratogenicity of the newer antiseizure medications is less clear. Nevertheless, antiepileptic medication must be given to pregnant women with epilepsy to prevent seizures, which can pose serious risk to the fetus from trauma, hypoxia, or other factors. In most patients with seizures of a single type, satisfactory control can be achieved with a single anticonvulsant drug. Treatment with two drugs may further reduce seizure frequency or severity but usually only at the cost of greater toxicity. Treatment with more than two drugs is almost always unhelpful unless the patient is having seizures of different types.

2. Monitoring—Monitoring serum drug levels has led to major advances in the management of seizure disorders. Individual differences in drug metabolism cause a given dose of a drug to produce different blood concentrations in different patients, and this will affect the therapeutic response. In general, the dose of an antiepileptic agent is increased depending on the clinical response regardless of the serum drug level. The trough drug level is then measured to provide a reference point for the maximum tolerated dose. Dosing should not be based simply on serum levels because some patients require levels that exceed the therapeutic range (“toxic levels”) but tolerate these without ill effect. Steady-state drug levels in the blood should be measured after treatment is initiated, dosage is changed, or another drug is added to the therapeutic regimen and when seizures are poorly controlled. Dose adjustments are then guided by the laboratory findings. The most common cause of a lower concentration of drug than expected for the prescribed dose is poor patient compliance. Compliance can be improved by limiting to a minimum the number of daily doses. Recurrent seizures or status epilepticus may result if drugs are taken erratically, and in some circumstances noncompliant patients may be better off without any medication.

All anticonvulsant drugs have side effects, and some of these are shown in Table 24–3.

In most patients, a complete blood count should be performed at least annually because of the risk of anemia or blood dyscrasia. Treatment with certain drugs may require more frequent monitoring or use of additional screening tests. For example, periodic tests of hepatic function are necessary if valproic acid, carbamazepine, or felbamate is used, and serial blood counts are important with carbamazepine, ethosuximide, or felbamate. Detailed medication-specific recommendations should be sought from a drug reference source before prescribing, since baseline studies are often necessary.

3. Discontinuance of medication—Only when adult patients have been seizure-free for 2 years should withdrawal of medication be considered. Unfortunately, there is no way of predicting which patients can be managed successfully without treatment, although seizure recurrence is more likely in patients who initially did not respond to therapy, those with seizures having focal features or of multiple types, and those with continuing electroencephalographic abnormalities. Dose reduction should be gradual (over weeks or months), and drugs should be withdrawn one at a time. If seizures recur, treatment is reinstated with the previously effective drug regimen.

Table 24-3. Drug treatment for seizures in adults.

Drug	Usual Adult Daily Oral Dose	Minimum No. of Daily Doses	Time to Steady State Drug Levels	Optimal Drug Level	Selected Side Effects and Idiosyncratic Reactions
Generalized or focal seizures					
Phenytoin	200–400 mg	1	5–10 days	10–20 mcg/mL	Nystagmus, ataxia, dysarthria, sedation, confusion, gingival hyperplasia, hirsutism, megaloblastic anemia, blood dyscrasias, skin rashes, fever, systemic lupus erythematosus, lymphadenopathy, peripheral neuropathy, dyskinesias.
Carbamazepine extended-release (ER) formulation	400–1600 mg ER	2	3–4 days	4–8 mcg/mL	Nystagmus, dysarthria, diplopia, ataxia, drowsiness, nausea, blood dyscrasias, hepatotoxicity, hyponatremia. May exacerbate myoclonic seizures.
Valproic acid	1500–2000 mg	2–3	2–4 days	50–100 mcg/mL	Nausea, vomiting, diarrhea, drowsiness, alopecia, weight gain, hepatotoxicity, thrombocytopenia, tremor, pancreatitis.
Phenobarbital	100–200 mg	1	14–21 days	10–40 mcg/mL	Drowsiness, nystagmus, ataxia, skin rashes, learning difficulties, hyperactivity.
Primidone	750–1500 mg	3	4–7 days	5–15 mcg/mL	Sedation, nystagmus, ataxia, vertigo, nausea, skin rashes, megaloblastic anemia, irritability.
Lamotrigine ^{1,2,5}	100–500 mg	2	4–5 days	?	Sedation, skin rash, visual disturbances, dyspepsia, ataxia.
Topiramate ^{1–4}	200–400 mg	2	4 days	?	Somnolence, nausea, dyspepsia, irritability, dizziness, ataxia, nystagmus, diplopia, glaucoma, renal calculi, weight loss, hypohidrosis, hyperthermia.
Oxcarbazepine ^{1,3}	900–1800 mg	2	2–3 days	?	As for carbamazepine.
Levetiracetam ^{1,2}	1000–3000 mg	2	2 days	?	Somnolence, ataxia, headache, behavioral changes.
Zonisamide ¹	200–600 mg	1	14 days	?	Somnolence, ataxia, anorexia, nausea, vomiting, rash, confusion, renal calculi. Do not use in patients with sulfonamide allergy.
Tiagabine ¹	32–56 mg	2	2 days	?	Somnolence, anxiety, dizziness, poor concentration, tremor, diarrhea.
Pregabalin ¹	150–300 mg	2	2–4 days	?	Somnolence, dizziness, poor concentration, weight gain, thrombocytopenia, skin rashes, anaphylactoid reactions.
Gabapentin ¹	900–3600 mg	3	1 day	?	Sedation, fatigue, ataxia, nystagmus, weight loss.
Felbamate ^{1,3,6}	1200–3600 mg	3	4–5 days	?	Anorexia, nausea, vomiting, headache, insomnia, weight loss, dizziness, hepatotoxicity, aplastic anemia.
Lacosamide ¹	100–400 mg	2	3 days	?	Vertigo, diplopia, nausea, headache, fatigue, ataxia, tremor, anaphylactoid reactions, PR prolongation, cardiac dysrhythmia, suicidality.
Ezogabine ¹	300–1200 mg	3	2–3 days	?	Dizziness, somnolence, confusion, vertigo, nausea, ataxia, psychiatric disturbances.
Absence seizures					
Ethosuximide	100–1500 mg	2	5–10 days	40–100 mcg/mL	Nausea, vomiting, anorexia, headache, lethargy, unsteadiness, blood dyscrasias, systemic lupus erythematosus, urticaria, pruritus.
Valproic acid	1500–2000 mg	3	2–4 days	50–100 mcg/mL	See above.
Clonazepam	0.04–0.2 mg/kg	2	?	20–80 ng/mL	Drowsiness, ataxia, irritability, behavioral changes, exacerbation of tonic-clonic seizures.
Myoclonic seizures					
Valproic acid	1500–2000 mg	3	2–4 days	50–100 mcg/mL	See above.
Clonazepam	0.04–0.2 mg/kg	2	?	20–80 ng/mL	See above.

¹Approved as adjunctive therapy for focal-onset seizures.²Approved as adjunctive therapy for primary generalized tonic-clonic seizures.³Approved as initial monotherapy for focal-onset seizures.⁴Approved as initial monotherapy for primary generalized tonic-clonic seizures.⁵Approved as monotherapy (after conversion from another drug) in focal-onset seizures.⁶Not to be used as a first-line drug; when used, blood counts should be performed regularly (every 2–4 weeks). Should be used only in selected patients because of risk of aplastic anemia and hepatic failure. It is advisable to obtain written informed consent before use.

4. Surgical treatment—Patients with seizures refractory to pharmacologic management may be candidates for operative treatment. Surgical resection is most efficacious when there is a single well-defined seizure focus, particularly in the temporal lobe. Among well-chosen patients, up to 70% remain seizure-free after extended follow-up. Using a different approach, a recent trial showed benefits of bilateral deep brain stimulation of the anterior thalamus for medically refractory focal-onset seizures.

5. Vagal nerve stimulation—Treatment by chronic vagal nerve stimulation for adults and adolescents with medically refractory focal seizures is approved in the United States and provides an alternative approach for patients who are not optimal candidates for surgical treatment. The mechanism of therapeutic action is unknown. Adverse effects consist mainly of transient hoarseness during stimulus delivery.

B. Special Circumstances

1. Solitary seizures—In patients who have had only one seizure or a flurry of seizures over a brief period of several hours, investigation as outlined above should exclude an underlying cause requiring specific treatment. An electroencephalogram should also be obtained, preferably within 24 hours after the seizure, because the findings may influence management—especially when focal abnormalities are present. Prophylactic anticonvulsant drug treatment is generally not required unless further attacks occur or investigations reveal some underlying pathology. The risk of seizure recurrence varies in different series between about 30% and 70%. Epilepsy should not be diagnosed on the basis of a solitary seizure. If seizures occur in the context of transient, nonrecurrent systemic disorders such as acute cerebral anoxia, the diagnosis of epilepsy is inaccurate, and long-term prophylactic anticonvulsant drug treatment is unnecessary.

2. Alcohol withdrawal seizures—One or more generalized tonic-clonic seizures may occur within 48 hours or so of withdrawal from alcohol after a period of high or prolonged intake. Patients should be hospitalized for at least 24 hours for observation and to follow the severity of withdrawal symptoms. If the seizures have consistently focal features, the possibility of an associated structural abnormality, often traumatic in origin, must be considered. Head CT scan or MRI should be performed in patients with new onset of generalized seizures and whenever there are focal features. Treatment with anticonvulsant drugs is generally not required for alcohol withdrawal seizures, since they are self-limited. Benzodiazepines (diazepam or lorazepam, dosed as needed to reduce withdrawal symptoms and to avoid oversedation) are effective and safe for preventing further seizures. Status epilepticus may rarely follow alcohol withdrawal and is managed along conventional lines (see below). Further attacks will not occur if the patient abstains from alcohol.

3. Tonic-clonic status epilepticus—Poor compliance with the anticonvulsant drug regimen is the most common cause; others include alcohol withdrawal, intracranial

infection or neoplasms, metabolic disorders, and drug overdose. The mortality rate may be as high as 20%, and among survivors the incidence of neurologic and cognitive sequelae may be high. The prognosis relates to the length of time between onset of status epilepticus and the start of effective treatment.

Status epilepticus is a medical emergency. Initial management includes maintenance of the airway and 50% dextrose (25–50 mL) intravenously in case hypoglycemia is responsible. If seizures continue, an intravenous bolus of lorazepam, 4 mg, is given at a rate of 2 mg/min and repeated once after 10 minutes if necessary; alternatively, 10 mg of diazepam is given intravenously over the course of 2 minutes, and again after 10 minutes if necessary. Diazepam can also be given rectally as a gel (0.2 mg/kg). These measures are usually effective in halting seizures for a brief period. Respiratory depression and hypotension may complicate the treatment of status epilepticus and are treated as in other circumstances; this treatment may include intubation and mechanical ventilation and admission to an intensive care unit.

Regardless of the response to lorazepam or diazepam, phenytoin (18–20 mg/kg) is given intravenously at a rate of 50 mg/min; this provides initiation of long-term seizure control. The drug is best injected directly but can also be given in saline; it precipitates, however, if injected into glucose-containing solutions. Because arrhythmias may develop during rapid administration of phenytoin, electrocardiographic monitoring is prudent. Hypotension may complicate phenytoin administration, especially if diazepam has also been given. In many countries, injectable phenytoin has been replaced by fosphenytoin, which is rapidly and completely converted to phenytoin following intravenous administration. No dosing adjustments are necessary because fosphenytoin is expressed in terms of phenytoin equivalents (PE); fosphenytoin is less likely to cause reactions at the infusion site, can be given with all common intravenous solutions, and may be administered at a faster rate (150 mg PE/min). It is also more expensive.

If seizures continue, phenobarbital is then given in a loading dose of 10–20 mg/kg intravenously by slow or intermittent injection (50 mg/min). Respiratory depression and hypotension are especially common with this therapy. Alternatively or additionally, intravenous valproate is used for status epilepticus (loading dose 25–30 mg/kg over 15 min; then 100 mg/h); although valproate has not yet been approved by the FDA for this indication, it has been used with success.

If these measures fail, general anesthesia with ventilatory assistance may be required. Intravenous midazolam may provide control of refractory status epilepticus; the suggested loading dose is 0.2 mg/kg, followed by 0.05–0.2 mg/kg/h. Propofol (1–2 mg/kg as an intravenous bolus, followed by infusion at 2–15 mg/kg/h depending on response) may also be used, as may pentobarbital (15 mg/kg intravenously, followed by 0.5–4 mg/kg/h).

After status epilepticus is controlled, an oral drug program for the long-term management of seizures is started, and investigations into the cause of the disorder are pursued.

4. Nonconvulsive status epilepticus—In some cases, status epilepticus presents not with convulsions, but with a fluctuating abnormal mental status, confusion, impaired responsiveness, and automatism. Electroencephalography is helpful in establishing the diagnosis. The treatment approach outlined above applies to any type of status epilepticus, although intravenous anesthesia is usually not necessary. The prognosis is a reflection of the underlying cause rather than of continuing seizures.

▶ When to Refer

- Behavioral episodes are of uncertain nature.
- Seizures are difficult to control or have focal features.
- There are accompanying neurologic signs.
- There is a progressive neurologic disorder.
- Status epilepticus.

▶ When to Admit

- Status epilepticus.
- For monitoring, when PNES are suspected.
- If surgery is contemplated.

DYSAUTONOMIA

ESSENTIALS OF DIAGNOSIS

- ▶ Abnormalities of blood pressure or heart rate regulation, sweating, intestinal motility, sphincter control, sexual function, respiration, or ocular function, occurring in isolation or any combination.

▶ General Considerations

Dysautonomia may occur as a result of central or peripheral pathologic processes. It is manifested by a variety of symptoms that may occur in isolation or in various combinations and relate to abnormalities of blood pressure regulation, thermoregulatory sweating, gastrointestinal function, sphincter control, sexual function, respiration, and ocular function. Syncope, a symptom of dysautonomia, is characterized by a transient loss of consciousness, usually accompanied by hypotension and bradycardia. It may occur in response to emotional stress, postural hypotension, vigorous exercise in a hot environment, obstructed venous return to the heart, acute pain or its anticipation, fluid loss, and a variety of other circumstances.

A. Central Neurologic Causes

Disease at certain sites in the central nervous system, regardless of its nature, may lead to dysautonomic symptoms. Postural hypotension, which is usually the most troublesome and disabling symptom, may result from spinal cord transection and other myelopathies (eg, due to tumor or syringomyelia) above the T6 level or from brainstem lesions such as syringobulbia and posterior fossa tumors. Sphincter or sexual disturbances may result from cord lesions below T6. Certain primary degenerative disorders are responsible for dysautonomia occurring in isolation (**pure autonomic failure**) or in association with more widespread abnormalities (**multisystem atrophy** or **Shy-Drager syndrome**) that may include parkinsonian, pyramidal symptoms, and cerebellar deficits.

B. Peripheral Neurologic Causes

A pure autonomic neuropathy may occur acutely or subacutely after a viral infection or as a paraneoplastic disorder related usually to small cell lung cancer, particularly in association with certain antibodies, such as anti-Hu or those directed at neuronal nicotinic acetylcholine receptors. Typically, presenting symptoms include postural hypotension, impaired thermoregulatory sweating, xerostomia or xerophthalmia, abnormal gastrointestinal motility, dilated pupils, or acute urinary retention. Dysautonomia is often conspicuous in patients with Guillain-Barré syndrome, manifesting with marked hypotension or hypertension or cardiac arrhythmias that may have a fatal outcome. It may also occur with diabetic, uremic, amyloidotic, and various other metabolic or toxic neuropathies; in association with leprosy or Chagas disease; and as a feature of certain hereditary neuropathies with autosomal dominant or recessive inheritance or an X-linked pattern. Autonomic symptoms are prominent in the crises of hepatic porphyria. Patients with botulism or the Lambert-Eaton myasthenic syndrome may have constipation, urinary retention, and a sicca syndrome as a result of impaired cholinergic function.

▶ Clinical Findings

A. Symptoms and Signs

Dysautonomic symptoms include syncope, postural hypotension, paroxysmal hypertension, persistent tachycardia

without other cause, facial flushing, hypohidrosis or hyperhidrosis, vomiting, constipation, diarrhea, dysphagia, abdominal distention, disturbances of micturition or defecation, erectile dysfunction, apneic episodes, and declining night vision. In syncope, prodromal malaise, nausea, headache, diaphoresis, pallor, visual disturbance, loss of postural tone, and a sense of weakness and impending loss of consciousness are followed by actual loss of consciousness. Although the patient is usually flaccid, some motor activity is not uncommon, and urinary (and rarely fecal) incontinence may also occur, thereby simulating a seizure. Recovery is rapid once the patient becomes recumbent, but headache, nausea, and fatigue are common postictally.

B. Evaluation of the Patient

Clinical evaluation is important to exclude reversible, non-neurologic causes of symptoms. Postural hypotension and syncope, for example, may relate to a reduced cardiac output (eg, from aortic stenosis or cardiomyopathy), paroxysmal cardiac dysrhythmias, volume depletion, various medications, and endocrine and metabolic disorders such as Addison disease, hypothyroidism or hyperthyroidism, pheochromocytoma, and carcinoid syndrome. Testing of autonomic function helps establish the diagnosis of dysautonomia, to exclude other causes of symptoms, to assess the severity of involvement, and to guide prognostication. Such testing includes evaluating the cardiovascular response to the Valsalva maneuver, startle, mental stress, postural change, and deep respiration, and the sudomotor (sweating) responses to warming or a deep inspiratory gasp. Tilt-table testing may reproduce syncopal or presyncopal symptoms. Pharmacologic studies to evaluate the pupillary responses, radiologic studies of the bladder or gastrointestinal tract, uroflowmetry and urethral pressure profiles, and recording of nocturnal penile tumescence may also be necessary in selected cases. Further investigation depends on the presence of other associated neurologic abnormalities. In patients with a peripheral cause, work-up for peripheral neuropathy may be required as discussed below and should include testing for ganglionic acetylcholine receptor antibody. For those with evidence of a central lesion, imaging studies will exclude a treatable structural cause.

► Treatment

The most disabling symptom of dysautonomia is usually postural hypotension and syncope. Abrupt postural change, prolonged recumbency, and other precipitants should be avoided. Medications associated with postural hypotension should be discontinued or reduced in dose. Treatment may include wearing waist-high elastic hosiery, salt supplementation, sleeping in a semierect position (which minimizes the natriuresis and diuresis that occur during recumbency), and fludrocortisone (0.1–0.2 mg daily). Vasoconstrictor agents may be helpful and include midodrine (2.5–10 mg three times daily) and ephedrine (15–30 mg three times daily). Other agents that have been used occasionally or experimentally are dihydroergotamine,

yohimbine, pyridostigmine, and clonidine; refractory cases may respond to erythropoietin (epoetin alfa) or desmopressin. Patients must be monitored for recumbent hypertension. Postprandial hypotension is helped by caffeine. There is no satisfactory treatment for disturbances of sweating, but an air-conditioned environment is helpful in avoiding extreme swings in body temperature.

► When to Refer

- When the diagnosis is uncertain.
- When symptoms persist despite conventional treatment.

SENSORY DISTURBANCES

Patients may complain of either lost or abnormal sensations. The term “numbness” is often used by patients to denote loss of feeling, but the word also has other meanings and the patient’s intention must be clarified. Abnormal spontaneous sensations are generally called paresthesias, and unpleasant or painful sensations produced by a stimulus that is usually painless are called dysesthesias.

Sensory symptoms may be due to disease located anywhere along the peripheral or central sensory pathways. The character, site, mode of onset, spread, and temporal profile of sensory symptoms must be established and any precipitating or relieving factors identified. These features—and the presence of any associated symptoms—help identify the origin of sensory disturbances, as do the physical signs as well. Sensory symptoms or signs may conform to the territory of individual peripheral nerves or nerve roots. Involvement of one side of the body—or of one limb in its entirety—suggests a central lesion. Distal involvement of all four extremities suggests polyneuropathy, a cervical cord or brainstem lesion, or—when symptoms are transient—a metabolic disturbance such as hyperventilation syndrome. Short-lived sensory complaints may be indicative of sensory seizures or cerebral ischemic phenomena as well as metabolic disturbances. In patients with cord lesions, there may be a transverse sensory level. “Dissociated sensory loss” is characterized by loss of some sensory modalities with preservation of others. Such findings may be encountered in patients with either peripheral or central disease and must therefore be interpreted in the clinical context in which they are found.

The absence of sensory signs in patients with sensory symptoms does not mean that symptoms have a nonorganic basis. Symptoms are often troublesome before signs of sensory dysfunction have had time to develop.

WEAKNESS & PARALYSIS

Loss of muscle power may result from central disease involving the upper or lower motor neurons; from peripheral disease involving the roots, plexus, or peripheral nerves; from disorders of neuromuscular transmission; or from primary disorders of muscle. The clinical findings help localize the lesion and thus reduce the number of diagnostic possibilities.

Weakness due to upper motor neuron lesions is characterized by selective involvement of certain muscle groups and is associated with spasticity, increased tendon reflexes, and extensor plantar responses. The site of upper motor neuron (pyramidal) involvement may be indicated by the presence of other clinical signs or by the distribution of the motor deficit. Lower motor neuron lesions lead to muscle wasting as well as weakness, with flaccidity and loss of tendon reflexes, but no change in the plantar responses unless the neurons subserving them are directly involved. Fasciculations may be evident over affected muscles. In distinguishing between a root, plexus, or peripheral nerve lesion, the distribution of the motor deficit and of any sensory changes is of particular importance. In patients with disturbances of neuromuscular transmission, weakness is patchy in distribution, often fluctuates over short periods of time, and is not associated with sensory changes. In myopathic disorders, weakness is usually most marked proximally in the limbs, is not associated with sensory loss or sphincter disturbance, and is not accompanied by muscle wasting or loss of tendon reflexes—at least not until an advanced stage.

TRANSIENT ISCHEMIC ATTACKS

ESSENTIALS OF DIAGNOSIS

- ▶ Focal neurologic deficit of acute onset.
- ▶ Clinical deficit resolves completely within 24 hours.
- ▶ Risk factors for vascular disease often present.

▶ General Considerations

Transient ischemic attacks are characterized by focal ischemic cerebral neurologic deficits that last for < 24 hours (usually < 1–2 hours). About 30% of patients with stroke have a history of transient ischemic attacks, and proper treatment of the attacks is an important means of prevention. The incidence of stroke does not relate to either the number or the duration of individual attacks but is increased in patients with hypertension or diabetes mellitus. The risk of stroke is highest in the month after a transient ischemic attack (particularly in the first 48 hours) and progressively declines thereafter.

▶ Etiology

An important cause of transient cerebral ischemia is embolization. In many patients with these attacks, a source is readily apparent in the heart or a major

extracranial artery to the head, and emboli sometimes are visible in the retinal arteries. Moreover, an embolic phenomenon explains why separate attacks may affect different parts of the territory supplied by the same major vessel. Cardiac causes of embolic ischemic attacks include atrial fibrillation, rheumatic heart disease, mitral valve disease, infective endocarditis, atrial myxoma, and mural thrombi complicating myocardial infarction. Atrial septal defects and patent foramen ovale may permit emboli from the veins to reach the brain (“paradoxical emboli”). An ulcerated plaque on a major artery to the brain may serve as a source of emboli. In the anterior circulation, atherosclerotic changes occur most commonly in the region of the carotid bifurcation extracranially, and these changes may cause a bruit. In some patients with transient ischemic attacks or strokes, an acute or recent hemorrhage is found to have occurred into this atherosclerotic plaque, and this finding may have pathologic significance. Patients with AIDS have an increased risk of developing transient ischemic deficits or strokes.

Less common abnormalities of blood vessels that may cause transient ischemic attacks include fibromuscular dysplasia, which affects particularly the cervical internal carotid artery; atherosclerosis of the aortic arch; inflammatory arterial disorders such as giant cell arteritis, systemic lupus erythematosus, polyarteritis, and granulomatous angiitis; and meningovascular syphilis. Hypotension may cause a reduction of cerebral blood flow if a major extracranial artery to the brain is markedly stenosed, but this is a rare cause of transient ischemic attack.

Hematologic causes of ischemic attacks include polycythemia, sickle cell disease, and hyperviscosity syndromes. Severe anemia may also lead to transient focal neurologic deficits in patients with preexisting cerebral arterial disease.

The **subclavian steal syndrome** may lead to transient vertebrobasilar ischemia. Symptoms develop when there is localized stenosis or occlusion of one subclavian artery proximal to the source of the vertebral artery, so that blood is “stolen” from this artery. A bruit in the supraclavicular fossa, unequal radial pulses, and a difference of 20 mm Hg or more between the systolic blood pressures in the arms should suggest the diagnosis in patients with vertebrobasilar transient ischemic attacks.

▶ Clinical Findings

A. Symptoms and Signs

The symptoms of transient ischemic attacks vary markedly among patients; however, the symptoms in a given individual tend to be constant in type. Onset is abrupt and without warning, and recovery usually occurs rapidly, often within a few minutes. The specific symptoms depend on the arterial distribution affected, as outlined in the subsequent section on stroke.

The natural history of attacks is variable. Some patients will have a major stroke after only a few attacks, whereas others may have frequent attacks for weeks or months without having a stroke. The risk of stroke is high in the

first 3 months after an attack, particularly in the first month and especially within the first 48 hours. Attacks may occur intermittently over a long period of time, or they may stop spontaneously. In general, carotid ischemic attacks are more liable than vertebrobasilar ischemic attacks to be followed by stroke. The stroke risk is greater in patients older than 60 years, in diabetics, or after transient ischemic attacks that last longer than 10 minutes and with symptoms or signs of weakness, speech impairment, or gait disturbance.

B. Imaging

CT or MRI scan is indicated within 24 hours of symptom onset, in part to exclude the possibility of a small cerebral hemorrhage or a cerebral tumor masquerading as a transient ischemic attack; MRI with diffusion-weighted sequences is particularly sensitive for revealing acute or subacute infarction. Noninvasive imaging of the cervical vasculature should also be performed. Carotid duplex ultrasonography is useful for detecting significant stenosis of the internal carotid artery, and MR or CT angiography permits broader visualization of cervical and intracranial vasculature. When noninvasive studies fail to reveal an etiology for transient ischemic attacks, conventional cerebral arteriography may be indicated. This technique is the gold standard for investigating the integrity of the cervical and cerebral vasculature, and allows for angioplasty or other interventions, if necessary.

C. Laboratory and Other Studies

Clinical and laboratory evaluation must include assessment for hypertension, heart disease, hematologic disorders, diabetes mellitus, hyperlipidemia, and peripheral vascular disease. It should include complete blood count, fasting blood glucose and serum cholesterol and homocysteine determinations, serologic tests for syphilis, and an ECG and chest radiograph. Echocardiography with bubble contrast is performed if a cardiac source is likely, and blood cultures are obtained if endocarditis is suspected. Holter monitoring is indicated if a transient, paroxysmal disturbance of cardiac rhythm is suspected.

Differential Diagnosis

Focal seizures usually cause abnormal motor or sensory phenomena such as clonic limb movements, paresthesias, or tingling, rather than weakness or loss of feeling. Symptoms generally spread (“march”) up the limb and may lead to a generalized tonic-clonic seizure.

Classic migraine is easily recognized by the visual premonitory symptoms, followed by nausea, headache, and photophobia, but less typical cases may be hard to distinguish. The patient’s age and medical history (including family history) may be helpful in this regard. Patients with migraine commonly have a history of episodes since adolescence and report that other family members have a similar disorder.

Focal neurologic deficits may occur during periods of hypoglycemia in diabetic patients receiving insulin or oral hypoglycemic agent therapy.

Treatment

Hospitalization should be considered for patients seen within 72 hours of the attack, when they are at increased risk for early recurrence. One commonly used method to assess recurrence risk is the ABCD² score; points are assigned for each of the following criteria: age 60 years or older (1 point), blood pressure $\geq 140/90$ mm Hg (1 point), clinical symptoms of focal weakness (2 points) or speech impairment without weakness (1 point), duration ≥ 60 minutes (2 points) or 10–59 minutes (1 point), or diabetes mellitus (1 point). An ABCD² score of 3 or more points has been suggested as a threshold for hospital admission. Admission is also advisable for patients with crescendo attacks, symptomatic carotid stenosis, or known cardiac source of emboli or hypercoagulable state; such hospitalization facilitates early intervention for any recurrence and rapid institution of secondary prevention measures. When arteriography reveals a surgically accessible high-grade stenosis (70–99% in luminal diameter) on the side appropriate to carotid ischemic attacks and there is relatively little atherosclerosis elsewhere in the cerebrovascular system, operative treatment (carotid endarterectomy) or endovascular intervention reduces the risk of ipsilateral carotid stroke, especially when transient ischemic attacks are of recent onset (<1 month). Some evidence suggests that transluminal angioplasty and stenting is inferior to aggressive medical management alone. There is a more moderate benefit for patients with 50–69% stenosis, and surgery is not indicated for mild stenosis (<50%); its benefits are unclear with severe stenosis plus diffuse intracranial atherosclerotic disease. In patients with carotid ischemic attacks who are poor operative candidates (and thus have not undergone arteriography) or who are found to have extensive vascular disease, medical treatment should be instituted. Similarly, patients with vertebrobasilar ischemic attacks are treated medically and are not subjected to arteriography unless there is clinical evidence of stenosis or occlusion in the carotid or subclavian arteries.

Medical treatment is aimed at preventing further attacks and stroke. Treat diabetes mellitus; hematologic disorders; and hypertension, preferably with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker. Consider starting a statin medication regardless of the current low-density lipoprotein level; in addition to reducing stroke risk, antecedent statin use may improve the outcome if an ischemic stroke does occur. Cigarette smoking should be stopped, and cardiac sources of embolization should be treated appropriately. Weight reduction and regular physical activity should be encouraged when appropriate.

A. Embolization from the Heart

Cardioembolism, especially in the setting of atrial fibrillation, is an indication for anticoagulation as a preventive treatment for stroke. If anticoagulants are indicated for the treatment of embolism from the heart, they should be started immediately, provided that the area of cerebral infarct is small and there is no contraindication to their use. There is no advantage in delay, and the common fear of causing hemorrhage into a previously infarcted area is

misplaced, since there is a far greater risk of further embolism to the cerebral circulation if treatment is withheld. Treatment with warfarin sodium is introduced in a daily dose of 5–15 mg orally, then adjusted based on the international normalized ratio (INR). Warfarin is more effective than aspirin in reducing the incidence of cardioembolic events, but when its use is contraindicated, aspirin (325 mg daily orally) may be used in patients with nonrheumatic atrial fibrillation to reduce the risk of stroke. (See Chapter 14.) Compared with warfarin, the direct thrombin inhibitor dabigatran (150 mg twice daily) offers improved reduction of stroke risk, similar or lower risk of hemorrhage, easier dosing, and no requirement for monitoring.

B. Noncardioembolic Attacks

Treatment with low-dose aspirin (81 mg daily orally) significantly reduces the frequency of transient ischemic attacks and the incidence of stroke. For patients who continue to experience transient ischemic attacks on low-dose aspirin, higher doses of aspirin show no additional benefit. However, low-dose aspirin combined with sustained-release dipyridamole (200 mg twice daily orally) has been shown to be more effective in preventing stroke than aspirin alone. Clopidogrel (75 mg daily orally) alone is marginally more efficacious than aspirin alone; combining clopidogrel with aspirin is not clearly better than clopidogrel alone but does increase the risk of bleeding complications. Cilostazol, another antiplatelet medication, appears to offer similar efficacy at stroke prevention as aspirin, and possibly less risk of hemorrhage. Anticoagulant drugs are not recommended, as they offer no benefit over antiplatelet therapy, and the risk of serious hemorrhagic adverse effects is greater.

► When to Refer

All patients should be referred for urgent investigation and treatment to prevent stroke.

► When to Admit

If seen within 72 hours of a transient ischemic attack, patients should be considered for admission when they have an ABCD² score of 3 points or more, when outpatient evaluation is impractical, or when there are crescendo attacks or other concern for early recurrence or stroke.

STROKE

ESSENTIALS OF DIAGNOSIS

- Sudden onset of characteristic neurologic deficit.
- Patient often has history of hypertension, diabetes mellitus, valvular heart disease, or atherosclerosis.
- Distinctive neurologic signs reflect the region of the brain involved.

► General Considerations

In the United States, stroke remains the third leading cause of death, despite a general decline in the incidence of stroke in the last 30 years. The precise reasons for this decline are uncertain, but increased awareness of risk factors (hypertension, diabetes mellitus, hyperlipidemia, cigarette smoking, cardiac disease, AIDS, recreational drug abuse, heavy alcohol consumption, family history of stroke) and improved prophylactic measures and surveillance of those at increased risk have been contributory. Elevation of the blood homocysteine level is also a risk factor for stroke, but it is unclear whether this risk is reduced by treatment to lower the level. A previous stroke makes individual patients more susceptible to additional strokes.

For years, strokes have been subdivided pathologically into infarcts (thrombotic or embolic) and hemorrhages, and clinical criteria for distinguishing between these possibilities have been emphasized. However, it is often difficult to determine on clinical grounds the pathologic basis for stroke (Table 24–4).

1. Lacunar Infarction

Lacunar infarcts are small lesions (usually <5 mm in diameter) that occur in the distribution of short penetrating arterioles in the basal ganglia, pons, cerebellum, internal capsule, thalamus and, less commonly, the deep cerebral white matter. Lacunar infarcts are associated with poorly controlled hypertension or diabetes and have been found in several clinical syndromes, including contralateral pure motor or pure sensory deficit, ipsilateral ataxia with crural paresis, and dysarthria with clumsiness of the hand. The neurologic deficit may progress over 24–36 hours before stabilizing.

Table 24-4. Features of the major stroke subtypes.

Stroke Type and Subtype	Clinical Features	Diagnosis	Treatment
Ischemic stroke			
Lacunar infarct	Small (< 5 mm) lesions in the basal ganglia, pons, cerebellum, or internal capsule; less often in deep cerebral white matter; prognosis generally good; clinical features depend on location, but may worsen over first 24-36 hours.	MRI with diffusion-weighted sequences usually defines the area of infarction; CT is insensitive acutely but can be used to exclude hemorrhage.	Aspirin; long-term management is to control risk factors (hypertension and diabetes mellitus).
Carotid circulation obstruction	See text—signs vary depending on occluded vessel.	Noncontrast CT to exclude hemorrhage but findings may be normal during first 6-24 hours of an ischemic stroke; diffusion-weighted MRI is gold standard for identifying acute stroke; electrocardiography, echocardiography, blood glucose, complete blood count, and tests for hypercoagulable states, hyperlipidemia are indicated; Holter monitoring in selected instances; carotid duplex studies, CTA, MRA, or conventional angiography in selected cases.	Select patients for intravenous thrombolytics or intra-arterial mechanical thrombolysis; aspirin is first-line therapy; anticoagulation with heparin for cardioembolic strokes when no contraindications exist.
Vertebrobasilar occlusion	See text—signs vary based on location of occluded vessel.	As for carotid circulation obstruction.	As for carotid circulation obstruction.
Hemorrhagic stroke			
Spontaneous intracerebral hemorrhage	Commonly associated with hypertension; also with bleeding disorders, amyloid angiopathy. Hypertensive hemorrhage is located commonly in the basal ganglia and less commonly in the pons, thalamus, cerebellum, or cerebral white matter.	Noncontrast CT is superior to MRI for detecting bleeds of < 48 hours duration; laboratory tests to identify bleeding disorder: angiography may be indicated to exclude aneurysm or AVM. Do not perform lumbar puncture.	Most managed supportively, but cerebellar bleeds or hematomas with gross mass effect may require urgent surgical evacuation.
Subarachnoid hemorrhage	Present with sudden onset of worst headache of life, may lead rapidly to loss of consciousness; signs of meningeal irritation often present; etiology usually aneurysm or AVM, but 20% have no source identified.	CT to confirm diagnosis, but may be normal in rare instances; if CT negative and suspicion high, perform lumbar puncture to look for red blood cells or xanthochromia; angiography to determine source of bleed in candidates for treatment.	See sections on AVM and aneurysm.
Intracranial aneurysm	Most located in the anterior circle of Willis and are typically asymptomatic until subarachnoid bleed occurs; 20% rebleed in first 2 weeks.	CT indicates subarachnoid hemorrhage, and angiography then demonstrates aneurysms; angiography may not reveal aneurysm if vasospasm present.	Prevent further bleeding by clipping aneurysm or coil embolization; nimodipine helps prevent vasospasm; reverse vasospasm by intravenous fluids and induced hypertension after aneurysm has been obliterated, if no other aneurysms are present; angioplasty may also reverse symptomatic vasospasm.
AVMs	Focal deficit from hematoma or AVM itself.	CT reveals bleed, and may reveal the AVM; may be seen by MRI. Angiography demonstrates feeding vessels and vascular anatomy.	Surgery indicated if AVM has bled or to prevent further progression of neurologic deficit; other modalities to treat nonoperable AVMs are available at specialized centers.

AVMs, arteriovenous malformations; CTA, computed tomography angiography; MRA, magnetic resonance angiography.

Lacunar infarcts are sometimes visible on CT scans as small, punched-out, hypodense areas, but in other patients no abnormality is seen. In some instances, patients with a clinical syndrome suggestive of lacunar infarction are found on CT scanning to have a severe hemispheric infarct. Diffusion-weighted MRI is sensitive to acute lesions, which later evolve into areas of T2 hyperintensity and eventually into small, punched-out, cerebrospinal fluid-filled spaces.

Early mortality and risk of stroke recurrence is higher for patients with nonlacunar than lacunar infarcts. The prognosis for recovery from the deficit produced by a lacunar infarct is usually good, with partial or complete resolution occurring over the following 4–6 weeks in many instances.

Donnan GA et al. Lacunes and lacunar syndromes. *Handb Clin Neurol*. 2008;93:559–75. [PMID: 18804668]

2. Cerebral Infarction

Thrombotic or embolic occlusion of a major vessel leads to cerebral infarction. Causes include the disorders predisposing to transient ischemic attacks (see above) and atherosclerosis of cerebral arteries. The resulting deficit depends on the particular vessel involved and the extent of any collateral circulation. Cerebral ischemia leads to release of excitatory and other neuropeptides that may augment calcium flux into neurons, thereby leading to cell death and increasing the neurologic deficit.

► Clinical Findings

A. Symptoms and Signs

Onset is usually abrupt, and there may then be very little progression except that due to brain swelling. Clinical evaluation should always include examination of the heart and auscultation over the subclavian and carotid vessels to determine whether there are any bruits.

1. Obstruction of carotid circulation—Occlusion of the ophthalmic artery is probably symptomless in most cases because of the rich orbital collaterals, but its transient embolic obstruction can lead to amaurosis fugax—sudden and brief loss of vision in one eye.

Occlusion of the anterior cerebral artery distal to its junction with the **anterior communicating artery** causes weakness and cortical sensory loss in the contralateral leg and sometimes mild weakness of the arm, especially proximally. There may be a contralateral grasp reflex, paratonic rigidity, and abulia (lack of initiative) or frank confusion. Urinary incontinence is not uncommon, particularly if behavioral disturbances are conspicuous. Bilateral anterior cerebral infarction is especially likely to cause marked behavioral changes and memory disturbances. Unilateral anterior cerebral artery occlusion proximal to the junction with the anterior communicating artery is generally well tolerated because of the collateral supply from the other side.

Middle cerebral artery occlusion leads to contralateral hemiplegia, hemisensory loss, and homonymous hemianopia (ie, bilaterally symmetric loss of vision in half of the visual

fields), with the eyes deviated to the side of the lesion. If the dominant hemisphere is involved, global aphasia is also present. It may be impossible to distinguish this clinically from occlusion of the internal carotid artery. With occlusion of either of these arteries, there may also be considerable swelling of the hemisphere, leading to drowsiness, stupor, and coma in extreme cases. Occlusions of different branches of the middle cerebral artery cause more limited findings. For example, involvement of the anterior main division leads to a predominantly expressive dysphasia and to contralateral paralysis and loss of sensations in the arm, the face and, to a lesser extent, the leg. Posterior branch occlusion produces a receptive (Wernicke) aphasia and a homonymous visual field defect. With involvement of the nondominant hemisphere, speech and comprehension are preserved, but there may be a left hemispatial neglect syndrome or constructional and visuospatial deficits.

2. Obstruction of vertebrobasilar circulation—Occlusion of the **posterior cerebral artery** may lead to a thalamic syndrome in which contralateral hemisensory disturbance occurs, followed by the development of spontaneous pain and hyperpathia. There is often a macular-sparing homonymous hemianopia and sometimes a mild, usually temporary, hemiparesis. Depending on the site of the lesion and the collateral circulation, the severity of these deficits varies and other deficits may also occur, including involuntary movements and alexia. Occlusion of the main artery beyond the origin of its penetrating branches may lead solely to a macular-sparing hemianopia.

Vertebral artery occlusion distally, below the origin of the anterior spinal and posterior inferior cerebellar arteries, may be clinically silent because the circulation is maintained by the other vertebral artery. If the remaining vertebral artery is congenitally small or severely atherosclerotic, however, a deficit similar to that of basilar artery occlusion is seen unless there is good collateral circulation from the anterior circulation through the circle of Willis. When the small paramedian arteries arising from the vertebral artery are occluded, contralateral hemiplegia and sensory deficit occur in association with an ipsilateral cranial nerve palsy at the level of the lesion. An obstruction of the **posterior inferior cerebellar artery** or an obstruction of the vertebral artery just before it branches to this vessel leads to ipsilateral spinothalamic sensory loss involving the face, ninth and tenth cranial nerve lesions, limb ataxia and numbness, and Horner syndrome, combined with contralateral spinothalamic sensory loss involving the limbs.

Occlusion of both **vertebral arteries** or the **basilar artery** leads to coma with pinpoint pupils, flaccid quadriplegia and sensory loss, and variable cranial nerve abnormalities. With partial basilar artery occlusion, there may be diplopia, visual loss, vertigo, dysarthria, ataxia, weakness or sensory disturbances in some or all of the limbs, and discrete cranial nerve palsies. In patients with hemiplegia of pontine origin, the eyes are often deviated to the paralyzed side, whereas in patients with a hemispheric lesion, the eyes commonly deviate from the hemiplegic side.

Occlusion of any of the major **cerebellar arteries** produces vertigo, nausea, vomiting, nystagmus, ipsilateral limb ataxia, and contralateral spinothalamic sensory loss in the

limbs. If the superior cerebellar artery is involved, the contralateral spinothalamic loss also involves the face; with occlusion of the anterior inferior cerebellar artery, there is ipsilateral spinothalamic sensory loss involving the face, usually in conjunction with ipsilateral facial weakness and deafness. Massive cerebellar infarction may lead to coma, tonsillar herniation, and death.

3. Coma—Infarction in either the carotid or vertebrobasilar territory may lead to loss of consciousness. For example, an infarct involving one cerebral hemisphere may lead to such swelling that the function of the other hemisphere or the rostral brainstem is disturbed and coma results. Similarly, coma occurs with bilateral brainstem infarction when this involves the reticular formation, and it occurs with brainstem compression after cerebellar infarction.

B. Imaging

A CT scan of the head (without contrast) should be performed immediately, before the administration of aspirin or other antithrombotic agents, to exclude cerebral hemorrhage. CT is relatively insensitive to acute ischemic stroke, and subsequent MRI with diffusion-weighted sequences should be performed to define the distribution and extent of infarction as well as to exclude tumor or other differential considerations. Perfusion-weighted MRI sequences can be useful for outlining any additional areas at risk for infarction, thus guiding treatment decisions; specific guidelines are still being determined. Imaging of the cervical vasculature is indicated as part of a search to identify the source of the stroke.

C. Laboratory and Other Studies

Investigations should include a complete blood count, erythrocyte sedimentation rate, blood glucose determination, and serologic tests for syphilis. Screening for antiphospholipid antibodies (lupus anticoagulants and anticardiolipin antibodies); the factor V Leiden mutation; abnormalities of protein C, protein S, or antithrombin; or a prothrombin gene mutation is indicated if a hypercoagulable disorder is suspected (eg, a young patient without apparent risk factors for stroke). Similarly, elevated serum cholesterol and lipids and serum homocysteine may indicate an increased risk of thrombotic stroke. Electrocardiography or continuous cardiac monitoring for at least 24 hours will help exclude a recent myocardial infarction or a cardiac arrhythmia that might be serving as a source of embolization. Blood cultures should be performed if endocarditis is suspected, echocardiography (bubble contrast study) if heart disease—especially valvular disease, left-to-right shunting, or cardiac thrombus—is a concern, and Holter monitoring if paroxysmal cardiac arrhythmia requires exclusion. Examination of the cerebrospinal fluid is not always necessary but may be helpful if cerebral vasculitis or another inflammatory or infectious cause of stroke is suspected, but it should be delayed until after CT or MRI to exclude any risk for herniation due to mass effect.

► Treatment

Prophylactic measures were considered earlier in discussing transient ischemic attacks. The management of acute

stroke should be in a stroke care unit, when feasible. Intravenous thrombolytic therapy with recombinant tissue plasminogen activator (rtPA; 0.9 mg/kg to a maximum of 90 mg, with 10% given as a bolus over 1 minute and the remainder over 1 hour) is effective in reducing the neurologic deficit in selected patients without CT evidence of intracranial hemorrhage when administered as soon as possible, but not more than 4.5 hours after the onset of ischemic symptoms. Treatment within 3 hours has the strongest evidence for benefit (and has FDA approval), but more recent data suggest that extending the treatment window to 4.5 hours still results in reduced disability at 90 days. Based on those data and the recommendations of professional societies, many emergency hospitals have adopted this longer treatment window. Recent hemorrhage, increased risk of hemorrhage (eg, treatment with anticoagulants), arterial puncture at a noncompressible site, and systolic pressure >185 mm Hg or diastolic pressure >110 mm Hg are among the contraindications to this treatment. In selected patients with thrombotic stroke, percutaneous procedures, including endovascular intra-arterial rtPA administration or mechanical removal of an embolus or clot from an occluded cerebral artery using an intra-arterial mechanical thrombolytic device, are also effective relative to non-thrombolytic medical treatment, despite an increased risk of intracranial hemorrhage; it is not clear how these invasive approaches compare to intravenous thrombolytic therapy.

Early management of a completed stroke otherwise requires general supportive measures. During the acute stage, there may be marked brain swelling and edema, with symptoms and signs of increasing intracranial pressure, an increasing neurologic deficit, or herniation syndrome. Elevated intracranial pressure is managed by head elevation and osmotic agents such as mannitol. Maintenance of an adequate cerebral perfusion pressure helps prevent further ischemia. Decompressive hemicraniectomy for malignant middle cerebral artery infarctions may reduce mortality and improve functional outcome in some instances. Attempts to lower the blood pressure of hypertensive patients during the acute phase (ie, within 2 weeks) of a stroke should generally be avoided, as there is loss of cerebral autoregulation, and lowering the blood pressure may further compromise ischemic areas. However, if the systolic pressure exceeds 220 mm Hg, it can be lowered using intravenous labetalol or nicardipine with continuous monitoring to 170–200 mm Hg and then, after 2 weeks, it can be reduced further to <140/90 mm Hg.

In patients not eligible for thrombolytic therapy, and in whom hemorrhage has been excluded by CT, the immediate administration of aspirin 325 mg orally daily is indicated. Anticoagulant drugs should be started in the setting of atrial fibrillation or other source of cardioembolism. Treatment is with warfarin (target INR 2.0–3.0) or dabigatran (150 mg twice daily). If the CT scan shows no evidence of hemorrhage and the cerebrospinal fluid is clear, anticoagulant treatment may be started without delay.

Physical therapy has an important role in the management of patients with impaired motor function. Passive movements at an early stage will help prevent contractures.

As cooperation increases and some recovery begins, active movements will improve strength and coordination. In all cases, early mobilization and active rehabilitation are important. Occupational therapy may improve morale and motor skills, while speech therapy may be beneficial in patients with expressive dysphasia or dysarthria. Because of the risk for dysphagia following stroke, access to food and drink is typically restricted until an appropriate swallowing evaluation. When there is a severe and persisting motor deficit, a device such as a leg brace, toe spring, frame, or cane may help the patient move about, and the provision of other aids to daily living may improve the quality of life.

► Prognosis

The prognosis for survival after cerebral infarction is better than after cerebral or subarachnoid hemorrhage. The only proved effective therapy for acute stroke requires initiation within 3–4.5 hours after stroke onset, and the prognosis therefore depends on the time that elapses before arrival at the hospital. Patients receiving such treatment with rtPA are at least 30% more likely to have minimal or no disability at 3 months than those not treated by this means. Loss of consciousness after a cerebral infarct implies a poorer prognosis than otherwise. The extent of the infarct governs the potential for rehabilitation. Patients who have had a cerebral infarct are at risk for additional strokes and for myocardial infarcts. Statin therapy to lower serum lipid levels may reduce this risk. Antiplatelet therapy reduces the recurrence rate by 30% among patients without a cardiac cause for the stroke who are not candidates for carotid endarterectomy. Nevertheless, the cumulative risk of recurrence of noncardioembolic stroke is still 3–7% annually.

Patients with massive strokes from which meaningful recovery is unlikely should receive palliative care (see Chapter 5).

► When to Refer

All patients should be referred.

► When to Admit

All patients should be hospitalized, preferably in a stroke care unit.

3. Intracerebral Hemorrhage

Spontaneous, nontraumatic intracerebral hemorrhage in patients with no angiographic evidence of an associated vascular anomaly (eg, aneurysm or angioma) is usually due to hypertension. The pathologic basis for hemorrhage is probably the presence of microaneurysms that develop on perforating vessels in hypertensive patients. Hypertensive intracerebral hemorrhage occurs most frequently in the basal ganglia and less commonly in the pons, thalamus, cerebellum, and cerebral white matter. Hemorrhage may extend into the ventricular system or subarachnoid space, and signs of meningeal irritation are then found. Hemorrhages usually occur suddenly and without warning, often during activity. In the elderly, cerebral amyloid angiopathy is another important and frequent cause of hemorrhage, which is usually lobar in distribution, sometimes recurrent, and associated with a better prognosis than hypertensive hemorrhage.

Other causes of nontraumatic intracerebral hemorrhage include hematologic and bleeding disorders (eg, leukemia, thrombocytopenia, hemophilia, or disseminated intravascular coagulation), anticoagulant therapy, liver disease, high alcohol intake, and primary or secondary brain tumors. There is also an association with advancing age and male sex. Bleeding is primarily into the subarachnoid space when it occurs from an intracranial aneurysm or arteriovenous malformation (see below), but it may be partly intraparenchymal as well. In some cases, no specific cause for cerebral hemorrhage can be identified.

► Clinical Findings

A. Symptoms and Signs

With hemorrhage into the cerebral hemisphere, consciousness is initially lost or impaired in about one-half of patients. Vomiting occurs very frequently at the onset of bleeding, and headache is sometimes present. Focal symptoms and signs then develop, depending on the site of the hemorrhage. With hypertensive hemorrhage, there is generally a rapidly evolving neurologic deficit with hemiplegia or hemiparesis. A hemisensory disturbance is also present with more deeply placed lesions. With lesions of the putamen, loss of conjugate lateral gaze may be conspicuous. With thalamic hemorrhage, there may be a loss of upward gaze, downward or skew deviation of the eyes, lateral gaze palsies, and pupillary inequalities.

Cerebellar hemorrhage may present with sudden onset of nausea and vomiting, dysequilibrium, headache, and loss of consciousness that may terminate fatally within 48 hours. Less commonly, the onset is gradual and the course episodic or slowly progressive—clinical features suggesting an expanding cerebellar lesion. In yet other cases, however, the onset and course are intermediate, and examination shows lateral conjugate gaze palsies to the side of the lesion; small reactive pupils; contralateral hemiplegia; peripheral facial weakness; ataxia of gait, limbs, or trunk; periodic respiration; or some combination of these findings.

B. Imaging

CT scanning (without contrast) is important not only in confirming that hemorrhage has occurred but also in determining the size and site of the hematoma. It is superior to MRI for detecting intracranial hemorrhage of < 48 hours duration. If the patient's condition permits further intervention, CT angiography, MR angiography, or cerebral angiography may be undertaken thereafter to determine whether an aneurysm or arteriovenous malformation is present (see below). Follow-up imaging during the hospitalization may reveal hematoma expansion, a predictor of poor outcome.

C. Laboratory and Other Studies

A complete blood count, platelet count, bleeding time, prothrombin and partial thromboplastin times, and liver and kidney function tests may reveal a predisposing cause for the hemorrhage. Lumbar puncture is contraindicated because it may precipitate a herniation syndrome in patients with a large hematoma, and CT scanning is superior in detecting intracerebral hemorrhage.

▶ Treatment

Neurologic management is generally conservative and supportive, regardless of whether the patient has a profound deficit with associated brainstem compression, in which case the prognosis is grim, or a more localized deficit not causing increased intracranial pressure or brainstem involvement. Such therapy may include ventilatory support, blood pressure regulation, seizure prophylaxis, control of fever, osmotherapy, and nutritional supplementation. Intracranial pressure may require monitoring. Ventricular drainage may be required in patients with intraventricular hemorrhage and acute hydrocephalus. Decompression may be helpful when a superficial hematoma in cerebral white matter is exerting a mass effect and causing incipient herniation. In patients with cerebellar hemorrhage, prompt surgical evacuation of the hematoma is appropriate, because spontaneous unpredictable deterioration may otherwise lead to a fatal outcome and because operative treatment may lead to complete resolution of the clinical deficit. The treatment of underlying structural lesions or bleeding disorders depends on their nature. Hemostatic therapy with recombinant activated factor VII has not improved survival or functional outcome. There is no specific treatment for cerebral amyloid angiopathy.

▶ When to Refer

All patients should be referred.

▶ When to Admit

All patients should be hospitalized.

4. Spontaneous Subarachnoid Hemorrhage

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden severe headache.
- ▶ Signs of meningeal irritation usually present.
- ▶ Obtundation is common.
- ▶ Focal deficits frequently absent.

▶ General Considerations

Between 5% and 10% of strokes are due to subarachnoid hemorrhage. Trauma is the most common cause of subarachnoid hemorrhage, the prognosis of which depends on the severity of the head injury. Spontaneous (nontraumatic) subarachnoid hemorrhage frequently results from the rupture of an arterial saccular (“berry”) aneurysm or from an arteriovenous malformation. Occasional patients with aneurysms have headaches, sometimes accompanied by nausea and neck stiffness, a few hours or days before massive subarachnoid hemorrhage occurs. This has been attributed to “warning leaks” of a small amount of blood from the aneurysm.

▶ Clinical Findings

A. Symptoms and Signs

Subarachnoid hemorrhage has a characteristic clinical picture. Its onset is with sudden headache of a severity never experienced previously by the patient. This may be followed by nausea and vomiting and by a loss or impairment of consciousness that can either be transient or progress inexorably to deepening coma and death. If consciousness is regained, the patient is often confused and irritable and may show other symptoms of an altered mental status. Neurologic examination generally reveals nuchal rigidity and other signs of meningeal irritation, except in deeply comatose patients.

Aneurysms may cause a focal neurologic deficit by compressing adjacent structures. However, most are asymptomatic or produce only nonspecific symptoms until they rupture, at which time subarachnoid hemorrhage results. A higher risk of subarachnoid hemorrhage is associated with older age, female sex, “nonwhite” ethnicity, hypertension, tobacco smoking, high alcohol consumption (exceeding 150 g per week), previous symptoms, posterior circulation aneurysms, and larger aneurysms. Focal neurologic signs are usually absent but, when present, may relate either to a focal intracerebral hematoma (from arteriovenous malformations) or to ischemia in the territory of the vessel with a ruptured aneurysm.

B. Imaging

A CT scan (preferably with CT angiography) should be performed immediately to confirm that hemorrhage has occurred and to search for clues regarding its source. It is preferable to MRI because it is faster and more sensitive in detecting hemorrhage in the first 24 hours. CT findings sometimes are normal in patients with suspected hemorrhage, and the cerebrospinal fluid must then be examined for the presence of blood or xanthochromia before the possibility of subarachnoid hemorrhage is discounted.

Cerebral arteriography is undertaken to determine the source of bleeding. In general, bilateral carotid and vertebral arteriography are necessary because aneurysms are often multiple, while arteriovenous malformations may be supplied from several sources. The procedure allows an interventional radiologist to treat an underlying aneurysm or arteriovenous malformation by various techniques. If arteriograms show no abnormality, the examination should be repeated after 2 weeks because vasospasm or thrombus may have prevented detection of an aneurysm or other vascular anomaly during the initial study. CT or MR angiography may also be revealing but is less sensitive than conventional arteriography.

C. Laboratory and Other Studies

The cerebrospinal fluid is bloodstained. Electrocardiographic evidence of arrhythmias or myocardial ischemia has been well described and probably relates to excessive sympathetic activity. Peripheral leukocytosis and transient glycosuria are also common findings.

► Treatment

All patients should be admitted to hospital and seen by a neurologist. The measures outlined below in the section on stupor and coma are applied to comatose patients. Conscious patients are confined to bed, advised against any exertion or straining, treated symptomatically for headache and anxiety, and given laxatives or stool softeners. If there is severe hypertension, the blood pressure can be lowered gradually, but not below a diastolic level of 100 mm Hg. Phenytoin is generally prescribed routinely to prevent seizures. If no cause for the hemorrhage can be identified, medical management is continued for about 6 weeks and is followed by gradual mobilization.

The major aim of treatment is to prevent further hemorrhage. The risk of further hemorrhage from a ruptured aneurysm is greatest within a few days of the first hemorrhage; approximately 20% of patients will have further bleeding within 2 weeks and 40% within 6 months. Definitive treatment, ideally within 2 days of the hemorrhage, requires surgical clipping of the aneurysm base or endovascular treatment by interventional radiologists; the latter is sometimes feasible even for inoperable aneurysms and has a lower morbidity than surgery.

► Complications

Spontaneous subarachnoid hemorrhage may result in severe complications, so monitoring is necessary, usually in an intensive care unit. Intrathecal thrombolytic therapy, presumably by speeding clearance of extravasated blood, appears to reduce the rate of these complications. Hemiplegia or other focal deficit sometimes may follow aneurysmal bleeding after a delay of 2–14 days due to focal arterial spasm. The etiology of vasospasm is uncertain and likely multifactorial, and it sometimes leads to significant cerebral ischemia or infarction and may further aggravate any existing increase in intracranial pressure. Transcranial Doppler ultrasound may be used to screen noninvasively for vasospasm, but conventional arteriography is required to document and treat vasospasm when the clinical suspicion is high. Calcium channel-blocking agents have helped reduce or reverse vasospasm experimentally, and nimodipine has been shown to reduce, in neurologically normal patients, the incidence of ischemic deficits from arterial spasm without producing any side effects. The dose of nimodipine is 60 mg every 4 hours orally for 21 days. Clazosentan, an endothelin receptor antagonist, has failed to affect vasospasm-related morbidity or mortality; the drug has not yet been approved by the US FDA. After surgical obliteration of all aneurysms, symptomatic vasospasm may also be treated by intravascular volume expansion and induced hypertension; transluminal balloon angioplasty of involved intracranial vessels is also helpful. Aspirin provides no benefit. Results from a randomized trial suggest that the prophylactic administration of intravenous magnesium sulfate, sufficient to achieve serum levels of 4.9–6.1 mg/dL (2–2.5 mmol/L), reduced the risk of transcranial ultrasound-detectable vasospasm and of vasospasm-induced cerebral infarction but did not change overall clinical outcomes.

Acute hydrocephalus, which sometimes occurs due to cerebrospinal fluid outflow disruption by the subarachnoid blood, should be suspected if the patient deteriorates clinically and a repeat CT scan should be done. Acute hydrocephalus frequently causes intracranial hypertension severe enough to require temporary, and less commonly prolonged or permanent, intraventricular cerebrospinal fluid shunting. Renal salt-wasting is another complication of subarachnoid hemorrhage that may develop abruptly during the first several days of hospitalization. The resulting hyponatremia and cerebral edema may exacerbate intracranial hypertension and may require carefully titrated treatment with oral sodium chloride or intravenous hyperosmotic sodium solution. Daily measurement of the serum

sodium level allows for the early detection of this complication. Hypopituitarism may occur as a late complication of subarachnoid hemorrhage.

5. Intracranial Aneurysm

ESSENTIALS OF DIAGNOSIS

- ▶ Subarachnoid hemorrhage or focal deficit.
- ▶ Abnormal imaging studies.

▶ General Considerations

Saccular aneurysms (“berry” aneurysms) tend to occur at arterial bifurcations, are frequently multiple (20% of cases), and are usually asymptomatic. They may be associated with polycystic kidney disease and coarctation of the aorta. Risk factors for aneurysm formation include smoking, hypertension, and hypercholesterolemia. Most aneurysms are located on the anterior part of the circle of Willis—particularly on the anterior or posterior communicating arteries, at the bifurcation of the middle cerebral artery, and at the bifurcation of the internal carotid artery. Mycotic aneurysms resulting from septic embolism occur in more distal vessels and often at the cortical surface. The most significant complication of intracranial aneurysms is a subarachnoid hemorrhage, which is discussed in the preceding section. A higher risk of subarachnoid hemorrhage is associated with older age, female sex, “non-white” ethnicity, hypertension, tobacco smoking, high alcohol consumption (exceeding 150 g per week), previous symptoms, posterior circulation aneurysms, and larger aneurysms.

▶ Clinical Findings

A. Symptoms and Signs

Aneurysms may cause a focal neurologic deficit by compressing adjacent structures. However, most are asymptomatic or produce only nonspecific symptoms until they rupture, at which time subarachnoid hemorrhage results. Its manifestations, complications, and management were outlined in the preceding section.

B. Imaging

Definitive evaluation is by angiography (bilateral carotid and vertebral studies), which generally indicates the size and site of the lesion, sometimes reveals multiple aneurysms, and may show arterial spasm if rupture has occurred. Visualization by CT or MR angiography is not usually adequate if operative treatment is under consideration because lesions may be multiple and small lesions are sometimes missed.

▶ Treatment

The major aim of treatment is to prevent hemorrhages. Management of ruptured aneurysms was described in the section on subarachnoid hemorrhage. Symptomatic but unruptured aneurysms merit prompt treatment, either surgically or by endovascular techniques, whereas small asymptomatic ones discovered incidentally are often monitored arteriographically and corrected only if they increase in size to over 10 mm.

▶ When to Refer

All patients should be referred.

▶ When to Admit

- All patients with a subarachnoid hemorrhage.
- All patients for detailed imaging.
- All patients undergoing surgical or endovascular treatment.

6. Arteriovenous Malformations

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of subarachnoid and intracerebral hemorrhage.
- ▶ Distinctive neurologic signs reflect the region of the brain involved.
- ▶ Signs of meningeal irritation in patients presenting with subarachnoid hemorrhage.
- ▶ Seizures or focal deficits may occur.

▶ General Considerations

Arteriovenous malformations are congenital vascular malformations that result from a localized maldevelopment of part of the primitive vascular plexus and consist of abnormal arteriovenous communications without intervening capillaries. They vary in size, ranging from massive lesions that are fed by multiple vessels and involve a large part of the brain to lesions so small that they are hard to identify at arteriography, surgery, or autopsy. In approximately 10% of cases, there is an associated arterial aneurysm, while 1–2% of patients presenting with aneurysms have associated arteriovenous malformations. Clinical presentation may relate to hemorrhage from the malformation or an associated aneurysm or may relate to cerebral ischemia due to diversion of blood by the anomalous arteriovenous shunt or due to venous stagnation. Regional maldevelopment of the brain, compression or distortion of adjacent cerebral tissue by enlarged anomalous vessels, and progressive gliosis due to mechanical and ischemic factors may also be contributory. In addition, communicating or obstructive hydrocephalus may occur and lead to symptoms.

▶ Clinical Findings

A. Symptoms and Signs

1. Supratentorial lesions—Most cerebral arteriovenous malformations are supratentorial, usually lying in the territory of the middle cerebral artery. Initial symptoms consist of hemorrhage in 30–60% of cases, recurrent seizures in 20–40%, headache in 5–25%, and miscellaneous complaints (including focal deficits) in 10–15%. Up to 70% of arteriovenous malformations bleed at some point in their natural history, most commonly before the patient reaches the age of 40 years. This tendency to bleed is unrelated to the lesion site or to the patient's sex, but small arteriovenous malformations are more likely to bleed than large ones. Arteriovenous malformations that have bled once are more likely to bleed again. Hemorrhage is commonly intracerebral as well as into the subarachnoid space, and it has a fatal outcome in about 10% of cases. Focal or generalized seizures may accompany or follow hemorrhage, or they may be the initial presentation, especially with frontal or parietal arteriovenous malformations. Headaches are especially

likely when the external carotid arteries are involved in the malformation. These sometimes simulate migraine but more commonly are nonspecific in character, with nothing about them to suggest an underlying structural lesion.

In patients presenting with subarachnoid hemorrhage, examination may reveal an abnormal mental status and signs of meningeal irritation. Additional findings may help localize the lesion and sometimes indicate that intracranial pressure is increased. A cranial bruit always suggests the possibility of a cerebral arteriovenous malformation, but bruits may also be found with aneurysms, meningiomas, acquired arteriovenous fistulas, and arteriovenous malformations involving the scalp, calvarium, or orbit. Bruits are best heard over the ipsilateral eye or mastoid region and are of some help in lateralization but of no help in localization. Absence of a bruit in no way excludes the possibility of arteriovenous malformation.

2. Infratentorial lesions—Brainstem arteriovenous malformations are often clinically silent, but they may hemorrhage, cause obstructive hydrocephalus, or lead to progressive or relapsing brainstem deficits. Cerebellar arteriovenous malformations may also be clinically inconspicuous but sometimes lead to cerebellar hemorrhage.

B. Imaging

In patients presenting with suspected hemorrhage, CT scanning indicates whether subarachnoid or intracerebral bleeding has recently occurred, helps localize its source, and may reveal the arteriovenous malformation. If the CT scan shows no evidence of bleeding but subarachnoid hemorrhage is diagnosed clinically, the cerebrospinal fluid should be examined.

When intracranial hemorrhage is confirmed but the source of hemorrhage is not evident on the CT scan, arteriography is necessary to exclude aneurysm or arteriovenous malformation. MR and CT angiography are not sensitive enough for this purpose. Even if the findings on CT scan suggest arteriovenous malformation, arteriography is required to establish the nature of the lesion with certainty and to determine its anatomic features so that treatment can be planned. The examination must generally include bilateral opacification of the internal and external carotid arteries and the vertebral arteries. Arteriovenous malformations typically appear as a tangled vascular mass with distended tortuous afferent and efferent vessels, a rapid circulation time, and arteriovenous shunting.

In patients presenting without hemorrhage, CT scan or MRI usually reveals the underlying abnormality, and MRI frequently also shows evidence of old or recent hemorrhage that may have been asymptomatic. The nature and detailed anatomy of any focal lesion identified by these means are delineated by angiography, especially if operative treatment is under consideration.

C. Laboratory and Other Studies

Electroencephalography is usually indicated in patients presenting with seizures and may show consistently focal or lateralized abnormalities resulting from the underlying

cerebral arteriovenous malformation. This should be followed by CT scanning.

► Treatment

Surgical treatment to prevent further hemorrhage is justified in patients with arteriovenous malformations that have bled, provided that the lesion is accessible and the patient has a reasonable life expectancy. Surgical treatment is also appropriate if intracranial pressure is increased and to prevent further progression of a focal neurologic deficit. In patients presenting solely with seizures, anticonvulsant drug treatment is usually sufficient, and operative treatment is unnecessary unless there are further developments.

Definitive operative treatment consists of excision of the arteriovenous malformation if it is surgically accessible. Arteriovenous malformations that are inoperable because of their location are sometimes treated solely by embolization; although the risk of hemorrhage is not reduced, neurologic deficits may be stabilized or even reversed by this procedure. Two other techniques for the treatment of intracerebral arteriovenous malformations are injection of a vascular occlusive polymer through a flow-guided microcatheter and permanent occlusion of feeding vessels by positioning detachable balloon catheters in the desired sites and then inflating them with quickly solidifying contrast material. Stereotactic radiosurgery with the gamma knife or related approaches is also useful in the management of inoperable cerebral arteriovenous malformations.

► When to Refer

All patients should be referred.

► When to Admit

- All patients with a subarachnoid or cerebral hemorrhage.
- All patients for detailed imaging.
- All patients undergoing surgical or endovascular treatment.

Sandalcioglu IE et al. The management of arteriovenous malformations. *J Neurosurg Sci.* 2011 Mar;55(1):57–69. [PMID: 21464810]

7. Intracranial Venous Thrombosis

Intracranial venous thrombosis may occur in association with intracranial or maxillofacial infections, hypercoagulable states, polycythemia, sickle cell disease, and cyanotic congenital heart disease and in pregnancy or during the puerperium. There is a genetic component to risk. It is characterized by headache, focal or generalized convulsions, drowsiness, confusion, increased intracranial pressure, and focal neurologic deficits—and sometimes by evidence of meningeal irritation. The diagnosis is confirmed by CT scanning, MRI, MR venography, or angiography.

Treatment includes anticonvulsant drugs if seizures have occurred and antiedema agents (eg, dexamethasone,

4 mg four times daily intravenously or intramuscularly and continued as necessary) or other measures to reduce intracranial pressure. Anticoagulation with dose-adjusted intravenous heparin or weight-adjusted subcutaneous low-molecular-weight heparin, followed by oral warfarin anticoagulation for 6 months reduces morbidity and mortality of venous sinus thrombosis. Concomitant intracranial hemorrhage related to the venous thrombosis does not contraindicate heparin therapy. In cases refractory to heparin, endovascular techniques including catheter-directed thrombolytic therapy (urokinase) and thrombectomy, are sometimes helpful but may increase risk for major hemorrhage.

Marjot T et al. Genes associated with adult cerebral venous thrombosis. *Stroke.* 2011 Apr;42(4):913–8. [PMID: 21350198]

► When to Refer

All patients should be referred.

► When to Admit

All patients should be hospitalized.

8. Spinal Cord Vascular Diseases

ESSENTIALS OF DIAGNOSIS

- Sudden onset of back or limb pain and neurologic deficit in limbs.
- Motor, sensory, or reflex changes in limbs depending on level of lesion.
- Imaging studies distinguish between infarct and hematoma.

► Infarction of the Spinal Cord

Infarction of the spinal cord is rare. It typically occurs in the territory of the anterior spinal artery because this vessel, which supplies the anterior two-thirds of the cord, is itself supplied by only a limited number of feeders. Infarction usually results from interrupted flow in one or more of these feeders, eg, with aortic dissection, aortography, polyarteritis, or severe hypotension, or after surgical resection of the thoracic aorta. The paired posterior spinal arteries, by contrast, are supplied by numerous arteries at different levels of the cord. Spinal cord hypoperfusion may lead to a central cord syndrome with distal weakness of lower motor neuron type and loss of pain and temperature appreciation, with preserved posterior column function.

Since the anterior spinal artery receives numerous feeders in the cervical region, infarcts almost always occur caudally. Clinical presentation is characterized by acute onset of flaccid, areflexive paraplegia that evolves after a

few days or weeks into a spastic paraplegia with extensor plantar responses. There is an accompanying dissociated sensory loss, with impairment of appreciation of pain and temperature but preservation of sensations of vibration and position. Treatment is symptomatic.

Novy J et al. Spinal cord ischemia: clinical and imaging patterns, pathogenesis, and outcomes in 27 patients. *Arch Neurol.* 2006 Aug;63(8):1113–20. [PMID: 16908737]

► Epidural or Subdural Hemorrhage

Epidural or subdural hemorrhage may lead to sudden severe back pain followed by an acute compressive myelopathy necessitating urgent spinal MRI or myelography and surgical evacuation. It may occur in patients with bleeding disorders or those who are taking anticoagulant drugs, sometimes following trauma or lumbar puncture. Epidural hemorrhage may also be related to a vascular malformation or tumor deposit.

► Spinal Dural Arteriovenous Fistulae

Spinal dural arteriovenous fistulae are congenital lesions that present with spinal subarachnoid hemorrhage or myeloradiculopathy. Since most of these malformations are located in the thoracolumbar region, they lead to motor and sensory disturbances in the legs and to sphincter disorders. Pain in the legs or back is often severe. Examination reveals an upper, lower, or mixed motor deficit in the legs; sensory deficits are also present and are usually extensive, although occasionally they are confined to radicular distribution. Cervical spinal dural arteriovenous fistulae lead also to symptoms and signs in the arms. Spinal MRI may not detect the spinal dural arteriovenous fistulae, and negative findings do not exclude the diagnosis. Myelography (performed with the patient prone and supine) detects serpiginous filling defects due to enlarged vessels. Selective spinal arteriography confirms the diagnosis. Most lesions are extramedullary, are posterior to the cord (lying either intradurally or extradurally), and can easily be treated by ligation of feeding vessels and excision of the fistulous anomaly or by embolization procedures. Delay in treatment may lead to increased and irreversible disability or to death from recurrent subarachnoid hemorrhage.

► When to Refer

All patients should be referred.

► When to Admit

All patients should be hospitalized.

Narvid J et al. Spinal dural arteriovenous fistulae: clinical features and long-term results. *Neurosurgery.* 2008 Jan;62(1):159–67. [PMID: 18300903]

INTRACRANIAL & SPINAL MASS LESIONS

1. Primary Intracranial Tumors

ESSENTIALS OF DIAGNOSIS

- Generalized or focal disturbance of cerebral function, or both.
- Increased intracranial pressure in some patients.
- Neuroradiologic evidence of space-occupying lesion.

► General Considerations

Half of all primary intracranial neoplasms (Table 24–5) are gliomas and the remainder are meningiomas, pituitary adenomas (see Chapter 26), neurofibromas, and other tumors. Certain tumors, especially neurofibromas, hemangioblastomas, and retinoblastomas, may have a familial basis, and congenital factors bear on the development of craniopharyngiomas. Tumors may occur at any age, but certain gliomas show particular age predilections (Table 24–5).

► Clinical Findings

A. Symptoms and Signs

Intracranial tumors may lead to a generalized disturbance of cerebral function and to symptoms and signs of increased intracranial pressure. In consequence, there may be personality changes, intellectual decline, emotional lability, seizures, headaches, nausea, and malaise. If the pressure is increased in a particular cranial compartment, brain tissue may herniate into a compartment with lower pressure. The most familiar syndrome is herniation of the temporal lobe uncus through the tentorial hiatus, which causes compression of the third cranial nerve, midbrain, and posterior cerebral artery. The earliest sign of this is ipsilateral pupillary dilation, followed by stupor, coma, decerebrate posturing, and respiratory arrest. Another important herniation syndrome consists of displacement of the cerebellar tonsils through the foramen magnum, which causes medullary compression leading to apnea, circulatory collapse, and death. Other herniation syndromes are less common and of less clear clinical importance.

Intracranial tumors also lead to focal deficits depending on their location.

1. Frontal lobe lesions—Tumors of the frontal lobe often lead to progressive intellectual decline, slowing of mental activity, personality changes, and contralateral grasp reflexes. They may lead to expressive aphasia if the posterior part of the left inferior frontal gyrus is involved. Anosmia may also occur as a consequence of pressure on the olfactory nerve. Precentral lesions may cause focal motor seizures or contralateral pyramidal deficits.

2. Temporal lobe lesions—Tumors of the uncinate region may be manifested by seizures with olfactory or

Table 24-5. Primary intracranial tumors.

Tumor	Clinical Features	Treatment and Prognosis
Glioblastoma multiforme	Presents commonly with nonspecific complaints and increased intracranial pressure. As it grows, focal deficits develop.	Course is rapidly progressive, with poor prognosis. Total surgical removal is usually not possible. Radiation therapy and chemotherapy may prolong survival.
Astrocytoma	Presentation similar to glioblastoma multiforme but course more protracted, often over several years. Cerebellar astrocytoma may have a more benign course.	Prognosis is variable. By the time of diagnosis, total excision is usually impossible; tumor may be radiosensitive and chemotherapy may also be helpful. In cerebellar astrocytoma, total surgical removal is often possible.
Medulloblastoma	Seen most frequently in children. Generally arises from roof of fourth ventricle and leads to increased intracranial pressure accompanied by brainstem and cerebellar signs. May seed subarachnoid space.	Treatment consists of surgery combined with radiation therapy and chemotherapy.
Ependymoma	Glioma arising from the ependyma of a ventricle, especially the fourth ventricle; leads to early signs of increased intracranial pressure. Arises also from central canal of cord.	Tumor is best treated surgically if possible. Radiation therapy may be used for residual tumor.
Oligodendroglioma	Slow-growing. Usually arises in cerebral hemisphere in adults. Calcification may be visible on skull radiograph.	Treatment is surgical and usually successful. Radiation and chemotherapy may be used if tumor has malignant features.
Brainstem glioma	Presents during childhood with cranial nerve palsies and then with long tract signs in the limbs. Signs of increased intracranial pressure occur late.	Tumor is inoperable; treatment is by irradiation and shunt for increased intracranial pressure.
Cerebellar heman-gioblastoma	Presents with dysequilibrium, ataxia of trunk or limbs, and signs of increased intracranial pressure. Sometimes familial. May be associated with retinal and spinal vascular lesions, polycythemia, and renal cell carcinoma.	Treatment is surgical. Radiation is used for residual tumor.
Pineal tumor	Presents with increased intracranial pressure, sometimes associated with impaired upward gaze (Parinaud syndrome) and other deficits indicative of midbrain lesion.	Ventricular decompression by shunting is followed by surgical approach to tumor; irradiation is indicated if tumor is malignant. Prognosis depends on histopathologic findings and extent of tumor.
Craniopharyngioma	Originates from remnants of Rathke pouch above the sella, depressing the optic chiasm. May present at any age but usually in childhood, with endocrine dysfunction and bitemporal field defects.	Treatment is surgical, but total removal may not be possible. Radiation may be used for residual tumor.
Acoustic neurinoma	Ipsilateral hearing loss is most common initial symptom. Subsequent symptoms may include tinnitus, headache, vertigo, facial weakness or numbness, and long tract signs. (May be familial and bilateral when related to neurofibromatosis.) Most sensitive screening tests are MRI and brainstem auditory evoked potential.	Treatment is excision by translabyrinthine surgery, craniectomy, or a combined approach. Outcome is usually good.
Meningioma	Originates from the dura mater or arachnoid; compresses rather than invades adjacent neural structures. Increasingly common with advancing age. Tumor size varies greatly. Symptoms vary with tumor site—eg, unilateral proptosis (sphenoidal ridge); anosmia and optic nerve compression (olfactory groove). Tumor is usually benign and readily detected by CT scanning; may lead to calcification and bone erosion visible on plain radiographs of skull.	Treatment is surgical. Tumor may recur if removal is incomplete.
Primary cerebral lymphoma	Associated with AIDS and other immunodeficient states. Presentation may be with focal deficits or with disturbances of cognition and consciousness. May be indistinguishable from cerebral toxoplasmosis.	Treatment is high-dose methotrexate followed by radiation therapy. Prognosis depends on CD4 count at diagnosis.

gustatory hallucinations, motor phenomena such as licking or smacking of the lips, and some impairment of external awareness without actual loss of consciousness. Temporal lobe lesions also lead to depersonalization, emotional changes, behavioral disturbances, sensations of déjà vu or jamais vu, micropsia or macropsia (objects appear

smaller or larger than they are), visual field defects (crossed upper quadrantanopia), and auditory illusions or hallucinations. Left-sided lesions may lead to dysnomia and receptive aphasia, while right-sided involvement sometimes disturbs the perception of musical notes and melodies.

3. Parietal lobe lesions—Tumors in this location characteristically cause contralateral disturbances of sensation and may cause sensory seizures, sensory loss or inattention, or some combination of these symptoms. The sensory loss is cortical in type and involves postural sensibility and tactile discrimination, so that the appreciation of shape, size, weight, and texture is impaired. Objects placed in the hand may not be recognized (astereognosis). Extensive parietal lobe lesions may produce contralateral hyperpathia and spontaneous pain (thalamic syndrome). Involvement of the optic radiation leads to a contralateral homonymous field defect that sometimes consists solely of lower quadrantanopia. Lesions of the left angular gyrus cause Gerstmann syndrome (a combination of alexia, agraphia, acalculia, right-left confusion, and finger agnosia), whereas involvement of the left submarginal gyrus causes ideational apraxia. Anosognosia (the denial, neglect, or rejection of a paralyzed limb) is seen in patients with lesions of the non-dominant (right) hemisphere. Constructional apraxia and dressing apraxia may also occur with right-sided lesions.

4. Occipital lobe lesions—Tumors of the occipital lobe characteristically produce crossed homonymous hemianopia or a partial field defect. With left-sided or bilateral lesions, there may be visual agnosia both for objects and for colors, while irritative lesions on either side can cause unformed visual hallucinations. Bilateral occipital lobe involvement causes cortical blindness in which there is preservation of pupillary responses to light and lack of awareness of the defect by the patient. There may also be loss of color perception, prosopagnosia (inability to identify a familiar face), simultagnosia (inability to integrate and interpret a composite scene as opposed to its individual elements), and Balint syndrome (failure to turn the eyes to a particular point in space, despite preservation of spontaneous and reflex eye movements). The denial of blindness or a field defect constitutes Anton syndrome.

5. Brainstem and cerebellar lesions—Brainstem lesions lead to cranial nerve palsies, ataxia, incoordination, nystagmus, and pyramidal and sensory deficits in the limbs on one or both sides. Intrinsic brainstem tumors, such as gliomas, tend to produce an increase in intracranial pressure only late in their course. Cerebellar tumors produce marked ataxia of the trunk if the vermis cerebelli is involved and ipsilateral appendicular deficits (ataxia, incoordination and hypotonia of the limbs) if the cerebellar hemispheres are affected.

6. False localizing signs—Tumors may lead to neurologic signs other than by direct compression or infiltration, thereby leading to errors of clinical localization. These false localizing signs include third or sixth nerve palsy and bilateral extensor plantar responses produced by herniation syndromes, and an extensor plantar response occurring ipsilateral to a hemispheric tumor as a result of compression of the opposite cerebral peduncle against the tentorium.

B. Imaging

MRI with gadolinium enhancement is the preferred method to detect the lesion and to define its location,

shape, and size; the extent to which normal anatomy is distorted; and the degree of any associated cerebral edema or mass effect. CT scanning with radiocontrast enhancement could be performed; however, it is less helpful than MRI for small lesions or tumors in the posterior fossa. The characteristic appearance of meningiomas on MRI or CT scanning is virtually diagnostic, ie, a lesion in a typical site (parasagittal and sylvian regions, olfactory groove, sphenoidal ridge, tuberculum sellae) that appears as a homogeneous area of increased density in noncontrast scans and enhances uniformly with contrast. Newer neuroimaging techniques may help identify brain tumors by increased blood perfusion (perfusion-weighted MRI, single photon-emission computed tomography, positron-emission tomography) and high metabolism or cell turnover (magnetic resonance spectroscopy, positron-emission tomography), but non-neoplastic diseases, such as stroke and inflammatory or infectious diseases, are sometimes associated with hyperperfusion and hypermetabolism. Diffusion-weighted MRI may also be helpful. Arteriography may show stretching or displacement of normal cerebral vessels by the tumor and the presence of tumor vascularity. The presence of an avascular mass is a nonspecific finding that could be due to tumor, hematoma, abscess, or any space-occupying lesion. In patients with normal hormone levels and an intrasellar mass, angiography is necessary to distinguish with confidence between a pituitary adenoma and an arterial aneurysm.

C. Laboratory and Other Studies

The electroencephalogram provides supporting information concerning cerebral function and may show either a focal disturbance due to the neoplasm or a more diffuse change reflecting altered mental status. Lumbar puncture is rarely necessary; the findings are seldom diagnostic, and the procedure carries the risk of causing a herniation syndrome.

► Treatment

Treatment depends on the type and site of the tumor (Table 24–5) and the condition of the patient. Some benign tumors, especially meningiomas discovered incidentally during brain imaging for another purpose, may be monitored with serial annual imaging. For symptomatic tumors, complete surgical removal may be possible if the tumor is extra-axial (eg, meningioma, acoustic neuroma) or is not in a critical or inaccessible region of the brain (eg, cerebellar hemangioblastoma). Surgery also permits the diagnosis to be verified and may be beneficial in reducing intracranial pressure and relieving symptoms even if the neoplasm cannot be completely removed. Clinical deficits are sometimes due in part to obstructive hydrocephalus, in which case simple surgical shunting procedures often produce dramatic benefit. In patients with malignant gliomas, radiation therapy increases median survival rates regardless of any preceding surgery, and its combination with chemotherapy provides additional benefit. Indications for irradiation in the treatment of patients with other primary intracranial neoplasms depend on tumor type

and accessibility and the feasibility of complete surgical removal. Temozolomide is a commonly used oral and intravenous chemotherapeutic for gliomas, and there is an increasing trend to use monoclonal antibodies as a component of therapy. Corticosteroids help reduce cerebral edema and are usually started before surgery. Herniation is treated with intravenous dexamethasone (10–20 mg as a bolus, followed by 4 mg every 6 hours) and intravenous mannitol (20% solution given in a dose of 1.5 g/kg over about 30 minutes). Anticonvulsants are also commonly administered in standard doses (see Table 24–3) but are not indicated for prophylaxis in patients who have no history of seizures. Long-term neurocognitive deficits may complicate radiation therapy. For those patients whose disease deteriorates despite treatment, palliative care is important (see Chapter 5).

► When to Refer

All patients should be referred.

► When to Admit

- All patients with increased intracranial pressure.
- All patients requiring biopsy, surgical treatment, or shunting procedures.

2. Metastatic Intracranial Tumors Cerebral Metastases

Metastatic brain tumors present in the same way as other cerebral neoplasms, ie, with increased intracranial pressure, with focal or diffuse disturbance of cerebral function, or with both of these manifestations. Indeed, in patients with a single cerebral lesion, the metastatic nature of the lesion may only become evident on histopathologic examination. In other patients, there is evidence of widespread metastatic disease, or an isolated cerebral metastasis develops during treatment of the primary neoplasm.

The most common source of intracranial metastasis is carcinoma of the lung; other primary sites are the breast, kidney, skin (melanoma), and gastrointestinal tract. Most cerebral metastases are located supratentorially. Laboratory and radiologic studies used to evaluate patients with metastases are those described for primary neoplasms. They include MRI and CT scanning performed both with and without contrast material. Lumbar puncture is necessary only in patients with suspected carcinomatous meningitis

(see below). In patients with verified cerebral metastasis from an unknown primary, investigation is guided by symptoms and signs. In women, mammography is indicated; in men under 50, germ cell origin is sought since both have therapeutic implications.

In patients with only a single, surgically accessible cerebral metastasis who are otherwise well (ie, a high level of functioning and little or no evidence of extracranial disease), it may be possible to remove the lesion and then treat with irradiation; the latter may also be selected as the sole treatment. In patients with multiple metastases or widespread systemic disease, the prognosis is poor; stereotactic radiosurgery, whole-brain radiotherapy, or both, may help in some instances, but in others treatment is palliative only.

Leptomeningeal Metastases (Carcinomatous Meningitis)

The neoplasms metastasizing most commonly to the leptomeninges are carcinoma of the breast, lymphomas, and leukemia. Leptomeningeal metastases lead to multifocal neurologic deficits, which may be associated with infiltration of cranial and spinal nerve roots, direct invasion of the brain or spinal cord, obstructive hydrocephalus, or some combination of these factors.

The diagnosis is confirmed by examination of the cerebrospinal fluid. Findings may include elevated cerebrospinal fluid pressure, pleocytosis, increased protein concentration, and decreased glucose concentration. Cytologic studies may indicate that malignant cells are present; if not, lumbar puncture should be repeated at least twice to obtain further samples for analysis.

CT scans showing contrast enhancement in the basal cisterns or showing hydrocephalus without any evidence of a mass lesion support the diagnosis. Gadolinium-enhanced MRI frequently shows enhancing foci in the leptomeninges. Myelography may show deposits on multiple nerve roots.

Treatment is by irradiation to symptomatic areas, combined with intrathecal methotrexate. The long-term prognosis is poor—only about 10% of patients survive for 1 year—and palliative care is therefore important (see Chapter 5).

3. Intracranial Mass Lesions in AIDS Patients

Primary cerebral lymphoma is a common complication in patients with AIDS. This leads to disturbances in

cognition or consciousness, focal motor or sensory deficits, aphasia, seizures, and cranial neuropathies. Similar clinical disturbances may result from **cerebral toxoplasmosis**, which is also a common complication in patients with AIDS (see Chapters 31 and 35). Neither CT nor MRI findings distinguish these two disorders, and serologic tests for toxoplasmosis are unreliable in AIDS patients. Accordingly, for neurologically stable patients, a trial of treatment for toxoplasmosis with sulfadiazine (100 mg/kg/d up to 8 g/d in four divided doses orally daily) and pyrimethamine (75 mg orally daily for 3 days, then 25 mg orally daily) is recommended for 3 weeks; the imaging studies are then repeated, and if any lesion has improved, the regimen is continued indefinitely. If any lesion does not improve, cerebral biopsy is necessary. Primary cerebral lymphoma is treated with whole-brain irradiation.

Cryptococcal meningitis is a common opportunistic infection in AIDS patients. Clinically, it may resemble cerebral toxoplasmosis or lymphoma, but cranial CT scans are usually normal. The diagnosis is made on the basis of cerebrospinal fluid studies, with positive India ink staining in 75–80% and cryptococcal antigen tests in 95% of cases. Treatment is with amphotericin B plus flucytosine, as set forth in Table 36–1, followed by fluconazole.

4. Primary & Metastatic Spinal Tumors

Approximately 10% of spinal tumors are intramedullary. Ependymoma is the most common type of intramedullary tumor; the remainder are other types of glioma. Extramedullary tumors may be extradural or intradural in location. Among the primary extramedullary tumors, neurofibromas and meningiomas are relatively common, are benign, and may be intradural or extradural. Carcinomatous metastases, lymphomatous or leukemic deposits, and myeloma are usually extradural; in the case of metastases, the prostate, breast, lung, and kidney are common primary sites.

Tumors may lead to spinal cord dysfunction by direct compression, by ischemia secondary to arterial or venous obstruction and, in the case of intramedullary lesions, by invasive infiltration.

► Clinical Findings

A. Symptoms and Signs

Symptoms usually develop insidiously. Pain is often conspicuous with extradural lesions; is characteristically aggravated by coughing or straining; may be radicular, localized to the back, or felt diffusely in an extremity; and may be accompanied by motor deficits, paresthesias, or numbness, especially in the legs. Bladder, bowel, and sexual dysfunction may occur. When sphincter disturbances occur, they are usually particularly disabling. Pain, however, often precedes specific neurologic symptoms from epidural metastases.

Examination may reveal localized spinal tenderness. A segmental lower motor neuron deficit or dermatomal sensory changes (or both) are sometimes found at the

level of the lesion, while an upper motor neuron deficit and sensory disturbance are found below it.

B. Imaging

CT myelography or, preferably, MRI with contrast is used to identify and localize the lesion. The combination of known tumor elsewhere in the body, back pain, and either abnormal plain films of the spine or neurologic signs of cord compression is an indication to perform these studies on an urgent basis. Some clinicians proceed to MRI or CT myelography based solely on new back pain in a cancer patient.

C. Laboratory Findings

The cerebrospinal fluid is often xanthochromic and contains a greatly increased protein concentration with normal cell content and glucose concentration.

► Treatment

Intramedullary tumors are treated by decompression and surgical excision (when feasible) and by irradiation. The prognosis depends on the cause and severity of cord compression before it is relieved.

Treatment of epidural spinal metastases consists of irradiation, irrespective of cell type. Dexamethasone is also given in a high dosage (eg, 25 mg four times daily for 3 days orally or intravenously, followed by rapid tapering of the dosage, depending on response) to reduce cord swelling and relieve pain. Surgical decompression is reserved for patients with tumors that are unresponsive to irradiation or have previously been irradiated and for cases in which there is some uncertainty about the diagnosis. The long-term outlook is poor, but radiation treatment may at least delay the onset of major disability.

5. Brain Abscess

ESSENTIALS OF DIAGNOSIS

- Symptoms and signs of expanding intracranial mass.
- Signs of primary infection or congenital heart disease are sometimes present.
- Fever may be absent.

► General Considerations

Brain abscess presents as an intracranial space-occupying lesion and arises as a sequela of disease of the ear or nose, may be a complication of infection elsewhere in the body, or may result from infection introduced intracranially by

trauma or surgical procedures. The most common infective organisms are streptococci, staphylococci, and anaerobes; mixed infections are not uncommon.

► Clinical Findings

A. Symptoms and Signs

Headache, drowsiness, inattention, confusion, and seizures are early symptoms, followed by signs of increasing intracranial pressure and then a focal neurologic deficit. There may be little or no systemic evidence of infection.

B. Imaging and Other Investigations

A CT scan of the head characteristically shows an area of contrast enhancement surrounding a low-density core. Similar abnormalities may be found in patients with metastatic neoplasms. MRI findings often permit earlier recognition of focal cerebritis or an abscess. Arteriography indicates the presence of a space-occupying lesion, which appears as an avascular mass with displacement of normal cerebral vessels. Stereotactic needle aspiration may enable a specific etiologic organism to be identified. Examination of the cerebrospinal fluid does not help in diagnosis and may precipitate a herniation syndrome. Peripheral leukocytosis is sometimes present.

► Treatment

Treatment consists of intravenous antibiotics, combined with surgical drainage (aspiration or excision) if necessary to reduce the mass effect, or sometimes to establish the diagnosis. Abscesses smaller than 2 cm can often be cured medically. Broad-spectrum antibiotics, selected based on risk factors and likely organisms, are used if the infecting organism is unknown (see Chapter 33). Initial empiric antibiotic regimens typically include ceftriaxone (2 g intravenously every 12 hours), metronidazole (15 mg/kg intravenous loading dose, followed by 7.5 mg/kg intravenously every 6 hours), and vancomycin (1 g intravenously every 12 hours). The regimen is altered once culture and sensitivity data are available. Antimicrobial treatment is usually continued parenterally for 6–8 weeks, followed by orally for 2–3 months. The patient should be monitored by serial CT scans or MRI every 2 weeks and at deterioration. Dexamethasone (4–25 mg four times daily intravenously or orally, depending on severity, followed by tapering of dose, depending on response) may reduce any associated edema, but intravenous mannitol is sometimes required.

Carpenter J et al. Retrospective analysis of 49 cases of brain abscess and review of the literature. *Eur J Clin Microbiol Infect Dis.* 2007 Jan;26(1):1–11. [PMID: 17180609]

NONMETASTATIC NEUROLOGIC COMPLICATIONS OF MALIGNANT DISEASE

A variety of nonmetastatic neurologic complications of malignant disease (see Table 39–2) can be recognized. Metabolic encephalopathy due to electrolyte abnormalities, infections, drug overdose, or the failure of some vital

organ may be reflected by drowsiness, lethargy, restlessness, insomnia, agitation, confusion, stupor, or coma. The mental changes are usually associated with tremor, asterixis, and multifocal myoclonus. The electroencephalogram is generally diffusely slowed. Laboratory studies are necessary to detect the cause of the encephalopathy, which must then be treated appropriately.

Immune suppression resulting from either the malignant disease or its treatment (eg, by chemotherapy) predisposes patients to brain abscess, progressive multifocal leukoencephalopathy, meningitis, herpes zoster infection, and other opportunistic infectious diseases. Moreover, an overt or occult cerebrospinal fluid fistula, as occurs with some tumors, may also increase the risk of infection. MRI or CT scanning aids in the early recognition of a brain abscess, but metastatic brain tumors may have a similar appearance. Examination of the cerebrospinal fluid is essential in the evaluation of patients with meningitis but is of no help in the diagnosis of brain abscess.

Cerebrovascular disorders that cause neurologic complications in patients with systemic cancer include nonbacterial thrombotic endocarditis and septic embolization. Cerebral, subarachnoid, or subdural hemorrhages may occur in patients with myelogenous leukemia and may be found in association with metastatic tumors, especially malignant melanoma. Spinal subdural hemorrhage sometimes occurs after lumbar puncture in patients with marked thrombocytopenia.

Disseminated intravascular coagulation occurs most commonly in patients with acute promyelocytic leukemia or with some adenocarcinomas and is characterized by a fluctuating encephalopathy, often with associated seizures, that frequently progresses to coma or death. There may be few accompanying neurologic signs. Venous sinus thrombosis, which usually presents with convulsions and headaches, may also occur in patients with leukemia or lymphoma. Examination commonly reveals papilledema and focal or diffuse neurologic signs. Anticonvulsants, anticoagulants, and drugs to lower the intracranial pressure may be of value.

Autoimmune paraneoplastic disorders occur when the immune system reacts against neuronal antigens expressed by tumor cells. The clinical manifestations depend on the autoantibody. Symptoms may precede those due to the neoplasm itself. Several distinct syndromes are common, including paraneoplastic cerebellar degeneration, limbic encephalitis, encephalomyelitis, anti-NMDA receptor-associated encephalitis, opsoclonus/myoclonus, sensory neuronopathy, and dermatomyositis.

Paraneoplastic cerebellar degeneration occurs most commonly in association with carcinoma of the lung, but also in breast and gynecologic cancers and Hodgkin lymphoma. Typically, there is a pancerebellar syndrome causing dysarthria, nystagmus, and ataxia of the trunk and limbs. The disorder is associated with anti-Yo, -Tr, -voltage-gated calcium channel (VGCC), and -Zic antibodies. Treatment is of the underlying malignant disease. **Limbic encephalitis**, characterized by impaired recent memory, disturbed affect, hallucinations, and seizures, occurs in some patients with tumors of the lungs, breast, thymus, and germ cells.

Associated antibodies include anti-Hu, -Ma2, -CV2/CRMP5, -voltage-gated potassium channel (VGKC), -AMPA receptor, and -GABA_B receptor. A more generalized **encephalomyelitis** occurs with anti-Hu, -CV2/CRMP5, -Ma2, and -amphiphysin antibodies in the context of a similar spectrum of tumors. **Anti-NMDA receptor-associated encephalitis** causes a characteristic syndrome of severe psychiatric symptoms, dyskinesias, dysautonomia, and hypoventilation, and is frequently associated with ovarian teratoma. **Opsoclonus/myoclonus**, a syndrome of involuntary, erratic, and conjugate saccadic eye movements and myoclonic movements of the limbs, occurs in patients with lung, breast, and gynecologic tumors, often without an identifiable antibody. **Sensory neuronopathy**, typically caused by anti-Hu antibodies in small cell lung cancer or other carcinomas, manifests itself with asymmetric, multifocal sensory nerve root deficits leading to pain, numbness, sensory ataxia, and sometimes hearing loss. **Dermatomyositis** (see Chapter 20) or the **Lambert-Eaton myasthenic syndrome** (discussed below) may be seen in patients with underlying carcinoma. Identification of an antibody is not always possible in a suspected autoimmune paraneoplastic condition, and a search for an underlying neoplasm should not be deterred. Treatment of the neoplasm takes priority and offers the best hope for stabilization or improvement of the neurologic symptoms, which often are not completely reversible. Specific treatment of the antibody-mediated symptoms by intravenous immunoglobulin (IVIG) administration, plasmapheresis, corticosteroids, or other immunosuppressive regimens, is frequently attempted despite limited efficacy. Encephalitides involving antibodies directed against neuronal cell surface antigens, such as VGKC or AMPA, NMDA, or GABA_B receptors, can occur either as paraneoplastic phenomena or in isolation, and typically respond well to immunotherapy.

PSEUDOTUMOR CEREBRI (Benign Intracranial Hypertension)

- ▶ Headache, worse on straining.
- ▶ Visual obscurations or diplopia may occur.
- ▶ Examination reveals papilledema.
- ▶ Abducens palsy is commonly present.

▶ General Considerations

There are many causes of pseudotumor cerebri. Thrombosis of the transverse venous sinus as a noninfectious complication

of otitis media or chronic mastoiditis is one cause, and sagittal sinus thrombosis may lead to a clinically similar picture. Other causes include chronic pulmonary disease, systemic lupus erythematosus, uremia, endocrine disturbances such as hypoparathyroidism, hypothyroidism, or Addison disease, vitamin A toxicity, and the use of tetracycline or oral contraceptives. Cases have also followed withdrawal of corticosteroids after long-term use. In most instances, however, no specific cause can be found, and the disorder remits spontaneously after several months. This idiopathic variety—known as **idiopathic intracranial hypertension**—occurs most commonly among overweight women aged 20–44. In all cases, screening for a space-occupying lesion of the brain is important.

▶ Clinical Findings

A. Symptoms and Signs

Symptoms consist of headache, diplopia, and other visual disturbances due to papilledema and abducens nerve dysfunction. Pulse-synchronous tinnitus may also occur. Examination reveals the papilledema and some enlargement of the blind spots, but patients otherwise look well.

B. Imaging

Investigations reveal no evidence of a space-occupying lesion. CT scan shows small or normal ventricles. MR venography is helpful in screening for thrombosis of the intracranial venous sinuses.

C. Laboratory Findings

Lumbar puncture confirms the presence of intracranial hypertension, but the cerebrospinal fluid is normal. Laboratory studies help exclude some of the other causes mentioned earlier.

▶ Treatment

Untreated intracranial hypertension sometimes leads to secondary optic atrophy and permanent visual loss. Acetazolamide (250–500 mg orally three times daily, increasing slowly to a maintenance dose of 1000–2000 mg daily, divided two to four times daily) reduces formation of cerebrospinal fluid and can be used to start treatment. Like acetazolamide, the antiepileptic drug topiramate (Table 24–3) is a carbonic anhydrase inhibitor and was shown to be similarly effective in an open label study; topiramate has the added benefit of causing weight loss. Corticosteroids (eg, prednisone, 60–80 mg daily) may also be necessary. Obese patients should be advised to lose weight. Repeated lumbar puncture to lower the intracranial pressure by removal of cerebrospinal fluid is effective as a temporizing measure, but pharmacologic approaches to treatment provide better long-term relief. Treatment is monitored by checking visual acuity and visual fields, funduscopic appearance, and pressure of the cerebrospinal fluid. The disorder may worsen after a period of stability, indicating the need for long-term follow-up.

If medical treatment fails to control the intracranial pressure, surgical placement of a lumboperitoneal or

ventriculoperitoneal shunt or optic nerve sheath fenestration should be undertaken to preserve vision.

In addition to the above measures, any specific cause of intracranial hypertension requires appropriate treatment. Thus, hormone therapy should be initiated if there is an underlying endocrine disturbance. Discontinuing the use of tetracycline, oral contraceptives, or vitamin A will allow for resolution of intracranial hypertension due to these agents. If corticosteroid withdrawal is responsible, the medication should be reintroduced and then tapered more gradually.

▶ When to Refer

All patients should be referred.

▶ When to Admit

All patients requiring shunt placement or optic nerve sheath fenestration should be hospitalized.

SELECTED NEURO CUTANEOUS DISEASES

Because the nervous system develops from the epithelial layer of the embryo, a number of congenital diseases include both neurologic and cutaneous manifestations. Among these disorders, three are discussed below, and **von Hippel–Lindau** disease is discussed in Chapter 26.

1. Tuberous Sclerosis

Tuberous sclerosis may occur sporadically or on a familial basis with autosomal dominant inheritance. The disease is caused by mutations that inactivate either the *TSC1* (hamartin) gene on chromosome 9 or the *TSC2* (tuberin) gene on chromosome 16, resulting in constitutive expression of mTOR (mammalian target of rapamycin) and impaired tumor suppression in multiple tissues. Neurologic presentation is with seizures and progressive psychomotor retardation beginning in early childhood. The cutaneous abnormality, adenoma sebaceum, becomes manifest usually between 5 and 10 years of age and typically consists of reddened nodules on the face (cheeks, nasolabial folds, sides of the nose, and chin) and sometimes on the forehead and neck. Other typical cutaneous lesions include subungual fibromas, shagreen patches (leathery plaques of subepidermal fibrosis, situated usually on the trunk), and leaf-shaped hypopigmented spots. Associated abnormalities include retinal lesions and tumors, benign rhabdomyomas of the heart, lung cysts, benign tumors in the viscera, and bone cysts.

The disease is slowly progressive and leads to increasing mental deterioration. There is no specific treatment, but anticonvulsant drugs may help in controlling seizures.

Franz DN et al. Tuberous sclerosis complex: neurological, renal and pulmonary manifestations. *Neuropediatrics.* 2010 Oct;41(5):199–208. [PMID: 21210335]

2. Neurofibromatosis

Neurofibromatosis may occur either sporadically or on a familial basis with autosomal dominant inheritance. Two distinct forms are recognized: **Type 1 (Recklinghausen disease)** is characterized by multiple hyperpigmented macules and neurofibromas, and results from mutations in the *NF1* gene on chromosome 17. **Type 2** is characterized by **eighth nerve tumors**, often accompanied by other intracranial or intraspinal tumors, and is associated with mutations in the *NF2* (merlin) gene on chromosome 22.

Neurologic presentation is usually with symptoms and signs of tumor. Multiple neurofibromas characteristically are present and may involve spinal or cranial nerves, especially the eighth nerve (Figure 24–1). Examination of the superficial cutaneous nerves usually reveals palpable mobile nodules. In some cases, there is an associated marked overgrowth of subcutaneous tissues (plexiform neuromas), sometimes with an underlying bony abnormality. Associated cutaneous lesions include axillary freckling and patches of cutaneous pigmentation (café au lait spots). Malignant degeneration of neurofibromas occasionally occurs and may lead to peripheral sarcomas. Meningiomas, gliomas (especially optic nerve gliomas), bone cysts, pheochromocytomas, scoliosis, and obstructive hydrocephalus may also occur.

3. Sturge-Weber Syndrome

Sturge-Weber syndrome consists of a congenital, usually unilateral, cutaneous capillary angioma involving the upper face, leptomeningeal angiomatosis and, in many patients, choroidal angioma. It has no sex predilection and usually occurs sporadically. The cutaneous angioma sometimes has a more extensive distribution over the head and neck and is often quite disfiguring, especially if there is associated overgrowth of connective tissue. Focal or generalized seizures are the usual neurologic presentation and may commence at any age. There may be contralateral homonymous hemianopia, hemiparesis and hemisensory disturbance, ipsilateral glaucoma, and mental subnormality. Skull radiographs taken after the first 2 years of life usually reveal gyriform (“tramline”) intracranial calcification, especially in the parieto-occipital region, due to mineral deposition in the cortex beneath the intracranial angioma.

Treatment is aimed at controlling seizures pharmacologically, but surgical treatment may be necessary. Ophthalmologic advice should be sought concerning the management of choroidal angioma and of increased intraocular pressure.

MOVEMENT DISORDERS

1. Benign Essential (Familial) Tremor

ESSENTIALS OF DIAGNOSIS

- ▶ Postural tremor of hands, head, or voice.
- ▶ Family history common.
- ▶ May improve temporarily with alcohol.
- ▶ No abnormal findings other than tremor.

▶ General Considerations

The cause of benign essential tremor is uncertain, but it is sometimes inherited in an autosomal dominant manner. Responsible genes have been identified at 3q13, 2p22-p25, and 6p23.

▶ Clinical Findings

Tremor may begin at any age and is enhanced by emotional stress. The tremor usually involves one or both hands, the head, or the hands and head, while the legs tend to be spared. Examination reveals no other abnormalities. Ingestion of a small quantity of alcohol commonly provides remarkable but short-lived relief by an unknown mechanism.

Although the tremor may become more conspicuous with time, it generally leads to little disability. Occasionally, it interferes with manual skills and leads to impairment of handwriting. Speech may also be affected if the laryngeal muscles are involved.

▶ Treatment

Treatment is often unnecessary. When it is required because of disability, propranolol may be helpful but will need to be continued indefinitely in doses of 60–240 mg daily orally. However, intermittent therapy is sometimes useful in patients whose tremor becomes exacerbated in specific predictable situations. Primidone may be helpful when propranolol is ineffective, but patients with essential tremor are often very sensitive to it. Therefore, the starting dose is 50 mg daily orally, and the daily dose is increased by 50 mg every 2 weeks depending on the patient’s response; a maintenance dose of 125 mg three times daily orally is commonly effective. Occasional patients do not respond to these measures but are helped by alprazolam (up to 3 mg daily in divided doses), topiramate (titrated up to a dose of 400 mg daily orally in divided doses over about 8 weeks), gabapentin (1800 mg daily orally in divided doses), mirtazapine (15 or 30 mg at night orally), or clozapine (30–50 mg twice daily orally). Other antiepileptic agents including levetiracetam and zonisamide are reportedly sometimes effective. Botulinum toxin A may reduce tremor, but adverse effects include dose-dependent weakness of the injected muscles. Pregabalin was recently shown to be ineffective.

Disabling tremor unresponsive to medical treatment may be helped by high-frequency thalamic stimulation to one or both hemispheres, according to the laterality of symptoms. Subdural motor cortex stimulation has also been effective in a small trial.

▶ When to Refer

All patients should be referred.

▶ When to Admit

Patients requiring surgical treatment (deep brain stimulation placement) should be hospitalized.

2. Parkinsonism

ESSENTIALS OF DIAGNOSIS

- ▶ Any combination of tremor, rigidity, bradykinesia, and progressive postural instability.
- ▶ Cognitive impairment is sometimes prominent.

► General Considerations

Parkinsonism is a relatively common disorder that occurs in all ethnic groups, with an approximately equal sex distribution. The most common variety, idiopathic Parkinson disease, begins most often between 45 and 65 years of age and is a progressive disease.

► Etiology

Parkinsonism may rarely occur on a familial basis, and the parkinsonian phenotype may result from mutations of several different genes (alpha-synuclein, parkin, *LRRK2*, *DJ1*, and *PINK1*). Mutations in *LRRK2* also account for some cases of apparently sporadic Parkinson disease. Postencephalitic parkinsonism is becoming increasingly rare. Exposure to certain toxins (eg, manganese dust, carbon disulfide) and severe carbon monoxide poisoning may lead to parkinsonism. Typical parkinsonism has occurred in individuals who have taken 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP) for recreational purposes. This compound is converted in the body to a neurotoxin that selectively destroys dopaminergic neurons in the substantia nigra. Reversible parkinsonism may develop in patients receiving neuroleptic drugs (see Chapter 25), reserpine, or metoclopramide. Only rarely is hemiparkinsonism the presenting feature of a progressive space-occupying lesion.

In idiopathic Parkinson disease, dopamine depletion due to degeneration of the dopaminergic nigrostriatal system leads to an imbalance of dopamine and acetylcholine, which are neurotransmitters normally present in the corpus striatum. Treatment is directed at redressing this imbalance by blocking the effect of acetylcholine with anticholinergic drugs or by the administration of levodopa, the precursor of dopamine. The serum urate level may be a prognostic indicator—the rate of progression declines as the urate level increases. Prior use of ibuprofen is associated with a decreased risk of developing Parkinson disease.

► Clinical Findings

Tremor, rigidity, bradykinesia, and postural instability are the cardinal features of parkinsonism and may be present in any combination. There may also be a mild decline in intellectual function. The tremor of about four to six cycles per second is most conspicuous at rest, is enhanced by emotional stress, and is often less severe during voluntary activity. Although it may ultimately be present in all limbs, the tremor is commonly confined to one limb or to the limbs on one side for months or years before it becomes more generalized. In some patients, tremor is absent.

Rigidity (an increase in resistance to passive movement) is responsible for the characteristically flexed posture seen in many patients, but the most disabling symptoms of parkinsonism are due to bradykinesia, manifested as a slowness of voluntary movement and a reduction in automatic movements such as swinging of the arms while walking. Curiously, however, effective voluntary activity may briefly be regained during an emergency (eg, the patient is able to leap aside to avoid an oncoming motor vehicle).

Clinical diagnosis of the well-developed syndrome is usually simple. The patient has a relatively immobile face

with widened palpebral fissures, infrequent blinking, and a certain fixity of facial expression. Seborrhea of the scalp and face is common. There is often mild blepharoclonus, and a tremor may be present about the mouth and lips. Repetitive tapping (about twice per second) over the bridge of the nose produces a sustained blink response (Myerson sign). Other findings may include saliva drooling from the mouth, perhaps due to impairment of swallowing; soft and poorly modulated voice; a variable rest tremor and rigidity in some or all of the limbs; slowness of voluntary movements; impairment of fine or rapidly alternating movements; and micrographia. There is typically no muscle weakness (provided that sufficient time is allowed for power to be developed) and no alteration in the tendon reflexes or plantar responses. It is difficult for the patient to arise from a sitting position and begin walking. The gait itself is characterized by small shuffling steps and a loss of the normal automatic arm swing; there may be unsteadiness on turning, difficulty in stopping, and a tendency to fall.

► Differential Diagnosis

Diagnostic problems may occur in mild cases, especially if tremor is minimal or absent. For example, mild hypokinesia or slight tremor is commonly attributed to old age. Depression, with its associated expressionless face, poorly modulated voice, and reduction in voluntary activity, can be difficult to distinguish from mild parkinsonism, especially since the two disorders may coexist; in some cases, a trial of antidepressant drug therapy is necessary. The family history, the character of the tremor, and lack of other neurologic signs should distinguish essential tremor from parkinsonism. **Wilson disease** can be distinguished by its early age at onset, the presence of other abnormal movements, Kayser-Fleischer rings, and chronic hepatitis, and by increased concentrations of copper in the tissues. **Huntington disease** presenting with rigidity and bradykinesia may be mistaken for parkinsonism unless the family history and accompanying dementia are recognized. In **multisystem atrophy** (previously called the **Shy-Drager syndrome**), autonomic insufficiency (leading to postural hypotension, anhidrosis, disturbances of sphincter control, erectile dysfunction, etc) may be accompanied by parkinsonism, pyramidal deficits, lower motor neuron signs, or cerebellar dysfunction. In **progressive supranuclear palsy**, bradykinesia and rigidity are accompanied by a supranuclear disorder of eye movements, pseudobulbar palsy, pseudo-emotional lability (pseudobulbar affect), and axial dystonia. **Jakob-Creutzfeldt disease** may be accompanied by features of parkinsonism, but dementia is usual, myoclonic jerking is common, ataxia and pyramidal signs may be conspicuous, and the electroencephalographic findings are usually characteristic. In **corticobasal degeneration**, asymmetric parkinsonism is accompanied by conspicuous signs of cortical dysfunction (eg, apraxia, sensory inattention, dementia, aphasia).

► Treatment

Treatment is symptomatic. There is great interest in developing disease-modifying therapies, and trials of several

putative neuroprotective agents are in progress, as are various trials of gene therapy.

A. Medical Measures

Drug treatment is not required early in the course of Parkinson disease, but the nature of the disorder and the availability of medical treatment for use when necessary should be discussed with the patient.

1. Amantadine—Patients with mild symptoms but no disability may be helped by amantadine. This drug improves all of the clinical features of parkinsonism, but its mode of action is unclear. Side effects include restlessness, confusion, depression, skin rashes, edema, nausea, constipation, anorexia, postural hypotension, and disturbances of cardiac rhythm. However, these are relatively uncommon with the usual dose (100 mg twice daily orally). It also ameliorates dyskinesias resulting from chronic levodopa therapy.

2. Anticholinergic drugs—Anticholinergics are more helpful in alleviating tremor and rigidity than bradykinesia. Treatment is started with a small dose (Table 24-6) and gradually increased until benefit occurs or side effects limit further increments. If treatment is ineffective, the drug is gradually withdrawn and another preparation then tried.

Common side effects include dryness of the mouth, nausea, constipation, palpitations, cardiac arrhythmias, urinary retention, confusion, agitation, restlessness, drowsiness, mydriasis, increased intraocular pressure, and defective accommodation.

Anticholinergic drugs are contraindicated in patients with prostatic hyperplasia, narrow-angle glaucoma, or obstructive gastrointestinal disease and are often tolerated poorly by the elderly. They are best avoided whenever cognitive impairment or a predisposition to delirium exists.

3. Levodopa—Levodopa, which is converted in the body to dopamine, improves all of the major features of parkinsonism, including bradykinesia, but does not stop progression of the disorder. The most common early side effects of levodopa are nausea, vomiting, and hypotension, but cardiac arrhythmias may also occur. Dyskinesias, restlessness, confusion, and other behavioral changes tend to occur

somewhat later and become more common with time. Levodopa-induced dyskinesias may take any conceivable form, including chorea, athetosis, dystonia, tremor, tics, and myoclonus. An even later complication is the “on-off phenomenon,” in which abrupt but transient fluctuations in the severity of parkinsonism occur unpredictably but frequently during the day. The “off” period of marked bradykinesia has been shown to relate in some instances to falling plasma levels of levodopa. During the “on” phase, dyskinesias are often conspicuous but mobility is increased.

Carbidopa, which inhibits the enzyme responsible for the breakdown of levodopa to dopamine, does not cross the blood-brain barrier. When levodopa is given in combination with carbidopa, the extracerebral breakdown of levodopa is diminished. This reduces the amount of levodopa required daily for beneficial effects, and it lowers the incidence of nausea, vomiting, hypotension, and cardiac irregularities. Such a combination does not prevent the development of the “on-off phenomenon,” and the incidence of other side effects (dyskinesias or psychiatric complications) may actually be increased.

Sinemet, a commercially available preparation that contains carbidopa and levodopa in a fixed ratio (1:10 or 1:4), is generally used. Treatment is started with a small dose—eg, one tablet of Sinemet 25/100 (containing 25 mg of carbidopa and 100 mg of levodopa) three times daily—and gradually increased depending on the response. Sinemet CR is a controlled-release formulation (containing 25 or 50 mg of carbidopa and 100 or 200 mg of levodopa). It is sometimes helpful in reducing fluctuations in clinical response to treatment and in reducing the frequency with which medication must be taken. The commercially available combination of levodopa with both carbidopa and entacapone (Stalevo) may also be helpful in this context and is discussed in the following section on COMT inhibitors. Response fluctuations are also reduced by keeping the daily intake of protein at the recommended minimum and taking the main protein meal as the last meal of the day.

The dyskinesias and behavioral side effects of levodopa are dose-related, but reduction in dose may eliminate any therapeutic benefit. Levodopa-induced dyskinesias may also respond to amantadine or possibly levetiracetam.

Levodopa therapy is contraindicated in patients with psychotic illness or narrow-angle glaucoma. It should not be given to patients taking monoamine oxidase A inhibitors or within 2 weeks of their withdrawal, because hypertensive crises may result. Levodopa should be used with care in patients with suspected malignant melanomas or with active peptic ulcers because of concerns that it may exacerbate these disorders.

4. Dopamine agonists—Dopamine agonists act directly on dopamine receptors, and their use in parkinsonism is associated with a lower incidence of the response fluctuations and dyskinesias that occur with long-term levodopa therapy. They were previously reserved for patients who had either become refractory to levodopa or developed the “on-off phenomenon.” However, they are now best given either before the introduction of levodopa or with a low dose of Sinemet 25/100 (carbidopa 25 mg and levodopa

Table 24-6. Some anticholinergic antiparkinsonian drugs.

Drug	Usual Daily Dose
Benztropine mesylate (Cogentin)	1-6 mg
Biperiden (Akineton)	2-12 mg
Orphenadrine (Disipal, Norflex)	150-400 mg
Procyclidine (Kemadrin)	7.5-30 mg
Trihexyphenidyl (Artane)	6-20 mg

Modified, with permission, from Aminoff MJ. Pharmacologic management of parkinsonism and other movement disorders. In: *Basic & Clinical Pharmacology*, 11th ed. Katzung BG (editor). McGraw-Hill, 2009.

100 mg), one tablet three times daily when dopaminergic therapy is first introduced; the dose of Sinemet is kept constant, while the dose of the agonist is gradually increased. Bromocriptine, an ergot derivative is not widely used in the United States because of side effects, including anorexia; nausea; vomiting; constipation; postural hypotension; digital vasospasm; cardiac arrhythmias; various dyskinesias and mental disturbances; headache; nasal congestion; erythromelalgia; pulmonary infiltrates; and pericardial, pleural, or pulmonary fibrosis. In 2007, the manufacturer of pergolide, another ergot derivative and dopamine agonist, withdrew the drug from the US market after two studies showed that serious cardiac valvular abnormalities developed in some patients while taking the drug.

Pramipexole and ropinirole are two newer dopamine agonists that are not ergot derivatives. They are effective in early Parkinson disease as well as in advanced stages of the disease. In each case, the daily dose is built up gradually. Pramipexole is started at a dosage of 0.125 mg three times daily orally, and the dose is doubled after 1 week and again after another week; the daily dose is then increased by 0.75 mg at weekly intervals depending on response and tolerance. Most patients require between 0.5 and 1.5 mg three times daily orally. Ropinirole is begun in a dosage of 0.25 mg three times daily orally, and the total daily dose is increased at weekly intervals by 0.75 mg until the fourth week and by 1.5 mg thereafter. Most patients require between 2 and 8 mg three times daily for benefit. Adverse effects include fatigue, somnolence, nausea, peripheral edema, dyskinesias, confusion, and postural hypotension. Less commonly, an irresistible urge to sleep may occur, sometimes in inappropriate and hazardous circumstances. Impulse control disorders involving gambling, shopping, or sexual activity have also been related to use of dopamine agonists. Extended-release, once-daily formulations of pramipexole and ropinirole are now available with similar efficacy and tolerability as the immediate release versions.

5. Selective monoamine oxidase inhibitors—Rasagiline, a selective monoamine oxidase B inhibitor, has a clear symptomatic benefit in a daily oral dose of 1 mg, taken in the morning; it may also be used for adjunctive therapy in patients with response fluctuations to levodopa. Selegiline (5 mg orally with breakfast and lunch) is another monoamine oxidase B inhibitor that is sometimes used as adjunctive treatment for parkinsonism. By inhibiting the metabolic breakdown of dopamine, these drugs may improve fluctuations or declining response to levodopa. Although it is sometimes advised that tyramine-rich foods be avoided when either rasagiline or selegiline is taken because of the theoretical possibility of a hypertensive (“cheese”) effect, there is no clinical evidence to support the need for such dietary precautions when they are taken at the recommended dosage.

Studies have suggested (but failed to show conclusively) that rasagiline may slow the progression of Parkinson disease, and it appears to delay the need for other symptomatic therapies. For these reasons, rasagiline is often started early, particularly for patients who are young or have mild disease. However, the FDA has rejected an expansion of rasagiline’s indication to include disease modification.

6. COMT inhibitors—Catecholamine-*O*-methyltransferase inhibitors reduce the metabolism of levodopa to 3-*O*-methyl-dopa and thereby alter the plasma pharmacokinetics of levodopa, leading to more sustained plasma levels and more constant dopaminergic stimulation of the brain. Two such agents, tolcapone and entacapone, are currently available and may be used as an adjunct to levodopa-carbidopa in patients with response fluctuations or an otherwise inadequate response. Treatment results in reduced response fluctuations, with a greater period of responsiveness to administered levodopa; however, the use of these agents does not delay the eventual development of levodopa-induced dyskinesias. Tolcapone is given in a dosage of 100 mg or 200 mg three times daily orally, and entacapone is given as 200 mg with each dose of Sinemet (levodopa-carbidopa). With either preparation, the dose of Sinemet taken concurrently may have to be reduced by up to one-third to avoid side effects such as dyskinesias, confusion, hypotension, and syncope. Diarrhea is sometimes troublesome. Because rare cases of fulminant hepatic failure have followed its use, tolcapone should be avoided in patients with preexisting liver disease. Serial liver function tests should be performed at 2-week intervals for the first year and at longer intervals thereafter in patients receiving the drug—as recommended by the manufacturer. Hepatotoxicity has not been reported with entacapone, which is therefore the preferred agent, and serial liver function tests are not required.

Stalevo is the commercial preparation of levodopa combined with both carbidopa and entacapone. It is best used in patients already stabilized on equivalent doses of carbidopa/levodopa and entacapone. It is priced at or below the price of the individual ingredients (ie, carbidopa/levodopa and entacapone) and has the added convenience of requiring fewer tablets to be taken daily. It is available in three strengths: Stalevo 50 (12.5 mg of carbidopa, 50 mg of levodopa, and 200 mg of entacapone), Stalevo 100 (25 mg of carbidopa, 100 mg of levodopa, and 200 mg of entacapone), and Stalevo 150 (37.5 mg of carbidopa, 150 mg of levodopa, and 200 mg of entacapone).

7. Atypical antipsychotics—Confusion and psychotic symptoms may occur as a side effect of dopaminergic therapy or as a part of the underlying illness. They often respond to atypical antipsychotic agents, which have few extrapyramidal side effects and do not block the effects of dopaminergic medication. Olanzapine, quetiapine, and risperidone may be tried, but the most effective of these agents is clozapine, a dibenzodiazepine derivative. Clozapine may rarely cause marrow suppression, and weekly blood counts are therefore necessary for patients taking it. The patient is started on 6.25 mg at bedtime and the dosage increased to 25–100 mg/d as needed. In low doses, it may also improve iatrogenic dyskinesias.

B. General Measures

Physical therapy or speech therapy helps many patients. Cognitive impairment and psychiatric symptoms may be helped by a cholinesterase inhibitor, such as rivastigmine (3–12 mg orally daily or 4.6 or 9.5 mg/24 hours transdermally daily). The quality of life can often be improved by

the provision of simple aids to daily living, eg, rails or banisters placed strategically about the home, special table cutlery with large handles, nonslip rubber table mats, and devices to amplify the voice.

C. Surgical Measures

Thalamotomy or pallidotomy may help patients who become unresponsive to medical treatment or have intolerable side effects from antiparkinsonian agents, especially if they have no evidence of diffuse vascular disease or significant cognitive decline. Ablative surgery should generally be confined to one side because the morbidity is considerably greater after bilateral procedures. Because of their morbidity, ablative procedures have generally been supplanted by deep brain stimulation.

D. Brain Stimulation

High-frequency stimulation of the subthalamic nuclei or globus pallidus internus may benefit all the major features of the disease. Electrical stimulation of the brain has the advantage over ablative procedures of being reversible and of causing minimal or no damage to the brain, and is therefore the preferred surgical approach to treatment. There is no evidence that the natural history of Parkinson disease is affected. Deep brain stimulation is reserved for patients without cognitive impairment or psychiatric disorder who have a good response to levodopa but in whom dyskinesias or response fluctuations are problematic. It frequently takes 3–6 months after surgery to adjust stimulator programming and to achieve optimal results. Side effects include depression, apathy, impulsivity, executive dysfunction, and decreased verbal fluency in a subset of patients.

E. Gene Therapy

Injections of adeno-associated viruses encoding various human genes have been made into the subthalamic nucleus or putamen in various phase I and phase II trials. These trials are currently ongoing, but the procedure appears to be safe. Early evidence suggests that transfer of the gene for glutamic acid decarboxylase (the enzyme that produces the inhibitory neurotransmitter GABA) into the subthalamic nucleus improves motor function in patients with Parkinson disease, but it is unclear whether there is any greater benefit than subthalamic deep-brain stimulation.

► When to Refer

All patients should be referred.

► When to Admit

Patients requiring surgical treatment should be admitted.

3. Huntington Disease

ESSENTIALS OF DIAGNOSIS

- Gradual onset and progression of chorea and dementia or behavioral change.
- Family history of the disorder.
- Responsible gene identified on chromosome 4.

► General Considerations

Huntington disease is characterized by chorea and dementia. It is inherited in an autosomal dominant manner and occurs throughout the world, in all ethnic groups, with a prevalence rate of about 5 per 100,000. There is an expanded and unstable CAG trinucleotide repeat in the huntingtin gene at 4p16.3; longer repeat lengths correspond to an earlier age of onset and faster disease progression.

► Clinical Findings

A. Symptoms and Signs

Clinical onset is usually between 30 and 50 years of age. The disease is progressive and usually leads to a fatal outcome within 15–20 years. The initial symptoms may consist of either abnormal movements or intellectual changes, but ultimately both occur. The earliest mental changes are often behavioral, with irritability, moodiness, antisocial behavior, or a psychiatric disturbance, but a more obvious dementia subsequently develops. The dyskinesia may initially be no more than an apparent fidgetiness or restlessness, but eventually choreiform movements and some dystonic posturing occur. Progressive rigidity and akinesia (rather than chorea) sometimes occur in association with dementia, especially in cases with childhood onset.

B. Imaging

CT scanning or MRI usually demonstrates cerebral atrophy and atrophy of the caudate nucleus in established cases.

Positron emission tomography (PET) has shown reduced striatal metabolic rate.

► Differential Diagnosis

The diagnosis is established with a widely available genetic test, although such testing should be pursued under the guidance of a licensed genetic counselor. Chorea developing with no family history of choreoathetosis should not be attributed to Huntington disease, at least not until other causes of chorea have been excluded clinically and by appropriate laboratory studies. Nongenetic causes of chorea include stroke, systemic lupus erythematosus and related disorders, paraneoplastic syndromes, infection with HIV, and various medications. In younger patients, self-limiting Sydenham chorea develops after group A streptococcal infections on rare occasions. If a patient presents solely with progressive intellectual failure, it may not be possible to distinguish Huntington disease from other causes of dementia unless there is a characteristic family history or a dyskinesia develops.

Huntington disease–like (HDL) disorders resemble Huntington disease but the CAG trinucleotide repeat number of the huntingtin gene is normal. There are autosomal dominant (HDL1, a familial prion disease involving a mutation in the *PRNP* gene on chromosome 20; and HDL2, a triplet repeat disease involving the gene for junctophilin-3 on chromosome 16) and recessive forms (HDL3, 4p15.3).

A clinically similar autosomal dominant disorder (**dentatorubral-pallidoluysian atrophy**), manifested by chorea, dementia, ataxia, and myoclonic epilepsy, is uncommon except in persons of Japanese ancestry. It is due to a mutation in the *ATN1* gene mapping to 12p13.31. Treatment is as for Huntington disease.

► Treatment

There is no cure for Huntington disease; progression cannot be halted; and treatment is purely symptomatic. The reported biochemical changes suggest a relative underactivity of neurons containing gamma-aminobutyric acid (GABA) and acetylcholine or a relative overactivity of dopaminergic neurons. Tetrabenazine, a drug that interferes with the vesicular storage of biogenic amines, is widely used to treat the dyskinesia. The starting dose is 12.5 mg twice or three times daily orally, increasing by 12.5 mg every 5 days depending on response and tolerance; the usual maintenance dose is 25 mg three times daily. Side effects include depression, postural hypotension, drowsiness, and parkinsonian features; tetrabenazine should not be given within 14 days of taking monoamine oxidase inhibitors and is not indicated for the treatment of levodopa-induced dyskinesias. Reserpine is similar in depleting central monoamines but has more peripheral effects and a worse side-effect profile, making its use problematic in Huntington disease; if utilized, the dose is built up gradually to between 2 mg and 5 mg orally daily, depending on the response. Treatment with drugs blocking dopamine receptors, such as phenothiazines or haloperidol, may control the dyskinesia and any behavioral disturbances.

Haloperidol treatment is usually begun with a dose of 1 mg once or twice daily orally, which is then increased every 3 or 4 days depending on the response; alternatively, atypical antipsychotic agents such as quetiapine (increasing from 25 mg daily orally up to 100 mg twice daily orally as tolerated) may be tried. Amantadine in a dose of 200 mg to 400 mg daily orally is sometimes helpful for chorea. Behavioral disturbances may respond to clozapine. Attempts to compensate for the relative GABA deficiency by enhancing central GABA activity or to compensate for the relative cholinergic underactivity by giving choline chloride have not been therapeutically helpful. Neuroprotective strategies are being explored.

Offspring should be offered genetic counseling. Genetic testing permits presymptomatic detection and definitive diagnosis of the disease.

► When to Refer

All patients should be referred.

4. Idiopathic Torsion Dystonia

ESSENTIALS OF DIAGNOSIS

- Dystonic movements and postures.
- Normal birth and developmental history. No other neurologic signs.
- Investigations (including CT scan or MRI) reveal no cause of dystonia.

► General Considerations

Idiopathic torsion dystonia may occur sporadically or on a hereditary basis, with autosomal dominant, autosomal recessive, and X-linked recessive modes of transmission. One responsible gene is located at 9q34 (and has been named *DYT1*) and involves a unique mutation consisting of a GAG deletion in the major dominantly inherited disorder, and maps to the long arm of the X chromosome in the X-linked recessive form; the responsible gene in the autosomal recessive disorder is unknown. Symptoms may begin in childhood or later and persist throughout life.

► Clinical Findings

The disorder is characterized by the onset of abnormal movements and postures in a patient with a normal birth and developmental history, no relevant past medical illness, and no other neurologic signs. Investigations (including CT scan) reveal no cause for the abnormal movements. Dystonic movements of the head and neck may take the form of torticollis, blepharospasm, facial grimacing, or forced opening or closing of the mouth. The limbs may also adopt abnormal but characteristic postures. The age at onset influences both the clinical findings and the prognosis. With onset in childhood, there is usually a family history of the disorder, symptoms commonly commence in the legs, and progression is likely until there is severe disability from generalized dystonia. In contrast, when onset is later, a positive family history is unlikely, initial symptoms are often in the arms or axial structures, and severe disability does not usually occur, although generalized dystonia may ultimately develop in some patients. If all cases are considered together, about one-third of patients eventually become so severely disabled that they are confined to chair or bed, while another one-third are affected only mildly.

► Differential Diagnosis

Before a diagnosis of idiopathic torsion dystonia is made, it is imperative to exclude other causes of dystonia. Perinatal anoxia, birth trauma, and kernicterus are common causes of dystonia, but abnormal movements usually then develop before the age of 5, the early development of the patient is usually abnormal, and a history of seizures is not unusual. Moreover, examination may reveal signs of mental retardation or pyramidal deficit in addition to the movement disorder. Dystonic posturing may also occur in Wilson disease, Huntington disease, or parkinsonism; as a sequela of encephalitis lethargica or previous neuroleptic drug therapy; and in certain other disorders. In these cases, diagnosis is based on the history and accompanying clinical manifestations.

► Treatment

Idiopathic torsion dystonia usually responds poorly to drugs. Levodopa, diazepam, baclofen, carbamazepine, amantadine, or anticholinergic medication (in high dosage) is occasionally helpful; if not, a trial of treatment with tetrabenazine, phenothiazines, or haloperidol may be worthwhile. In each case, the dose has to be individualized, depending on response and tolerance. However, the doses of these latter drugs that are required for benefit lead usually to mild parkinsonism. Pallidal deep brain stimulation is helpful for medically refractory dystonia and has a lower morbidity than stereotactic thalamotomy, which is sometimes helpful in patients with predominantly unilateral limb dystonia. Potential adverse events of deep brain stimulation include cerebral infection or hemorrhage, broken leads, affective changes, and dysarthria.

A distinct variety of dominantly inherited dystonia, caused by a mutation in the gene for GTP cyclohydrolase I on chromosome 14q, is remarkably responsive to levodopa.

► When to Refer

All patients should be referred.

► When to Admit

Patients requiring surgical treatment should be admitted.

Ostrem JL et al. Treatment of dystonia with deep brain stimulation. *Neurotherapeutics*. 2008 Apr;5(2):320–30. [PMID: 18394573]

5. Focal Torsion Dystonia

A number of the dystonic manifestations that occur in idiopathic torsion dystonia may also occur as isolated phenomena. They are best regarded as focal dystonias that either occur as formes frustes of idiopathic torsion dystonia in patients with a positive family history or represent a focal manifestation of the adult-onset form of that disorder when there is no family history. Mapping of responsible genes to chromosome 8 (*DYT6*) and chromosome 18 (*DYT7*) has been reported in some instances of cervical or cranial dystonia. Medical treatment is generally unsatisfactory. A trial of the drugs used in idiopathic torsion dystonia is worthwhile, however, since a few patients do show some response. In addition, with restricted dystonias such as blepharospasm or torticollis, local injection of botulinum A toxin into the overactive muscles may produce worthwhile benefit for several weeks or months and can be repeated as needed.

Both blepharospasm and oromandibular dystonia may occur as an isolated focal dystonia. The former is characterized by spontaneous involuntary forced closure of the eyelids for a variable interval. Oromandibular dystonia is manifested by involuntary contraction of the muscles about the mouth causing, for example, involuntary opening or closing of the mouth, roving or protruding tongue movements, and retraction of the platysma.

Spasmodic torticollis, usually with onset between 25 and 50 years of age, is characterized by a tendency for the neck to twist to one side. This initially occurs episodically, but eventually the neck is held to the side. Spontaneous resolution may occur in the first year or so. The disorder is otherwise usually lifelong. Selective section of the spinal accessory nerve and the upper cervical nerve roots is sometimes helpful if medical treatment is unsuccessful. Local injection of botulinum A toxin provides benefit in most cases.

Writer's cramp is characterized by dystonic posturing of the hand and forearm when the hand is used for writing and sometimes when it is used for other tasks, eg, playing the piano or using a screwdriver or eating utensils. Drug treatment is usually unrewarding, and patients are often best advised to learn to use the other hand for activities requiring manual dexterity. Injections of botulinum A toxin are helpful in some instances.

6. Myoclonus

Occasional myoclonic jerks may occur in anyone, especially when drifting into sleep. General or multifocal myoclonus

is common in patients with idiopathic epilepsy and is especially prominent in certain hereditary disorders characterized by seizures and progressive intellectual decline, such as the lipid storage diseases. It is also a feature of various rare degenerative disorders, notably Ramsay Hunt syndrome, and is common in subacute sclerosing panencephalitis and Jakob-Creutzfeldt disease. Generalized myoclonic jerking may accompany uremic and other metabolic encephalopathies, result from therapy with levodopa or cyclic antidepressants, occur in alcohol or drug withdrawal states, or follow anoxic brain damage. It also occurs on a hereditary or sporadic basis as an isolated phenomenon in otherwise healthy subjects.

Segmental myoclonus is a rare manifestation of a focal spinal cord lesion. It may also be the clinical expression of **epilepsia partialis continua**, a disorder in which a repetitive focal epileptic discharge arises in the contralateral sensorimotor cortex, sometimes from an underlying structural lesion. An electroencephalogram is often helpful in clarifying the epileptic nature of the disorder, and CT or MRI scan may reveal the causal lesion.

Myoclonus may respond to certain anticonvulsant drugs, especially valproic acid, or to one of the benzodiazepines, particularly clonazepam (see Table 24–3). It may also respond to piracetam (up to 16.8 g daily). Myoclonus following anoxic brain damage is often responsive to oxitriptan (5-hydroxytryptophan), an investigational agent that is the precursor of serotonin, and sometimes to clonazepam. Oxitriptan is given in gradually increasing doses up to 1–1.5 mg daily. In patients with segmental myoclonus, a localized lesion should be searched for and treated appropriately.

Chang VC et al. Myoclonus. *Curr Treat Options Neurol*. 2008 May;10(3):222–9. [PMID: 18579026]

7. Wilson Disease

In this metabolic disorder, abnormal movement and posture may occur with or without coexisting signs of liver involvement. Psychiatric and neuropsychological manifestations are common. Wilson disease is discussed in Chapter 16.

Lorincz MT. Neurologic Wilson's disease. *Ann N Y Acad Sci*. 2010 Jan;1184:173–87. [PMID: 20146697]

8. Drug-Induced Abnormal Movements

Phenothiazines, butyrophenones, and metoclopramide may produce a wide variety of abnormal movements, including parkinsonism, akathisia (ie, motor restlessness), acute dystonia, chorea, and tardive dyskinesias or dystonia; several of these are also produced by aripiprazole. These complications are discussed in Chapter 25. Chorea may also develop in patients receiving levodopa, bromocriptine, anticholinergic drugs, phenytoin, carbamazepine, lithium, amphetamines, or oral contraceptives, and it resolves with withdrawal of the offending substance. Similarly, dystonia may be produced by levodopa, bromocriptine, lithium, or carbamazepine; and parkinsonism

by reserpine and tetrabenazine. Postural tremor may occur with a variety of drugs, including epinephrine, isoproterenol, theophylline, caffeine, lithium, thyroid hormone, tricyclic antidepressants, and valproic acid.

9. Restless Legs Syndrome

This disorder may occur as a primary (idiopathic) disorder or in relation to Parkinson disease, pregnancy, iron deficiency anemia, peripheral neuropathy (especially uremic or diabetic), or periodic leg movements of sleep. It may have a hereditary basis, and several genetic loci have been associated with the disorder (12q12–q21, 14q13–q21, 9p24–p22, 2q33, 20p13, 6p21, and 2p14–p13). Restlessness and curious sensory disturbances lead to an irresistible urge to move the limbs, especially during periods of relaxation. Disturbed nocturnal sleep and excessive daytime somnolence may result. Therapy is with nonergot dopamine agonists, such as pramipexole (0.125–0.5 mg once daily or ropinirole (0.25–4 mg once daily) 2 to 3 hours before bedtime, or with benzodiazepines, such as clonazepam. Gabapentin (starting with 300 mg daily, increasing to approximately 1800 mg daily depending on response and tolerance), pregabalin (150–300 mg divided twice to three times daily), or gabapentin enacarbil (600 mg extended release daily) are related drugs that improve symptoms. Levodopa is helpful but may lead to an augmentation of symptoms, so that its use is generally reserved for those who do not respond to other measures. In some instances, opioids are required to control symptoms.

10. Gilles de la Tourette Syndrome

ESSENTIALS OF DIAGNOSIS

- ▶ Multiple motor and phonic tics.
- ▶ Symptoms begin before age 21 years.
- ▶ Tics occur frequently for at least 1 year.
- ▶ Tics vary in number, frequency, and nature over time.

▶ Clinical Findings

Motor tics are the initial manifestation in 80% of cases and most commonly involve the face, whereas in the remaining

20%, the initial symptoms are phonic tics; ultimately a combination of different motor and phonic tics develop in all patients. These are noted first in childhood, generally between the ages of 2 and 15. Motor tics occur especially about the face, head, and shoulders (eg, sniffing, blinking, frowning, shoulder shrugging, head thrusting, etc). Phonic tics commonly consist of grunts, barks, hisses, throat-clearing, coughs, etc, but sometimes also of verbal utterances including coprolalia (obscene speech). There may also be echolalia (repetition of the speech of others), echopraxia (imitation of others' movements), and palilalia (repetition of words or phrases). Some tics may be self-mutilating in nature, such as nail-biting, hair-pulling, or biting of the lips or tongue. The disorder is chronic, but the course may be punctuated by relapses and remissions. Obsessive-compulsive behaviors are commonly associated and may be more disabling than the tics themselves. A family history is sometimes obtained, and a mutation in the histidine decarboxylase gene on chromosome 15 was recently reported in one family with an autosomal dominant form of the disease. Prior reports of a linkage to chromosome 13q have been called into question.

Examination usually reveals no abnormalities other than the tics. In addition to obsessive-compulsive behavior disorders, psychiatric disturbances may occur because of the associated cosmetic and social embarrassment. The diagnosis of the disorder is often delayed for years, the tics being interpreted as psychiatric illness or some other form of abnormal movement. Patients are thus often subjected to unnecessary treatment before the disorder is recognized. The tic-like character of the abnormal movements and the absence of other neurologic signs should differentiate this disorder from other movement disorders presenting in childhood. Wilson disease, however, can simulate the condition and should be excluded.

▶ Treatment

Treatment is symptomatic and may need to be continued indefinitely. Cognitive behavioral therapy or other forms of behavioral intervention can be effective alone or in combination with pharmacotherapy. α -Adrenergic agonists, such as clonidine (start 0.05 mg orally at bedtime, titrating to 0.3–0.4 mg orally daily, divided three to four times per day) or guanfacine (start 0.5 mg orally at bedtime, titrating to a maximum of 3–4 mg orally daily, divided twice daily) are first-line therapies because of a favorable side-effect profile compared with typical antipsychotics, which are the only FDA-approved therapies for the disorder. Topiramate has shown promise in a double-blind, placebo-controlled study, and the use of tetrabenazine has been described but not rigorously tested. Atypical antipsychotics, including risperidone and aripiprazole, have shown possible efficacy and may be tried before the typical antipsychotic agents. When a typical antipsychotic is required in cases of severe tics, haloperidol is generally regarded as the drug of choice. It is started in a low dose (0.25 mg daily orally) that is gradually increased (by 0.25 mg every 4 or 5 days) until there is maximum benefit with a minimum of side effects or until side effects limit further increments. A total daily oral dose

of between 2 mg and 8 mg is usually optimal, but higher doses are sometimes necessary. Fluphenazine (2–15 mg orally daily) or pimozide (1–10 mg orally daily) are alternatives. Typical antipsychotics can cause significant weight gain and carry a risk of tardive dyskinesias and other long-term, potentially irreversible motor side effects.

Injection of botulinum toxin type A at the site of the most distressing tics is sometimes worthwhile. Bilateral high-frequency deep brain stimulation at various sites has been helpful in some, otherwise intractable, cases.

▶ When to Refer

All patients with Gilles de la Tourette syndrome should be referred.

▶ When to Admit

Patients undergoing surgical (deep brain stimulation) treatment should be admitted.

Jankovic J et al. A randomised, double-blind, placebo-controlled study of topiramate in the treatment of Tourette syndrome. *J Neurol Neurosurg Psychiatry*. 2010 Jan;81(1):70–3. [PMID: 19726418]

Sassi M et al. Deep brain stimulation therapy for treatment-refractory Tourette's syndrome: a review. *Acta Neurochir (Wien)*. 2011 Mar;153(3):639–45. [PMID: 20853121]

DEMENTIA

ESSENTIALS OF DIAGNOSIS

- ▶ Progressive intellectual decline.
- ▶ Not due to delirium or psychiatric disease.
- ▶ Age is the main risk factor, followed by family history and vascular disease risk factors.

▶ General Considerations

Dementia is a progressive decline in intellectual function that is severe enough to compromise social or occupational functioning. “Mild cognitive impairment” describes a decline that has not resulted in a change in the level of function. Although a few patients identify a precipitating event, most experience an insidious onset and gradual progression of symptoms.

Dementia typically begins after age 60, and the prevalence doubles approximately every 5 years thereafter; in persons aged 85 and older, around half have dementia. In most, the cause of dementia is acquired, either as a sporadic primary neurodegenerative disease or as the result of another disorder, such as stroke. Other risk factors for dementia include family history, diabetes mellitus and other vascular disease risk factors, and a history of significant head injury. Dementia is more prevalent among women, but this is accounted for by their longer life expectancy. Education and ongoing intellectual stimulation may

be protective, perhaps by promoting a “cognitive reserve,” an improved capacity to compensate for insidious neurodegeneration.

Dementia is distinct from delirium and psychiatric disease. **Delirium** is an acute confusional state that often occurs in response to an identifiable trigger, such as drug or alcohol intoxication or withdrawal (eg, Wernicke encephalopathy, described below); medication side effects (especially drugs with anticholinergic properties, antihistamines, benzodiazepines, sleeping aids, opioids, neuroleptics, corticosteroids, and other sedative or psychotropic agents), infection (consider occult urinary tract infection or pneumonia in elderly patients), metabolic disturbance (including an electrolyte abnormality; hypoglycemia or hyperglycemia; or a nutritional, endocrine, renal, or hepatic disorder), sleep deprivation, or other neurologic disease (seizure, including a postictal state, or stroke). A delirium typically involves fluctuating level of arousal, including drowsiness or agitation, and it improves after removal or treatment of the precipitating factor. Patients with dementia are especially susceptible to episodes of delirium, but recognition of the dementia is not possible until the delirium lifts. For this reason, dementia is typically diagnosed in outpatients who are otherwise medically stable, rather than in acutely ill patients in the hospital.

Psychiatric disease sometimes leads to complaints of impaired cognition. Impaired attention is usually to blame, and in some patients with depression or anxiety, poor focus and concentration may even be a primary complaint. The symptoms should improve with appropriate psychiatric treatment. Mood disorders are commonly seen in patients with neurodegenerative disease and in some cases are an early symptom. There is some evidence that a persistent, untreated mood disorder may predispose to the development of an age-related dementia, and psychiatric symptoms can clearly exacerbate cognitive impairment in patients who already have dementia; therefore, suspicion of dementia should not distract from appropriate screening for and treatment of depression or anxiety.

► Clinical Findings

A. Symptoms and Signs

Physicians should be aware that a patient’s insight into a cognitive change may be vague or absent, and collateral history is essential to a proper evaluation. As patients age, primary care clinicians should inquire periodically about the presence of any cognitive symptoms.

Symptoms depend on the area of the brain affected. **Short-term memory loss**, involving the repeating of questions or stories and a diminished ability to recall the details of recent conversations or events, frequently results from pathologic changes in the hippocampus. **Word-finding difficulty** often involves difficulty recalling the names of people, places, or objects, with low-frequency words affected first, eventually resulting in speech laden with pronouns and circumlocutions. This problem is thought to arise from pathology at the temporoparietal junction of the left hemisphere. Problems with articulation, fluency, comprehension, or word meaning are anatomically distinct and

less common. **Visuospatial dysfunction** may result in poor navigation and getting lost in familiar places, impaired recognition of previously familiar faces and buildings, or trouble discerning an object against a background. The right parietal lobe is one of the brain areas implicated in such symptoms. **Executive dysfunction** may manifest by easy distractibility, impulsivity, mental inflexibility, concrete thought, slowed processing speed, poor planning and organization, or impaired judgment. Localization may vary and could include the frontal lobes or subcortical areas like the basal ganglia or cerebral white matter. **Apathy** or indifference, separate from depression, is common and may have a similar anatomy as executive dysfunction. **Apraxia**, or the loss of learned motor behaviors, may result from dysfunction of the frontal or parietal lobes, especially the left parietal lobe.

The time of symptom onset must be established, but subtle, early symptoms are often apparent only in retrospect. Another event, such as an illness or hospitalization, may lead to a new recognition of existing symptoms. Symptoms often accumulate over time, and the nature of the earliest symptom is most helpful in forming the differential diagnosis. The history should establish risk factors for dementia, including family history, other chronic illnesses, and vascular disease risk factors. Finally, it is important to document the patient’s current capacity to perform basic and instrumental activities of daily living (see Chapter 4) and to note the extent of decline from the premorbid level of function. Indeed, it is this functional assessment that defines the presence and severity of a dementia.

The physical examination is important to identify any occult medical illness. In addition, eye movement abnormalities, parkinsonism (see above), or other motor abnormalities may help identify an underlying neurologic condition. The workup should prioritize the exclusion of conditions that are reversible or require separate therapy. Screening for depression is necessary, along with imaging and laboratory workup, as indicated below.

B. Neuropsychological Assessment

Brief quantification of cognitive impairment is indicated in a patient complaining of cognitive symptoms. The Folstein Mini Mental State Exam (MMSE) is commonly used, and can be administered in approximately 5 minutes. The Montreal Cognitive Assessment takes slightly longer and may be slightly more sensitive. These tests are useful because they are objective and widely used, but both have important limitations: they are insensitive to mild cognitive impairment, they may be biased negatively by the presence of language or attention problems, and they do not correlate with functional capacity.

An evaluation by a trained neuropsychologist or psychometrician may be appropriate. The goal of such testing is to enhance localization by defining the cognitive domains that are impaired as well as to quantify the degree of impairment. There is no standard battery of tests, but a variety of metrics are commonly used to assess all of the symptom types highlighted above. Assessments are most accurate when a patient is well-rested, comfortable, and otherwise medically stable.

In an asymptomatic patient, there is no screening guideline. Because occult cognitive impairment can lead to morbidity through isolation and poor attentiveness to basic needs (for instance, in an elderly individual living alone), periodic screening is prudent for patients in their 70s and older: Ask the patient to repeat three simple nouns (not referring to objects in the room), then to draw a clock face with numbers in the correct place and the hands indicating a time of 11:10, and finally to recall the three nouns; recall of fewer than three words or any abnormality in the clock drawing may signify the need to continue with the full MMSE and to pursue further questioning and workup.

C. Imaging

Brain imaging is indicated in any patient with a new, progressive cognitive complaint. The goal is to exclude occult cerebrovascular disease, tumor, or other identifiable structural abnormality, rather than to provide positive evidence of a neurodegenerative disease. Global or focal brain atrophy may be worse than expected for age and could suggest a particular neurodegenerative process, but such findings are rarely specific. MRI is preferred, but CT scan will suffice; no contrast is necessary. If MRI is obtained, then diffusion-weighted sequences may be helpful if acute stroke or prion disease is a consideration.

Positron-emission tomography (PET) with fluorodeoxyglucose (FDG) may identify particular brain structures that are hypometabolic and thus likely to harbor pathology. PET imaging does not confirm or exclude any specific cause of dementia but may be useful as an element of the workup in specific clinical circumstances, such as discriminating between Alzheimer disease and frontotemporal dementia in a patient with some symptoms of each. PET imaging with a radiolabeled ligand for β -amyloid, one of the pathologic proteins in Alzheimer disease, is nearing FDA approval and may soon be available. This technique may be quite helpful in diagnosing Alzheimer disease in younger patients. However, after age 60 or 70, amyloid plaques can accumulate in the absence of cognitive impairment; thus, the specificity of a positive amyloid scan diminishes with age. Single photon-emission computed tomography offers similar information as FDG-PET but is less sensitive.

D. Laboratory Findings

Serum levels of vitamin B₁₂, free T₄, and thyroid-stimulating hormone should be measured for any patient with cognitive symptoms. A serum rapid plasma regain (RPR) used to be obtained routinely, but now is done only if there is a risk factor or suspicion for a remote, untreated syphilis infection. Other testing should be driven by clinical suspicion, and often includes a complete blood count, serum electrolytes, glucose, and lipid profile. Also prudent is age-appropriate cancer screening.

Other tests are available if Alzheimer disease is a consideration: ApoE genotyping is clinically available, and the presence of one or two ApoE ϵ 4 alleles indicates an increased risk of Alzheimer disease. Importantly, the gene does not cause Alzheimer disease; familial Alzheimer disease is rare and is caused by mutations in the amyloid

precursor protein or presenilin genes. Finding an ApoE ϵ 4 allele in a young patient with dementia might raise the index of suspicion for Alzheimer disease. Obtaining a genotype in an elderly patient is unlikely to be helpful, and doing so in an asymptomatic patient as a marker of risk for Alzheimer disease is inappropriate until a preventive therapy becomes available. Spinal fluid protein measurements are also now clinically available. Levels of β -amyloid decrease and tau protein increase in Alzheimer disease, but the sensitivity and specificity at discriminating from other causes of dementia is uncertain.

► Differential Diagnosis

In elderly patients with gradually progressive cognitive symptoms and no other complaint or sign, a neurodegenerative disease is likely (Table 24–7). Decline beginning before age 60, rapid progression, fluctuating course, unintended weight loss, systemic complaints, or other unexplained symptoms or signs raise suspicion for another process. In this case, the differential is broad and includes infection or inflammatory disease (consider a lumbar puncture to screen for cells or antibodies in the spinal fluid), neoplasm or a paraneoplastic condition, endocrine or metabolic disease, drugs or toxins, or other conditions. **Normal pressure hydrocephalus** is a difficult diagnosis to establish. Symptoms include gait apraxia (sometimes described as a “magnetic” gait, as if the feet are stuck to the floor), urinary incontinence, and dementia. CT scanning or MRI of the brain reveals ventricles that are enlarged in obvious disproportion to sulcal widening and overall brain atrophy. When drainage of a large volume (30–50 mL) of cerebrospinal fluid by lumbar puncture results in objective improvement of gait (such as in the time to walk 20 feet), then consideration is often given to the placement of a lumboperitoneal shunt. Unfortunately, gait disorders, incontinence, and cognitive dysfunction often occur together nonspecifically in elderly patients, and distinguishing normal pressure hydrocephalus from cerebral atrophy is not straightforward. Because of the surgical risks associated with shunt placement, as well as a strong risk for future shunt malfunction requiring further surgical intervention, the procedure should be avoided except in clear-cut cases. In general, it is the gait apraxia that is most likely to improve after surgery; the cognitive impairment is least likely to respond.

► Treatment

A. Nonpharmacologic Approaches

Aerobic exercise (45 minutes most days of the week) and frequent mental stimulation may reduce the rate of functional decline and decrease the demented patient's caregiving needs, and these interventions may reduce the risk of dementia in normal individuals. The most efficacious manner of mental stimulation is a matter of debate: maintaining as active a role in the family and community as practically possible is most likely to be of benefit, emphasizing activities at which the patient feels confident. Patients with neurodegenerative diseases have a limited capacity to regain lost skills; for instance, memory drills in a patient

Table 24-7. Common causes of age-related dementia.

Disorder	Pathology	Clinical Features
Alzheimer disease	Plaques containing β -amyloid peptide, and neurofibrillary tangles containing tau protein, occur throughout the neocortex	<ul style="list-style-type: none"> • Most common age-related neurodegenerative disease; incidence doubles every 5 years after age 60 • Short-term memory impairment is early and prominent in most cases • Variable deficits of executive function, visuospatial function, and language
Vascular dementia	Multifocal ischemic change	<ul style="list-style-type: none"> • Stepwise or progressive accumulation of cognitive deficits in association with repeated strokes • Symptoms depend on localization of strokes
Dementia with Lewy bodies	Histologically indistinguishable from Parkinson disease: α -synuclein-containing Lewy bodies occur in the brainstem, midbrain, olfactory bulb, and neocortex. Alzheimer pathology may coexist.	<ul style="list-style-type: none"> • Cognitive dysfunction, with prominent visuospatial and executive deficits • Psychiatric disturbance, with anxiety, visual hallucinations, and fluctuating delirium • Parkinsonian motor deficits with or after other features • Cholinesterase inhibitors lessen delirium; poor tolerance of many psychoactive medications, including neuroleptics and dopaminergics
Frontotemporal dementia (FTD)	Neuropathology is variable and defined by the protein found in intraneuronal aggregates. Tau protein, TAR DNA-binding protein 43 (TDP-43), or fused-in-sarcoma (FUS) protein account for most cases.	<ul style="list-style-type: none"> • Peak incidence in the sixth decade; approximately equal to Alzheimer disease as a cause of dementia in patients under 60 years old. • Familial cases result from mutations in genes for tau, progranulin, or others <p>Behavioral variant FTD</p> <ul style="list-style-type: none"> • Deficits in empathy, social comportment, insight, abstract thought, and executive function • Behavior is disinhibited, impulsive, and ritualistic, with prominent apathy and increased interest in sex or sweet/fatty foods • Relative preservation of memory • Focal right frontal atrophy • Association with amyotrophic lateral sclerosis <p>Semantic dementia</p> <ul style="list-style-type: none"> • Deficits in word-finding, single word comprehension, object and category knowledge, and face recognition • Behaviors may be rigid, ritualistic, or similar to behavioral variant FTD • Focal, asymmetric temporal pole atrophy <p>Progressive nonfluent aphasia</p> <ul style="list-style-type: none"> • Speech is effortful with dysarthria, phonemic errors, sound distortions, and poor grammar • Focal extrapyramidal signs and apraxia of the right arm and leg are common • On a diagnostic and pathological continuum with corticobasal degeneration • Focal left frontal atrophy

with Alzheimer disease are more likely to lead to frustration than benefit and studies show that computerized cognitive training does not improve cognition or function in demented patients.

B. Cognitive Symptoms

Cholinesterase inhibitors are first-line therapy for Alzheimer disease and dementia with Lewy bodies. They provide mild, symptomatic treatment for cognitive dysfunction and may prolong the capacity for independence. However, they do

not prevent disease progression. Commonly used medications include donepezil (start at 5 mg orally daily for 4 weeks, then increase to 10 mg daily; a 23 mg daily dose is newly approved for moderate to severe Alzheimer disease, although its additional efficacy over the 10-mg dose is modest); rivastigmine (start at 1.5 mg orally twice daily, then increasing every 2 weeks by 1.5 mg twice daily to a goal of 3–6 mg twice daily); and galantamine (start at 4 mg orally twice daily, then increasing every 4 weeks by 4 mg twice daily to a goal of 8–12 mg twice daily). Cholinesterase inhibitors are not given for frontotemporal dementia because they may

worsen behavioral symptoms. Nausea and diarrhea are common side effects; syncope and cardiac dysrhythmia are uncommon but more serious. An ECG is often obtained before and after starting therapy, particularly in a patient with cardiac disease or a history of syncope.

Memantine (start at 5 mg orally daily, then increase by 5 mg per week up to a target of 10 mg twice daily) is approved for the treatment of moderate to severe Alzheimer disease. In frontotemporal dementia, some open-label studies support its use, and blinded, placebo-controlled trials are underway. There is some evidence that memantine may improve cognition and behavior among patients with dementia with Lewy bodies.

Disease-modifying drugs are not yet available for Alzheimer disease. Active and passive immunotherapy directed against β -amyloid is currently being explored. Such treatment appears to increase the risk for meningeal inflammation or brain edema, especially in patients with an ApoE ϵ 4 allele, and it remains to be seen whether a counterbalancing benefit exists; phase III trials are ongoing.

C. Mood and Behavioral Disturbances

Selective serotonin reuptake inhibitors are generally safe and well-tolerated in elderly, cognitively impaired patients, and they may be efficacious for the treatment of depression, anxiety, or agitation. However, paroxetine should be avoided because it has anticholinergic effects. Other antidepressant agents, such as bupropion or venlafaxine, may also be tried. Studies on the efficacy of antidepressant therapy in this population are conflicting, but these medications are better tolerated than some alternatives (discussed here).

Insomnia is common, and trazodone (25–50 mg orally at bedtime as needed) can be safe and effective. Over-the-counter antihistamine hypnotics must be avoided, along with benzodiazepines, because of their tendency to worsen cognition and precipitate delirium. Other prescription hypnotics such as zolpidem may result in similar adverse reactions.

For agitation, impulsivity, and other behaviors that interfere with safe caregiving, causes of delirium (detailed above) should first be considered. When no reversible trigger is identified, treatment should be approached in a staged manner. Behavioral interventions, such as reorientation and distraction from anxiety-provoking stimuli, are first-line. Ensure that the patient is kept active during the day with both physical exercise and mentally stimulating activities, and that there is adequate sleep at night. Reassess the level of caregiving, and consider increasing the time spent directly with an attendant. Next, ensure that appropriate pharmacologic treatment of cognition and mood is maximized. Finally, as a last resort, when other measures prove insufficient and the patient's behaviors raise safety concerns, consider low doses of an atypical antipsychotic medication, such as quetiapine (start 25 mg orally daily as needed, increasing to two to three times daily as needed); even though atypical agents cause extrapyramidal side effects less frequently than typical antipsychotics, they should be used with particular

caution in a patient at risk for falls, especially if parkinsonian signs are already present. Regularly scheduled dosing is not recommended, and if implemented should be reassessed on a frequent basis (eg, weekly), with attempts to taper off as tolerated. There is an FDA black box warning against the use of all antipsychotic medications in demented patients because of an association with death from cardiovascular and infectious diseases, and other causes. Benzodiazepines, such as lorazepam (0.5 mg as needed, up to one to two times daily) may be used as an alternative, but they may sometimes worsen rather than ameliorate agitation.

Finally, psychostimulants like methylphenidate have been studied as a means to treat apathy in dementia. While such treatment may be of benefit to selected patients, the possibility of causing agitation or cardiovascular strain limits routine use.

► Special Circumstances

A. Rapidly Progressive Dementia

When dementia develops quickly, with obvious decline over a few weeks to a few months, the syndrome may be classified as a rapidly progressive dementia. The differential diagnosis for typical dementias is still relevant, but additional etiologies must be considered, including prion disease; infections; toxins; neoplasms; and autoimmune and inflammatory diseases, including corticosteroid-responsive (Hashimoto) encephalopathy and antibody-mediated paraneoplastic syndromes. Workup should begin with brain MRI with contrast and diffusion-weighted imaging, routine laboratory studies (serum vitamin B₁₂, free T₄, and thyroid-stimulating hormone levels), serum RPR, HIV antibody, Lyme serology, rheumatologic tests (erythrocyte sedimentation rate, C-reactive protein, and antinuclear antibody), anti-thyroglobulin and anti-thyroperoxidase antibody levels, paraneoplastic autoimmune antibodies, and cerebrospinal fluid studies (cell count and differential; protein and glucose levels; protein electrophoresis for oligoclonal bands; IgG index [spinal-fluid-to-serum gammaglobulin level] ratio; and VDRL). Depending on the clinical context, it may be necessary to exclude Wilson disease (24-hour urine copper level), heavy metal intoxication (24-hour urine heavy metal panel), and infectious encephalitis (cerebrospinal fluid polymerase chain reaction for Whipple disease, herpes simplex virus, cytomegalovirus, varicella-zoster virus, and other viruses).

Jakob-Creutzfeldt disease is a relatively common cause of rapidly progressive dementia (see Chapter 32). Family history is important since mutations in *PRNP*, the gene for the prion protein, account for around 15% of cases. Diffusion-weighted MRI is the most helpful diagnostic tool, classically revealing cortical ribboning (a gyral pattern of hyperintensity) as well as restricted diffusion in the caudate and anterior putamen. Reflecting the high rate of neuronal death, cerebrospinal fluid levels of the intraneuronal proteins tau, 14-3-3, and neuron-specific enolase are often elevated, although this finding is neither sensitive nor specific. An electroencephalogram often shows periodic complexes.

B. Driving and Dementia

It is recommended that any patient with mild dementia or worse should discontinue driving. Most states have laws regulating driving among cognitively impaired individuals, and many require the physician to report the patient's diagnosis to the public health department or department of motor vehicles. There is no evidence that driving classes help patients with neurodegenerative diseases.

▶ When to Refer

All patients with new, unexplained cognitive decline should be referred.

▶ When to Admit

Dementia alone is not an indication for admission, but admission is sometimes necessary when a superimposed delirium poses safety risks at home.

MULTIPLE SCLEROSIS

ESSENTIALS OF DIAGNOSIS

- ▶ Episodic neurologic symptoms.
- ▶ Patient usually under 55 years of age at onset.
- ▶ Single pathologic lesion cannot explain clinical findings.
- ▶ Multiple foci best visualized by MRI.

▶ General Considerations

This common neurologic disorder, which probably has an autoimmune basis, has its greatest incidence in young adults. Epidemiologic studies indicate that multiple sclerosis is much more common in persons of western European lineage who live in temperate zones. No population with a high risk for multiple sclerosis exists between latitudes 40° N and 40° S. A genetic susceptibility to the disease is present, based on twin studies, familial cases, and an association with specific HLA antigens (HLA-DR2) and alleles of

IL2RA (the interleukin-2 receptor α gene) and *IL7RA* (the interleukin-7 receptor α gene). Pathologically, focal—often perivenular—areas of demyelination with reactive gliosis are found scattered in the white matter of brain and spinal cord and in the optic nerves. Axonal damage also occurs.

▶ Clinical Findings

A. Symptoms and Signs

The common initial presentation is weakness, numbness, tingling, or unsteadiness in a limb; spastic paraparesis; retrobulbar optic neuritis; diplopia; dysequilibrium; or a sphincter disturbance such as urinary urgency or hesitancy. Symptoms may disappear after a few days or weeks, although examination often reveals a residual deficit.

Several forms of the disease are recognized. In most patients, there is an interval of months or years after the initial episode before new symptoms develop or the original ones recur (**relapsing-remitting disease**). Eventually, however, relapses and usually incomplete remissions lead to increasing disability, with weakness, spasticity, and ataxia of the limbs, impaired vision, and urinary incontinence. The findings on examination at this stage commonly include optic atrophy; nystagmus; dysarthria; and pyramidal, sensory, or cerebellar deficits in some or all of the limbs. In some of these patients, the clinical course changes so that a steady deterioration occurs, unrelated to acute relapses (**secondary progressive disease**). Less commonly, symptoms are steadily progressive from their onset, and disability develops at a relatively early stage (**primary progressive disease**). The diagnosis cannot be made with confidence unless the total clinical picture indicates involvement of different parts of the central nervous system at different times. Fatigue is common in all forms of the disease.

A number of factors (eg, infection) may precipitate or trigger exacerbations. Relapses are reduced in pregnancy but are more likely during the 2 or 3 months following pregnancy, possibly because of the increased demands and stresses that occur in the postpartum period.

B. Imaging

MRI of the brain or cervical cord has a major role in demonstrating the presence of multiple lesions. In T1-weighted images, hypointense "black holes" probably represent areas of permanent axonal damage; hyperintense lesions are also found. Gadolinium-enhanced T1-weighted images may highlight areas of inflammation with breakdown of the blood-brain barrier, which helps identify newer lesions. T2-weighted images provide information about disease burden or total number of lesions, which typically appear as areas of high signal intensity. CT scans are less helpful than MRI.

In patients with myelopathy alone and in whom there is no clinical or laboratory evidence of more widespread disease, MRI or myelography may be necessary to exclude a congenital or acquired surgically treatable lesion. The foramen magnum region must be visualized to exclude the possibility of Arnold-Chiari malformation, in which parts of the cerebellum and the lower brainstem are displaced

into the cervical canal and produce mixed pyramidal and cerebellar deficits in the limbs.

C. Laboratory and Other Studies

A definitive diagnosis can never be based solely on the laboratory findings. If there is clinical evidence of only a single lesion in the central nervous system, multiple sclerosis cannot properly be diagnosed unless it can be shown that other regions are affected subclinically. The electrocerebral responses evoked by monocular visual stimulation with a checkerboard pattern stimulus, by monaural click stimulation, and by electrical stimulation of a sensory or mixed peripheral nerve have been used to detect subclinical involvement of the visual, brainstem auditory, and somatosensory pathways, respectively. Other disorders may also be characterized by multifocal electrophysiologic abnormalities.

There may be mild lymphocytosis or a slightly increased protein concentration in the cerebrospinal fluid, especially soon after an acute relapse. Elevated IgG in cerebrospinal fluid and discrete bands of IgG (oligoclonal bands) are present in many patients. The presence of such bands is not specific, however, since they have been found in a variety of inflammatory neurologic disorders and occasionally in patients with vascular or neoplastic disorders of the nervous system.

D. Diagnosis

Multiple sclerosis should not be diagnosed unless there is evidence that two or more different regions of the central white matter have been affected at different times. A diagnosis of clinically definite disease can be made in patients with a relapsing-remitting course and evidence on examination of at least two lesions involving different regions of the central white matter. The diagnosis is probable in patients with multifocal white matter disease but only one clinical attack, or with a history of at least two clinical attacks but signs of only a single lesion. Imaging may reveal involvement of the nervous system at different times if a gadolinium-enhancing lesion is present at least 3 months after an initial clinical event at a different site than one corresponding to that event or if a new T2 lesion is found at any time compared with a baseline scan obtained at least 30 days after the initial clinical event. Dissemination in space requires three of the following: (1) at least one gadolinium-enhancing lesion or nine T2 hyperintense lesions if there is no enhancing lesion; (2) one or more infratentorial (or spinal cord) lesions; (3) one or more juxtacortical lesions; and (4) at least three periventricular lesions.

In patients with a single clinical event who do not satisfy criteria for multiple sclerosis, a diagnosis of a **clinically isolated syndrome (CIS)** is made. Such patients are at risk for developing multiple sclerosis and are sometimes offered β -interferon or glatiramer acetate therapy, which may delay progression to clinically definite disease. Follow-up MRI should be considered 6–12 months later to assess for the presence of any new lesion.

► Treatment

At least partial recovery from acute exacerbations can reasonably be expected, but further relapses may occur

without warning, and there is no means of preventing progression of the disorder. Some disability is likely to result eventually, but about half of all patients are without significant disability even 10 years after onset of symptoms.

Recovery from acute relapses may be hastened by treatment with corticosteroids, but the extent of recovery is unchanged. Intravenous therapy is given first—typically methylprednisolone 1 g daily for 3 days—followed by oral prednisone at 60–80 mg daily for 1 week with a taper over the ensuing 2–3 weeks. Long-term treatment with corticosteroids provides no benefit and does not prevent further relapses.

In patients with relapsing-remitting or secondary progressive disease, indefinite treatment with β -interferon (interferon β -1a 30 mcg intramuscularly once weekly, or 44 mcg subcutaneously three times per week; or interferon β -1b 0.25 mg subcutaneously every other day) or with subcutaneous administration of glatiramer acetate (20 mg daily) reduces the frequency of exacerbations with equal efficacy. Natalizumab, an α 4 integrin antagonist that reduces the development of brain lesions in experimental models, reduces the relapse rate when given intravenously once monthly. However, natalizumab treatment is associated with an increased risk of the development of progressive multifocal leukoencephalopathy. Its use is therefore restricted to patients with relapsing-remitting disease who have not responded to other therapies or who have a particularly aggressive initial disease course. It should be used alone and not in combination with β -interferon, glatiramer acetate, or other immune-modifying therapies. Fingolimod (0.5 mg orally daily) reduces the relapse rate in multiple sclerosis, possibly with more efficacy than interferon β -1a. Cladribine and alemtuzumab are being investigated for this indication. Several studies have suggested that immunosuppressive therapy with cyclophosphamide, azathioprine, methotrexate, or mitoxantrone may help arrest the course of secondary progressive multiple sclerosis. The evidence of benefit is incomplete, however. Plasmapheresis is sometimes helpful in patients with severe relapses unresponsive to corticosteroids. Intravenous immunoglobulins (IVIGs) may reduce the clinical attack rate in relapsing-remitting disease, but the available studies are inadequate to permit treatment recommendations. Statins may have immunomodulatory effects, and their possible role in the treatment of multiple sclerosis is being studied.

Symptomatic therapy for spasticity (see below), neurogenic bladder, or fatigue may be required. Fatigue is especially common in multiple sclerosis, and modafinil (200 mg orally every morning) is an effective and FDA-approved therapy for this indication. Dalfampridine (an extended-release formulation of 4-aminopyridine administered as 10 mg orally twice daily) is efficacious at improving timed gait in multiple sclerosis. Depression and even suicidality can occur in multiple sclerosis and may worsen with interferon β -1a therapy; screening and conventional treatment of such symptoms are appropriate.

► When to Refer

All patients, but especially those with progressive disease despite standard therapy, should be referred.

▶ When to Admit

- Patients requiring plasma exchange.
- During severe relapses.
- Patient unable to manage at home.

NEUROMYELITIS OPTICA

This disorder is characterized by optic neuritis and acute myelitis with MRI changes that extend over at least three segments of the spinal cord. An isolated myelitis or optic neuritis may also occur. Previously known as Devic disease and once regarded as a variant of multiple sclerosis, neuromyelitis optica is associated with a specific antibody marker (NMO-IgG) targeting the water channel aquaporin-4. MRI of the brain typically does not show widespread white matter involvement, but such changes do not exclude the diagnosis. Treatment is by long-term immunosuppression. Rituximab may help in reducing the risk of relapses and is undergoing clinical trials; no standard dosing regimen is yet available.

Jacob A et al. Treatment of neuromyelitis optica with rituximab: retrospective analysis of 25 patients. *Arch Neurol.* 2008 Nov; 65(11):1443–8. [PMID: 18779415]

VITAMIN E DEFICIENCY

Vitamin E deficiency may produce a disorder somewhat similar to Friedreich ataxia (see below). There is

spinocerebellar degeneration involving particularly the posterior columns of the spinal cord and leading to limb ataxia, sensory loss, absent tendon reflexes, slurring of speech and, in some cases, pigmentary retinal degeneration. The disorder may occur as a consequence of malabsorption or on a hereditary basis (eg, abetalipoproteinemia). Treatment is with α -tocopheryl acetate as discussed in Chapter 29.

SPASTICITY

The term “spasticity” is commonly used for an upper motor neuron deficit, but it properly refers to a velocity-dependent increase in resistance to passive movement that affects different muscles to a different extent, is not uniform in degree throughout the range of a particular movement, and is commonly associated with other features of pyramidal deficit. It is often a major complication of stroke, cerebral or spinal injury, static perinatal encephalopathy, and multiple sclerosis.

Physical therapy with appropriate stretching programs is important during rehabilitation after the development of an upper motor neuron lesion and in subsequent management of the patient. The aim is to prevent joint and muscle contractures and perhaps to modulate spasticity.

Drug management is important also, but treatment may increase functional disability when increased extensor tone is providing additional support for patients with weak legs. Dantrolene weakens muscle contraction by interfering with the role of calcium. It is best avoided in patients with poor respiratory function or severe myocardial disease. Treatment is begun with 25 mg once daily, and the daily dose is built up by 25 mg increments every 3 days, depending on tolerance, to a maximum of 100 mg four times daily. Side effects include diarrhea, nausea, weakness, hepatic dysfunction (that may rarely be fatal, especially in women older than 35), drowsiness, light-headedness, and hallucinations.

Baclofen is an effective drug for treating spasticity of spinal origin and painful flexor (or extensor) spasms. The maximum recommended daily oral dose is 80 mg; treatment is started with a dose of 5 or 10 mg twice daily orally and then built up gradually. Side effects include gastrointestinal disturbances, lassitude, fatigue, sedation, unsteadiness, confusion, and hallucinations. Diazepam may modify spasticity by its action on spinal interneurons and perhaps also by influencing supraspinal centers, but effective doses often cause intolerable drowsiness and vary with different patients. Tizanidine, a centrally acting α_2 -adrenergic agonist, is as effective as these other agents and is probably better tolerated. The daily dose is built up gradually, usually to 8 mg taken three times daily. Side effects include sedation, lassitude, hypotension, and dryness of the mouth.

Intramuscular injection of botulinum toxin has been used to relax targeted muscles.

In patients with severe spasticity that is unresponsive to other therapies and is associated with marked disability, intrathecal injection of phenol or alcohol may be helpful. Surgical options include implantation of an intrathecal baclofen pump, rhizotomy, or neurectomy. Severe contractures may be treated by surgical tendon release.

Spasticity may be exacerbated by decubitus ulcers, urinary or other infections, and nociceptive stimuli.

Maanum G et al. Effects of botulinum toxin A in ambulant adults with spastic cerebral palsy: a randomized double-blind placebo controlled-trial. *J Rehabil Med*. 2011 Mar;43(4):338–47. [PMID: 21305227]

MYELOPATHIES IN AIDS

A variety of myelopathies may occur in patients with AIDS. These are discussed in Chapter 31.

MYELOPATHY OF HUMAN T CELL LEUKEMIA VIRUS INFECTION

Human T cell leukemia virus (HTLV-1), a human retrovirus, is transmitted by breast-feeding, sexual contact, blood transfusion, and contaminated needles. Most patients are asymptomatic, but after a variable latent period (which may be as long as several years) a myelopathy develops in some instances. The MRI, electrophysiologic, and cerebrospinal fluid findings are similar to those of multiple sclerosis, but HTLV-1 antibodies are present in serum and spinal fluid. There is no specific treatment, but intravenous or oral corticosteroids may help in the initial inflammatory phase of the disease. Prophylactic measures are important. Needles or syringes should not be shared; infected patients should not breastfeed their infants or donate blood, semen, or other tissue. Infected patients should use condoms to prevent sexual transmission.

Biswas HH et al. Neurologic abnormalities in HTLV-I- and HTLV-II-infected individuals without overt myelopathy. *Neurology*. 2009 Sep 8;73(10):781–9. [PMID: 19738173]

SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD

Subacute combined degeneration of the spinal cord is due to vitamin B₁₂ deficiency, such as occurs in pernicious anemia. It is characterized by myelopathy with predominant pyramidal and posterior column deficits, sometimes in association with polyneuropathy, mental changes, or optic neuropathy. Megaloblastic anemia may also occur, but this does not parallel the neurologic disorder, and the former may be obscured if folic acid supplements have been taken. Treatment is with vitamin B₁₂. For pernicious anemia, a convenient therapeutic regimen is 100 mg cyanocobalamin intramuscularly daily for 1 week, then weekly for 1 month, and then monthly for the remainder of the patient's life.

WERNICKE ENCEPHALOPATHY & KORSAKOFF SYNDROME

Wernicke encephalopathy is characterized by confusion, ataxia, and nystagmus leading to ophthalmoplegia (lateral rectus muscle weakness, conjugate gaze palsies); peripheral neuropathy may also be present. It is due to thiamine deficiency and in the United States occurs most commonly in alcoholics. It may also occur in patients with AIDS or hyperemesis gravidarum, and after surgery for obesity. In suspected cases, thiamine (100 mg) is given intravenously immediately and then intramuscularly on a daily basis until a satisfactory diet can be ensured. Intravenous glucose given before thiamine may precipitate the syndrome or worsen the symptoms. The diagnosis is confirmed by the response in 1 or 2 days to treatment, which must not be delayed while awaiting laboratory confirmation of thiamine deficiency from a blood sample obtained prior to thiamine administration. **Korsakoff syndrome** occurs in more severe cases; it includes anterograde and retrograde amnesia and sometimes confabulation, and may not be recognized until after the initial delirium has lifted.

STUPOR & COMA

ESSENTIALS OF DIAGNOSIS

- ▶ Level of consciousness is depressed.
- ▶ Stuporous patients respond only to repeated vigorous stimuli.
- ▶ Comatose patients are unarousable and unresponsive.

▶ General Considerations

The patient who is stuporous is unresponsive except when subjected to repeated vigorous stimuli, while the comatose patient is unarousable and unable to respond to external events or inner needs, although reflex movements and posturing may be present.

Coma is a major complication of serious central nervous system disorders. It can result from seizures, hypothermia, metabolic disturbances, or structural lesions causing bilateral cerebral hemispheric dysfunction or a disturbance of the brainstem reticular activating system. A mass lesion involving one cerebral hemisphere may cause coma by compression of the brainstem. All comatose patients should be admitted to hospital and referred to a neurologist or neurosurgeon.

▶ Assessment & Emergency Measures

The diagnostic workup of the comatose patient must proceed concomitantly with management. Supportive therapy

for respiration or blood pressure is initiated; in hypothermia, all vital signs may be absent and all such patients should be rewarmed before the prognosis is assessed.

The patient can be positioned on one side with the neck partly extended, dentures removed, and secretions cleared by suction; if necessary, the patency of the airways is maintained with an oropharyngeal airway. Blood is drawn for serum glucose, electrolyte, and calcium levels; arterial blood gases; liver and kidney function tests; and toxicologic studies as indicated. Dextrose 50% (25 g), naloxone (0.4–1.2 mg), and thiamine (100 mg) are given intravenously without delay.

Further details are then obtained from attendants of the patient's medical history, the circumstances surrounding the onset of coma, and the time course of subsequent events. Abrupt onset of coma suggests subarachnoid hemorrhage, brainstem stroke, or intracerebral hemorrhage, whereas a slower onset and progression occur with other structural or mass lesions. Urgent noncontrast CT scanning of the head is appropriate if it can be obtained directly from the emergency department, in order to identify intracranial hemorrhage, brain herniation, or other structural lesion that may require immediate neurosurgical intervention. A metabolic cause is likely with a preceding intoxicated state or agitated delirium. On examination, attention is paid to the behavioral response to painful stimuli, the pupils and their response to light, the position of the eyes and their movement in response to passive movement of the head and ice-water caloric stimulation, and the respiratory pattern.

A. Response to Painful Stimuli

Purposive limb withdrawal from painful stimuli implies that sensory pathways from and motor pathways to the stimulated limb are functionally intact. Unilateral absence of responses despite application of stimuli to both sides of the body in turn implies a corticospinal lesion; bilateral absence of responsiveness suggests brainstem involvement, bilateral pyramidal tract lesions, or psychogenic unresponsiveness. Inappropriate responses may also occur. Decorticate posturing may occur with lesions of the internal capsule and rostral cerebral peduncle, decerebrate posturing with dysfunction or destruction of the midbrain and rostral pons, and decerebrate posturing in the arms accompanied by flaccidity or slight flexor responses in the legs in patients with extensive brainstem damage extending down to the pons at the trigeminal level.

B. Ocular Findings

1. Pupils—Hypothalamic disease processes may lead to unilateral Horner syndrome, while bilateral diencephalic involvement or destructive pontine lesions may lead to small but reactive pupils. Ipsilateral pupillary dilation with no direct or consensual response to light occurs with compression of the third cranial nerve, eg, with uncal herniation. The pupils are slightly smaller than normal but responsive to light in many metabolic encephalopathies; however, they may be fixed and dilated following overdose

with atropine or scopolamine, and pinpoint (but responsive) with opioids. Pupillary dilation for several hours following cardiopulmonary arrest implies a poor prognosis.

2. Eye movements—Conjugate deviation of the eyes to the side suggests the presence of an ipsilateral hemispheric lesion or a contralateral pontine lesion. A mesencephalic lesion leads to downward conjugate deviation. Dysconjugate ocular deviation in coma implies a structural brainstem lesion unless there was preexisting strabismus.

The oculomotor responses to passive head turning and to caloric stimulation relate to each other and provide complementary information. In response to brisk rotation of the head from side to side and to flexion and extension of the head, normally conscious patients with open eyes do not exhibit contraversive conjugate eye deviation (doll's-head eye response) unless there is voluntary visual fixation or bilateral frontal pathology. With cortical depression in lightly comatose patients, a brisk doll's-head eye response is seen. With brainstem lesions, this oculocephalic reflex becomes impaired or lost, depending on the site of the lesion.

The oculovestibular reflex is tested by caloric stimulation using irrigation with ice water. In normal subjects, jerk nystagmus is elicited for about 2 or 3 minutes, with the slow component toward the irrigated ear. In unconscious patients with an intact brainstem, the fast component of the nystagmus disappears, so that the eyes tonically deviate toward the irrigated side for 2–3 minutes before returning to their original position. With impairment of brainstem function, the response becomes perverted and finally disappears. In metabolic coma, oculocephalic and oculovestibular reflex responses are preserved, at least initially.

C. Respiratory Patterns

Diseases causing coma may lead to respiratory abnormalities. Cheyne-Stokes respiration (in which episodes of deep breathing alternate with periods of apnea) may occur with bihemispheric or diencephalic disease or in metabolic disorders. Central neurogenic hyperventilation occurs with lesions of the brainstem tegmentum; apneustic breathing (in which there are prominent end-inspiratory pauses) suggests damage at the pontine level (eg, due to basilar artery occlusion); and atactic breathing (a completely irregular pattern of breathing with deep and shallow breaths occurring randomly) is associated with lesions of the lower pontine tegmentum and medulla.

1. Stupor & Coma Due to Structural Lesions

Supratentorial mass lesions tend to affect brain function in an orderly way. There may initially be signs of hemispheric dysfunction, such as hemiparesis. As coma develops and deepens, cerebral function becomes progressively disturbed, producing a predictable progression of neurologic signs that suggest rostrocaudal deterioration.

Thus, as a supratentorial mass lesion begins to impair the diencephalon, the patient becomes drowsy, then

stuporous, and finally comatose. There may be Cheyne-Stokes respiration; small but reactive pupils; doll's-head eye responses with side-to-side head movements but sometimes an impairment of reflex upward gaze with brisk flexion of the head; tonic ipsilateral deviation of the eyes in response to vestibular stimulation with cold water; and initially a positive response to pain but subsequently only decorticate posturing. With further progression, midbrain failure occurs. Motor dysfunction progresses from decorticate to bilateral decerebrate posturing in response to painful stimuli; Cheyne-Stokes respiration is gradually replaced by sustained central hyperventilation; the pupils become middle-sized and fixed; and the oculocephalic and oculovestibular reflex responses become impaired, perverted, or lost. As the pons and then the medulla fail, the pupils remain unresponsive; oculovestibular responses are unobtainable; respiration is rapid and shallow; and painful stimuli may lead only to flexor responses in the legs. Finally, respiration becomes irregular and stops, the pupils often then dilating widely.

In contrast, a subtentorial (ie, brainstem) lesion may lead to an early, sometimes abrupt disturbance of consciousness without any orderly rostrocaudal progression of neurologic signs. Compressive lesions of the brainstem, especially cerebellar hemorrhage, may be clinically indistinguishable from intraparenchymal processes.

A structural lesion is suspected if the findings suggest focality. In such circumstances, a CT scan should be performed before, or instead of, a lumbar puncture in order to avoid any risk of cerebral herniation. Further management is of the causal lesion and is considered separately under the individual disorders.

In some cases of traumatic brain injury, swelling may be diffuse rather than focal. Decompressive craniectomy may reduce otherwise refractory intracranial hypertension but does not improve neurologic outcome. Hypothermic therapy is controversial.

Clifton GL et al. Very early hypothermia induction in patients with severe brain injury (the National Acute Brain Injury Study: Hypothermia II): a randomised trial. *Lancet Neurol*. 2011 Feb;10(2):131–9. [PMID: 21169065]

Cooper DJ et al. Decompressive craniectomy in diffuse traumatic brain injury. *N Engl J Med*. 2011 Apr 21;364(16):1493–502. [PMID: 21434843]

2. Stupor & Coma Due to Metabolic Disturbances

Patients with a metabolic cause of coma generally have signs of patchy, diffuse, and symmetric neurologic involvement that cannot be explained by loss of function at any single level or in a sequential manner, although focal or lateralized deficits may occur in hypoglycemia. Moreover, pupillary reactivity is usually preserved, while other brainstem functions are often grossly impaired. Comatose patients with meningitis, encephalitis, or subarachnoid hemorrhage may also exhibit little in the way of

focal neurologic signs, however, and clinical evidence of meningeal irritation is sometimes very subtle in comatose patients. Examination of the cerebrospinal fluid in such patients is essential to establish the correct diagnosis.

In patients with coma due to cerebral ischemia and hypoxia, the absence of pupillary light reflexes at the time of initial examination indicates that there is little chance of regaining independence; by contrast, preserved pupillary light responses, the development of spontaneous eye movements (roving, conjugate, or better), and extensor, flexor, or withdrawal responses to pain at this early stage imply a relatively good prognosis.

Treatment of metabolic encephalopathy is of the underlying disturbance and is considered in other chapters. If the cause of the encephalopathy is obscure, all drugs except essential ones may have to be withdrawn in case they are responsible for the altered mental status.

Stevens RD et al. Approach to the comatose patient. *Crit Care Med*. 2006 Jan;34(1):31–41. [PMID: 16374153]

Wijdicks EF et al. Practice parameter: Prediction of outcome in comatose survivors after cardiopulmonary resuscitation (an evidence-based review): Report of the Quality Standards Subcommittee of the American Academy of Neurology. *Neurology*. 2006 Jul 25;67(2):203–10. [PMID: 16864809]

3. Brain Death

The definition of brain death is controversial, and diagnostic criteria have been published by many different professional organizations. In order to establish brain death, the irreversibly comatose patient must be shown to have lost all brainstem reflex responses, including the pupillary, corneal, oculovestibular, oculocephalic, oropharyngeal, and respiratory reflexes, and should have been in this condition for at least 6 hours. Spinal reflex movements do not exclude the diagnosis, but ongoing seizure activity or decerebrate or decorticate posturing is not consistent with brain death. The apnea test (presence or absence of spontaneous respiratory activity at a $Paco_2$ of at least 60 mm Hg) serves to determine whether the patient is capable of respiratory activity.

Reversible coma simulating brain death may be seen with hypothermia (temperature $<32^\circ\text{C}$) and overdosage with central nervous system depressant drugs, and these conditions must be excluded. Certain ancillary tests may assist the determination of brain death but are not essential. An isoelectric electroencephalogram, when the recording is made according to the recommendations of the American Electroencephalographic Society, may help in confirming the diagnosis. Alternatively, the demonstration of an absent cerebral circulation by intravenous radioisotope cerebral angiography or by four-vessel contrast cerebral angiography is confirmatory.

Wijdicks EF. The case against confirmatory tests for determining brain death in adults. *Neurology*. 2010 Jul 6;75(1):77–83. [PMID: 20603486]

4. Persistent Vegetative State

Patients with severe bilateral hemispheric disease may show some improvement from an initially comatose state, so that, after a variable interval, they appear to be awake but lie motionless and without evidence of awareness or higher mental activity. This persistent vegetative state has been variously referred to as akinetic mutism, apallic state, or coma vigil. Most patients in this persistent vegetative state will die in months or years, but partial recovery has occasionally occurred and in rare instances has been sufficient to permit communication or even independent living.

5. Minimally Conscious State

In this state, patients exhibit inconsistent evidence of consciousness. There is some degree of functional recovery of behaviors suggesting self- or environmental awareness, such as basic verbalization or context-appropriate gestures, emotional responses (eg, smiling) to emotional but not neutral stimuli, or purposive responses to environmental stimuli (eg, a finger movement or eye blink apparently to command). Further improvement is manifest by the restoration of communication with the patient. The minimally conscious state may be temporary or permanent. Little information is available about its natural history or long-term outlook, which reflect the underlying cause. The likelihood of useful functional recovery diminishes with time; after 12 months, patients are likely to remain severely disabled and without a reliable means of communication. Prognostication is difficult.

6. Locked-In Syndrome (De-efferented State)

Acute destructive lesions (eg, infarction, hemorrhage, demyelination, encephalitis) involving the ventral pons and sparing the tegmentum may lead to a mute, quadriparetic but conscious state in which the patient is capable of blinking and of voluntary eye movement in the vertical plane, with preserved pupillary responses to light. Such a patient can mistakenly be regarded as comatose. Physicians should recognize that “locked-in” individuals are fully aware of their surroundings. The prognosis is usually poor, but recovery has occasionally been reported in some cases, including resumption of independent daily life.

Wilson BA et al. A case study of locked-in-syndrome: psychological and personal perspectives. *Brain Inj*. 2011;25(5):526–38. [PMID: 21457000]

HEAD INJURY

Trauma is the most common cause of death in young people, and head injury accounts for almost half of these trauma-related deaths. The incidence of head injury can be reduced by, for example, using bicycle helmets and protective equipment in sports.

The prognosis following head injury depends on the site and severity of brain damage. Some guide to prognosis

is provided by the mental status, since loss of consciousness implies a worse prognosis than otherwise. Similarly, the degree of retrograde and posttraumatic amnesia provides an indication of the severity of injury and thus of the prognosis. Absence of skull fracture does not exclude the possibility of severe head injury. During the physical examination, special attention should be given to the level of consciousness and extent of any brainstem dysfunction.

Note: Patients (especially elderly, >65 years) who are intoxicated with drugs or alcohol or have evidence of soft-tissue injury above the clavicles following head injury should be admitted to the hospital for observation, as should patients with recurrent vomiting, persistent anterograde amnesia, retrograde amnesia for more than 30 minutes, focal neurologic deficits, lethargy, or skull fractures. If admission is declined, responsible family members should be given clear instructions about the need for, and manner of, checking on them at regular (hourly) intervals and for obtaining additional medical help if necessary.

Skull radiographs or CT scans may provide evidence of fractures. Because injury to the spine may have accompanied head trauma, cervical spine radiographs (especially in the lateral projection) should always be obtained in comatose patients and in patients with severe neck pain or a deficit possibly related to cord compression.

CT scanning has an important role in demonstrating intracranial hemorrhage and may also provide evidence of cerebral edema and displacement of midline structures.

1. Cerebral Injuries

These are summarized in Table 24–8. Increased intracranial pressure may result from ventilatory obstruction, abnormal neck position, seizures, dilutional hyponatremia, or cerebral edema; an intracranial hematoma requiring surgical evacuation may also be responsible. Other measures that may be necessary to reduce intracranial pressure include induced hyperventilation, intravenous mannitol infusion, and intravenous furosemide; corticosteroids provide no benefit in this context. Overall, treatment is mainly supportive. The role of induced hypothermia in reducing long-term neurologic deficits is currently under investigation.

2. Scalp Injuries & Skull Fractures

Scalp lacerations and depressed or compound depressed skull fractures should be treated surgically as appropriate. Simple skull fractures require no specific treatment.

The clinical signs of basilar skull fracture include bruising about the orbit (raccoon sign), blood in the external auditory meatus (Battle sign), and leakage of cerebrospinal fluid (which can be identified by its glucose content) from the ear or nose. Cranial nerve palsies (involving especially the first, second, third, fourth, fifth, seventh, and eighth nerves in any combination) may also occur. If there is any leakage of cerebrospinal fluid, conservative treatment, with elevation of the head, restriction of fluids, and administration of acetazolamide (250 mg four times daily), is often helpful; but if the leak continues for more than a few days, lumbar subarachnoid drainage may be necessary.

Table 24-8. Acute cerebral sequelae of head injury.

Sequelae	Clinical Features	Pathology
Concussion	A transient, trauma-induced alteration in mental status that may or may not involve loss of consciousness. Symptoms and signs include headache, nausea, disorientation, irritability, amnesia, clumsiness, visual disturbances, and focal neurologic deficit.	Bruising on side of impact (coup injury) or contralaterally (contrecoup injury).
Cerebral contusion or laceration	Loss of consciousness longer than with concussion. Focal neurologic deficits are often present. May lead to death or severe residual neurologic deficit.	Vasogenic edema, multiple petechial hemorrhages, and mass effect. May have subarachnoid bleeding. Herniation may occur in severe cases. Cerebral laceration specifically involves tearing of the cerebral tissue and pia-arachnoid overlying a contusion.
Acute epidural hemorrhage	Headache, confusion, somnolence, seizures, and focal deficits occur several hours after injury and lead to coma, respiratory depression, and death unless treated by surgical evacuation.	Tear in meningeal artery, vein, or dural sinus, leading to hematoma visible on CT scan.
Acute subdural hemorrhage	Similar to epidural hemorrhage, but interval before onset of symptoms is longer. Treatment is by surgical evacuation.	Hematoma from tear in veins from cortex to superior sagittal sinus or from cerebral laceration, visible on CT scan.
Cerebral hemorrhage	Generally develops immediately after injury. Clinically resembles hypertensive hemorrhage. Surgical evacuation is sometimes helpful.	Hematoma, visible on CT scan.
Diffuse axonal injury	Persistent loss of consciousness, coma, or persistent vegetative state resulting from severe rotational shearing forces or deceleration.	Imaging may be normal or may show tiny, scattered white matter hemorrhages. Histology reveals torn axons.

Antibiotics are given if infection occurs, based on culture and sensitivity studies. Only very occasional patients require intracranial repair of the dural defect because of persistence of the leak or recurrent meningitis.

3. Late Complications of Head Injury

The relationship of chronic subdural hemorrhage to head injury is not always clear. In many elderly persons there is no history of trauma, but in other cases a head injury, often trivial, precedes the onset of symptoms by several weeks. The clinical presentation is usually with mental changes such as slowness, drowsiness, headache, confusion, memory disturbances, personality change, or even dementia. Focal neurologic deficits such as hemiparesis or hemisensory disturbance may also occur but are less common. CT scan is an important means of detecting the hematoma, which is sometimes bilateral. Treatment is by surgical evacuation to prevent cerebral compression and tentorial herniation. There is no clear evidence that prophylactic anticonvulsant therapy reduces the incidence of post-traumatic seizures.

After major head injury causing severe, acute mental status changes, cognitive deficits may persist indefinitely. Memory training may be a helpful component of rehabilitation. In addition, there is an association between head trauma and the later development of a neurodegenerative disease, such as Alzheimer or Parkinson disease and amyotrophic lateral sclerosis.

Normal-pressure hydrocephalus may follow head injury, subarachnoid hemorrhage, or meningoencephalitis. Other late complications of head injury include posttraumatic seizure disorder, headache, vertigo, and hyposmia.

▶ When to Refer

- Patients with focal neurologic deficits, altered consciousness, or skull fracture.
- Patients with late complications of head injury, eg, post-traumatic seizure disorder or normal pressure hydrocephalus.

▶ When to Admit

- Patients (especially elderly, >65 years) who are intoxicated with drugs or alcohol or have evidence of soft-tissue injury above the clavicles should be admitted for observation.
- Patients with recurrent vomiting, focal neurologic deficits, persistent anterograde amnesia, retrograde amnesia for more than 30 minutes, altered consciousness, or skull fracture.
- Patients with acute epidural, subdural, or cerebral hematoma.
- Patients requiring shunt placement for normal pressure hydrocephalus.

SPINAL TRAUMA

ESSENTIALS OF DIAGNOSIS

- ▶ History of preceding trauma.
- ▶ Development of acute neurologic deficit.
- ▶ Signs of myelopathy on examination.

▶ General Considerations

While spinal cord damage may result from whiplash injury, severe injury usually relates to fracture-dislocation causing compression or angular deformity of the cord either cervically or in the lower thoracic and upper lumbar regions. Extreme hypotension following injury may also lead to cord infarction.

▶ Clinical Findings

Total cord transection results in immediate flaccid paralysis and loss of sensation below the level of the lesion. Reflex activity is lost for a variable period, and there is urinary and fecal retention. As reflex function returns over the following days and weeks, spastic paraplegia or quadriplegia develops, with hyperreflexia and extensor plantar responses, but a flaccid atrophic (lower motor neuron) paralysis may be found depending on the segments of the cord that are affected. The bladder and bowels also regain some reflex function, permitting urine and feces to be expelled at intervals. As spasticity increases, flexor or extensor spasms (or both) of the legs become troublesome, especially if the patient develops bed sores or a urinary tract infection. Paraplegia with the legs in flexion or extension may eventually result.

With lesser degrees of injury, patients may be left with mild limb weakness, distal sensory disturbance, or both. Sphincter function may also be impaired, urinary urgency and urgency incontinence being especially common. More particularly, a unilateral cord lesion leads to an ipsilateral motor disturbance with accompanying impairment of proprioception and contralateral loss of pain and temperature appreciation below the lesion (Brown-Séquard syndrome). A central cord syndrome may lead to a lower motor neuron deficit and loss of pain and temperature appreciation, with sparing of posterior column functions. A radicular deficit may occur at the level of the injury—or, if the cauda equina is involved, there may be evidence of disturbed function in several lumbosacral roots.

▶ Treatment

Treatment of the injury consists of immobilization and—if there is cord compression—early decompressive laminectomy and fusion (within 24 hours). Early treatment with high doses of corticosteroids (eg, methylprednisolone, 30 mg/kg by intravenous bolus, followed by 5.4 mg/kg/h for 23 hours) may improve neurologic recovery if commenced within 8 hours after injury; the findings from various studies are conflicting, however, and evaluation of the published evidence suggest that significant benefit is unlikely. Anatomic realignment of the spinal cord by traction and other orthopedic procedures is important. Subsequent care of the residual neurologic deficit—paraplegia or quadriplegia—requires treatment of spasticity and care of the skin, bladder, and bowels.

▶ When to Refer

All patients with focal neurologic deficits should be referred.

▶ When to Admit

- Patients with neurologic deficits.
- Patients with spinal cord injury, compression, or acute epidural or subdural hematoma.
- Patients with vertebral fracture-dislocation likely to compress the cord.

SYRINGOMYELIA

Destruction or degeneration of gray and white matter adjacent to the central canal of the cervical spinal cord leads to cavitation and accumulation of fluid within the spinal cord. The precise pathogenesis is unclear, but many cases are associated with Arnold-Chiari malformation, in which there is displacement of the cerebellar tonsils, medulla, and fourth ventricle into the spinal canal, sometimes with accompanying meningocele. In such circumstances, the cord cavity connects with and may merely represent a dilated central canal. In other cases, the cause of cavitation is less clear. There is a characteristic clinical picture, with segmental atrophy, areflexia and loss of pain and temperature appreciation in a “cape” distribution, owing to the destruction of fibers crossing in front of the central canal in the mid-cervical spinal cord. Thoracic kyphoscoliosis is usually present. With progression, involvement of the long motor and sensory tracts occurs as well, so that a pyramidal and sensory deficit develops in the legs. Upward extension

of the cavitation (syringobulbia) leads to dysfunction of the lower brainstem and thus to bulbar palsy, nystagmus, and sensory impairment over one or both sides of the face.

Syringomyelia, ie, cord cavitation, may also occur in association with an intramedullary tumor or following severe cord injury, and the cavity then does not communicate with the central canal.

In patients with Arnold-Chiari malformation, CT scans reveal a small posterior fossa and enlargement of the foramen magnum, along with other associated skeletal abnormalities at the base of the skull and upper cervical spine. MRI reveals the syrinx as well as the characteristic findings of the Arnold-Chiari malformation, including the caudal displacement of the fourth ventricle and herniation of the cerebellar tonsils through the foramen magnum. Focal cord enlargement is found at myelography or by MRI in patients with cavitation related to past injury or intramedullary neoplasms.

Treatment of Arnold-Chiari malformation with associated syringomyelia is by suboccipital craniectomy and upper cervical laminectomy, with the aim of decompressing the malformation at the foramen magnum. The cord cavity should be drained, and if necessary an outlet for the fourth ventricle can be made. In cavitation associated with intra-medullary tumor, treatment is surgical, but radiation therapy may be necessary if complete removal is not possible. Posttraumatic syringomyelia is also treated surgically if it leads to increasing neurologic deficits or to intolerable pain.

Aghakhani N et al. Long-term follow-up of Chiari-related syringomyelia in adults: analysis of 157 surgically treated cases. *Neurosurgery*. 2009 Feb;64(2):308–15. [PMID: 19190458]

DEGENERATIVE MOTOR NEURON DISEASES

ESSENTIALS OF DIAGNOSIS

- ▶ Weakness.
- ▶ No sensory loss or sphincter disturbance.
- ▶ Progressive course.
- ▶ No identifiable underlying cause other than genetic basis in familial cases.

▶ General Considerations

This group of degenerative disorders is characterized clinically by weakness and variable wasting of affected muscles, without accompanying sensory changes.

Motor neuron disease in adults generally commences between 30 and 60 years of age. There is degeneration of the anterior horn cells in the spinal cord, the motor nuclei of the lower cranial nerves, and the corticospinal and corticobulbar pathways. The disorder is usually sporadic, but familial cases may occur and several genetic mutations or loci have been identified. Cigarette smoking may be one risk factor.

▶ Classification

Five varieties have been distinguished on clinical grounds.

A. Progressive Bulbar Palsy

Bulbar involvement predominates owing to disease processes affecting primarily the motor nuclei of the cranial nerves.

B. Pseudobulbar Palsy

Bulbar involvement predominates in this variety also, but it is due to bilateral corticobulbar disease and thus reflects upper motor neuron dysfunction. There may be a “pseudobulbar affect,” with uncontrollable episodes of laughing or crying to stimuli that would not normally have elicited such marked reactions.

C. Progressive Spinal Muscular Atrophy

This is characterized primarily by a lower motor neuron deficit in the limbs due to degeneration of the anterior horn cells in the spinal cord.

D. Primary Lateral Sclerosis

There is a purely upper motor neuron deficit in the limbs.

E. Amyotrophic Lateral Sclerosis

A mixed upper and lower motor neuron deficit is found in the limbs. This disorder is sometimes associated with cognitive decline (in a pattern consistent with frontotemporal dementia), a pseudobulbar affect, or parkinsonism.

▶ Clinical Findings

A. Symptoms and Signs

Difficulty in swallowing, chewing, coughing, breathing, and talking (dysarthria) occur with bulbar involvement. In progressive bulbar palsy, there is drooping of the palate; a depressed gag reflex; pooling of saliva in the pharynx; a weak cough; and a wasted, fasciculating tongue. In pseudobulbar palsy, the tongue is contracted and spastic and cannot be moved rapidly from side to side. Limb involvement is characterized by motor disturbances (weakness, stiffness, wasting, fasciculations) reflecting lower or upper motor neuron dysfunction; there are no objective changes on sensory examination, although there may be vague sensory complaints. The sphincters are generally spared. Cognitive changes or pseudobulbar affect may be present. The disorder is progressive, and amyotrophic lateral sclerosis is usually fatal within 3–5 years; death usually results from pulmonary infections. Patients with bulbar involvement generally have the poorest prognosis, while patients with primary lateral sclerosis often have a longer survival despite profound quadriparesis and spasticity.

B. Laboratory and Other Studies

Electromyography may show changes of chronic partial denervation, with abnormal spontaneous activity in the resting muscle and a reduction in the number of motor

units under voluntary control. In patients with suspected spinal muscular atrophy or amyotrophic lateral sclerosis, the diagnosis should not be made with confidence unless such changes are found in at least three spinal regions (cervical, thoracic, lumbosacral) or two spinal regions and the bulbar musculature. Motor conduction velocity is usually normal but may be slightly reduced, and sensory conduction studies are also normal. Biopsy of a wasted muscle shows the histologic changes of denervation. The serum creatine kinase may be slightly elevated but never reaches the extremely high values seen in some of the muscular dystrophies. The cerebrospinal fluid is normal.

Approximately 10% of cases of amyotrophic lateral sclerosis are familial and have been associated with mutations at several different genetic loci. The spinal muscular atrophies (SMAs) are inherited syndromes caused most often by mutations of the survival motor neuron (SMN) gene on chromosome 5. Different mutations result in more or less severe disruptions of the protein, resulting in an age of onset that ranges from infancy (SMA type I; Werdnig-Hoffmann disease), to early (type II) or late childhood (type III; Kugelberg-Welander syndrome), to adulthood (type IV). X-linked bulbosplinal neuronopathy (Kennedy syndrome) is associated with an expanded trinucleotide repeat sequence on the androgen receptor gene and carries a more benign prognosis than other forms of motor neuron disease. There have been recent reports of juvenile spinal muscular atrophy due to hexosaminidase deficiency, with abnormal findings on rectal biopsy and reduced hexosaminidase A in serum and leukocytes. Pure motor syndromes resembling motor neuron disease may also occur in association with monoclonal gammopathy or multifocal motor neuropathies with conduction block. A motor neuronopathy may also develop in Hodgkin disease and has a relatively benign prognosis. Infective anterior horn cell diseases (polio virus or West Nile virus infection) can generally be distinguished by the acute onset and monophasic course of the illness, as discussed in Chapter 32.

► Treatment

Riluzole, 50 mg orally twice daily, which reduces the pre-synaptic release of glutamate, may slow progression of amyotrophic lateral sclerosis. There is otherwise no specific treatment except in patients with gammopathy, in whom plasmapheresis and immunosuppression may lead to improvement. Therapeutic trials of various neurotrophic factors and other agents to slow disease progression have yielded generally disappointing results. Symptomatic and supportive measures may include prescription of anticholinergic drugs (such as trihexyphenidyl, amitriptyline, or atropine) or use of a portable suction machine if drooling is troublesome, braces or a walker to improve mobility, and physical therapy to prevent contractures. Behavioral modification (eg, exercising facial muscles and encouraging frequent swallowing) or over-the-counter decongestants may also help mild drooling. Spasticity may be helped by baclofen or diazepam. A semiliquid diet or nasogastric tube feeding may be needed if dysphagia is severe. Gastrostomy or cricopharyngomyotomy is sometimes resorted to in extreme cases of predominant bulbar involvement, and

tracheostomy may be necessary if respiratory muscles are severely affected; however, in the terminal stages of these disorders, the aim of treatment should be to keep patients as comfortable as possible. Information on palliative care is provided in Chapter 5.

► When to Refer

All patients (to exclude other treatable causes of symptoms and signs) should be referred.

► When to Admit

Patients should be admitted during the terminal stages of the disorders for palliative care.

PERIPHERAL NEUROPATHIES

Peripheral neuropathies can be categorized on the basis of the structure primarily affected. The predominant pathologic feature may be axonal degeneration (axonal or neuronal neuropathies) or paranodal or segmental demyelination. The distinction may be possible on the basis of neurophysiologic findings. Motor and sensory conduction velocity can be measured in accessible segments of peripheral nerves. In axonal neuropathies, conduction velocity is normal or reduced only mildly and needle electromyography provides evidence of denervation in affected muscles. In demyelinating neuropathies, conduction may be slowed considerably in affected fibers, and in more severe cases, conduction is blocked completely, without accompanying electromyographic signs of denervation.

Nerves may be injured or compressed by neighboring anatomic structures at any point along their course. Common **mononeuropathies** of this sort are considered below. They lead to a sensory, motor, or mixed deficit that is restricted to the territory of the affected nerve. A similar clinical disturbance is produced by peripheral nerve tumors, but these are rare except in patients with neurofibromatosis type 1. Multiple mononeuropathies suggest a patchy multifocal disease process such as vasculopathy (eg, diabetes, arteritis), an infiltrative process (eg, leprosy, sarcoidosis), radiation damage, or an immunologic disorder (eg, brachial plexopathy). Diffuse **polyneuropathies** lead to a symmetric sensory, motor, or mixed deficit, often most marked distally. They include the hereditary, metabolic,

and toxic disorders; idiopathic inflammatory polyneuropathy (Guillain-Barré syndrome); and the peripheral neuropathies that may occur as a nonmetastatic complication of malignant diseases. Involvement of motor fibers leads to flaccid weakness that is most marked distally; dysfunction of sensory fibers causes impaired sensory perception. Tendon reflexes are depressed or absent. Paresthesias, pain, and muscle tenderness may also occur.

POLYNEUROPATHIES & MONONEURITIS MULTIPLEX

ESSENTIALS OF DIAGNOSIS

- ▶ Weakness, sensory disturbances, or both in the extremities.
- ▶ Pain sometimes common.
- ▶ Depressed or absent tendon reflexes.
- ▶ May be family history of neuropathy.
- ▶ May be history of systemic illness or toxic exposure.

The cause of polyneuropathy or mononeuritis multiplex is suggested by the history, mode of onset, and predominant clinical manifestations. Laboratory workup includes a complete blood count and erythrocyte sedimentation rate, serum protein electrophoresis, and immunophoresis, determination of plasma urea and electrolytes, liver and thyroid function tests, tests for rheumatoid factor and anti-nuclear antibody, HBsAg determination, a serologic test for syphilis, fasting blood glucose level, urinary heavy metal levels, cerebrospinal fluid examination, and chest radiography. These tests should be ordered selectively, as guided by symptoms and signs. Measurement of nerve conduction velocity is important in confirming the peripheral nerve origin of symptoms and providing a means of following clinical changes, as well as indicating the likely disease process (ie, axonal or demyelinating neuropathy). Cutaneous nerve biopsy may help establish a precise diagnosis (eg, polyarteritis, amyloidosis). In about half of cases, no specific cause can be established; of these, slightly less than half are subsequently found to be familial.

Treatment is of the underlying cause, when feasible, and is discussed below under the individual disorders. Physical therapy helps prevent contractures, and splints can maintain a weak extremity in a position of useful function. Anesthetic extremities must be protected from injury. To guard against burns, patients should check the temperature of water and hot surfaces with a portion of skin having normal sensation, measure water temperature with a thermometer, and use cold water for washing or lower the temperature setting of their hot-water heaters. Shoes should be examined frequently during the day for grit or foreign objects in order to prevent pressure lesions.

Patients with polyneuropathies or mononeuritis multiplex are subject to additional nerve injury at pressure points and should therefore avoid such behavior as leaning on elbows or sitting with crossed legs for lengthy periods.

Neuropathic, burning pain is sometimes troublesome and may respond to simple analgesics, such as aspirin or nonsteroidal anti-inflammatory agents, and to gabapentin (300 mg orally three times daily, titrated up to a maximum of 1200 mg orally three times daily as necessary). Duloxetine (60 mg orally daily) or venlafaxine (start 37.5 mg orally twice daily, and titrate up to 75 mg orally two to three times daily) may be helpful, especially in painful diabetic neuropathy. Opioids may be necessary for severe hyperpathia or pain induced by minimal stimuli, but their use should be avoided as much as possible. The use of a frame or cradle to reduce contact with bedclothes may be helpful. Many patients experience episodic stabbing pains, which may respond to gabapentin, pregabalin (100 mg orally three times daily), carbamazepine (start 100 mg orally twice daily, and titrate up to 400 mg orally twice daily), or tricyclic antidepressants (eg, amitriptyline 10–150 mg orally at bedtime daily).

Symptoms of autonomic dysfunction are occasionally troublesome. Postural hypotension is often helped by wearing waist-high elastic stockings and sleeping in a semierect position at night. Fludrocortisone reduces postural hypotension, but doses as high as 1 mg/d are sometimes necessary in diabetics and may lead to recumbent hypertension. Midodrine, an α -agonist, is sometimes helpful in a dose of 2.5–10 mg three times daily. Erectile dysfunction and diarrhea are difficult to treat; a flaccid neuropathic bladder may respond to parasympathomimetic drugs such as bethanechol chloride, 10–50 mg three or four times daily.

1. Inherited Neuropathies

A. Charcot-Marie-Tooth Disease (HMSN Type I, II)

Several distinct varieties of Charcot-Marie-Tooth disease can be recognized. There is usually an autosomal dominant mode of inheritance, but occasional cases occur on a sporadic, recessive, or X-linked basis. The responsible gene is commonly located on the short arm of chromosome 17 and less often shows linkage to chromosome 1 or the X chromosome. It has also been linked to several other chromosomes, emphasizing the genetic heterogeneity of the disorder. Clinical presentation may be with foot deformities or gait disturbances in childhood or early adult life. Slow progression leads to the typical features of polyneuropathy, with distal weakness and wasting that begin in the legs, a variable amount of distal sensory loss, and depressed or absent tendon reflexes. Tremor is a conspicuous feature

in some instances. Electrodiagnostic studies show a marked reduction in motor and sensory conduction velocity (hereditary motor and sensory neuropathy [HMSN] type I).

In other instances (HMSN type II), motor conduction velocity is normal or only slightly reduced, sensory nerve action potentials may be absent, and signs of chronic partial denervation are found in affected muscles electromyographically. The predominant pathologic change is axonal loss rather than segmental demyelination.

A similar disorder may occur in patients with progressive distal spinal muscular atrophy, but there is no sensory loss; electrophysiologic investigation reveals that motor conduction velocity is normal or only slightly reduced, and nerve action potentials are normal.

B. Dejerine-Sottas Disease (HMSN Type III)

The disorder may occur on a sporadic, autosomal dominant or, less commonly, autosomal recessive basis. Onset in infancy or childhood leads to a progressive motor and sensory polyneuropathy with weakness, ataxia, sensory loss, and depressed or absent tendon reflexes. The peripheral nerves may be palpably enlarged and are characterized pathologically by segmental demyelination, Schwann cell hyperplasia, and thin myelin sheaths. Electrophysiologically, there is slowing of conduction, and sensory action potentials may be unrecordable.

C. Friedreich Ataxia

This disorder, the only known autosomal recessive trinucleotide repeat disease, is caused by expansion of a poly-GAA locus in the gene for frataxin on chromosome 9, leading to symptoms in childhood or early adult life. The gait becomes ataxic, the hands become clumsy, and other signs of cerebellar dysfunction develop accompanied by weakness of the legs and extensor plantar responses. Involvement of peripheral sensory fibers leads to sensory disturbances in the limbs and depressed tendon reflexes. There is bilateral pes cavus. Pathologically, there is a marked loss of cells in the posterior root ganglia and degeneration of peripheral sensory fibers. In the central nervous system, changes are conspicuous in the posterior and lateral columns of the cord. Electrophysiologically, conduction velocity in motor fibers is normal or only mildly reduced, but sensory action potentials are small or absent. Cardiac disease is the most common cause of death.

In the differential diagnosis for Friedreich ataxia are other spinocerebellar ataxias, a growing group of at least 29 inherited disorders, each involving a different identified gene. These heterogeneous disorders, which frequently (but not exclusively) exhibit an autosomal dominant inheritance pattern and poly-CAG expansion of the affected gene, typically cause cerebellar ataxia and varying combinations of other symptoms (such as peripheral neuropathy, ophthalmoparesis, dysarthria, and pyramidal and extrapyramidal signs).

Koeppen AH. Friedreich's ataxia: pathology, pathogenesis, and molecular genetics. *J Neurol Sci.* 2011 Apr 15;303(1-2):1-12. [PMID: 21315377]

D. Refsum Disease (HMSN Type IV)

This autosomal recessive disorder is due to a disturbance in phytanic acid metabolism. Clinically, pigmentary retinal degeneration is accompanied by progressive sensorimotor polyneuropathy and cerebellar signs. Auditory dysfunction, cardiomyopathy, and cutaneous manifestations may also occur. Motor and sensory conduction velocity are reduced, often markedly, and there may be electromyographic evidence of denervation in affected muscles. Dietary restriction of phytanic acid and its precursors may be helpful therapeutically. Plasmapheresis to reduce stored phytanic acid may help at the initiation of treatment.

E. Porphyria

Peripheral nerve involvement may occur during acute attacks in both variegate porphyria and acute intermittent porphyria. Motor symptoms usually occur first, and weakness is often most marked proximally and in the upper limbs rather than the lower. Sensory symptoms and signs may be proximal or distal in distribution. Autonomic involvement is sometimes pronounced. The electrophysiologic findings are in keeping with the results of neuropathologic studies suggesting that the neuropathy is axonal in type. Hematin (4 mg/kg intravenously over 15 minutes once or twice daily) may lead to rapid improvement. A high-carbohydrate diet and, in severe cases, intravenous glucose or levulose may also be helpful. Propranolol (up to 100 mg orally every 4 hours) may control tachycardia and hypertension in acute attacks.

2. Neuropathies Associated with Systemic & Metabolic Disorders

A. Diabetes Mellitus

In this disorder, involvement of the peripheral nervous system may lead to symmetric sensory or mixed polyneuropathy, asymmetric motor radiculoneuropathy or plexopathy (diabetic amyotrophy), thoracoabdominal radiculopathy, autonomic neuropathy, or isolated lesions of individual nerves. These may occur singly or in any combination and are discussed in Chapter 27.

Bansal D et al. Amitriptyline vs. pregabalin in painful diabetic neuropathy: a randomized double blind clinical trial. *Diabet Med.* 2009 Oct;26(10):1019-26. [PMID: 19900234]
Zochodne DW. Diabetic polyneuropathy: an update. *Curr Opin Neurol.* 2008 Oct;21(5):527-33. [PMID: 18769245]

B. Uremia

Uremia may lead to a symmetric sensorimotor polyneuropathy that tends to affect the lower limbs more than the upper limbs and is more marked distally than proximally (see Chapter 22). The diagnosis can be confirmed electrophysiologically, for motor and sensory conduction velocity is moderately reduced. The neuropathy improves both clinically and electrophysiologically with kidney transplantation and to a lesser extent with chronic dialysis.

Krishnan AV et al. Uremic neuropathy: clinical features and new pathophysiological insights. *Muscle Nerve*. 2007 Mar;35(3):273–90. [PMID: 17195171]

C. Alcoholism and Nutritional Deficiency

Many alcoholics have an axonal distal sensorimotor polyneuropathy that is frequently accompanied by painful cramps, muscle tenderness, and painful paresthesias and is often more marked in the legs than in the arms. Symptoms of autonomic dysfunction may also be conspicuous. Motor and sensory conduction velocity may be slightly reduced, even in subclinical cases, but gross slowing of conduction is uncommon. A similar distal sensorimotor polyneuropathy is a well-recognized feature of beriberi (thiamine deficiency). In vitamin B₁₂ deficiency, distal sensory polyneuropathy may develop but is usually overshadowed by central nervous system manifestations (eg, myelopathy, optic neuropathy, or intellectual changes).

D. Paraproteinemias

A symmetric sensorimotor polyneuropathy that is gradual in onset, progressive in course, and often accompanied by pain and dysesthesias in the limbs may occur in patients (especially men) with multiple myeloma. The neuropathy is of the axonal type in classic lytic myeloma, but segmental demyelination (primary or secondary) and axonal loss may occur in sclerotic myeloma and lead to predominantly motor clinical manifestations. Both demyelinating and axonal neuropathies are also observed in patients with paraproteinemias without myeloma. A small fraction will develop myeloma if serially followed. The demyelinating neuropathy in these patients may be due to the monoclonal protein's reacting to a component of the nerve myelin. The neuropathy of classic multiple myeloma is poorly responsive to therapy. The polyneuropathy of benign monoclonal gammopathy may respond to immunosuppressant drugs and plasmapheresis.

Polyneuropathy may also occur in association with macroglobulinemia and cryoglobulinemia and sometimes responds to plasmapheresis. Entrapment neuropathy, such as carpal tunnel syndrome, is more common than polyneuropathy in patients with (nonhereditary) generalized amyloidosis. With polyneuropathy due to amyloidosis, sensory and autonomic symptoms are especially conspicuous, whereas distal wasting and weakness occur later; there is no specific treatment.

3. Neuropathies Associated with Infectious & Inflammatory Diseases

A. Leprosy

Leprosy is an important cause of peripheral neuropathy in certain parts of the world. Sensory disturbances are mainly due to involvement of intracutaneous nerves. In tuberculoïd leprosy, they develop at the same time and in the same distribution as the skin lesion but may be more extensive if nerve trunks lying beneath the lesion are also involved. In lepromatous leprosy, there is more extensive sensory loss, and this develops earlier and to a greater extent in the

coolest regions of the body, such as the dorsal surfaces of the hands and feet, where the bacilli proliferate most actively. Motor deficits result from involvement of superficial nerves where their temperature is lowest, eg, the ulnar nerve in the region proximal to the olecranon groove, the median nerve as it emerges from beneath the forearm flexor muscle to run toward the carpal tunnel, the peroneal nerve at the head of the fibula, and the posterior tibial nerve in the lower part of the leg; patchy facial muscular weakness may also occur owing to involvement of the superficial branches of the seventh cranial nerve.

Motor disturbances in leprosy are suggestive of multiple mononeuropathy, whereas sensory changes resemble those of distal polyneuropathy. Examination, however, relates the distribution of sensory deficits to the temperature of the tissues; in the legs, for example, sparing frequently occurs between the toes and in the popliteal fossae, where the temperature is higher. Treatment is with antileprotic agents (see Chapter 33).

B. AIDS

A variety of neuropathies occur in HIV-infected patients (see Chapter 31). Patients with AIDS may develop a chronic symmetric sensorimotor axonal **polyneuropathy** associated usually with no abnormal cerebrospinal fluid findings. Treatment is symptomatic. AIDS patients may also develop progressive **polyradiculopathy** or radiculomyelopathy that leads to leg weakness and urinary retention; sensory loss is less conspicuous than in polyneuropathy. The cerebrospinal fluid may show mononuclear pleocytosis and increased protein and low glucose concentrations. Cytomegalovirus is responsible in at least some cases. The prognosis is generally poor, but some patients respond to intravenous ganciclovir (2.5 mg/kg every 8 hours for 10 days, then 7.5 mg/kg daily 5 days per week).

An inflammatory **demyelinating polyradiculoneuropathy** sometimes occurs in HIV-seropositive patients without AIDS and may follow an acute, subacute, or chronic course. Weakness is usually more conspicuous distally than proximally and tends to overshadow sensory symptoms. Tendon reflexes are depressed or absent. The cerebrospinal fluid shows an increased cell count and protein concentration. Treatment with plasmapheresis has helped some patients. Spontaneous improvement may also occur. Seropositive patients without AIDS may also develop a **mononeuropathy multiplex** that sometimes responds to treatment with plasmapheresis.

Evans SR et al. Peripheral neuropathy in HIV: prevalence and risk factors. *AIDS*. 2011 Apr 24;25(7):919–28. [PMID: 21330902]

C. Lyme Borreliosis

The neurologic manifestations of Lyme disease include meningitis, meningoencephalitis, polyradiculoneuropathy, mononeuropathy multiplex, and cranial neuropathy. Serologic tests establish the underlying disorder. Lyme disease and its treatment are discussed in depth in Chapter 34.

D. Sarcoidosis

Cranial nerve palsies (especially facial palsy), multiple mononeuropathy and, less commonly, symmetric polyneuropathy may all occur, the latter sometimes preferentially affecting either motor or sensory fibers. Improvement may occur with use of corticosteroids.

E. Polyarteritis

Involvement of the vasa nervorum by the vasculitic process may result in infarction of the nerve. Clinically, one encounters an asymmetric sensorimotor polyneuropathy (mononeuritis multiplex) that pursues a waxing and waning course. Corticosteroids and cytotoxic agents—especially cyclophosphamide—may be of benefit in severe cases.

F. Rheumatoid Arthritis

Compressive or entrapment neuropathies, ischemic neuropathies, mild distal sensory polyneuropathy, and severe progressive sensorimotor polyneuropathy can occur in rheumatoid arthritis.

4. Neuropathy Associated with Critical Illness

Patients in intensive care units with sepsis and multiorgan failure sometimes develop polyneuropathies. This may be manifested initially by unexpected difficulty in weaning patients from a mechanical ventilator and in more advanced cases by wasting and weakness of the extremities and loss of tendon reflexes. Sensory abnormalities are relatively inconspicuous. The neuropathy is axonal in type. Its pathogenesis is obscure, and treatment is supportive. The prognosis is good provided patients recover from the underlying critical illness.

5. Toxic Neuropathies

Axonal polyneuropathy may follow exposure to industrial agents or pesticides such as acrylamide, organophosphorus compounds, hexacarbon solvents, methyl bromide, and carbon disulfide; metals such as arsenic, thallium, mercury, and lead; and drugs such as phenytoin, perhexiline, isoniazid, nitrofurantoin, vincristine, and pyridoxine in high doses. Detailed occupational, environmental, and medical histories and recognition of clusters of cases are important in suggesting the diagnosis. Treatment is by preventing further exposure to the causal agent. Isoniazid neuropathy is prevented by pyridoxine supplementation.

Diphtheritic neuropathy results from a neurotoxin released by the causative organism and is common in many areas. Palatal weakness may develop 2–4 weeks after infection of the throat, and infection of the skin may similarly be followed by focal weakness of neighboring muscles. Disturbances of accommodation may occur about 4–5 weeks after infection and distal sensorimotor demyelinating polyneuropathy after 1–3 months.

6. Neuropathies Associated with Malignant Diseases

Both a sensorimotor and a purely sensory polyneuropathy may occur as a nonmetastatic complication of malignant diseases, and have been associated with circulating anti-MAG or anti-Hu antibodies that can be detected by a paraneoplastic antibody panel that is available commercially. The sensorimotor polyneuropathy may be mild and occur in the course of known malignant disease, or it may have an acute or subacute onset, lead to severe disability, and occur before there is any clinical evidence of the cancer, occasionally following a remitting course. An autonomic neuropathy may also occur as a paraneoplastic disorder related to the presence of anti-Hu antibodies or to an antibody against ganglionic acetylcholine receptors (anti-nAChR).

7. Acute Idiopathic Polyneuropathy (Guillain-Barré Syndrome)

ESSENTIALS OF DIAGNOSIS

- ▶ Acute or subacute progressive polyradiculoneuropathy.
- ▶ Weakness is more severe than sensory disturbances.
- ▶ Acute dysautonomia may be life-threatening.

▶ General Considerations

This acute or subacute polyradiculoneuropathy sometimes follows infective illness, inoculations, or surgical procedures. There is an association with preceding *Campylobacter jejuni* enteritis. The disorder probably has an immunologic basis, but the precise mechanism is unclear.

▶ Clinical Findings

A. Symptoms and Signs

The main complaint is of weakness that varies widely in severity in different patients and often has a proximal emphasis and symmetric distribution. It usually begins in the legs, spreading to a variable extent but frequently involving the arms and often one or both sides of the face. The muscles of respiration or deglutition may also be affected. Sensory symptoms are usually less conspicuous than motor ones, but distal paresthesias and dysesthesias are common, and neuropathic or radicular pain is present in many patients. Autonomic disturbances are also common, may be severe, and are sometimes life-threatening; they include tachycardia, cardiac irregularities, hypotension or hypertension, facial flushing, abnormalities of sweating, pulmonary dysfunction, and impaired sphincter control. The axonal subtypes of the syndrome (acute motor axonal neuropathy [AMAN] and acute motor and sensory axonal neuropathy [AMSAN]) are caused by antibodies to gangliosides on the axon membrane, including

anti-GM1, anti-GM1b, anti-GD1a, anti-GD1b, and (in AMAN) anti-GalNAC-GD1a antibodies. The Miller Fisher syndrome, another subtype, is characterized by the clinical triad of ophthalmoplegia, ataxia, and areflexia, and is associated with anti-GQ1b antibodies.

B. Laboratory Findings

The cerebrospinal fluid characteristically contains a high protein concentration with a normal cell content, but these changes may take 2 or 3 weeks to develop. Electrophysiologic studies may reveal marked abnormalities, which do not necessarily parallel the clinical disorder in their temporal course. Pathologic examination shows primary demyelination or, less commonly, axonal degeneration.

► Differential Diagnosis

When the diagnosis is made, the history and appropriate laboratory studies should exclude the possibility of porphyric, diphtheritic, or toxic (heavy metal, hexacarbon, organophosphate) neuropathies. The temporal course excludes other peripheral neuropathies. Poliomyelitis, botulism, and tick paralysis must also be considered as they cause weakness of acute onset. The presence of pyramidal signs, a markedly asymmetric motor deficit, a sharp sensory level, or early sphincter involvement should suggest a focal cord lesion.

► Treatment

Treatment with prednisone is ineffective and may prolong recovery time. Plasmapheresis is of value; it is best performed within the first few days of illness and is particularly useful for clinically severe or rapidly progressive cases or those with ventilatory impairment. IVIG (400 mg/kg/d for 5 days) is equally helpful and imposes less stress on the cardiovascular system than plasmapheresis. Patients should be admitted to intensive care units if their forced vital capacity is declining, and intubation is considered if the forced vital capacity reaches 15 mL/kg, the mean inspiratory force reaches -40 mm Hg, dyspnea becomes evident, or the oxygen saturation declines. Respiratory toilet and chest physical therapy help prevent atelectasis. Marked hypotension may respond to volume replacement or pressor agents. Low-dose heparin to prevent pulmonary embolism should be considered.

Approximately 3% of patients with acute idiopathic polyneuropathy have one or more clinically similar relapses, sometimes several years after the initial illness. Plasma exchange therapy may produce improvement in chronic and relapsing inflammatory polyneuropathy.

► Prognosis

Most patients eventually make a good recovery, but this may take many months, and about 20% of patients are left with persisting disability.

► When to Refer

All patients should be referred.

► When to Admit

All patients should be hospitalized until their condition is stable and there is no respiratory compromise.

8. Chronic Inflammatory Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy, an acquired immunologically mediated disorder, is clinically similar to Guillain-Barré syndrome except that it has a relapsing or steadily progressive course over months or years and that autonomic dysfunction is generally less common. It may present as an exclusively motor disorder or with a mixed sensorimotor disturbance. In the relapsing form, partial recovery may occur after some relapses, but in other instances there is no recovery between exacerbations. Although remission may occur spontaneously with time, the disorder frequently follows a progressive downhill course leading to severe functional disability.

Electrodiagnostic studies show marked slowing of motor and sensory conduction, and focal conduction block. Signs of partial denervation may also be present owing to secondary axonal degeneration. Nerve biopsy may show chronic perivascular inflammatory infiltrates in the endoneurium and epineurium, without accompanying evidence of vasculitis. However, a normal nerve biopsy result or the presence of nonspecific abnormalities does not exclude the diagnosis.

Corticosteroids may arrest or reverse the downhill course. Treatment is usually begun with prednisone, 60–80 mg daily, continued for 2–3 months or until a definite response has occurred. If no response has occurred despite 3 months of treatment, a higher dose may be tried. In responsive cases, the dose is gradually tapered, but most patients become corticosteroid-dependent, often requiring prednisone, 20 mg daily on alternate days, on a long-term basis. IVIG can be used in place of, or in addition to corticosteroids and is best used as the initial treatment in pure motor syndromes. When both IVIG and corticosteroids are ineffective, plasma exchange may be worthwhile. Consistent with the notion that the condition is antibody mediated, rituximab has shown promise. Immunosuppressant or immunomodulatory drugs (such as azathioprine) may be added when the response to other

measures is unsatisfactory or to enable maintenance doses of corticosteroids to be lowered. Symptomatic treatment is also important.

MONONEUROPATHIES

ESSENTIALS OF DIAGNOSIS

- ▶ Focal motor or sensory deficit.
- ▶ Deficit is in territory of an individual peripheral nerve.

An individual nerve may be injured along its course or may be compressed, angulated, or stretched by neighboring anatomic structures, especially at a point where it passes through a narrow space (entrapment neuropathy). The relative contributions of mechanical factors and ischemia to the local damage are not clear. With involvement of a sensory or mixed nerve, pain is commonly felt distal to the lesion. Symptoms never develop with some entrapment neuropathies, resolve rapidly and spontaneously in others, and become progressively more disabling and distressing in yet other cases. The precise neurologic deficit depends on the nerve involved. Percussion of the nerve at the site of the lesion may lead to paresthesias in its distal distribution.

Entrapment neuropathy may be the sole manifestation of subclinical polyneuropathy, and this must be borne in mind and excluded by nerve conduction studies. Such studies are also indispensable for the accurate localization of the focal lesion.

In patients with acute compression neuropathy such as may occur in intoxicated individuals (“Saturday night palsy”), no treatment is necessary. Complete recovery generally occurs, usually within 2 months, presumably because the underlying pathology is demyelination. However, axonal degeneration can occur in severe cases, and recovery then takes longer and may never be complete.

In chronic compressive or entrapment neuropathies, avoidance of aggravating factors and correction of any underlying systemic conditions are important. Local

infiltration of the region about the nerve with corticosteroids may be of value; in addition, surgical decompression may help if there is a progressively increasing neurologic deficit or if electrodiagnostic studies show evidence of partial denervation in weak muscles.

Peripheral nerve tumors are uncommon, except in neurofibromatosis type 1, but also give rise to mononeuropathy. This may be distinguishable from entrapment neuropathy only by noting the presence of a mass along the course of the nerve and by demonstrating the precise site of the lesion with appropriate electrophysiologic studies. Treatment of symptomatic lesions is by surgical removal if possible.

1. Carpal Tunnel Syndrome

See Chapter 20.

2. Pronator Teres or Anterior Interosseous Syndrome

The median nerve gives off its motor branch, the anterior interosseous nerve, below the elbow as it descends between the two heads of the pronator teres muscle. A lesion of either nerve may occur in this region, sometimes after trauma or owing to compression from, for example, a fibrous band. With anterior interosseous nerve involvement, there is no sensory loss, and weakness is confined to the pronator quadratus, flexor pollicis longus, and the flexor digitorum profundus to the second and third digits. Weakness is more widespread and sensory changes occur in an appropriate distribution when the median nerve itself is affected. The prognosis is variable. If improvement does not occur spontaneously, decompressive surgery may be helpful.

3. Ulnar Nerve Lesions

Ulnar nerve lesions are likely to occur in the elbow region as the nerve runs behind the medial epicondyle and descends into the cubital tunnel. In the condylar groove, the ulnar nerve is exposed to pressure or trauma. Moreover, any increase in the carrying angle of the elbow, whether congenital, degenerative, or traumatic, may cause excessive stretching of the nerve when the elbow is flexed. Ulnar nerve lesions may also result from thickening or distortion of the anatomic structures forming the cubital tunnel, and the resulting symptoms may also be aggravated by flexion of the elbow, because the tunnel is then narrowed by tightening of its roof or inward bulging of its floor. A severe lesion at either site causes sensory changes in the medial 1½ digits and along the medial border of the hand. There is weakness of the ulnar-innervated muscles in the forearm and hand. With a cubital tunnel lesion, however, there may be relative sparing of the flexor carpi ulnaris muscle. Electrophysiologic evaluation using nerve stimulation techniques allows more precise localization of the lesion.

If conservative measures are unsuccessful in relieving symptoms and preventing further progression, surgical treatment may be necessary. This consists of nerve transposition if the lesion is in the condylar groove, or a release procedure if it is in the cubital tunnel.

Ulnar nerve lesions may also develop at the wrist or in the palm of the hand, usually owing to repetitive trauma or to compression from ganglia or benign tumors. They can be subdivided depending on their presumed site. Compressive lesions are treated surgically. If repetitive mechanical trauma is responsible, this is avoided by occupational adjustment or job retraining.

Watts AC et al. Patient-rated outcome of ulnar nerve decompression: a comparison of endoscopic and open in situ decompression. *J Hand Surg Am.* 2009 Oct;34(8):1492–8. [PMID: 19695795]

4. Radial Nerve Lesions

The radial nerve is particularly liable to compression or injury in the axilla (eg, by crutches or by pressure when the arm hangs over the back of a chair). This leads to weakness or paralysis of all the muscles supplied by the nerve, including the triceps. Sensory changes may also occur but are often surprisingly inconspicuous, being marked only in a small area on the back of the hand between the thumb and index finger. Injuries to the radial nerve in the spiral groove occur characteristically during deep sleep, as in intoxicated individuals (Saturday night palsy), and there is then sparing of the triceps muscle, which is supplied more proximally. The nerve may also be injured at or above the elbow; its purely motor posterior interosseous branch, supplying the extensors of the wrist and fingers, may be involved immediately below the elbow, but then there is sparing of the extensor carpi radialis longus, so that the wrist can still be extended. The superficial radial nerve may be compressed by handcuffs or a tight watch strap.

5. Femoral Neuropathy

The clinical features of femoral nerve palsy consist of weakness and wasting of the quadriceps muscle, with sensory impairment over the anteromedian aspect of the thigh and sometimes also of the leg to the medial malleolus, and a depressed or absent knee jerk. Isolated femoral neuropathy may occur in diabetics or from compression by retroperitoneal neoplasms or hematomas (eg, expanding aortic aneurysm). Femoral neuropathy may also result from pressure from the inguinal ligament when the thighs are markedly flexed and abducted, as in the lithotomy position.

6. Meralgia Paresthetica

The lateral femoral cutaneous nerve, a sensory nerve arising from the L2 and L3 roots, may be compressed or stretched in obese or diabetic patients and during pregnancy. The nerve usually runs under the outer portion of the inguinal ligament to reach the thigh, but the ligament sometimes splits to enclose it. Hyperextension of the hip or increased lumbar lordosis—such as occurs during pregnancy—leads to nerve compression by the posterior fascicle of the ligament. However, entrapment of the nerve at any point along its course may cause similar symptoms, and several other anatomic variations predispose the nerve to damage when it is stretched. Pain, paresthesia, or

numbness occurs about the outer aspect of the thigh, usually unilaterally, and is sometimes relieved by sitting. Examination shows no abnormalities except in severe cases when cutaneous sensation is impaired in the affected area. Symptoms are usually mild and commonly settle spontaneously. Hydrocortisone injections medial to the antero-superior iliac spine often relieve symptoms temporarily, while nerve decompression by transposition may provide more lasting relief.

7. Sciatic & Common Peroneal (Fibular) Nerve Palsies

Misplaced deep intramuscular injections are probably still the most common cause of sciatic nerve palsy. Trauma to the buttock, hip, or thigh may also be responsible. The resulting clinical deficit depends on whether the whole nerve has been affected or only certain fibers. In general, the peroneal (fibular) fibers of the sciatic nerve are more susceptible to damage than those destined for the tibial nerve. A sciatic nerve lesion may therefore be difficult to distinguish from peroneal (fibular) neuropathy unless there is electromyographic evidence of involvement of the short head of the biceps femoris muscle. The common peroneal (fibular) nerve itself may be compressed or injured in the region of the head and neck of the fibula, eg, by sitting with crossed legs or wearing high boots. There is weakness of dorsiflexion and eversion of the foot, accompanied by numbness or blunted sensation of the anterolateral aspect of the calf and dorsum of the foot.

8. Tarsal Tunnel Syndrome

The tibial nerve, the other branch of the sciatic, supplies several muscles in the lower extremity, gives origin to the sural nerve, and then continues as the posterior tibial nerve to supply the plantar flexors of the foot and toes. It passes through the tarsal tunnel behind and below the medial malleolus, giving off calcaneal branches and the medial and lateral plantar nerves that supply small muscles of the foot and the skin on the plantar aspect of the foot and toes. Compression of the posterior tibial nerve or its branches between the bony floor and ligamentous roof of the tarsal tunnel leads to pain, paresthesias, and numbness over the bottom of the foot, especially at night, with sparing of the heel. Muscle weakness may be hard to recognize clinically. Compressive lesions of the individual plantar nerves may also occur more distally, with clinical features similar to those of the tarsal tunnel syndrome. Treatment is surgical decompression.

9. Facial Neuropathy

An isolated facial palsy is most often idiopathic (Bell palsy) but may occur in patients with HIV seropositivity, sarcoidosis, Lyme disease (Figure 24–2; also see Chapter 34) or with any process causing an inflammatory reaction in the subarachnoid space, such as meningitis. Whenever facial palsies occur bilaterally, or a facial palsy occurs in conjunction with other neurologic deficits, MRI brain imaging should be undertaken and other investigations considered.

▲ **Figure 24-2.** Facial palsy caused by an infection with *Borrelia burgdorferi* (Lyme disease). (Public Health Image Library, CDC.)

▶ When to Refer

- If there is uncertainty about the diagnosis.
- Symptoms or signs are progressing despite treatment.

▶ When to Admit

When a patient should be hospitalized depends on the cause and treatment.

BELL PALSY

ESSENTIALS OF DIAGNOSIS

- ▶ Sudden onset of lower motor neuron facial palsy.
- ▶ Hyperacusis or impaired taste may occur.
- ▶ No other neurologic abnormalities.

▶ General Considerations

Bell palsy is an idiopathic facial paresis of lower motor neuron type that has been attributed to an inflammatory reaction involving the facial nerve near the stylomastoid foramen or in the bony facial canal. Increasing evidence incriminates reactivation of herpes simplex or varicella zoster virus infection in the geniculate ganglion at least in

some instances. The disorder is more common in pregnant women or in persons with diabetes mellitus.

▶ Clinical Findings

The facial palsy (Figure 24–2) generally comes on abruptly, but it may worsen over the following day or so. Pain about the ear precedes or accompanies the weakness in many cases but usually lasts for only a few days. The face itself feels stiff and pulled to one side. There may be ipsilateral restriction of eye closure and difficulty with eating and fine facial movements. A disturbance of taste is common, owing to involvement of chorda tympani fibers, and hyperacusis due to involvement of fibers to the stapedius occurs occasionally.

▶ Treatment

Other disorders that can produce a facial palsy and require specific treatment, such as tumors, Lyme disease, AIDS, sarcoidosis, and herpes zoster infection of the geniculate ganglion, must be excluded. The management of Bell palsy is controversial. Approximately 60% of cases recover completely without treatment, presumably because the lesion is so mild that it leads merely to conduction block. Considerable improvement occurs in most other cases, and only about 10% of all patients have permanent disfigurement or other long-term sequelae. Treatment is unnecessary in most cases but is indicated for patients in whom an unsatisfactory outcome can be predicted. The best clinical guide to prognosis is the severity of the palsy during the first few days after presentation. Patients with clinically complete palsy when first seen are less likely to make a full recovery than those with an incomplete one. A poor prognosis for recovery is also associated with advanced age, hyperacusis, and severe initial pain. Electromyography and nerve excitability or conduction studies provide a guide to prognosis but not early enough to aid in the selection of patients for treatment.

The only medical treatment that may influence the outcome is administration of corticosteroids, but this must be commenced within 5 days of onset. Treatment with prednisone, 60–80 mg orally daily for 4 or 5 days, followed by tapering of the dose over the next 7–10 days, is a satisfactory regimen; prednisolone (50 mg daily orally) for 10 days is another acceptable alternative. It is helpful to protect the eye with lubricating drops (or lubricating ointment at night) and a patch if eye closure is not possible. Acyclovir does not confer any additional benefit. There is no evidence that surgical procedures to decompress the facial nerve are of benefit.

DISCOGENIC NECK PAIN

ESSENTIALS OF DIAGNOSIS

- ▶ Neck pain, sometimes radiating to arms.
- ▶ Restricted neck movements.
- ▶ Motor, sensory, or reflex changes in arms with root involvement.
- ▶ Neurologic deficit in legs, gait disorder, or sphincter disturbance with cord involvement.

▶ General Considerations

A variety of congenital abnormalities may involve the cervical spine and lead to neck pain; these include hemivertebrae, fused vertebrae, basilar impression, and instability of the atlantoaxial joint. Traumatic, degenerative, infective, and neoplastic disorders may also lead to pain in the neck. When rheumatoid arthritis involves the spine, it tends to affect especially the cervical region, leading to pain, stiffness, and reduced mobility; displacement of vertebrae or atlantoaxial subluxation may lead to cord compression that can be life-threatening if not treated by fixation. Further details are given in Chapter 20 (including a discussion on low back pain), and discussion here is restricted to disk disease.

1. Acute Cervical Disk Protrusion

Acute cervical disk protrusion leads to pain in the neck and radicular pain in the arm, exacerbated by head movement. With lateral herniation of the disk, motor, sensory, or reflex changes may be found in a radicular (usually C6 or C7) distribution on the affected side (Figure 24–3); with more centrally directed herniations, the spinal cord may also be involved, leading to spastic paraparesis and sensory disturbances in the legs, sometimes accompanied by impaired sphincter function. The diagnosis is confirmed by MRI or CT myelography. In mild cases, bed rest or intermittent neck traction may help, followed by immobilization of the neck in a collar for several weeks. If these measures are unsuccessful or the patient has a significant neurologic deficit, surgical removal of the protruding disk may be necessary.

2. Cervical Spondylosis

Cervical spondylosis results from chronic cervical disk degeneration, with herniation of disk material, secondary calcification, and associated osteophytic outgrowths. One or more of the cervical nerve roots may be compressed, stretched, or angulated; and myelopathy may also develop as a result of compression, vascular insufficiency, or recurrent minor trauma to the cord. Patients present with neck pain and restricted head movement, occipital headaches, radicular pain and other sensory disturbances in the arms, weakness of the arms or legs, or some combination of these symptoms. Examination generally reveals that lateral

flexion and rotation of the neck are limited. A segmental pattern of weakness or dermatomal sensory loss (or both) may be found unilaterally or bilaterally in the upper limbs, and tendon reflexes mediated by the affected root or roots are depressed. The C5 and C6 nerve roots are most commonly involved, and examination frequently then reveals weakness of muscles supplied by these roots (eg, deltoids, supraspinatus and infraspinatus, biceps, brachioradialis), pain or sensory loss about the shoulder and outer border of the arm and forearm, and depressed biceps and brachioradialis reflexes. Spastic paraparesis may also be present if there is an associated myelopathy, sometimes accompanied by posterior column or spinothalamic sensory deficits in the legs.

Plain radiographs of the cervical spine show osteophyte formation, narrowing of disk spaces, and encroachment on the intervertebral foramina, but such changes are common in middle-aged persons and may be unrelated to the presenting complaint. CT or MRI helps confirm the diagnosis and exclude other structural causes of the myelopathy.

Restriction of neck movements by a cervical collar may relieve pain. Operative treatment may be necessary to prevent further progression if there is a significant neurologic deficit or if root pain is severe, persistent, and unresponsive to conservative measures.

▶ When to Refer

- Pain unresponsive to simple measures.
- Patients with neurologic deficits.
- Patients in whom surgical treatment is under consideration.

▶ When to Admit

- Patients with progressive or significant neurologic deficit.
- Patients with sphincter involvement (from cord compression).
- Patients requiring surgical treatment.

Matz PG et al; Joint Section on Disorders of the Spine and Peripheral Nerves of the American Association of Neurological Surgeons and Congress of Neurological Surgeons. The natural history of cervical spondylotic myelopathy. *J Neurosurg Spine*. 2009 Aug;11(2):104–11. [PMID: 19769489]

BRACHIAL & LUMBAR PLEXUS LESIONS

1. Brachial Plexus Neuropathy

Brachial plexus neuropathy may be idiopathic, sometimes occurring in relationship to a number of different nonspecific illnesses or factors. In other instances, brachial plexus lesions follow trauma or result from congenital anomalies, neoplastic involvement, or injury by various physical agents. In rare instances, the disorder occurs on a familial basis.

Idiopathic brachial plexus neuropathy (neuralgic amyotrophy) characteristically begins with severe pain about the shoulder, followed within a few days by weakness,

▲ **Figure 24-3.** Cutaneous innervation. The segmental or radicular (root) distribution is shown on the left side of the body and the peripheral nerve distribution on the right side. Above: anterior view; facing page: posterior view. (Reproduced, with permission, from Simon RP et al. *Clinical Neurology*, 7th ed. McGraw-Hill, 2009.)

reflex changes, and sensory disturbances involving especially the C5 and C6 segments but affecting any nerve in the brachial plexus. Symptoms and signs are usually unilateral but may be bilateral. Wasting of affected muscles is sometimes profound. The disorder relates to disturbed function of cervical roots or part of the brachial plexus,

but its precise cause is unknown. Recovery occurs over the ensuing months but may be incomplete. Treatment is purely symptomatic.

van Alfen N et al. The clinical spectrum of neuralgic amyotrophy in 246 cases. *Brain*. 2006 Feb;129(Pt 2):438–50. [PMID: 16371410]

▲ **Figure 24-3.** (Continued)

2. Cervical Rib Syndrome

Compression of the C8 and T1 roots or the lower trunk of the brachial plexus by a cervical rib or band arising from the seventh cervical vertebra leads to weakness and wasting of intrinsic hand muscles, especially those in the thenar eminence, accompanied by pain and numbness in the medial two fingers and the ulnar border of the hand and forearm. The subclavian artery may also be compressed,

and this forms the basis of Adson test for diagnosing the disorder; the radial pulse is diminished or obliterated on the affected side when the seated patient inhales deeply and turns the head to one side or the other. Electromyography, nerve conduction studies, and somatosensory evoked potential studies may help confirm the diagnosis. MRI may be especially helpful in revealing the underlying compressive structure. Plain radiographs or CT scanning sometimes shows the cervical rib or a large

transverse process of the seventh cervical vertebra, but normal findings do not exclude the possibility of a cervical band. Treatment of the disorder is by surgical excision of the rib or band.

3. Lumbosacral Plexus Lesions

A lumbosacral plexus lesion may develop in association with diseases such as diabetes, cancer, or bleeding disorders or in relation to injury. It occasionally occurs as an isolated phenomenon similar to idiopathic brachial plexopathy, and pain and weakness then tend to be more conspicuous than sensory symptoms. The distribution of symptoms and signs depends on the level and pattern of neurologic involvement.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

1. Myasthenia Gravis

ESSENTIALS OF DIAGNOSIS

- ▶ Fluctuating weakness of commonly used voluntary muscles, producing symptoms such as diplopia, ptosis, and difficulty in swallowing.
- ▶ Activity increases weakness of affected muscles.
- ▶ Short-acting anticholinesterases transiently improve the weakness.

▶ General Considerations

Myasthenia gravis occurs at all ages, sometimes in association with a thymic tumor or thyrotoxicosis, as well as in rheumatoid arthritis and lupus erythematosus. It is most common in young women with HLA-DR3; if thymoma is associated, older men are more commonly affected. Onset is usually insidious, but the disorder is sometimes unmasked by a coincidental infection that leads to exacerbation of symptoms. Exacerbations may also occur before the menstrual period and during or shortly after pregnancy. Symptoms are due to a variable degree of block of neuromuscular transmission caused by autoantibodies binding to acetylcholine receptors; these are found in most patients with the disease and have a primary role in reducing the number of functioning acetylcholine receptors. Additionally, cellular immune activity against the receptor is found. Clinically, this leads to weakness; initially powerful movements fatigue readily. The external ocular muscles and certain other cranial muscles, including the masticatory, facial, and pharyngeal muscles, are especially likely to be affected, and the respiratory and limb muscles may also be involved.

▶ Clinical Findings

A. Symptoms and Signs

Patients present with ptosis, diplopia, difficulty in chewing or swallowing, respiratory difficulties, limb weakness, or some combination of these problems. Weakness may remain localized to a few muscle groups, especially the ocular muscles, or may become generalized. Symptoms often fluctuate in intensity during the day, and this diurnal variation is superimposed on a tendency to longer-term spontaneous relapses and remissions that may last for weeks. Nevertheless, the disorder follows a slowly progressive course and may have a fatal outcome owing to respiratory complications such as aspiration pneumonia.

Clinical examination confirms the weakness and fatigability of affected muscles. In most cases, the extraocular muscles are involved, and this leads to ocular palsies and ptosis, which are commonly asymmetric. Pupillary responses are normal. The bulbar and limb muscles are often weak, but the pattern of involvement is variable. Sustained activity of affected muscles increases the weakness, which improves after a brief rest. Sensation is normal, and there are usually no reflex changes.

Life-threatening exacerbations of myasthenia (so-called **myasthenic crisis**) may lead to respiratory weakness requiring immediate admission to the intensive care unit, where respiratory function can be monitored and ventilator support is readily available.

B. Imaging

A CT scan of the chest with and without contrast should be obtained to demonstrate a coexisting thymoma, but a normal study does not exclude this possibility.

C. Laboratory and Other Studies

Electrophysiologic demonstration of a decrementing muscle response to repetitive 2- or 3-Hz stimulation of motor nerves indicates a disturbance of neuromuscular transmission. Such an abnormality may even be detected in clinically strong muscles with certain provocative procedures. Needle electromyography of affected muscles shows a marked variation in configuration and size of individual motor unit potentials, and single-fiber electromyography reveals an increased jitter, or variability, in the time interval between two muscle fiber action potentials from the same motor unit.

Assay of serum for elevated levels of circulating acetylcholine receptor antibodies is useful because it has a sensitivity of 80–90% for the diagnosis of myasthenia gravis. Certain patients without antibodies to acetylcholine receptors have serum antibodies to muscle-specific tyrosine kinase (MuSK), which should therefore be determined; these patients are more likely to have facial, respiratory, and proximal muscle weakness than those with antibodies to acetylcholine receptors.

▶ Treatment

Medication such as aminoglycosides that may exacerbate myasthenia gravis should be avoided. Anticholinesterase

drugs provide symptomatic benefit without influencing the course of the disease. Neostigmine, pyridostigmine, or both can be used, the dose being determined on an individual basis. The usual dose of neostigmine is 7.5–30 mg (average, 15 mg) orally taken four times daily; of pyridostigmine, 30–180 mg (average, 60 mg) orally four times daily. Overmedication may temporarily increase weakness.

Thymectomy usually leads to symptomatic benefit or remission and should be considered in all patients younger than age 60, unless weakness is restricted to the extraocular muscles. If the disease is of recent onset and only slowly progressive, operation is sometimes delayed for a year or so, in the hope that spontaneous remission will occur.

Treatment with corticosteroids is indicated for patients who have responded poorly to anticholinesterase drugs and have already undergone thymectomy. It is often introduced with the patient in the hospital, since weakness may initially be aggravated. Once weakness has stabilized after 2–3 weeks or any improvement is sustained, further management can be on an outpatient basis. Alternate-day treatment is usually well tolerated, but if weakness is enhanced on the nontreatment day it may be necessary for medication to be taken daily. The dose of corticosteroids is determined on an individual basis, but an initial high daily dose (eg, prednisone, 60–100 mg orally daily) can gradually be tapered to a relatively low maintenance level as improvement occurs; total withdrawal is difficult, however. Treatment with azathioprine may also be effective. The usual dose is 2–3 mg/kg orally daily after a lower initial dose.

In patients with major disability, plasmapheresis or IVIG therapy may be beneficial and have similar efficacy. It is also useful for stabilizing patients before thymectomy and for managing acute crisis. Mycophenolate mofetil, an immunosuppressant, may provide symptomatic benefit and allow the corticosteroid dose to be reduced.

▶ When to Refer

All patients should be referred.

▶ When to Admit

- Patients with acute exacerbation or respiratory involvement.
- Patients requiring plasmapheresis.
- Patients who are starting corticosteroid therapy.
- For thymectomy.

2. Myasthenic Syndrome (Lambert-Eaton Syndrome)

ESSENTIALS OF DIAGNOSIS

- ▶ Variable weakness, typically improving with activity.
- ▶ Dysautonomic symptoms may also be present.
- ▶ A history of malignant disease may be obtained.

▶ General Considerations

Myasthenic syndrome may be associated with small-cell carcinoma, sometimes developing before the tumor is diagnosed, and occasionally occurs with certain autoimmune diseases. There is defective release of acetylcholine in response to a nerve impulse, caused by P/Q-type voltage-gated calcium-channel antibody, and this leads to weakness, especially of the proximal muscles of the limbs. Unlike myasthenia gravis, however, power steadily increases with sustained contraction. The diagnosis can be confirmed electrophysiologically, because the muscle response to stimulation of its motor nerve increases remarkably if the nerve is stimulated repetitively at high rates, even in muscles that are not clinically weak.

Treatment with plasmapheresis and immunosuppressive drug therapy (prednisone and azathioprine) may lead to clinical and electrophysiologic improvement, in addition to therapy aimed at tumor when present. Prednisone is usually initiated in a daily dose of 60–80 mg and azathioprine in a daily dose of 2 mg/kg. Symptomatic therapy includes the use of potassium channel antagonists; of these, 3,4-diaminopyridine (60–80 mg/d orally in three divided doses) has been best studied and appears efficacious. Guanidine hydrochloride (25–50 mg/kg/d orally in divided doses) is an alternative and is occasionally helpful in seriously disabled patients, but adverse effects of the drug include marrow suppression. The response to treatment with anticholinesterase drugs such as pyridostigmine or neostigmine is usually disappointing.

3. Botulism

The toxin of *Clostridium botulinum* prevents the release of acetylcholine at neuromuscular junctions and autonomic synapses. Botulism occurs most commonly following the ingestion of contaminated home-canned food and should be suggested by the development of sudden, fluctuating, severe weakness in a previously healthy person. Symptoms begin within 72 hours following ingestion of the toxin and may progress for several days. Typically, there is diplopia, ptosis, facial weakness, dysphagia, and nasal

speech, followed by respiratory difficulty and finally by weakness that appears last in the limbs. Blurring of vision (with unreactive dilated pupils) is characteristic, and there may be dryness of the mouth, constipation (paralytic ileus), and postural hypotension. Sensation is preserved, and the tendon reflexes are not affected unless the involved muscles are very weak. If the diagnosis is suspected, the local health authority should be notified and a sample of serum and contaminated food (if available) sent to be assayed for toxin. Support for the diagnosis may be obtained by electrophysiologic studies; with repetitive stimulation of motor nerves at fast rates, the muscle response increases in size progressively.

Patients should be hospitalized in case respiratory assistance becomes necessary. Treatment is with trivalent antitoxin, once it is established that the patient is not allergic to horse serum. Potassium channel antagonists may provide symptomatic relief as they do in Lambert-Eaton myasthenic syndrome (see above). Anticholinesterase drugs are of no value. Respiratory assistance and other supportive measures should be provided as necessary. Further details are provided in Chapter 33.

4. Disorders Associated with Use of Aminoglycosides

Aminoglycoside antibiotics, eg, gentamicin, may produce a clinical disturbance similar to botulism by preventing the release of acetylcholine from nerve endings, but symptoms subside rapidly as the responsible drug is eliminated from the body. These antibiotics are particularly dangerous in patients with preexisting disturbances of neuromuscular transmission and are therefore best avoided in patients with myasthenia gravis.

MYOPATHIC DISORDERS

1. Muscular Dystrophies

ESSENTIALS OF DIAGNOSIS

- ▶ Muscle weakness, often in a characteristic distribution.
- ▶ Age at onset and inheritance pattern depend on the specific dystrophy.

▶ General Considerations

These inherited myopathic disorders are characterized by progressive muscle weakness and wasting. They are subdivided by mode of inheritance, age at onset, and clinical features, as shown in Table 24–9. In the Duchenne type, pseudohypertrophy of muscles frequently occurs at some stage; intellectual retardation is common; and there may be skeletal deformities, muscle contractures, and cardiac involvement. The serum creatine kinase level is increased, especially in the Duchenne and Becker varieties, and mildly

increased also in limb-girdle dystrophy. Electromyography may help confirm that weakness is myopathic rather than neurogenic. Similarly, histopathologic examination of a muscle biopsy specimen may help confirm that weakness is due to a primary disorder of muscle and to distinguish between various muscle diseases.

A genetic defect on the short arm of the X chromosome has been identified in Duchenne dystrophy. The affected gene codes for the protein dystrophin, which is markedly reduced or absent from the muscle of patients with the disease. Dystrophin levels are generally normal in the Becker variety, but the protein is qualitatively altered.

Duchenne muscular dystrophy can now be recognized early in pregnancy in about 95% of women by genetic studies; in late pregnancy, DNA probes can be used on fetal tissue obtained for this purpose by amniocentesis. The genes causing some of the other muscular dystrophies are listed in Table 24–9.

There is no specific treatment for the muscular dystrophies, but it is important to encourage patients to lead as normal lives as possible. Prednisone (0.75 mg/kg orally daily) improves muscle strength and function in boys with Duchenne dystrophy, but side effects need to be monitored. Prolonged bed rest must be avoided, as inactivity often leads to worsening of the underlying muscle disease. Physical therapy and orthopedic procedures may help counteract deformities or contractures.

 Tawil R et al. Facioscapulohumeral muscular dystrophy. *Muscle Nerve*. 2006 Jul;34(1):1–15. [PMID: 16508966]

2. Myotonic Dystrophy

Myotonic dystrophy, a slowly progressive, dominantly inherited disorder, usually manifests itself in the third or fourth decade but occasionally appears early in childhood. Myotonic dystrophy type 1 results from an expanded CTG repeat in a protein kinase gene on chromosome 19; in type 2, the defect is a CCTG repeat expansion in the gene for zinc-finger protein-9 on chromosome 3. Myotonia leads to complaints of muscle stiffness and is evidenced by the marked delay that occurs before affected muscles can relax after a contraction. This can often be demonstrated clinically by delayed relaxation of the hand after sustained grip or by percussion of the belly of a muscle. In addition, there is weakness and wasting of the facial, sternocleidomastoid, and distal limb muscles. Associated clinical features include cataracts, frontal baldness, testicular atrophy, diabetes mellitus, cardiac abnormalities, and intellectual changes. Electromyographic sampling of affected muscles reveals myotonic discharges in addition to changes suggestive of myopathy.

It is difficult to determine whether drug therapy for myotonia is safe or effective. When myotonia is disabling, treatment with a sodium channel blocker—such as phenytoin

Table 24-9. The muscular dystrophies.¹

Disorder	Inheritance	Age at Onset (years)	Distribution	Prognosis	Genetic Association
Duchenne type	X-linked recessive	1-5	Pelvic, then shoulder girdle; later, limb and respiratory muscles.	Rapid progression. Death within about 15 years after onset.	Xp21 Dystrophin (loss of functional expression)
Becker	X-linked recessive	5-25	Pelvic, then shoulder girdle.	Slow progression. May have normal life span.	Xp21 Dystrophin (reduced functional expression)
Limb-girdle (Erb)	Autosomal recessive, dominant or sporadic	10-30	Pelvic or shoulder girdle initially, with later spread to the other.	Variable severity and rate of progression. Possible severe disability in middle life.	Multiple
Facioscapulohumeral	Autosomal dominant	Any age	Face and shoulder girdle initially; later, pelvic girdle and legs.	Slow progression. Minor disability. Usually normal life span.	4q35
Emery-Dreifuss	X-linked recessive or autosomal dominant	5-10	Humeroperoneal or scapuloperoneal.	Variable.	Xq28; Emerin (X-linked) 1q21.2; Laminin A/C (chromosome 1) Others
Distal	Autosomal dominant or recessive	40-60	Onset distally in extremities; proximal involvement later.	Slow progression.	14q12; Myosin heavy chain 7 2p13 Dysferlin
Ocular	Autosomal dominant (may be recessive)	Any age (usually 5-30)	External ocular muscles; may also be mild weakness of face, neck, and arms.		
Oculopharyngeal	Autosomal dominant	Any age	As in the ocular form but with dysphagia.		14q11.2-q13 Poly (A)-binding protein-2
Myotonic dystrophy	Autosomal dominant	Any age (usually 20-40)	Face, neck, distal limbs.	Slow progression.	19q13.2-q13.3; Dystrophia myotonica protein kinase 3q13.3-q24; Zinc-finger protein-9

¹Not all possible genetic loci are shown.

(100 mg orally three times daily), procainamide (0.5–1 g orally four times daily), or mexiletine (150–200 mg orally three times daily)—may be helpful, but the associated side effects, particularly for antiarrhythmic drugs, are often limiting. Neither the weakness nor the course of the disorder is influenced by treatment.

Gagnon C et al; DMI Expert Panel. Health supervision and anticipatory guidance in adult myotonic dystrophy type 1. *Neuromuscul Disord.* 2010 Dec;20(12):847–51. [PMID: 20884209]

Logigian EL et al. Mexiletine is an effective antimyotonia treatment in myotonic dystrophy type 1. *Neurology.* 2010 May 4;74(18):1441–8. [PMID: 20439846]

Miller TM. Differential diagnosis of myotonic disorders. *Muscle Nerve.* 2008 Mar;37(3):293–9. [PMID: 18067134]

3. Myotonia Congenita

Myotonia congenita is commonly inherited as a dominant trait. The responsible gene on chromosome 7 encodes a voltage-gated chloride channel. Generalized myotonia

without weakness is usually present from birth, but symptoms may not appear until early childhood. Patients complain of muscle stiffness that is enhanced by cold and inactivity and relieved by exercise. Muscle hypertrophy, at times pronounced, is also a feature. A recessive form with later onset is associated with slight weakness and atrophy of distal muscles. Treatment with procainamide, tocainide, mexiletine, or phenytoin may help the myotonia, as in myotonic dystrophy.

4. Polymyositis & Dermatomyositis

See Chapter 20.

5. Inclusion Body Myositis

This disorder, of unknown cause, begins insidiously, usually after middle age, with progressive proximal weakness of first the lower and then the upper extremities, and affecting facial and pharyngeal muscles. Weakness often begins in the quadriceps femoris in the lower limbs and the forearm flexors in the upper limbs. Distal weakness is usually mild. Serum creatine kinase levels may be normal or increased. The diagnosis is confirmed by muscle biopsy. Corticosteroid and immunosuppressive therapy is usually ineffective, but IVIG therapy is occasionally of mild benefit.

Lloyd TE. Novel therapeutic approaches for inclusion body myositis. *Curr Opin Rheumatol*. 2010 Nov;22(6):658–64. [PMID: 20827206]

Machado P et al. Sporadic inclusion body myositis: an unsolved mystery. *Acta Rheumatol Port*. 2009 Apr–Jun;34(2A):161–82. [PMID: 19474772]

6. Mitochondrial Myopathies

The mitochondrial myopathies are a clinically diverse group of disorders that on pathologic examination of skeletal muscle with the modified Gomori stain show characteristic “ragged red fibers” containing accumulations of abnormal mitochondria. Patients may present with progressive external ophthalmoplegia or with limb weakness that is exacerbated or induced by activity. Other patients present with central neurologic dysfunction, eg, myoclonic epilepsy (**myoclonic epilepsy**, ragged red fiber syndrome, or **MERRF**), or the combination of myopathy, encephalopathy, lactic acidosis, and **stroke-like episodes** (**MELAS**). These disorders result from separate abnormalities of mitochondrial DNA. (See also Chapter 20.) Treatment is symptomatic and palliative, but various experimental approaches are being explored.

A mitochondrial myopathy may develop in patients receiving zidovudine for treatment of AIDS, and patients receiving highly active antiretroviral therapy (HAART) for HIV-1 infection may develop a **lipodystrophy**, with fat accumulating in muscle.

Rahman S et al. Diagnosis and therapy in neuromuscular disorders: diagnosis and new treatments in mitochondrial diseases. *J Neurol Neurosurg Psychiatry*. 2009 Sep;80(9):943–53. [PMID: 19684231]

7. Myopathies Associated with Other Disorders

Myopathy may occur in association with chronic hypokalemia, any endocrinopathy, and in patients taking corticosteroids, chloroquine, colchicine, clofibrate, emetine, aminocaproic acid, lovastatin, bretylium tosylate, or drugs causing potassium depletion. Weakness is mainly proximal, and serum creatine kinase is typically normal, except in hypothyroidism and some of the toxic myopathies. Treatment is of the underlying cause. Myopathy also occurs with chronic alcoholism, whereas acute reversible muscle necrosis may occur shortly after acute alcohol intoxication. Inflammatory myopathy may occur in patients taking penicillamine; myotonia may be induced by clofibrate, and preexisting myotonia may be exacerbated or unmasked by depolarizing muscle relaxants (eg, suxamethonium), β -blockers (eg, propranolol), fenoterol, ritodrine and, possibly, certain diuretics.

► When to Refer

All patients should be referred (to establish the diagnosis and underlying cause).

► When to Admit

- For respiratory assistance.
- For rhabdomyolysis.

PERIODIC PARALYSIS SYNDROMES

Periodic paralysis may have a familial (dominant inheritance) basis. The syndromes to be described are channelopathies that manifest as abnormal, often potassium-sensitive, muscle-membrane excitability and lead clinically to episodes of flaccid weakness or paralysis, sometimes in association with abnormalities of the plasma potassium level. Strength is normal between attacks. Mutations in genes encoding three ion channels [*CACNA1S* (1q32), *SCN4A* (17q23.1-q25.3), and *KCNJ2* (17q23.1-q24.2)] account for most cases. **Hypokalemic periodic paralysis** has been related to mutations in the *CACNL1A3*, *SCN4A*, or *KCNE3* (11q13-q14) gene and is characterized by attacks that tend to occur on awakening, after exercise, or after a heavy meal and may last for several days. Patients should avoid excessive exertion. A low-carbohydrate and low-salt diet may help prevent attacks, as may acetazolamide, 250–750 mg/d. Nonselective β -adrenergic blockers may also prevent recurrent paralytic attacks. An ongoing attack may be aborted by potassium chloride given orally or by intravenous drip, provided the ECG can be monitored and kidney function is satisfactory. In young Asian men, it is commonly associated with hyperthyroidism and has been related to polymorphism in the *CACNA1S* gene; treatment of the endocrine disorder prevents recurrences. In **hyperkalemic periodic paralysis**, which is mostly associated with

mutations in the *SCN4A* gene, attacks also tend to occur after exercise but usually last for < 1 hour. They may be terminated by intravenous calcium gluconate (1–2 g) or by intravenous diuretics (furosemide, 20–40 mg), glucose, or glucose and insulin; daily acetazolamide or chlorothiazide may prevent recurrences. **Normokalemic periodic paralysis** is similar clinically to the hyperkalemic variety, but the plasma potassium level remains normal during attacks; treatment is with acetazolamide.

▶ When to Refer

All patients should be referred.

Psychiatric Disorders

Stuart J. Eisendrath, MD

Jonathan E. Lichtmacher, MD

COMMON PSYCHIATRIC DISORDERS

STRESS & ADJUSTMENT DISORDERS (Situational Disorders)

ESSENTIALS OF DIAGNOSIS

- ▶ Anxiety or depression clearly secondary to an identifiable stress.
- ▶ Subsequent symptoms of anxiety or depression commonly elicited by similar stress of lesser magnitude.
- ▶ Alcohol and other drugs are commonly used in self-treatment.

▶ General Considerations

Stress exists when the adaptive capacity of the individual is overwhelmed by events. The event may be an insignificant one objectively considered, and even favorable changes (eg, promotion and transfer) requiring adaptive behavior can produce stress. For each individual, stress is subjectively defined, and the response to stress is a function of each person's personality and physiologic endowment.

Opinion differs about what events are most apt to produce stress reactions. The causes of stress are different at different ages—eg, in young adulthood, the sources of stress are found in the marriage or parent-child relationship, the employment relationship, and the struggle to achieve financial stability; in the middle years, the focus shifts to changing spousal relationships, problems with aging parents, and problems associated with having young adult offspring who themselves are encountering stressful situations; in old age, the principal concerns are apt to be retirement, loss of physical capacity, major personal losses, and thoughts of death.

▶ Clinical Findings

An individual may react to stress by becoming anxious or depressed, by developing a physical symptom, by running

away, having a drink, overeating, starting an affair, or in limitless other ways. Common subjective responses are fear (of repetition of the stress-inducing event), rage (at frustration), guilt (over aggressive impulses), and shame (over helplessness). Acute and reactivated stress may be manifested by restlessness, irritability, fatigue, increased startle reaction, and a feeling of tension. Inability to concentrate, sleep disturbances (insomnia, bad dreams), and somatic preoccupations often lead to self-medication, most commonly with alcohol or other central nervous system depressants. Maladaptive behavior in response to stress is called adjustment disorder, with the major symptom specified (eg, "adjustment disorder with depressed mood").

▶ Differential Diagnosis

Adjustment disorders must be distinguished from anxiety disorders, affective disorders, and personality disorders exacerbated by stress and from somatic disorders with psychic overlay. Adjustment disorders may have symptoms that overlap with other disorders, such as anxiety symptoms, but they occur in reaction to an identifiable life stressor such as a difficult work situation or romantic breakup. Adjustment disorders are diagnosed when the symptoms do not fit with a more specific diagnosis such as major depressive disorder which requires at least five criteria. Patients with adjustment disorders have marked distress after a stressor and significant impairment in social or occupational functioning. Adjustment disorders are regarded as acute if less than 6 months or chronic if longer.

▶ Treatment

A. Behavioral

Stress reduction techniques include immediate symptom reduction (eg, rebreathing in a bag for hyperventilation) or early recognition and removal from a stress source before full-blown symptoms appear. It is often helpful for the patient to keep a daily log of stress precipitators, responses, and alleviators. Relaxation, mindfulness-based stress reduction, and exercise techniques are also helpful in reducing the reaction to stressful events.

B. Social

The stress reactions of life crisis problems are a function of psychosocial upheaval, and patients frequently present with somatic symptoms. While it is not easy for the patient to make necessary changes (or they would have been made long ago), it is important for the clinician to establish the framework of the problem, since the patient's denial system may obscure the issues. Clarifying the problem allows the patient to begin viewing it within the proper context and facilitates the sometimes difficult decisions the patient eventually must make (eg, change of job or relocation of adult-dependent offspring).

C. Psychological

Prolonged in-depth psychotherapy is seldom necessary in cases of isolated stress response or adjustment disorder. Supportive psychotherapy (see above) with an emphasis on the here and now and strengthening of existing coping mechanisms is a helpful approach so that time and the patient's own resiliency can restore the previous level of function.

D. Medical

Judicious use of sedatives (eg, lorazepam, 0.5–1 mg two or three times daily orally) for a limited time and as part of an overall treatment plan can provide relief from acute anxiety symptoms. Problems arise when the situation becomes chronic through inappropriate treatment or when the treatment approach supports the development of chronicity.

► Prognosis

Return to satisfactory function after a short period is part of the clinical picture of this syndrome. Resolution may be delayed if others' responses to the patient's difficulties are thoughtlessly harmful or if the secondary gains outweigh the advantages of recovery. The longer the symptoms persist, the worse the prognosis.

Birnie K et al. Psychological benefits for cancer patients and their partners participating in mindfulness-based stress reduction (MBSR). *Psychooncology*. 2010 Sep;19(9):1004–9. [PMID: 19918956]

POSTTRAUMATIC STRESS DISORDER

ESSENTIALS OF DIAGNOSIS

- ▶ Exposure to traumatic (life-threatening) event.
- ▶ Symptoms, such as flashbacks, intrusive images, and nightmares, often represent reexperiencing the event.
- ▶ Avoidance symptoms, including numbing, social withdrawal, and avoidance of stimuli associated with the event.
- ▶ Increased vigilance, such as startle reactions and difficulty falling asleep.
- ▶ Symptoms impair functioning.

► General Considerations

Posttraumatic stress disorder (PTSD)—included among the anxiety disorders in the Diagnostic Statistical Manual-IV (*DSM-IV*)—is a syndrome characterized by “reexperiencing” a traumatic event (eg, rape, severe burns, military combat) and decreased responsiveness and avoidance of current events associated with the trauma. The National Veterans Vietnam Readjustment Survey indicated that 53.4% of male and 48.1% of female Vietnam war veterans experienced some symptoms of PTSD, with approximately 60% of these affected veterans experiencing the full syndrome. Of the male veterans, 44.7% experienced a lifetime prevalence of alcohol or drug abuse, with 13% experiencing current abuse or dependence. Data indicate that 13% of veterans who served in Iraq and 6% of those who served in Afghanistan have experienced PTSD. The 2005 National Comorbidity Survey Report estimated the lifetime prevalence of PTSD among adult Americans at 6.8% with a current prevalence of 3.6% and with women having rates twice as high as men. PTSD is more common when the event is associated with physical injury than when it is not. Many individuals with PTSD (20–40%) have experienced other associated problems, including divorce, parenting problems, difficulties with the law, and substance abuse. Since the terrorist attacks in the United States on September 11, 2001, estimates of PTSD have ranged from 4.7% to 10.2% in those witnessing the live attacks and have been associated with functional impairment as well as increased rates of substance use.

► Clinical Findings

Patients with PTSD experience physiologic hyperarousal, including startle reactions, intrusive thoughts, illusions, overgeneralized associations, sleep problems, nightmares, dreams about the precipitating event, impulsivity, difficulties in concentration, and hyperalertness. The symptoms may be precipitated or exacerbated by events that are a reminder of the original stress. Symptoms frequently arise after a long latency period (eg, child abuse can result in later-onset posttraumatic stress disorder).

► Differential Diagnosis

In 75% of cases, PTSD occurs with comorbid depression or panic disorder, and there is considerable overlap in the symptom complexes of all three conditions. The key to establishing the PTSD diagnosis lies in the history of exposure to a life-threatening event followed by intrusive (eg, flashbacks, nightmares) or avoidance (eg, withdrawal) symptoms. Acute stress disorder occurs during or shortly after a traumatic event and has many of the same symptoms as PTSD but lasts between 2 and 28 days. Some individuals with dissociative features, such as borderline personality disorders, may mimic some of the symptoms of PTSD, but those disorders are typically more related to chronic childhood maltreatment not a specific traumatic event.

► Treatment

A. Psychotherapy

Psychotherapy should be initiated as soon as possible after the traumatic event, and it should be brief (typically 8-12 sessions), once the individual is in a safe environment. Cognitive behavior therapy, exposure therapy, and eye-movement desensitization reprocessing have been effective in significantly reducing the duration of symptoms. In all of these approaches, the individual confronts the traumatic situation and learns to view it with less reactivity. Psychological debriefing in a single session, once a mainstay in prevention of PTSD, is now considered to be ineffective and possibly harmful. Posttraumatic stress syndromes respond to interventions that help patients integrate the event in an adaptive way with some sense of mastery in having survived the trauma. Marital problems are a major area of concern, and it is important that the clinician have available a dependable referral source when marriage counseling is indicated.

Treatment initiated later, when symptoms have crystallized, includes programs for cessation of alcohol and other drug abuse, group and individual psychotherapy, and improved social support systems. The therapeutic approach is to facilitate the normal recovery that was blocked at the time of the trauma.

B. Medication

Early treatment of anxious arousal with β -blockers (eg, propranolol, 80–160 mg orally daily) may lessen the peripheral symptoms of anxiety (eg, tremors, palpitations) but has not been shown to help prevent development of PTSD. Antidepressant medications—particularly selective serotonin reuptake inhibitors (SSRIs)—in full dosage are helpful in ameliorating depression, panic attacks, sleep disruption, and startle responses in chronic PTSD. Sertraline and paroxetine are approved by the US Food and Drug Administration (FDA) for this purpose. Antiseizure medications such as carbamazepine (400–800 mg orally daily) will often mitigate impulsivity and difficulty with anger management. Benzodiazepines, such as clonazepam (1–4 mg daily orally, divided into one or two doses), will reduce anxiety and panic attacks when used in adequate dosage, but dependency problems are a concern, particularly when the patient has had such problems in the past. The α -adrenergic blocking agent prazosin (2–10 mg orally at bedtime) has been successfully used to decrease nightmares and improve quality of sleep in PTSD.

► Prognosis

The sooner therapy is initiated after the trauma, the better the prognosis. Approximately half of patients experience chronic symptoms. Prognosis is best in those with good premorbid psychiatric functioning. Individuals experiencing an acute stress disorder typically do better than those experiencing a delayed posttraumatic disorder. Individuals who experience trauma resulting from a natural disaster (eg, earthquake or hurricane) tend to do better than those who experience a traumatic interpersonal encounter (eg, rape or combat).

ANXIETY DISORDERS & DISSOCIATIVE DISORDERS

ESSENTIALS OF DIAGNOSIS

- Overt anxiety or an overt manifestation of a coping mechanism (such as a phobia), or both.
- Not limited to an adjustment disorder.
- Somatic symptoms referable to the autonomic nervous system or to a specific organ system (eg, dyspnea, palpitations, paresthesias).
- Not a result of physical disorders, psychiatric conditions (eg, schizophrenia), or drug abuse (eg, cocaine).

► General Considerations

Stress, fear, and anxiety all tend to be interactive. The principal components of anxiety are **psychological** (tension, fears, difficulty in concentration, apprehension) and **somatic** (tachycardia, hyperventilation, palpitations, tremor, sweating). Other organ systems (eg, gastrointestinal) may be involved in multiple-system complaints. Fatigue and sleep disturbances are common. Sympathomimetic symptoms of anxiety are both a response to a central nervous system state and a reinforcement of further anxiety. Anxiety can become self-generating, since the symptoms reinforce the reaction, causing it to spiral. This is often the case when the anxiety is an epiphenomenon of other medical or psychiatric disorders.

Anxiety may be free-floating, resulting in acute anxiety attacks, occasionally becoming chronic. When one or several coping mechanisms (see above) are functioning, the consequences are well-known problems such as phobias, conversion reactions, dissociative states, obsessions, and compulsions. Lack of structure is frequently a contributing factor, as noted in those people who have “Sunday neuroses.” They do well during the week with a planned work schedule but cannot tolerate the unstructured weekend. Planned-time activities tend to bind anxiety, and many people have increased difficulties when this is lost, as in retirement.

Some believe that various manifestations of anxiety are not a result of unconscious conflicts but are “habits”—persistent patterns of nonadaptive behavior acquired by learning. The “habits,” being nonadaptive, are unsatisfactory ways of dealing with life’s problems—hence the resultant anxiety. Help is sought only when the anxiety becomes too painful. Exogenous factors such as stimulants (eg, caffeine, cocaine) must be considered as a contributing factor.

► Clinical Findings

A. Generalized Anxiety Disorder

This is the most common of the clinically significant anxiety disorders. Initial manifestations appear at age 20–35 years, and there is a slight predominance in women. The anxiety symptoms of apprehension, worry, irritability, difficulty in concentrating, insomnia, and somatic complaints are present more days than not for at least 6 months. Manifestations can include cardiac (eg, tachycardia, increased blood pressure), gastrointestinal (eg, increased acidity, nausea, epigastric pain), and neurologic (eg, headache, near-syncope) systems. The focus of the anxiety may be a number of everyday activities.

B. Panic Disorder

This is characterized by short-lived, recurrent, unpredictable episodes of intense anxiety accompanied by marked physiologic manifestations. **Agoraphobia**, fear of being in places where escape is difficult, such as open spaces or public places where one cannot easily hide, may be present and may lead the individual to confine his or her life to the home environment. Distressing symptoms and signs such as dyspnea, tachycardia, palpitations, headaches, dizziness, paresthesias, choking, smothering feelings, nausea, and bloating are associated with feelings of impending doom (alarm response). Although these symptoms may lead to overlap with some of the same bodily complaints found in the somatoform disorders, the key to the diagnosis of panic disorder is the psychic pain and suffering the individual expresses. Recurrent **sleep panic attacks** (not nightmares) occur in about 30% of panic disorders. Anticipatory anxiety develops in all these patients and further constricts their daily lives. Panic disorder tends to be familial, with onset usually under age 25; it affects 3–5% of the population, and the female-to-male ratio is 2:1. The premenstrual period is one of heightened vulnerability. Patients frequently undergo emergency medical evaluations (eg, for “heart attacks” or “hypoglycemia”) before the correct diagnosis is made. Gastrointestinal symptoms are especially common, occurring in about one-third of cases. Myocardial infarction, pheochromocytoma, hyperthyroidism, and various recreational drug reactions can mimic panic disorder. Mitral valve prolapse may be present but is not usually a significant factor. Patients who have recurrent panic disorder often become **demoralized, hypochondriacal, agoraphobic, and depressed**. These individuals are at increased risk for major depression and the suicide attempts associated with that disorder. Alcohol abuse (in about 20%) results from self-treatment and is not infrequently combined with dependence on sedatives. Some patients have atypical panic attacks associated with seizure-like symptoms that often include psychosensory phenomena (a history of stimulant abuse often emerges). About 25% of panic disorder patients also have obsessive-compulsive disorder (OCD).

C. Obsessive-Compulsive Disorder

In the obsessive-compulsive reaction, the irrational idea or the impulse persistently intrudes into awareness. Obsessions

(constantly recurring thoughts such as fears of exposure to germs) and compulsions (repetitive actions such as washing the hands many times) are recognized by the individual as absurd and are resisted, but anxiety is alleviated only by ritualistic performance of the action or by deliberate contemplation of the intruding idea or emotion. Many patients do not mention the symptoms and must be asked about them. These patients are usually predictable, orderly, conscientious, and intelligent—traits that are seen in many compulsive behaviors such as food binging and purging and compulsive exercise. There is an overlapping of OCD and other behaviors (“OCD spectrum”), including tics, trichotillomania (hair pulling), onychophagia (nail biting), hypochondriasis, Tourette syndrome, and eating disorders (see Chapter 29). The 2–3% incidence of OCD in the general population is much higher than was previously recognized. In addition, there is a high comorbidity of OCD and major depression; two-thirds of OCD patients will develop major depression during their lifetime. Male to female ratios are similar, with the highest rates occurring in the young, divorced, separated, and unemployed (all high-stress categories). Neurologic abnormalities of fine motor coordination and involuntary movements are common. Under extreme stress, these patients sometimes exhibit paranoid and delusional behaviors, often associated with depression, and can mimic schizophrenia.

D. Phobic Disorder

Phobic ideation can be considered a form of “displacement” in which patients transfer feelings of anxiety from their true object to one that can be avoided. However, since phobias are ineffective coping mechanisms, there tends to be an increase in their scope, intensity, and number. Social phobias are global or specific; in the former, all social situations are poorly tolerated, while the latter group includes performance anxiety or well-delineated phobias (eg, fear of bridges). Agoraphobia is frequently associated with severe panic attacks, and it often develops in early adult life, making a normal lifestyle difficult.

E. Dissociative Disorder

Fugue (the sudden, unexpected travel away from one's home with inability to recall one's past), amnesia, somnambulism, dissociative identity disorder (multiple personality disorder), and depersonalization are all dissociative states. The reaction is precipitated by emotional crisis. The symptom produces anxiety reduction and a temporary solution of the crisis. Mechanisms include repression and isolation as well as particularly limited scope of attention as seen in hypnotic states. Dissociative symptoms are similar in many ways to symptoms seen in patients with temporal lobe dysfunction.

► Treatment

In all cases, underlying medical disorders must be ruled out (eg, cardiovascular, endocrine, respiratory, and neurologic disorders and substance-related syndromes, both intoxication and withdrawal states). These and other disorders can coexist with panic disorder.

A. Medical

1. Generalized anxiety—Benzodiazepines are the anxiolytics of choice in the acute management of generalized anxiety (Table 25–1). They are almost immediately effective. Antidepressants can be efficacious for the long-term treatment of generalized anxiety disorder, panic disorder, social phobia, and OCD.

All of the benzodiazepines may be given orally, and several are available in parenteral formulations. Benzodiazepines such as lorazepam are absorbed rapidly when given intramuscularly. In psychiatric disorders, the

benzodiazepines are usually given orally; in controlled medical environments (eg, the ICU), where the rapid onset of respiratory depression can be assessed, they are often given intravenously. Onset of action is a function of the rate of absorption (related to lipophilic property) and varies, with diazepam and clonazepam being the most rapidly absorbed orally. This characteristic, along with high lipid solubility, may explain the popularity of diazepam. In the average case of anxiety, diazepam, 5–10 mg orally twice daily as needed, is a reasonable starting regimen.

The duration of action of the benzodiazepines varies as a function of the active metabolites they produce.

Table 25–1. Commonly used antianxiety and hypnotic agents.

Drug	Usual Daily Oral Doses	Usual Daily Maximum Doses	Cost for 30 Days Treatment Based on Maximum Dosage ¹
Benzodiazepines (used for anxiety)			
Alprazolam (Xanax) ²	0.5 mg	4 mg	\$115.20
Chlordiazepoxide (Librium) ³	10–20 mg	100 mg	\$46.80
Clonazepam (Klonopin) ³	1–2 mg	10 mg	\$169.50
Clorazepate (Tranxene) ³	15–30 mg	60 mg	\$260.40
Diazepam (Valium) ³	5–15 mg	30 mg	\$18.00
Lorazepam (Ativan) ²	2–4 mg	4 mg	\$73.20
Oxazepam (Serax) ²	10–30 mg	60 mg	\$95.40
Benzodiazepines (used for sleep)			
Estazolam (Prosom) ²	1 mg	2 mg	\$29.70
Flurazepam (Dalmane) ³	15 mg	30 mg	\$10.50
Midazolam (Versed IV) ⁴	5 mg IV		\$1.04/dose
Quazepam (Doral) ³	7.5 mg	15 mg	\$138.00
Temazepam (Restoril) ²	15 mg	30 mg	\$26.40
Triazolam (Halcion) ⁵	0.125 mg	0.25 mg	\$20.10
Miscellaneous (used for anxiety)			
Buspirone (Buspar) ²	10–30 mg	60 mg	\$218.40
Phenobarbital ³	15–30 mg	90 mg	\$3.30
Miscellaneous (used for sleep)			
Chloral hydrate (Noctec) ²	500 mg	1000 mg	\$85.20
Eszopiclone (Lunesta) ⁵	2–3 mg	3 mg	\$235.50
Hydroxyzine (Vistaril) ²	50 mg	100 mg	\$66.60
Ramelteon (Rozerem)	8 mg	8 mg	\$189.60
Zaleplon (Sonata) ⁶	5–10 mg	10 mg	\$112.50
Zolpidem (Ambien) ⁵	5–10 mg	10 mg	\$138.60

²Intermediate physical half-life (10–20 hours).

³Long physical half-life (> 20 hours).

⁴Intravenously for procedures.

⁵Short physical half-life (1–6 hours).

⁶Short physical half-life (about 1 hour).

Benzodiazepines such as lorazepam do not produce active metabolites and have intermediate half-lives of 10–20 hours, characteristics useful in treating elderly patients. Ultra-short-acting agents such as triazolam have half-lives of 1–3 hours and may lead to rebound withdrawal anxiety. Longer-acting benzodiazepines such as flurazepam and diazepam produce active metabolites, have half-lives of 20–120 hours, and should be avoided in the elderly. Since people vary widely in their response and since the medications are long-lasting, the dosage must be individualized. Once this is established, an adequate dose early in the course of symptom development will obviate the need for “pill popping,” which contributes to dependency problems. Panic disorder does not usually respond to benzodiazepines other than clonazepam and alprazolam. Those high-potency benzodiazepines and the antidepressants are most commonly used for panic disorder. Notably, alprazolam has a relatively short half-life and over time can lead to interdose rebound anxiety, although the extended release form is available and obviates this difficulty.

Whether the indications for benzodiazepines are anxiety or insomnia, the medications should be used judiciously. The longer-acting benzodiazepines are used for the treatment of alcohol withdrawal and anxiety symptoms; the intermediate medications are useful as sedatives for insomnia (eg, lorazepam), while short-acting agents (eg, midazolam) are used for medical procedures such as endoscopy.

The side effects of all the benzodiazepine antianxiety agents are patient and dose dependent. As the dosage exceeds the levels necessary for sedation, the side effects include disinhibition, ataxia, dysarthria, nystagmus, and delirium. (The patient should be told not to operate machinery until he or she is well stabilized without side effects.)

Paradoxical agitation, anxiety, psychosis, confusion, mood lability, and anterograde amnesia have been reported, particularly with the shorter-acting benzodiazepines. These agents produce cumulative clinical effects with repeated dosage (especially if the patient has not had time to metabolize the previous dose), additive effects when given with other classes of sedatives or alcohol (many apparently “accidental” deaths are the result of concomitant use of sedatives and alcohol), and residual effects after termination of treatment (particularly in the case of medications that undergo slow biotransformation).

Overdosage results in respiratory depression, hypotension, shock syndrome, coma, and death. Flumazenil, a benzodiazepine antagonist, is effective in overdosage. Overdosage (see Chapter 38) and withdrawal states are medical emergencies. Serious side effects of chronic excessive dosage are development of tolerance, resulting in increasing dose requirements, and physiologic dependence, resulting in withdrawal symptoms similar in appearance to alcohol and barbiturate withdrawal (withdrawal effects must be distinguished from reemergent anxiety). Abrupt withdrawal of sedative medications may cause serious and even fatal convulsive seizures. Psychosis, delirium, and autonomic dysfunction have also been described. Both duration of action and duration of exposure are major factors related to likelihood of withdrawal.

Table 25–2. Benzodiazepine interactions with other medications.

Drug	Effects
Antacids	Decreased absorption of benzodiazepines
Cimetidine	Increased half-life of diazepam and triazolam
Contraceptives	Increased levels of diazepam and triazolam
Digoxin	Alprazolam and diazepam raise digoxin level
Disulfiram	Increased duration of action of sedatives
Isoniazid	Increased plasma diazepam
Levodopa	Inhibition of antiparkinsonism effect
Propoxyphene	Impaired clearance of diazepam
Rifampin	Decreased plasma diazepam
Warfarin	Decreased prothrombin time

Common withdrawal symptoms after low to moderate daily use of benzodiazepines are classified as **somatic** (disturbed sleep, tremor, nausea, muscle aches), **psychological** (anxiety, poor concentration, irritability, mild depression), or **perceptual** (poor coordination, mild paranoia, mild confusion). The presentation of symptoms will vary depending on the half-life of the drug. There are no significant side effects on organ systems other than the brain, and the medications are safe in most medical conditions. Benzodiazepine interactions with other medications are listed in Table 25–2.

Antidepressants are the first-line medications for sustained treatment of generalized anxiety disorder, having the advantage of not causing serious physiologic dependency problems. At initiation of treatment, antidepressants can themselves be anxiogenic—thus, an initial dose, in conjunction with short-term treatment with a benzodiazepine, is often indicated. Venlafaxine and duloxetine (serotonin and norepinephrine reuptake inhibitors) are FDA-approved for the treatment of generalized anxiety disorder in usual antidepressant doses. Initial daily dosing should start low (37.5–75 mg for venlafaxine and 30 mg for duloxetine) and be titrated upward as needed. SSRIs, such as paroxetine, are also used. Similarly, buspirone, sometimes used as an augmenting agent in the treatment of depression and compulsive behaviors, is also effective for generalized anxiety. Buspirone is usually given in a total dosage of 15–60 mg/d in three divided doses. Higher doses tend to be counterproductive and produce gastrointestinal symptoms and dizziness. There is a 2- to 4-week delay before antidepressants and buspirone take effect, and patients require education regarding this lag. Sleep is sometimes negatively affected. β -Blockers such as propranolol may help reduce peripheral somatic symptoms. Alcohol is the most frequently self-administered drug and should be interdicted. The highly addicting medications with a narrow margin of safety such as glutethimide, ethchlorvynol, methprylon, meprobamate, and the barbiturates (with the exception of phenobarbital) should be

avoided. Phenobarbital, in addition to its anticonvulsant properties, is a reasonably safe and very inexpensive sedative but has the disadvantage of causing hepatic microsomal enzyme stimulation (not the case with benzodiazepines), which may affect the metabolism of other medications.

2. Panic attacks—Panic attacks may be treated in several ways. A sublingual dose of alprazolam (0.5–1 mg) is often effective for urgent treatment. For sustained treatment, SSRIs are the initial medications of choice (adequate blood levels will require dosages similar to those used in the treatment of depression). For example, sertraline starting at 25 mg/d and increased after 1 week to 50 mg/d may be effective. Because of initial agitation in response to antidepressants, doses should start low and be very gradually increased. High-potency benzodiazepines may be used for symptomatic treatment as the antidepressant dose is titrated upward. Clonazepam (1–6 mg/d orally) and alprazolam (0.5–6 mg/d orally) are effective alternatives to antidepressants. Both medications may produce marked withdrawal if stopped abruptly and should always be tapered. Because of chronicity of the disorders and the problem of dependency with benzodiazepine medications, it is generally desirable to use antidepressant medications as the principal pharmacologic approach. Antidepressants have been used in conjunction with β -blockers in resistant cases. Propranolol (40–160 mg/d orally) can mute the peripheral symptoms of anxiety without significantly affecting motor and cognitive performance. They block symptoms mediated by sympathetic stimulation (eg, palpitations, tremulousness) but not nonadrenergic symptoms (eg, diarrhea, muscle tension). Contrary to a common misunderstanding, they usually do not cause depression as a side effect and can be used cautiously in patients with depression. Valproate has been found to be as effective in panic disorder as the antidepressants and is another useful alternative.

3. Phobic disorder—Phobic disorder may be part of the panic disorder and is treated within that framework. Global social phobias may be treated with SSRIs, such as paroxetine, sertraline, and fluvoxamine, or monoamine oxidase (MAO) inhibitors in the same dosage as used for depression. Gabapentin, an anticonvulsant with anxiolytic properties, may be an alternative to antidepressants in the treatment of social phobia in a dosage of 300–3600 mg/d, depending on response versus sedation. Specific phobias such as performance anxiety may respond to moderate doses of β -blockers, such as propranolol, 20–40 mg 1 hour prior to exposure. D-cycloserine (DCS), an antituberculosis drug, has been investigated as an augmenting agent in exposure treatment. As a partial agonist at the NMDA receptor in the amygdala, DCS appears to slightly speed up in vivo reduction of fear responses. Importantly, such medications must be used in combination with cognitive behavioral exposure strategies.

4. Obsessive-compulsive disorder—OCD responds to serotonergic medications in about 60% of cases and usually requires a longer response time than for depression (up to 12 weeks). Clomipramine has proved effective in doses equivalent to those used for depression. Fluoxetine (an SSRI drug) has been widely used in this disorder but in

doses higher than those used in depression (up to 60–80 mg/d). The other SSRI medications such as sertraline, paroxetine, and fluvoxamine are being used with comparable efficacy, each with its own side-effect profile. Buspirone in doses of 15–60 mg/d appears to be effective primarily as an anti-obsessional augmenting agent for the SSRI medications. There is some evidence that antipsychotics may be helpful as adjuncts to the SSRIs in treatment-resistant cases. Psychosurgery has a limited place in selected cases of severe unremitting OCD. The stereotactic techniques now being used, including modified cingulotomy, are great improvements over the crude methods of the past. Experimental work has suggested a role for deep brain stimulation in OCD.

B. Behavioral

Behavioral approaches are widely used in various anxiety disorders, often in conjunction with medication. Any of the behavioral techniques can be used beneficially in altering the contingencies (precipitating factors or rewards) supporting any anxiety-provoking behavior. Relaxation techniques can sometimes be helpful in reducing anxiety. Desensitization, by exposing the patient to graded doses of a phobic object or situation, is an effective technique and one that the patient can practice outside the therapy session. Emotive imagery, wherein the patient imagines the anxiety-provoking situation while at the same time learning to relax, helps decrease the anxiety when the patient faces the real-life situation. Physiologic symptoms in panic attacks respond well to relaxation training. Exposure techniques with response prevention are useful for OCD.

C. Psychological

Cognitive behavioral approaches have been effective in treatment of panic disorders, phobias, and OCD when erroneous beliefs need correction. These approaches share a common behavioral technique of exposing the individual to the feared object or situation. The combination of medical and cognitive behavioral therapy is more effective than either alone. Group therapy is the treatment of choice when the anxiety is clearly a function of the patient's difficulties in dealing with social settings. Acceptance and commitment therapy is a new psychotherapy that has been used with some success in anxiety disorders. It encourages individuals to keep focused on life goals while they "accept" the presence of anxiety in their lives.

D. Social

Peer support groups for panic disorder and agoraphobia have been particularly helpful. Social modification may require measures such as family counseling to aid acceptance of the patient's symptoms and avoid counterproductive behavior in behavioral training. Any help in maintaining the social structure is anxiety-alleviating, and work, school, and social activities should be maintained. School and vocational counseling may be provided by professionals, who often need help from the clinician in defining the patient's limitations.

► Prognosis

Anxiety disorders are usually long-standing and may be quite difficult to treat. All can be relieved to varying degrees with medications and behavioral techniques. The prognosis is much better if the commonly observed anxiety-panic-phobia-depression cycle can be broken with a combination of the therapeutic interventions discussed above.

SOMATOFORM DISORDERS (Abnormal Illness Behaviors)

ESSENTIALS OF DIAGNOSIS

- Physical symptoms may involve one or more organ systems and are not intentional.
- Subjective complaints exceed objective findings.
- Correlations of symptom development and psychosocial stresses.
- Combination of biogenetic and developmental patterns.

► General Considerations

Somatoform disorders can occur focused on any organ system. Vulnerability in one or more organ systems and exposure to family members with somatization problems play a major role in the development of particular symptoms, and the “functional” versus “organic” dichotomy is a hindrance to good treatment. Clinicians should suspect psychiatric disorders in a number of conditions. For example, 45% of patients complaining of palpitations had lifetime psychiatric diagnoses including generalized anxiety, depression, panic, and somatization disorders. Similarly, 33–44% of patients who undergo coronary angiography for chest pain but have negative results have been found to have panic disorder.

In any patient presenting with a condition judged to be somatoform, depression must be considered in the diagnosis.

► Clinical Findings

A. Conversion Disorder

“Conversion” (formerly “hysterical conversion”) of psychic conflict into physical symptoms in parts of the body innervated by the sensorimotor system (eg, paralysis, aphonia) is a disorder that is more common in individuals from lower socioeconomic classes and certain cultures. The coping mechanisms used in this condition are repression (a barring from consciousness) and isolation (a splitting of the affect from the idea). The somatic manifestation that takes the place of anxiety is often paralysis, and in some instances the organ dysfunction may have symbolic meaning (eg, arm paralysis in marked anger so the individual cannot use the arm to strike someone). Pseudoepileptic (“hysterical”) seizures are often difficult to differentiate from intoxication states or panic attacks. Retention of consciousness, random flailing with asynchronous movements of the right and left sides, and resistance to having the nose and mouth pinched closed during the attack, all point toward a pseudoepileptic event. Electroencephalography, particularly in a video-electroencephalography assessment unit, during the attack is the most helpful diagnostic aid in excluding genuine seizure states. Serum prolactin levels rise abruptly in the postictal state only in true epilepsy. La belle indifférence (an unconcerned affect) is not a significant identifying characteristic, as commonly believed, since individuals even with genuine medical illness, may exhibit a high level of denial. Important conversion disorder criteria include a history of conversion or somatization disorder, modeling the symptom after someone else who had a similar presentation, a serious precipitating emotional event, associated psychopathology (eg, depression, schizophrenia, personality disorders), a temporal correlation between the precipitating event and the symptom, and a temporary “solving of the problem” by the conversion. It is important to identify physical disorders with unusual presentations (eg, multiple sclerosis, systemic lupus erythematosus).

B. Somatization Disorder (Briquet Syndrome, Hysteria)

This is characterized by multiple physical complaints referable to several organ systems. Anxiety, panic disorder, and depression are often present, and **major depression** is an important consideration in the differential diagnosis. There is a significant relationship (20%) to a lifetime history of panic-agoraphobia-depression. It usually occurs before age 30 and is ten times more common in women. Polysurgery is often a feature of the history. Preoccupation with medical and surgical therapy becomes a lifestyle that excludes most other activities. The symptoms indicate maladaptive coping techniques and there is often evidence of long-standing somatic complaints, including multiple pain and gastrointestinal symptoms (such as dyspareunia, dysmenorrhea, headache, backache, abdominal pain, vomiting, bloating) and pseudoneurologic symptoms (such as amnesia or pseudoepileptic seizures), often with a history of similar organ system involvement in other family members. Multiple symptoms that constantly change and the

inability of more than three doctors to make a diagnosis are strong clues to the problem.

C. Pain Disorder Associated with Psychological Factors (Formerly Somatoform Pain Disorder)

This involves a long history of complaints of severe pain out of proportion to any biomedical findings that are present. This diagnosis must not be one of exclusion and should be made only after extended evaluation has established a clear correlation of psychogenic factors with exacerbations and remissions of complaints.

D. Hypochondriasis

This is a fear of disease and preoccupation with the body, with perceptual amplification and heightened responsiveness. A process of social learning is usually involved, frequently with a role model who was a member of the family and may be a part of the underlying psychodynamic causation. It is common in panic disorders.

E. Factitious Disorders

These disorders, in which symptom production is intentional, are not somatoform conditions in that symptoms are produced consciously, in contrast to the unconscious process of the above conditions. They are characterized by self-induced symptoms or false physical and laboratory findings for the purpose of deceiving clinicians or other hospital personnel. The deceptions may involve self-mutilation, fever, hemorrhage, hypoglycemia, seizures, and an almost endless variety of manifestations—often presented in an exaggerated and dramatic fashion (**Munchausen syndrome**). “Munchausen by proxy” is the term used when a parent creates an illness in a child so the adult (usually the mother) can maintain a relationship with clinicians. The duplicity may be either simple or extremely complex and difficult to recognize. The patients are frequently connected in some way with the health professions; they are often migratory; and there is no apparent external motivation other than achieving the patient role.

► Complications

A poor clinician-patient relationship, with iatrogenic disorders and “doctor shopping,” tends to exacerbate the problem. Sedative and analgesic dependency is the most common iatrogenic complication.

► Treatment

A. Medical

Medical support with careful attention to building a therapeutic practitioner-patient relationship is the mainstay of treatment. It must be accepted that the patient's distress is real. Every problem not found to have an organic basis is not necessarily a mental disease. Diligent attempts should be made to relate symptoms to adverse developments in the patient's life. It may be useful to have the patient keep a meticulous diary, paying particular attention to various pertinent factors evident in the history. Regular, frequent,

short appointments that are not symptom-contingent may be helpful. Medications (frequently abused) should not be prescribed to replace appointments. One person should be the primary clinician, and consultants should be used mainly for evaluation. An empathic, realistic, optimistic approach must be maintained in the face of the expected ups and downs. Ongoing reevaluation is necessary, since somatization can coexist with a concurrent physical illness.

B. Psychological

Psychological approaches can be used by the primary clinician when it is clear that the patient is ready to make some changes in lifestyle in order to achieve symptomatic relief. This is often best approached on a here-and-now basis and oriented toward pragmatic changes rather than an exploration of early experiences that the patient frequently fails to relate to current distress. Group therapy with other individuals who have similar problems is sometimes of value to improve coping, allow ventilation, and focus on interpersonal adjustment. Hypnosis or lorazepam interviews used early are helpful in resolving conversion disorders. If the primary clinician has been working with the patient on psychological problems related to the physical illness, the groundwork is often laid for successful psychiatric referral.

For patients who have been identified as having a factitious disorder, early psychiatric consultation is indicated. There are two main treatment strategies for these patients. One consists of a conjoint confrontation of the patient by both the primary clinician and the psychiatrist. The patient's disorder is portrayed as a cry for help, and psychiatric treatment is recommended. The second approach avoids direct confrontation and attempts to provide a face-saving way to relinquish the symptom without overt disclosure of the disorder's origin. Techniques such as biofeedback and self-hypnosis may foster recovery using this strategy. Another face-saving approach is to use a double bind with the patient. For example, the patient is told there are two possible diagnoses: (1) an organic disease that should respond to the next medical intervention (usually modest and noninvasive), or (2) factitious disorder for which the patient will need psychiatric treatment. Given these options, many patients will choose to recover and not have to admit the origin of their problem.

C. Behavioral

Behavioral therapy is probably best exemplified by biofeedback techniques. In biofeedback, the particular abnormality (eg, increased peristalsis) must be recognized and monitored by the patient and therapist (eg, by an electronic stethoscope to amplify the sounds). This is immediate feedback, and after learning to recognize it, the patient can then learn to identify any change thus produced (eg, a decrease in bowel sounds) and so become a conscious originator of the feedback instead of a passive recipient. Relief of the symptom operantly conditions the patient to utilize the maneuver that relieves symptoms (eg, relaxation causing a decrease in bowel sounds). With emphasis on this

type of learning, the patient is able to identify symptoms early and initiate the countermeasures, thus decreasing the symptomatic problem. Migrainoid and tension headaches have been particularly responsive to biofeedback methods.

D. Social

Social endeavors include family, work, and other interpersonal activity. Family members should come for some appointments with the patient so they can learn how best to live with the patient. This is particularly important in treatment of somatization and pain disorders. Peer support groups provide a climate for encouraging the patient to accept and live with the problem. Ongoing communication with the employer may be necessary to encourage long-term continued interest in the employee. Employers can become just as discouraged as clinicians in dealing with employees who have chronic problems.

► Prognosis

The prognosis is much better if the primary clinician is able to intervene early before the situation has deteriorated. After the problem has crystallized into chronicity, it is very difficult to effect change.

CHRONIC PAIN DISORDERS

ESSENTIALS OF DIAGNOSIS

- ▶ Chronic complaints of pain.
- ▶ Symptoms frequently exceed signs.
- ▶ Minimal relief with standard treatment.
- ▶ History of having seen many clinicians.
- ▶ Frequent use of several nonspecific medications.

► General Considerations

A problem in the management of pain is the lack of distinction between acute and chronic pain syndromes. Most clinicians are adept at dealing with acute pain problems but have difficulty handling the patient with a chronic pain disorder. This type of patient frequently takes too many medications, stays in bed a great deal, has seen many clinicians, has lost skills, and experiences little joy in either work or play. All relationships suffer (including those with clinicians), and life becomes a constant search for succor. The

search results in complex clinician-patient relationships that usually include many drug trials, particularly sedatives, with adverse consequences (eg, irritability, depressed mood) related to long-term use. Treatment failures provoke angry responses and depression from both the patient and the clinician, and the pain syndrome is exacerbated. When frustration becomes too great, a new clinician is found, and the cycle is repeated. The longer the existence of the pain disorder, the more important become the psychological factors of anxiety and depression. As with all other conditions, it is counterproductive to speculate about whether the pain is “real.” It is real to the patient, and acceptance of the problem must precede a mutual endeavor to alleviate the disturbance.

► Clinical Findings

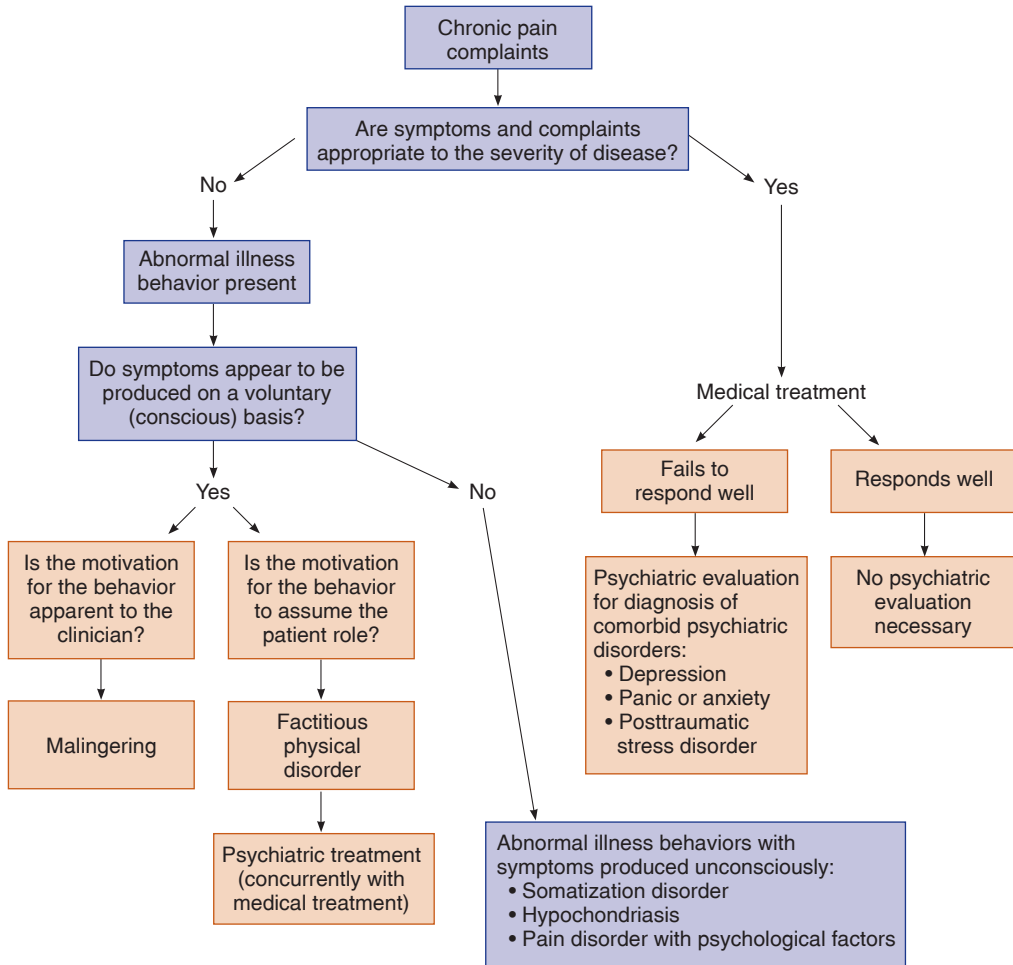

Components of the chronic pain syndrome consist of anatomic changes, chronic anxiety and depression, anger, and changed lifestyle. Usually, the anatomic problem is irreversible, since it has already been subjected to many interventions with increasingly unsatisfactory results. An algorithm for assessing chronic pain and differentiating it from other psychiatric conditions is illustrated in Figure 25–1.

Chronic anxiety and depression produce heightened irritability and overreaction to stimuli. A marked decrease in pain threshold is apparent. This pattern develops into a hypochondriacal preoccupation with the body and a constant need for reassurance. The pressure on the clinician becomes wearing and often leads to covert rejection of the patient, such as not being available or making referrals to other clinicians.

This is perceived by the patient, who then intensifies the effort to find help, and the typical cycle is repeated. Anxiety and depression are seldom discussed, almost as if there is a tacit agreement not to deal with these issues.

Changes in lifestyle involve some of the pain behaviors. These usually take the form of a family script in which the patient accepts the role of being sick, and this role then becomes the focus of most family interactions and may become important in maintaining the family, so that neither the patient nor the family wants the patient’s role to change. Demands for attention and efforts to control the behavior of others revolve around the central issue of control of other people (including clinicians). Cultural factors frequently play a role in the behavior of the patient and how the significant people around the patient cope with the problem. Some cultures encourage demonstrative behavior, while others value the stoic role.

Another secondary gain that frequently maintains the patient in the sick role is financial compensation or other benefits. Frequently, such systems are structured so that they reinforce the maintenance of sickness and discourage any attempts to give up the role. Clinicians unwittingly reinforce this role because of the very nature of the practice of medicine, which is to respond to complaints of illness. Helpful suggestions from the clinician are often met with responses like, “Yes, but . . .” Medications then become the principal approach, and drug dependency problems may develop.

► Treatment

A. Behavioral

The cornerstone of a unified approach to chronic pain syndromes is a comprehensive behavioral program. This is necessary to identify and eliminate pain reinforcers, to decrease drug use, and to use effectively those positive reinforcers that shift the focus from the pain. It is critical that the patient be made a partner in the effort to manage and function better in the setting of ongoing pain symptoms. The clinician must shift from the idea of biomedical cure to ongoing care of the patient. The patient should agree to discuss the pain only with the clinician and not with family members; this tends to stabilize the patient's personal life, since the family is usually tired of the subject. At the beginning of treatment, the patient should be assigned self-help tasks graded up to maximal activity as a means of positive reinforcement. The tasks should not exceed capability. The patient can also be asked to keep a self-rating chart to log accomplishments, so that progress can be measured and remembered. Instruct the patient to record degrees of pain on a self-rating scale in relation to various situations and

mental attitudes so that similar circumstances can be avoided or modified.

Avoid positive reinforcers for pain such as marked sympathy and attention to pain. Emphasize a positive response to productive activities, which remove the focus of attention from the pain. Activity is also desensitizing, since the patient learns to tolerate increasing activity levels.

Biofeedback techniques (see Somatoform Disorders, above) and hypnosis have been successful in ameliorating some pain syndromes. Hypnosis tends to be most effective in patients with a high level of denial, who are more responsive to suggestion. Hypnosis can be used to lessen anxiety, alter perception of the length of time that pain is experienced, and encourage relaxation. Mindfulness-based stress reduction programs have been useful in helping individuals develop an enhanced capacity to live a higher quality life with persistent pain.

B. Medical

A single clinician in charge of the comprehensive treatment approach is the highest priority. Consultations as indicated

and technical procedures done by others are appropriate, but the care of the patient should remain in the hands of the primary clinician. Referrals should not be allowed to raise the patient's hopes unrealistically or to become a way for the clinician to reject the case. The attitude of the clinician should be one of honesty, interest, and hopefulness—not for a cure but for control of pain and improved function. If the patient manifests opioid addiction, detoxification may be an early treatment goal.

Nonsteroidal anti-inflammatory medications are often the first-line of treatment for pain. If opioid analgesics or sedatives are prescribed, they should not be given on an “as-needed” schedule (see Chapter 5). A fixed schedule lessens the conditioning effects of these medications. Tricyclic antidepressants (TCAs) (eg, nortriptyline), venlafaxine, and duloxetine in doses up to those used in depression may be helpful, particularly in neuropathic pain syndromes. In other conditions, their effects on pain may be less clear, but ameliorating depression is usually important nonetheless. Gabapentin, an anticonvulsant with possible applications in the treatment of anxiety disorders, has been shown to be useful in postherpetic and diabetic neuropathy and somatoform disorders.

In addition to medications, a variety of nonpharmacologic strategies may be offered, including physical therapy and acupuncture.

C. Social

Involvement of family members and other significant persons in the patient's life should be an early priority. The best efforts of both patient and therapists can be unwittingly sabotaged by other persons who may feel that they are “helping” the patient. They frequently tend to reinforce the negative aspects of the chronic pain disorder. The patient becomes more dependent and less active, and the pain syndrome becomes an immutable way of life. The more destructive pain behaviors described by many experts in chronic pain disorders are the results of well-meaning but misguided efforts of family members. Ongoing therapy with the family can be helpful in the early identification and elimination of these behavior patterns.

D. Psychological

In addition to group therapy with family members and others, groups of patients can be helpful if properly led. The major goal, whether of individual or group therapy, is to gain patient involvement. A group can be a powerful instrument for achieving this goal, with the development of group loyalties and cooperation. People will frequently make efforts with group encouragement that they would never make alone. Individual therapy should be directed toward strengthening existing coping mechanisms and improving self-esteem. For example, teaching patients to challenge expectations induced by chronic pain may lead to improved functioning. As an illustration, many chronic pain patients, making assumptions more derived from acute injuries, incorrectly believe they will damage themselves by attempting to function. The rapport between patient and clinician, as in all psychotherapeutic efforts, is the major factor in therapeutic success.

PSYCHOSEXUAL DISORDERS

The stages of sexual activity include **excitement** (arousal), **orgasm**, and **resolution**. The precipitating excitement or arousal is psychologically determined. Arousal response leading to plateau is a physiologic and psychological phenomenon of vasocongestion, a parasympathetic reaction causing erection in men and labial-clitoral congestion in women. The orgasmic response includes emission in men and clonic contractions of the analogous striated perineal muscles of both men and women. Resolution is a gradual return to normal physiologic status.

While the arousal stimuli—vasocongestive and orgasmic responses—constitute a single response in a well-adjusted person, they can be considered as separate stages that can produce different syndromes responding to different treatment procedures.

► Clinical Findings

There are three major groups of sexual disorders.

A. Paraphilias (Sexual Arousal Disorders)

In these conditions, formerly called “deviations” or “variations,” the excitement stage of sexual activity is associated with sexual objects or orientations different from those usually associated with adult sexual stimulation. The stimulus may be a woman's shoe, a child, animals, instruments of torture, or incidents of aggression. The pattern of sexual stimulation is usually one that has early psychological roots. Poor experiences with sexual activity frequently reinforce this pattern over time.

Exhibitionism is the impulsive behavior of exposing the genitalia to unsuspecting strangers in order to achieve sexual excitation. It is a childhood sexual behavior carried into adult life.

Transvestism consists of recurrent cross-dressing behavior in a heterosexual man for the purpose of sexual excitation. Such fetishistic behavior can be part of masturbation foreplay. Transvestism in homosexuality and transsexualism is not for the purpose of sexual excitement but is a function of preference or gender identity disorder.

Voyeurism involves the achievement of sexual arousal by watching the activities of an unsuspecting person, usually in various stages of undress or sexual activity. In both exhibitionism and voyeurism, excitation leads to masturbation as a replacement for sexual activity.

Pedophilia is the use of a child of either sex to achieve sexual arousal and, in many cases, gratification. Contact is frequently oral, with either participant being dominant, but pedophilia includes intercourse of any type. Adults of both sexes engage in this behavior, but because of social and cultural factors it is more commonly identified with men.

The pedophile has difficulty in adult sexual relationships, and men who perform this act are frequently impotent.

Incest involves a sexual relationship with a person in the immediate family, most frequently a child. In many ways it is similar to pedophilia (intrafamilial pedophilia). Incestuous feelings are fairly common, but cultural mores are usually sufficiently strong to act as a barrier to the expression of sexual feelings.

Sexual sadism is the attainment of sexual arousal by inflicting pain upon the sexual object. Much sexual activity has aggressive components (eg, biting, scratching). However, forced sexual acquiescence (eg, rape) is considered to be primarily an act of aggression.

Sexual masochism is the achievement of erotic pleasure by being humiliated, enslaved, physically bound, and restrained. It may be life-threatening, since neck binding or partial asphyxiation usually forms part of the ritual. The practice is much more common in men than in women.

B. Gender Identity Disorder

Core gender identity reflects a biologic self-image—the conviction that “I am a boy” or “I am a girl” that is usually well developed by age 3 or 4. Gender dysphoria refers to the development of a sexual identity that is the opposite of the biologic one.

Transsexualism is an attempt to deny and reverse biologic sex by maintaining sexual identity with the opposite gender. Transsexuals do not alternate between gender roles; rather, they assume a fixed role of attitudes, feelings, fantasies, and choices consonant with those of the opposite sex, all of which clearly date back to early development. For example, male to female transsexuals in early childhood behave, talk, and fantasize as if they were girls. They do not grow out of feminine patterns; they do not work in professions traditionally considered to be masculine; and they have no interest in their own penises either as evidence of maleness or as organs for erotic behavior. The desire for sex change starts early and may culminate in assumption of a feminine lifestyle, hormonal treatment, and use of surgical procedures, eg, castration and vaginoplasty.

C. Psychosexual Dysfunction

This category includes a large group of vasocongestive and orgasmic disorders. Often, they involve problems of sexual adaptation, education, and technique that are often initially discussed with, diagnosed by, and treated by the primary care provider.

There are two conditions common in men: erectile dysfunction and ejaculation disturbances.

Erectile dysfunction is inability to achieve or maintain an erection firm enough for satisfactory intercourse; patients sometimes use the term to mean premature ejaculation. Careful questioning is necessary, since causes of this vasocongestive disorder can be psychological, physiologic, or both. The majority are pathophysiologic and, to varying degrees, treatable. After onset of the problem, a history of occasional erections—especially nocturnal penile tumescence, which may be evaluated by a simple monitoring device, or a sleep study in the sleep laboratory—is usually evidence that the dysfunction is psychological in origin,

with the caveat that decreased nocturnal penile tumescence occurs in some depressed patients. **Psychological erectile dysfunction** is caused by interpersonal or intrapsychic factors (eg, marital disharmony, depression). **Organic factors** are discussed in Chapter 23.

Ejaculation disturbances include premature ejaculation, inability to ejaculate, and retrograde ejaculation. (Ejaculation is possible in patients with erectile dysfunction.) Ejaculation is usually connected with orgasm, and ejaculatory control is an acquired behavior that is minimal in adolescence and increases with experience. Pathogenic factors are those that interfere with learning control, most frequently sexual ignorance. Intrapsychic factors (anxiety, guilt, depression) and interpersonal maladaptation (marital problems, unresponsiveness of mate, power struggles) are also common. Organic causes include interference with sympathetic nerve distribution (often due to surgery or trauma) and the effects of pharmacologic agents (eg, SSRIs or sympatholytics).

In women, the two most common forms of sexual dysfunction are vaginismus and frigidity.

Vaginismus is a conditioned response in which a spasm of the perineal muscles occurs if there is any stimulation of the area. The desire is to avoid penetration. Sexual responsiveness and vasocongestion may be present, and orgasm can result from clitoral stimulation.

Frigidity is a complex condition in which there is a general lack of sexual responsiveness. The woman has difficulty in experiencing erotic sensation and does not have the vasocongestive response. Sexual activity varies from active avoidance of sex to an occasional orgasm. Orgasmic dysfunction—in which a woman has a vasocongestive response but varying degrees of difficulty in reaching orgasm—is sometimes differentiated from frigidity. Causes for the dysfunctions include poor sexual techniques, early traumatic sexual experiences, interpersonal disharmony (marital struggles, use of sex as a means of control), and intrapsychic problems (anxiety, fear, guilt). Organic causes include any conditions that might cause pain in intercourse, pelvic pathology, mechanical obstruction, and neurologic deficits.

Disorders of sexual desire consist of diminished or absent libido in either sex and may be a function of organic or psychological difficulties (eg, anxiety, phobic avoidance). Any chronic illness can reduce desire. Hormonal disorders, including hypogonadism or use of antiandrogen compounds such as cyproterone acetate, and chronic kidney disease contribute to deterioration in sexual desire. Although menopause may lead to diminution of sexual desire in some women, the relationship between menopause and libido is complicated and may be influenced by sociocultural factors. Alcohol, sedatives, opioids, marijuana, and some medications may affect sexual drive and performance.

▶ Treatment

A. Paraphilias and Gender Identity Disorders

1. Psychological—Sexual arousal disorders involving variant sexual activity (paraphilia), particularly those of a more superficial nature (eg, voyeurism) and those of recent onset, are responsive to psychotherapy in a moderate

percentage of cases. The prognosis is much better if the motivation comes from the individual rather than the legal system; unfortunately, however, judicial intervention is frequently the only stimulus to treatment, because the condition persists and is reinforced until conflict with the law occurs. Therapies frequently focus on barriers to normal arousal response; the expectation is that the variant behavior will decrease as normal behavior increases.

2. Behavioral—Aversive and operant conditioning techniques have been tried frequently in gender role disorders but have only occasionally been successful. In some cases, the sexual arousal disorders improve with modeling, role-playing, and conditioning procedures. Emotive imagery is occasionally helpful in lessening anxiety in fetish problems.

3. Social—Although they do not produce a change in sexual arousal patterns or gender role, self-help groups have facilitated adjustment to an often hostile society. Attention to the family is particularly important in helping persons in such groups to accept their situation and alleviate their guilt about the role they think they had in creating the problem.

4. Medical—Medroxyprogesterone acetate, a suppressor of libidinal drive, is used to mute disruptive sexual behavior in men of all ages. Onset of action is usually within 3 weeks, and the effects are generally reversible. Fluoxetine or other SSRIs at depression doses (see Table 25–8) may reduce some of the compulsive sexual behaviors including the paraphilias. A focus of study in the treatment of severe paraphilia has been agonists of luteinizing hormone–releasing hormone. Although some transsexuals are treated with genital reconstructive surgery, many others are screened out by trial periods of living as the other sex prior to operation.

B. Psychosexual Dysfunction

1. Medical—Identification of a contributory reversible cause is most important. Even if the condition is not reversible, identification of the specific cause helps the patient to accept the condition. Marital disharmony, with its exacerbating effects, may thus be avoided. Of all the sexual dysfunctions, erectile dysfunction is the condition most likely to have an organic basis. Sildenafil, tadalafil, and vardenafil are phosphodiesterase type 5 inhibitors that are effective oral agents for the treatment of penile erectile dysfunction (eg, sildenafil 25–100 mg orally 1 hour prior to intercourse). These agents are effective for SSRI-induced erectile dysfunction in men and in some cases for SSRI-associated sexual dysfunction in women. Use of the medications in conjunction with any nitrates, particularly in individuals with coronary artery disease, can have significant hypotensive effects leading to death in some cases. The medication, which does not appear to impact sexual desire, should be used only once a day. Because of their common effect in delaying ejaculation, the SSRIs have been effective in premature ejaculation.

2. Behavioral—Syndromes resulting from conditioned responses have been treated by conditioning techniques, with excellent results. Vaginismus responds well to desensitization with graduated Hegar dilators along with relaxation techniques. Masters and Johnson have used behavioral

approaches in all of the sexual dysfunctions, with concomitant supportive psychotherapy and with improvement of the communication patterns of the couple.

3. Psychological—The use of psychotherapy by itself is best suited for those cases in which interpersonal difficulties or intrapsychic problems predominate. Anxiety and guilt about parental injunctions against sex may contribute to sexual dysfunction. Even in these cases, however, a combined behavioral-psychological approach usually produces results most quickly.

4. Social—The proximity of other people (eg, a mother-in-law) in a household is frequently an inhibiting factor in sexual relationships. In such cases, some social engineering may alleviate the problem.

Eardley I et al. Pharmacotherapy for erectile dysfunction. *J Sex Med.* 2010 Jan;7(1 Pt 2):524–40. [PMID: 20092451]

PERSONALITY DISORDERS

ESSENTIALS OF DIAGNOSIS

- ▶ Long history dating back to childhood.
- ▶ Recurrent maladaptive behavior.
- ▶ Low self-esteem and lack of confidence.
- ▶ Minimal introspective ability with a tendency to blame others for all problems.
- ▶ Major difficulties with interpersonal relationships or society.
- ▶ Depression with anxiety when maladaptive behavior fails.

▶ General Considerations

An individual's personality structure, or character, is an integral part of self-image. It reflects genetics, interpersonal influences, and recurring patterns of behavior adopted in order to cope with the environment. The classification of subtypes of personality disorders depends on the predominant symptoms and their severity. The most severe disorders—those that bring the patient into greatest conflict with society—tend to be classified as antisocial (psychopathic) or borderline.

Personality disorders can be considered a matrix for some of the more severe psychiatric problems (eg, schizotypal, relating to schizophrenia, and avoidance types, relating to some anxiety disorders).

▶ Classification & Clinical Findings

See Table 25–3.

▶ Differential Diagnosis

Patients with personality disorders tend to show anxiety and depression when pathologic coping mechanisms fail, and their symptoms can be similar to those disorders.

Table 25-3. Personality disorders: Classification and clinical findings.

Personality Disorder	Clinical Findings
Antisocial	Selfish, callous, promiscuous, impulsive, unable to learn from experience, often has legal problems.
Avoidant	Fears rejection, hyperreacts to rejection and failure, with poor social endeavors and low self-esteem.
Borderline	Impulsive; has unstable and intense interpersonal relationships; is suffused with anger, fear, and guilt; lacks self-control and self-fulfillment; has identity problems and affective instability; is suicidal (a serious problem—up to 80% of hospitalized borderline patients make an attempt at some time during treatment, and the incidence of completed suicide is as high as 5%); aggressive behavior, feelings of emptiness, and occasional psychotic decompensation. This group has a high drug abuse rate, which plays a role in symptoms. There is extensive overlap with other diagnostic categories, particularly mood disorders and posttraumatic stress disorder.
Dependent	Passive, overaccepting, unable to make decisions, lacks confidence, with poor self-esteem.
Histrionic (hysterical)	Dependent, immature, seductive, egocentric, vain, emotionally labile.
Narcissistic	Exhibitionist, grandiose, preoccupied with power, lacks interest in others, with excessive demands for attention.
Obsessive compulsive	Perfectionist, egocentric, indecisive, with rigid thought patterns and need for control.
Paranoid	Defensive, oversensitive, secretive, suspicious, hyperalert, with limited emotional response.
Schizoid	Shy, introverted, withdrawn, avoids close relationships.
Schizotypal	Superstitious, socially isolated, suspicious, with limited interpersonal ability, eccentric behaviors, and odd speech.

Occasionally, the more severe cases may decompensate into psychosis under stress and mimic other psychotic disorders.

► Treatment

A. Social

Social and therapeutic environments such as day hospitals, halfway houses, and self-help communities utilize peer pressures to modify the self-destructive behavior. The patient with a personality disorder often has failed to profit from experience, and difficulties with authority impair the learning experience. The use of peer relationships and the repetition possible in a structured setting of a helpful community enhance the behavioral treatment opportunities and increase learning. When problems are detected early, both the school and the home can serve as foci of intensified social pressure to change the behavior, particularly with the use of behavioral techniques.

B. Behavioral

The behavioral techniques used are principally operant conditioning and aversive conditioning. The former simply emphasizes the recognition of acceptable behavior and its reinforcement with praise or other tangible rewards. Aversive responses usually mean punishment, although this can range from a mild rebuke to some specific punitive responses such as deprivation of privileges. Extinction plays a role in that an attempt is made not to respond to inappropriate behavior, and the lack of response eventually causes the person to abandon that type of behavior. Pouting and tantrums, for example, diminish quickly when such behavior elicits no reaction. Dialectical behavioral therapy is a program of individual and group therapy specifically designed for patients with chronic suicidality and borderline personality disorder. It blends mindfulness and a

cognitive-behavioral model to address self-awareness, interpersonal functioning, affective lability, and reactions to stress.

C. Psychological

Psychological intervention is best conducted in group settings. Group therapy is helpful when specific interpersonal behavior needs to be improved. This mode of treatment also has a place with so-called “acting-out” patients, ie, those who frequently act in an impulsive and inappropriate way. The peer pressure in the group tends to impose restraints on rash behavior. The group also quickly identifies the patient’s types of behavior and helps improve the validity of the patient’s self-assessment, so that the antecedents of the unacceptable behavior can be effectively handled, thus decreasing its frequency. Individual therapy should initially be supportive, ie, helping the patient to restabilize and mobilize coping mechanisms. If the individual has the ability to observe his or her own behavior, a longer-term and more introspective therapy may be warranted. The therapist must be able to handle countertransference feelings (which are frequently negative), maintain appropriate boundaries in the relationship (no physical contacts, however well-meaning), and refrain from premature confrontations and interpretations.

D. Medical

Hospitalization is indicated in the case of serious suicidal or homicidal danger. In most cases, treatment can be accomplished in the day treatment center or self-help community. Antipsychotics may be required for short periods in conditions that have temporarily decompensated into transient psychoses (eg, olanzapine [2.5–10 mg/d orally], risperidone [0.5–2 mg/d orally], or haloperidol [0.5–2 mg/d orally, split into two doses]). In some cases, these medications are required only for several days and can be

discontinued after the patient has regained a previously established level of adjustment; they can also provide ongoing support. Carbamazepine, 400–800 mg orally daily in divided doses, decreases the severity of behavioral dyscontrol. Antidepressants have improved anxiety, depression, and sensitivity to rejection in some borderline patients. SSRIs may have a role in reducing aggressive behavior in impulsive aggressive patients.

► Prognosis

Antisocial and borderline categories generally have a guarded prognosis. Those patients with a history of parental abuse and a family history of mood disorder tend to have the most challenging treatments.

McMain SF et al. A randomized trial of dialectical behavior therapy versus general psychiatric management for borderline personality disorder. *Am J Psychiatry*. 2009 Dec;166(12):1365–74. [PMID: 19755574]

SCHIZOPHRENIA & OTHER PSYCHOTIC DISORDERS

ESSENTIALS OF DIAGNOSIS

- ▶ Social withdrawal, usually slowly progressive, often with deterioration in personal care.
- ▶ Loss of ego boundaries, with inability to perceive oneself as a separate entity.
- ▶ Loose thought associations, often with slowed thinking or overinclusive and rapid shifting from topic to topic.
- ▶ Autistic absorption in inner thoughts and frequent sexual or religious preoccupations.
- ▶ Auditory hallucinations, often of a derogatory nature.
- ▶ Delusions, frequently of a grandiose or persecutory nature.
- ▶ Symptoms of at least 6 months' duration.

Frequent additional signs:

- ▶ Flat affect and rapidly alternating mood shifts irrespective of circumstances.
- ▶ Hypersensitivity to environmental stimuli, with a feeling of enhanced sensory awareness.
- ▶ Variability or changeable behavior incongruent with the external environment.
- ▶ Concrete thinking with inability to abstract; inappropriate symbolism.
- ▶ Impaired concentration worsened by hallucinations and delusions.
- ▶ Depersonalization, wherein one behaves like a detached observer of one's own actions.

► General Considerations

The schizophrenic disorders are a group of syndromes manifested by massive disruption of thinking, mood, and overall behavior as well as poor filtering of stimuli. The characterization and nomenclature of the disorders are quite arbitrary and are influenced by sociocultural factors and schools of psychiatric thought.

It is currently believed that the schizophrenic disorders are of multifactorial cause, with genetic, environmental, and neurotransmitter pathophysiologic components. At present, there is no laboratory method for confirming the diagnosis of schizophrenia. There may or may not be a history of a major disruption in the individual's life (failure, loss, physical illness) before gross psychotic deterioration is evident.

Schizophrenic symptoms have been classified into positive and negative categories. Positive symptoms include hallucinations, delusions, and formal thought disorders; these symptoms appear to be related to increased dopaminergic (D_2) activity in the mesolimbic region. Negative symptoms include diminished sociability, restricted affect, and poverty of speech; these symptoms appear to be related to decreased D_2 activity in the mesocortical system.

“Other psychotic disorders” are conditions that are similar to schizophrenic disorders in their acute symptoms but have a less pervasive influence over the long term. The patient usually attains higher levels of functioning. The acute psychotic episodes tend to be less disruptive of the person's lifestyle, with a fairly quick return to previous levels of functioning.

► Classification

A. Schizophrenic Disorders

Schizophrenic disorders are subdivided on the basis of certain prominent phenomena that are frequently present. **Disorganized (hebephrenic) schizophrenia** is characterized by marked incoherence and an incongruous or silly affect. **Catatonic schizophrenia** is distinguished by a marked psychomotor disturbance of either excitement (purposeless and stereotyped) or rigidity with mutism. Infrequently, there may be rapid alternation between excitement and stupor (see under catatonic syndrome, below). **Paranoid schizophrenia** includes marked persecutory or grandiose delusions often consonant with hallucinations of similar content and with less marked disorganization of speech and behavior. **Undifferentiated schizophrenia** denotes a category in which symptoms are not specific enough to warrant inclusion of the illness in the other subtypes. **Residual schizophrenia** is a classification that includes persons who have clearly had an episode warranting a diagnosis of schizophrenia but who at present have no overt psychotic symptoms, although they show milder signs such as social withdrawal, flat affect, and eccentric behaviors.

B. Delusional Disorders

Delusional disorders are psychoses in which the predominant symptoms are persistent, nonbizarre delusions with

minimal impairment of daily functioning. (The schizophrenic disorders show significant impairment.) Intellectual and occupational activities are little affected, whereas social and marital functioning tend to be markedly involved. Hallucinations are not usually present. Common delusional themes include paranoid delusions of persecution, delusions of being related to or loved by a well-known person, and delusions that one's partner is unfaithful.

C. Schizoaffective Disorders

Schizoaffective disorders are those cases that fail to fit comfortably either in the schizophrenic or in the affective categories. They are usually cases with affective symptoms that precede or develop concurrently with psychotic manifestations. There has been increasing interest in studying prodromal schizophrenia with a goal of prevention or early treatment.

D. Schizophreniform Disorders

Schizophreniform disorders are similar in their symptoms to schizophrenic disorders except that the duration of prodromal, acute, and residual symptoms is > 1 week but < 6 months.

E. Brief Psychotic Disorders

These disorders last < 1 week. They are the result of psychological stress. The shorter duration is significant and correlates with a more acute onset and resolution as well as a much better prognosis.

F. Late Life Psychosis

Brain abnormalities occur in 40% of patients who develop psychotic symptoms after age 60. The psychotic symptoms are typical, and there are other findings such as low IQ scores and diminished cognitive function.

G. Atypical Psychoses

This group includes a wide range of conditions with psychotic symptoms. The cause is often not clear, but later events (eg, new symptoms) may clarify the diagnosis. The most common example is chronic psychosis developing either during periods of heavy abuse of drugs or at some time after the drug use has ceased. Other conditions include temporal lobe dysfunction, HIV infection, and a number of the conditions noted in the differential diagnosis (see below). They often have a good premorbid history, a precipitous onset, and an episodic course with symptom-free intervals.

► Clinical Findings

A. Symptoms and Signs

The symptoms and signs of schizophrenia vary markedly among individuals as well as in the same person at different times. The patient's **appearance** may be bizarre, although the usual finding is a mild to moderate unkempt blandness. **Motor activity** is generally reduced, although extremes

ranging from catatonic stupor to frenzied excitement occur. **Social behavior** is characterized by marked withdrawal coupled with disturbed interpersonal relationships and a reduced ability to experience pleasure. Dependency and a poor self-image are common. **Verbal utterances** are variable, the language being concrete yet symbolic, with unassociated rambling statements (at times interspersed with mutism) during an acute episode. Neologisms (made-up words or phrases), echolalia (repetition of words spoken by others), and verbigeration (repetition of senseless words or phrases) are occasionally present. **Affect** is usually flattened, with occasional inappropriateness. **Depression** is present in almost all cases but may be less apparent during the acute psychotic episode and more obvious during recovery. Depression is sometimes confused with akinetic side effects of antipsychotic medications. It is also related to **boredom**, which increases symptoms and decreases the response to treatment. Work is generally unavailable and time unfilled, providing opportunities for counterproductive activities such as drug abuse, withdrawal, and increased psychotic symptoms.

Thought content may vary from a paucity of ideas to a rich complex of delusional fantasy with archaic thinking. One frequently notes after a period of conversation that little if any information has actually been conveyed. Incoming stimuli produce varied responses. In some cases a simple question may trigger explosive outbursts, whereas at other times there may be no overt response whatsoever (catatonia). When paranoid ideation is present, the patient is often irritable and less cooperative. **Delusions** (false beliefs) are characteristic of paranoid thinking, and they usually take the form of a preoccupation with the supposedly threatening behavior exhibited by other individuals. This ideation may cause the patient to adopt active countermeasures such as locking doors and windows, taking up weapons, covering the ceiling with aluminum foil to counteract radar waves, and other bizarre efforts. Somatic delusions revolve around issues of bodily decay or infestation. **Perceptual distortions** usually include auditory hallucinations—visual hallucinations are more commonly associated with organic mental states—and may include illusions (distortions of reality) such as figures changing in size or lights varying in intensity. Cenesthetic hallucinations (eg, a burning sensation in the brain, feeling blood flowing in blood vessels) occasionally occur. Lack of humor, feelings of dread, depersonalization (a feeling of being apart from the self), and fears of annihilation may be present. Any of the above symptoms generate higher anxiety levels, with heightened arousal and occasional panic and suicidal ideation, as the individual fails to cope.

The development of the acute episode in schizophrenia frequently is the end product of a gradual decompensation. Frustration and anxiety appear early, followed by depression and alienation, along with progressive ineffectiveness in day-to-day coping. This often leads to feelings of panic and increasing disorganization, with loss of the ability to test and evaluate the reality of perceptions. The stage of so-called psychotic resolution includes delusions, autistic pre-occupations, and psychotic insight, with acceptance of the decompensated state. The process is frequently complicated

by the use of caffeine, alcohol, and other recreational drugs. Life expectancy of schizophrenic patients is as much as 20% shorter than that of cohorts in the general population and is often associated with comorbid conditions such as the metabolic syndrome.

Polydipsia may produce water intoxication with hyponatremia—characterized by symptoms of confusion, lethargy, psychosis, seizures, and occasionally death—in any psychiatric disorder, but most commonly in schizophrenia. These problems exacerbate the schizophrenic symptoms and can be confused with them. Possible pathogenetic factors in polydipsia include a hypothalamic defect, inappropriate antidiuretic hormone (ADH) secretion, neuroleptic medications (anticholinergic effects, stimulation of hypothalamic thirst center, effect on ADH), smoking (nicotine and syndrome of inappropriate antidiuretic hormone [SIADH]), psychotic thought processes (delusions), and other medications (eg, diuretics, antidepressants, lithium, alcohol). Other causes of polydipsia must be ruled out (eg, diabetes mellitus, diabetes insipidus, kidney disease).

B. Imaging

Ventricular enlargement and cortical atrophy, as seen on CT scan, have been correlated with chronic course, severe cognitive impairment, and nonresponsiveness to neuroleptic medications. Decreased frontal lobe activity seen on PET scan has been associated with negative symptoms.

► Differential Diagnosis

One should not hesitate to reconsider the diagnosis of schizophrenia in any person who has received that diagnosis in the past, particularly when the clinical course has been atypical. A number of these patients have been found to actually have atypical episodic affective disorders that have responded well to lithium. Manic episodes often mimic schizophrenia. Furthermore, schizophrenia has been diagnosed in many individuals because of inadequacies in psychiatric nomenclature. Thus, schizophrenia was often inappropriately diagnosed in persons with brief reactive psychoses, OCD, paranoid disorders, and schizophreniform disorders.

Psychotic depressions, psychotic organic mental states, and any illness with psychotic ideation tend to be confused with schizophrenia, partly because of the regrettable tendency to use the terms interchangeably. Adolescent phases of growth and counterculture behaviors constitute another area of diagnostic confusion. It is particularly important to avoid a misdiagnosis in these groups, because of the long-term implications arising from having such a serious diagnosis made in a formative stage of life.

Medical disorders such as thyroid dysfunction, adrenal and pituitary disorders, reactions to toxic materials (eg, mercury, PCBs), and almost all of the organic mental states in the early stages must be ruled out. Postpartum psychosis is discussed under Mood Disorders. **Complex partial seizures**, especially when psychosensory phenomena are present, are an important differential consideration. Toxic drug states arising from prescription, over-the-counter, herbal and street drugs may mimic all of the psychotic disorders.

The chronic use of amphetamines, cocaine, and other stimulants frequently produces a psychosis that is almost identical to the acute paranoid schizophrenic episode. The presence of formication (sensation of insects crawling on or under the skin) and stereotypy suggests the possibility of stimulant abuse. Phencyclidine (see below), a very common street drug, may cause a reaction that is difficult to distinguish from other psychotic disorders. Cerebellar signs, excessive salivation, dilated pupils, and increased deep tendon reflexes should alert the clinician to the possibility of a toxic psychosis. Industrial chemical toxicity (both organic and metallic), degenerative disorders, and metabolic deficiencies must be considered in the differential diagnosis.

Catatonic syndrome, frequently assumed to exist solely as a component of schizophrenic disorders, is actually the end product of a number of illnesses, including various organic conditions. Neoplasms, viral and bacterial encephalopathies, central nervous system hemorrhage, metabolic derangements such as diabetic ketoacidosis, sedative withdrawal, and hepatic and renal malfunction have all been implicated. It is particularly important to realize that drug toxicity (eg, overdoses of antipsychotic medications such as fluphenazine or haloperidol) can cause catatonic syndrome, which may be misdiagnosed as a catatonic schizophrenic disorder and inappropriately treated with more antipsychotic medication.

► Treatment

A. Medical

Hospitalization is often necessary, particularly when the patient's behavior shows gross disorganization. The presence of competent family members lessens the need for hospitalization, and each case should be judged individually. The major considerations are to prevent self-inflicted harm or harm to others and to provide the patient's basic needs. A full medical evaluation and CT scan or MRI of the brain should be considered in first episodes of schizophreniform disorder and other psychotic episodes of unknown cause.

Antipsychotic medications (see below) are the treatment of choice. The relapse rate can be reduced by 50% with proper maintenance neuroleptic therapy. Long-acting, injectable depot neuroleptics are used in noncompliant patients or nonresponders to oral medication.

Antipsychotic medications include the **"typical"** neuroleptics phenothiazines, thioxanthenes (both similar in structure), butyrophenones, dihydroindolones, dibenzoxazepines, and benzisoxazoles, and the newer **"atypical"** neuroleptics clozapine, risperidone, olanzapine, quetiapine, aripiprazole, ziprasidone, paliperidone, iloperidone, and lurasidone (Table 25–4). Generally, increasing milligram potency of the typical neuroleptics is associated with decreasing anticholinergic and adrenergic side effects and increasing extrapyramidal symptoms (Table 25–5). For example, chlorpromazine has lower potency and more severe anticholinergic and adrenergic side effects. The increased anticholinergic effect of chlorpromazine, however, lowers the risk of extrapyramidal symptoms.

Table 25-4. Commonly used antipsychotics and medications.

Drug	Usual Daily Oral Dose	Usual Daily Maximum Dose ¹	Cost per Unit	Cost for 30 Days Treatment Based on Maximum Dosage ²
Aripiprazole (Abilify)	10-15 mg	30 mg	\$30.95/30 mg	\$928.50
Asenapine (Saphris)	10-20 mg	20 mg	\$11.53/10 mg	\$691.80
Chlorpromazine (Thorazine; others)	100-400 mg	1 g	\$2.90/200 mg	\$435.00
Clozapine (Clozaril)	300-450 mg	900 mg	\$3.33/100 mg	\$899.10
Fluphenazine (Permitil, Prolixin) ³	2-10 mg	60 mg	\$1.15/10 mg	\$207.00
Haloperidol (Haldol)	2-5 mg	60 mg	\$2.76/20 mg	\$248.40
lloperidone (Fanapt)	12-24 mg	24 mg	\$12.68/12 mg	\$760.80
Loxapine (Loxitane)	20-60 mg	200 mg	\$2.57/50 mg	\$308.40
Lurasidone (Latuda)	40-80 mg	80 mg	\$18.46/80 mg	\$553.80
Olanzapine (Zyprexa)	5-10 mg	15 mg	\$20.97/10 mg	\$927.90
Paliperidone (Invega)	6-12 mg	12 mg	\$14.31/6 mg	\$858.46
Perphenazine (Trilafon) ³	16-32 mg	64 mg	\$1.95/16 mg	\$234.00
Quetiapine (Seroquel)	200-400 mg	800 mg	\$14.37/200 mg	\$1329.00
Risperidone (Risperdal) ⁴	2-6 mg	10 mg	\$7.59/2 mg	\$946.16
Thioridazine (Mellaril)	100-400 mg	600 mg	\$.67/100 mg	\$120.60
Thiothixene (Navane) ³	5-10 mg	80 mg	\$0.65/10 mg	\$156.00
Trifluoperazine (Stelazine)	5-15 mg	60 mg	\$1.58/10 mg	\$284.40
Ziprasidone (Geodon)	40-160 mg	160 mg	\$12.08/80 mg	\$724.80

³Indicates piperazine structure.

⁴For risperidone, daily doses above 6 mg increase the risk of extrapyramidal syndrome. Risperidone 6 mg is approximately equivalent to haloperidol 20 mg.

The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) study compared “atypical” and “typical” neuroleptic medications. Although it was not definitive, it suggested similar antipsychotic efficacy for both classes and a tendency for the atypicals, particularly olanzapine, to be better tolerated leading to enhanced compliance. It also highlighted lack of patient adherence as a major factor in treatments.

The phenothiazines comprise the bulk of the currently used “typical” neuroleptic medications. The only butyrophenone commonly used in psychiatry is haloperidol, which is different in structure but similar in action and side effects to the piperazine phenothiazines such as fluphenazine, perphenazine, and trifluoperazine. These medications and haloperidol (dopamine [D₂] receptor blockers) have high potency and a paucity of autonomic side effects and act to markedly lower arousal levels. Molindone and loxapine, while less potent, are similar in action, side effects, and safety to the piperazine phenothiazines.

The first “atypical” (novel) antipsychotic drug developed, clozapine, a dibenzodiazepine derivative, has dopamine (D₄) receptor-blocking activity as well as central serotonergic, histaminergic, and α -noradrenergic receptor-blocking activity. It is effective in the treatment of about 30% of psychoses resistant to other neuroleptic medications. Research suggests that clozapine may have specific efficacy in decreasing suicidality in patients with schizophrenia. It is associated with a 1% risk of agranulocytosis, which requires weekly white blood cell count monitoring for the first 6 months followed by monitoring every other week. Weekly monitoring for 1 month after discontinuation of the medication is recommended. Because of an association between clozapine and myocarditis, the drug is contraindicated in patients with severe heart disease. Risperidone is an antipsychotic that blocks some serotonin receptors (5-HT₂) and dopamine receptors (D₂). Risperidone causes fewer extrapyramidal side effects than the typical antipsychotics at doses < 6 mg.

Table 25-5. Relative potency and side effects of antipsychotic medications.

Drug	Chlorpromazine: Drug Potency Ratio	Anticholinergic Effects ¹	Extrapyramidal Effect ¹
Aripiprazole	1:20	1	0
Chlorpromazine	1:1	4	1
Clozapine	1:1	4	—
Fluphenazine	1:50	1	4
Haloperidol	1:50	1	4
lloperidone	1:25	1	1
Loxapine	1:10	2	3
Lurasidone	1:5	1	2
Olanzapine	1:20	1	1
Perphenazine	1:10	2	3
Quetiapine	1:1	1	—
Risperidone	1:50	1	1
Thioridazine	1:1	4	1
Thiothixene	1:20	1	4
Trifluoperazine	1:20	1	4
Ziprasidone	1:1	1	1

¹1, weak effect; 4, strong effect.

It appears to be as effective as haloperidol and possibly as effective as clozapine in treatment-resistant patients without requiring weekly white cell counts. Risperidone-induced hyperprolactinemia, even on low doses, has been reported, and that effect is thought to be more common with risperidone than with other atypical antipsychotics. Risperidone is available in a long-acting injectable preparation.

Olanzapine is a potent blocker of muscarinic, anticholinergic, 5-HT₂, and dopamine D₁, D₂, and D₄ receptors. High doses of olanzapine (12.5–17.5 mg daily) appear to be more effective than lower doses. The drug appears to be more effective than haloperidol in the treatment of negative symptoms, such as withdrawal, psychomotor retardation, and poor interpersonal relationships. It is available in an orally disintegrating form for patients who are unable to tolerate standard oral dosing and in an injectable form for the management of acute agitation associated with schizophrenia and bipolar disorder. Olanzapine tends to result in elevations of serum alanine aminotransferase more commonly than does haloperidol. Olanzapine is associated with a much lower incidence of dystonic reaction than haloperidol and is perhaps less likely to induce tardive dyskinesia. Its most common side effects include somnolence, agitation, nervousness, headache, insomnia, dizziness, and significant weight gain. Multiple case reports have linked olanzapine and clozapine to new-onset type 2 diabetes, and all atypical medications should be monitored

for this adverse effect as well. The manufacturer has alerted physicians to an association between olanzapine and a significantly higher risk of stroke and death in elderly patients, which has also been noted with other atypical and typical agents (see below).

Quetiapine is a neuroleptic with greater 5-HT₂ relative to D₂ receptor blockade as well as a relatively high affinity for α_1 - and α_2 -adrenergic receptors. It appears to be as efficacious as haloperidol in treating positive and negative symptoms of schizophrenia, with less extrapyramidal side effects even at high doses. More common side effects include somnolence, dizziness, and postural hypotension. Because of an association with lens changes seen in patients on long-term treatment, an eye examination to detect cataract formation is recommended at initiation of treatment and then at 6-month intervals during treatment. Quetiapine may cause QT prolongation particularly when prescribed with other medications that effect the QT interval and in overdose.

Ziprasidone has both anti-dopamine receptor and antiserotonin receptor effects, with good efficacy for both positive and negative symptoms of schizophrenia. In one study of 146 treatment-resistant schizophrenic patients, ziprasidone was as effective as clozapine. Ziprasidone is not associated with significant weight gain, hyperlipidemia, or new-onset diabetes and offers a good alternative for some patients. It has been implicated in QTc interval delay of > 500 ms in some patients, although in several cases of

overdose there were no incidents of torsades de pointes or sudden death. Patients taking ziprasidone should be screened for cardiac risk factors. A pretreatment ECG is indicated for patients at risk for cardiac sequelae (including patients taking other medications that might prolong the QTc interval).

Aripiprazole is the first neuroleptic that is a dopamine stabilizer. A partial agonist at the dopamine D₂ and serotonin 5-HT₁ receptors and an antagonist at 5-HT₂ receptors, it is effective against positive and negative symptoms of schizophrenia. It functions as an antagonist or agonist, depending on the dopaminergic activity at the dopamine receptors. This may help decrease side effects. More activating than sedating, aripiprazole is thought to impose a low risk of extrapyramidal symptoms, weight gain, hyperprolactinemia, and delayed QT interval. Aripiprazole has been approved as an augmentation agent for treatment-resistant depression even when psychosis is not present. Asenapine, approved for the treatment of schizophrenia and bipolar disorder (mixed or manic state), appears to be particularly helpful in treating negative symptoms of schizophrenia. Paliperidone, the active metabolite of risperidone, is available as a capsule and a monthly injection. It has the advantage of low associations with diabetes mellitus, weight gain, and dyslipidemia. Both asenapine and paliperidone increase the risk of QT interval prolongation and should be avoided in patients with risk factors for this ECG finding. Asenapine can cause hyperprolactinemia and weight gain. Asenapine carries a warning of possible serious allergic reaction, even after the first dose including anaphylaxis, low blood pressure, and difficulty breathing. Patients should be appropriately cautioned. Iloperidone has low incidence of extrapyramidal side effects that is similar to the other atypical agents but requires careful initial titration due to the risk of orthostatic hypotension and possibility of lengthening the QT interval. When coadministered with paroxetine or clarithromycin, the dose of iloperidone must be halved because of decreased hepatic metabolism by the cytochrome P450 CYP2D6 and CYP3A4 isozymes. Lurasidone, approved by the FDA in 2011 has been shown to be effective in treating acute decompensation in patients with chronic schizophrenia. This medication is distinguished by low incidence of weight gain, increased lipids or prolonged QT interval, but clinicians should be mindful of side effects of akathisia, elevated prolactin and in higher doses, somnolence. None of the antipsychotics produce true physical dependency. All decrease adrenergic responses. Despite higher costs, atypical neuroleptics are often considered preferable to traditional antipsychotics because they are thought to be associated with reduced extrapyramidal symptoms and a lesser risk of tardive dyskinesia.

► Clinical Indications

The antipsychotics are used to treat all forms of the schizophrenias as well as psychotic ideation in organic brain psychoses, delirium and dementia, drug-induced psychoses, psychotic depression, and mania. They are also

effective in Tourette disorder. They quickly lower the arousal (activity) level and, perhaps indirectly, gradually improve socialization and thinking. The improvement rate is about 80%. Patients whose behavioral symptoms worsen with use of antipsychotic medications may have an undiagnosed organic condition such as anticholinergic toxicity.

Symptoms that are ameliorated by these medications include hyperactivity, hostility, aggression, delusions, hallucinations, irritability, and poor sleep. Individuals with acute psychosis and good premorbid function respond quite well. The most common cause of failure in the treatment of acute psychosis is inadequate dosage, and the most common cause of relapse is noncompliance.

Although typical antipsychotics are efficacious in the treatment of positive symptoms of schizophrenia, such as hallucinations and delusions, atypical antipsychotics are thought to have efficacy in reducing both positive and negative symptoms. Antidepressant medications may be used in conjunction with neuroleptics if significant depression is present. Resistant cases may require concomitant use of lithium, carbamazepine, or valproic acid. The addition of a benzodiazepine drug to the neuroleptic regimen may prove helpful in treating the agitated or catatonic psychotic patient who has not responded to neuroleptics alone—lorazepam, 1–2 mg orally, can produce a rapid resolution of catatonic symptoms and may allow maintenance with a lower neuroleptic dose. Electroconvulsive therapy (ECT) has also been effective in treating catatonia.

► Dosage Forms & Patterns

The dosage range is quite broad. For example, risperidone, 0.25–1 mg orally at bedtime, may be sufficient for the elderly person with mild dementia with psychosis (especially in view of the increased risk of stroke and death in the elderly), whereas up to 6 mg/d may be used in a young patient with acute schizophrenia. For quick response, an atypical antipsychotic may be started in combination with a benzodiazepine (eg, risperidone oral solution, 2 mg, or olanzapine, 10 mg orally, and lorazepam, 2 mg orally, every 2–4 hours as needed). In an acutely distressed, psychotic patient one might use haloperidol, 10 mg intramuscularly, which is absorbed rapidly and achieves an initial tenfold plasma level advantage over equal oral doses. Psychomotor agitation, racing thoughts, and general arousal are quickly reduced. The dose can be repeated every 3–4 hours; when the patient is less symptomatic, oral doses can replace parenteral administration in most cases. In the elderly, both atypical (eg, risperidone 0.25 mg–0.5 mg daily or olanzapine 1.25 mg daily) and typical (eg haloperidol 0.5 mg daily or perphenazine 2 mg daily) antipsychotics, often used effectively in small doses for behavioral control, have been linked to premature death in some cases.

Absorption of oral medications may be increased or decreased by concomitant administration of other medications (eg, antacids tend to decrease the absorption of

antidepressants). Previous gastrointestinal surgery may alter pH, motility, and surface areas available for drug absorption. There are racial differences in metabolizing the neuroleptic medications—eg, many Asians require only about half the usual dosage. Bioavailability is influenced by other factors such as smoking or hepatic microsomal enzyme stimulation with alcohol or barbiturates and enzyme-altering medications such as carbamazepine or methylphenidate. Neuroleptic plasma drug level determinations are not currently of major clinical assistance.

Divided daily doses are not necessary after a maintenance dose has been established, and most patients can then be maintained on a single daily dose, usually taken at bedtime. This is particularly appropriate in a case where the sedative effect of the drug is desired for nighttime sleep, and undesirable sedative effects can be avoided during the day. Risperidone is an exception, being given twice daily. First-episode patients especially should be tapered off medications after about 6 months of stability and carefully monitored; their rate of relapse is lower than that of multiple-episode patients.

Psychiatric patients—particularly paranoid individuals—often neglect to take their medication. In these cases and in nonresponders to oral medication, the enanthate and decanoate (the latter is slightly longer-lasting and has fewer extrapyramidal side effects) forms of fluphenazine or the decanoate form of haloperidol may be given by deep subcutaneous injection or intramuscularly to achieve an effect that will usually last 7–28 days. A patient who cannot be depended on to take oral medication (or who overdoses on minimal provocation) will generally agree to come to the clinician's office for a "shot." The usual dose of the fluphenazine long-acting preparations is 25 mg every 2 weeks. Dosage and frequency of administration vary from about 100 mg weekly to 12.5 mg monthly. Use the smallest effective amount as infrequently as possible. A monthly injection of 25 mg of fluphenazine decanoate is equivalent to about 15–20 mg of oral fluphenazine daily. Risperidone is the first atypical neuroleptic available in a long-acting injectable form (25–50 mg intramuscularly every 2 weeks). Concomitant use of a benzodiazepine (eg, lorazepam, 2 mg orally twice daily) may permit reduction of the required dosage of oral or parenteral antipsychotic drug.

Intravenous haloperidol, the neuroleptic most commonly used by this route, is often used in critical care units in the management of agitated, delirious patients. Intravenous haloperidol should be given no faster than 1 mg/min to reduce cardiovascular side effects, such as torsades de pointes. Current practice indicates that ECG monitoring should be used whenever haloperidol is being administered intravenously.

► Side Effects

For both typical and atypical neuroleptic agents, a range of side effects has been reported. The most common anticholinergic side effects include **dry mouth** (which can lead to ingestion of caloric liquids and weight gain or hyponatremia),

blurred near vision, urinary retention (particularly in elderly men with enlarged prostates), **delayed gastric emptying, esophageal reflux, ileus, delirium**, and precipitation of **acute glaucoma** in patients with narrow anterior chamber angles. Other autonomic effects include **orthostatic hypotension** and **sexual dysfunction**—problems in achieving erection, ejaculation (including retrograde ejaculation), and orgasm in men (approximately 50% of cases) and women (approximately 30%). Delay in achieving orgasm is often a factor in medication noncompliance. **Electrocardiographic changes** occur frequently, but clinically significant arrhythmias are much less common. Elderly patients and those with preexisting cardiac disease are at greater risk. The most frequently seen electrocardiographic changes include diminution of the T wave amplitude, appearance of prominent U waves, depression of the ST segment, and prolongation of the QT interval. Thioridazine has been given an FDA warning for dose-related QTc delay and risk of fatal cardiac arrhythmias. As noted above, ziprasidone can produce QTc prolongation. An ECG prior to treatment in some patients may be indicated. In some critical care patients, torsades de pointes has been associated with the use of high-dose intravenous haloperidol (usually > 30 mg/24 h).

Associations have been suggested between the atypical neuroleptics and **new-onset diabetes, hyperlipidemia, QTc prolongation**, and **weight gain** (Table 25–6). The FDA has particularly noted the risk of hyperglycemia and new-onset diabetes in this class of medication that is not related to weight gain. The risk of diabetes mellitus is increased in patients taking clozapine and olanzapine. Monitoring of weight, fasting blood sugar and lipids prior to initiation of treatment and at regular intervals thereafter is an important part of medication monitoring. Early research suggests that the addition of metformin to olanzapine may improve drug-induced weight gain in patients with drug-naïve, first-episode schizophrenia. Neuroleptic medications in general may have **metabolic** and **endocrine effects**, including weight gain, hyperglycemia, impaired temperature regulation in hot weather, and water intoxication, that may be due to inappropriate ADH secretion. Lactation and menstrual irregularities are common (antipsychotic medications should be avoided, if possible, in breast cancer patients because of potential trophic effects of elevated prolactin levels on the breast). Both antipsychotic and antidepressant medications inhibit sperm motility. **Bone marrow depression** and **cholestatic jaundice** occur rarely; these are hypersensitivity reactions, and they usually appear in the first 2 months of treatment. They subside on discontinuance of the drug. There is cross-sensitivity among all of the phenothiazines, and a drug from a different group should be used when allergic reactions occur.

Clozapine is associated with a 1.6% risk of **agranulocytosis** (higher in persons of Ashkenazi Jewish ancestry), and its use must be strictly monitored with weekly blood counts during the first 6 months of treatment, with monitoring every other week thereafter. Discontinuation of the medication requires weekly monitoring of the white blood cell count for 1 month. Clozapine has been associated with

Table 25-6. Adverse factors associated with atypical antipsychotic medications.

	Weight Gain	Hyperlipidemia	New-Onset Diabetes Mellitus	QTc Prolongation ¹

Paliperidone	+	+/-	+/-	+++
Quetiapine	++	++	++	+++
Risperidone	++	++	++	+
Ziprasidone	+/-	-	-	+++

¹QTc prolongation is a side effect of many medications and suggests a possible risk for arrhythmia. Prescriber's Letter 2011; 18(12):271207.

fatal myocarditis and is contraindicated in patients with severe heart disease. In addition, clozapine lowers the seizure threshold and has many side effects, including sedation, hypotension, increased liver enzyme levels, hypersalivation, respiratory arrest, weight gain, and changes in both the ECG and the electroencephalogram.

Photosensitivity, retinopathy, and hyperpigmentation are associated with use of fairly high dosages of chlorpromazine and thioridazine. The appearance of particulate melanin deposits in the lens of the eye is related to the total dose given, and patients on long-term medication should have periodic eye examinations. Teratogenicity has not been causally related to these medications, but prudence is indicated particularly in the first trimester of pregnancy. The seizure threshold is lowered, but it is safe to use these medications in epileptics who take anticonvulsants.

The **neuroleptic malignant syndrome (NMS)** is a catatonia-like state manifested by extrapyramidal signs, blood pressure changes, altered consciousness, and hyperpyrexia; it is an uncommon but serious complication of neuroleptic treatment. Muscle rigidity, involuntary movements, confusion, dysarthria, and dysphagia are accompanied by pallor, cardiovascular instability, fever, pulmonary congestion, and diaphoresis and may result in stupor, coma, and death. The cause may be related to a number of factors, including poor dosage control of neuroleptic medication, affective illness, decreased serum iron, dehydration, and increased sensitivity of dopamine receptor sites. Lithium in combination with a neuroleptic drug may increase vulnerability, which is already increased in patients with an affective disorder. In most cases, the symptoms develop within the first 2 weeks of antipsychotic drug treatment. The syndrome may occur with small doses of the medications. Intramuscular administration is a risk factor. Elevated creatine kinase and leukocytosis with a shift to the left are present early in about half of cases. Treatment includes controlling fever and providing fluid support. Dopamine agonists such as bromocriptine,

2.5–10 mg orally three times a day, and amantadine, 100–200 mg orally twice a day, have also been useful. Dantrolene, 50 mg intravenously as needed, is used to alleviate rigidity (do not exceed 10 mg/kg/d due to hepatotoxicity risk). There is ongoing controversy about the efficacy of these three agents as well as the use of calcium channel blockers and benzodiazepines. ECT has been used effectively in resistant cases. Clozapine has been used with relative safety and fair success as an antipsychotic drug for patients who have had NMS. The syndrome must be differentiated from acute lethal catatonia, malignant hyperthermia, neurotoxic syndromes (including AIDS), and a variety of other conditions such as viral encephalitis, Wilson disease, central anticholinergic syndrome, and hypertonic states (eg, tetany, strychnine poisoning).

Akathisia is the most common (about 20%) extrapyramidal symptom. It usually occurs early in treatment (but may persist after neuroleptics are discontinued) and is frequently mistaken for anxiety or exacerbation of psychosis. It is characterized by a subjective desire to be in constant motion followed by an inability to sit or stand still and consequent pacing. It may induce suicidality or feelings of fright, rage, terror, or sexual torment. Insomnia is often present. It is crucial to educate patients in advance about these potential side effects so that the patients do not misinterpret them as signs of increased illness. In all cases, reevaluate the dosage requirement or the type of neuroleptic drug. One should inquire also about cigarette smoking, which in women has been associated with an increased incidence of akathisia. Antiparkinsonism medications (such as trihexyphenidyl, 2–5 mg orally three times daily) may be helpful, but first-line treatment often includes a benzodiazepine (such as clonazepam 0.5–1 mg orally three times daily). In resistant cases, symptoms may be alleviated by propranolol, 30–80 mg/d orally, diazepam, 5 mg orally three times daily, or amantadine, 100 mg orally three times daily.

Acute dystonias usually occur early, although a late (tardive) occurrence is reported in patients (mostly men

after several years of therapy) who previously had early severe dystonic reactions and a mood disorder (see below). Younger patients are at higher risk for acute dystonias. The most common signs are bizarre muscle spasms of the head, neck, and tongue. Frequently present are torticollis, oculogyric crises, swallowing or chewing difficulties, and masseter spasms. Laryngospasm is particularly dangerous. Back, arm, or leg muscle spasms are occasionally reported. Diphenhydramine, 50 mg intramuscularly, is effective for the acute crisis; one should then give benztropine mesylate, 2 mg orally twice daily, for several weeks, and then discontinue gradually, since few of the extrapyramidal symptoms require long-term use of the antiparkinsonism medications (all of which are about equally efficacious—though trihexyphenidyl tends to be mildly stimulating and benztropine mildly sedating).

Drug-induced parkinsonism is indistinguishable from idiopathic parkinsonism, but it is reversible, occurs later in treatment than the preceding extrapyramidal symptoms, and in some cases appears after neuroleptic withdrawal. The condition includes the typical signs of apathy and reduction of facial and arm movements (akinesia, which can mimic depression), festinating gait, rigidity, loss of postural reflexes, and pill-rolling tremor. AIDS patients seem particularly vulnerable to extrapyramidal side effects. High-potency neuroleptics often require antiparkinsonism medications (see Table 24–6). The neuroleptic dosage should be reduced, and immediate relief can be achieved with antiparkinsonism medications in the same dosages as above. After 4–6 weeks, these antiparkinsonism medications can often be discontinued with no recurrent symptoms. In any of the extrapyramidal symptoms, amantadine, 100–400 mg orally daily, may be used instead of the antiparkinsonism medications. Neuroleptic-induced catatonia is similar to catatonic stupor with rigidity, drooling, urinary incontinence, and cogwheeling. It usually responds slowly to withdrawal of the offending medication and use of antiparkinsonism agents.

Tardive dyskinesia is a syndrome of abnormal involuntary stereotyped movements of the face, mouth, tongue, trunk, and limbs that may occur after months or (usually) years of treatment with neuroleptic agents. The syndrome affects 20–35% of patients who have undergone long-term neuroleptic therapy. Predisposing factors include older age, many years of treatment, cigarette smoking, and diabetes mellitus. Pineal calcification is higher in this condition by a margin of 3:1. There are no clearcut differences among the antipsychotic medications in the development of tardive dyskinesia. (Although the atypical antipsychotics appear to offer a lower risk of tardive dyskinesia, long-term effects have not been investigated.) Early manifestations of tardive dyskinesia include fine worm-like movements of the tongue at rest, difficulty in sticking out the tongue, facial tics, increased blink frequency, or jaw movements of recent onset. Later manifestations may include bucco-linguo-masticatory movements, lip smacking, chewing motions, mouth opening and closing, disturbed gag reflex, puffing of the cheeks, disrupted speech, respiratory distress, or choreoathetoid movements of the

extremities (the last being more prevalent in younger patients). The symptoms do not necessarily worsen and in rare cases may lessen even though neuroleptic medications are continued. The dyskinesias do not occur during sleep and can be voluntarily suppressed for short periods. Stress and movements in other parts of the body will often aggravate the condition.

Early signs of dyskinesia must be differentiated from those reversible signs produced by ill-fitting dentures or nonneuroleptic medications such as levodopa, TCAs, antiparkinsonism agents, anticonvulsants, and antihistamines. Other neurologic conditions such as Huntington chorea can be differentiated by history and examination.

The emphasis should be on prevention of side effects. Use the least amount of neuroleptic drug necessary to mute the psychotic symptoms, and use atypical antipsychotics as first line agents. Detect early manifestations of dyskinesias. When these occur, stop anticholinergic medications and gradually discontinue neuroleptic medications, if clinically feasible. Weight loss and cachexia sometimes appear on withdrawal of neuroleptics. In an indeterminate number of cases, the dyskinesias will remit. Keep the patient off the medications until reemergent psychotic symptoms dictate their resumption, at which point they are restarted in low doses and gradually increased until there is clinical improvement. If neuroleptic medications are restarted, clozapine and olanzapine appear to offer less risk of recurrence. The use of adjunctive agents such as benzodiazepines or lithium may help directly or indirectly by allowing control of psychotic symptoms with a low dosage of neuroleptics. If the dyskinesic syndrome recurs and it is necessary to continue neuroleptic medications to control psychotic symptoms, informed consent should be obtained. Benzodiazepines, buspirone (in doses of 15–60 mg/d orally), phosphatidylcholine, clonidine, calcium channel blockers, vitamin E, omega-3 fatty acids, and propranolol all have had limited usefulness in treating the dyskinetic side effects.

B. Social

Environmental considerations are most important in the individual with a chronic illness, who usually has a history of repeated hospitalizations, a continued low level of functioning, and symptoms that never completely remit. Family rejection and work failure are common. In these cases, board and care homes staffed by personnel experienced in caring for psychiatric patients are most important. There is frequently an inverse relationship between stability of the living situation and the amounts of required antipsychotic medications, since the most salutary environment is one that reduces stimuli. Nonresidential self-help groups such as Recovery, Inc., should be utilized whenever possible. They provide a setting for sharing, learning, and mutual support and are frequently the only social involvement with which this type of patient is comfortable. Vocational rehabilitation and work agencies (eg, Goodwill Industries, Inc.) provide assessment, training, and job opportunities at a level commensurate with the person's clinical condition.

C. Psychological

The need for psychotherapy varies markedly depending on the patient's current status and history. In a person with a single psychotic episode and a previously good level of adjustment, supportive psychotherapy may help the patient reintegrate the experience, gain some insight into antecedent problems, and become a more self-observant individual who can recognize early signs of stress. Insight-oriented psychotherapy is often counterproductive in this type of disorder. Research suggests that cognitive behavioral therapy—in conjunction with medication management—may have some efficacy in the treatment of symptoms of schizophrenia. Cognitive behavioral therapy for schizophrenia involves helping the individual challenge psychotic thinking and alters response to hallucinations. Similarly, a form of psychotherapy called acceptance and commitment therapy has shown value in helping prevent hospitalizations in schizophrenia. Cognitive remediation therapy is another approach to treatment that shows promise in helping schizophrenics become better able to focus their disorganized thinking. Family therapy may also help alleviate the patient's stress and to assist relatives in coping with the patient.

D. Behavioral

Behavioral techniques (see above) are most frequently used in therapeutic settings such as day treatment centers, but there is no reason why they cannot be incorporated into family situations or any therapeutic setting. Many behavioral techniques (eg, positive reinforcement—whether it be a word of praise or an approving nod—after some positive behavior), can be a powerful instrument for helping a person learn behaviors that will facilitate social acceptance. Music from portable digital players with earphones is one of many ways to divert the patient's attention from auditory hallucinations.

► Prognosis

In any psychosis, in the large majority of patients the prognosis is excellent for alleviation of positive symptoms such as hallucinations or delusions treated with medication. Negative symptoms such as diminished affect and sociability are much more difficult to treat but appear responsive to atypical antipsychotics. Unavailability of structured work situations and lack of family therapy are two other reasons why the prognosis is so guarded in such a large percentage of schizophrenic patients. Psychosis connected with a history of serious drug abuse has a guarded prognosis because of the central nervous system damage, usually from the medications themselves and associated medical illnesses.

MOOD DISORDERS (Depression & Mania)

ESSENTIALS OF DIAGNOSIS

Present in most depressions:

- ▶ Mood varies from mild sadness to intense feelings of guilt, worthlessness, and hopelessness.
- ▶ Difficulty in thinking, including inability to concentrate, ruminations, and lack of decisiveness.
- ▶ Loss of interest, with diminished involvement in work and recreation.
- ▶ Somatic complaints such as headache; disrupted, lessened, or excessive sleep; loss of energy; change in appetite; decreased sexual drive.
- ▶ Anxiety.

Present in some severe depressions:

- ▶ Psychomotor retardation or agitation.
- ▶ Delusions of a hypochondriacal or persecutory nature.
- ▶ Withdrawal from activities.
- ▶ Physical symptoms of major severity, eg, anorexia, insomnia, reduced sexual drive, weight loss, and various somatic complaints.
- ▶ Suicidal ideation.

Present in mania:

- ▶ Mood ranging from euphoria to irritability.
- ▶ Sleep disruption.
- ▶ Hyperactivity.
- ▶ Racing thoughts.
- ▶ Grandiosity.
- ▶ Variable psychotic symptoms.

► General Considerations

Depression is extremely common, with up to 30% of primary care patients having depressive symptoms. Depression may be the final expression of (1) genetic factors (neurotransmitter dysfunction), (2) developmental problems (personality problems, childhood events), or (3) psychosocial stresses (divorce, unemployment). It frequently presents in the form of somatic complaints with negative medical workups. Although sadness and grief are normal responses to loss, depression is not. Patients experiencing normal grief tend to produce sympathy and sadness in the clinician caregiver; depression often produces frustration and irritation in the clinician. Grief is usually accompanied by intact self-esteem, whereas depression is marked by a sense of guilt and worthlessness.

Mania is often combined with depression and may occur alone, together with depression in a mixed episode, or in cyclic fashion with depression.

► Clinical Findings

In general, there are four major types of depressions, with similar symptoms in each group.

A. Adjustment Disorder with Depressed Mood

Depression may occur in reaction to some identifiable stressor or adverse life situation, usually loss of a person by death (grief reaction), divorce, etc; financial reversal (crisis); or loss of an established role, such as being needed. Anger is frequently associated with the loss, and this in turn often produces a feeling of guilt. The disorder occurs within 3 months of the stressor and causes significant impairment in social or occupational functioning. The symptoms range from mild sadness, anxiety, irritability, worry, lack of concentration, discouragement, and somatic complaints to the more severe symptoms of frank depression. When the full criteria for major depressive disorder are present (see below), then that diagnosis should be made and treatment instituted even when there is a known stressor. The presence of a stressor is not the determining diagnostic driver, it is the resultant syndromal complex. One should not neglect treatment for major depression simply because it may appear to be an understandable reaction to a particular stress or difficulty.

B. Depressive Disorders

The subclassifications include major depressive disorder and dysthymia.

1. Major depressive disorder—A major depressive disorder (eg, “endogenous” unipolar disorder, melancholia) consists of at least one episode of serious mood depression that occurs at any time of life. Many consider a physiologic or metabolic aberration to be causative. Complaints vary widely but most frequently include a loss of interest and pleasure (anhedonia), withdrawal from activities, and feelings of guilt. Also included are inability to concentrate, some cognitive dysfunction, anxiety, chronic fatigue, feelings of worthlessness, somatic complaints (unexplained somatic complaints frequently indicate depression), loss of sexual drive, and thoughts of death. Diurnal variation with improvement as the day progresses is common. Vegetative signs that frequently occur are insomnia, anorexia with weight loss, and constipation. Occasionally, severe agitation and psychotic ideation (paranoid thinking, somatic delusions) are present. These symptoms are more common in depressed persons who are older than 50 years. Paranoid symptoms may range from general suspiciousness to ideas of reference with delusions. The somatic delusions frequently revolve around feelings of impending annihilation or hypochondriacal beliefs (eg, that the body is rotting away with cancer). Hallucinations are uncommon.

Subcategories include **major depression with atypical features** characterized by hypersomnia, overeating, lethargy, and rejection sensitivity. **Major depression with a seasonal onset (seasonal affective disorder)** is a dysfunction of circadian rhythms that occurs more commonly in the winter months and is believed to be due to decreased

exposure to full-spectrum light. Common symptoms include carbohydrate craving, lethargy, hyperphagia, and hypersomnia. **Major depression with postpartum onset** usually occurs 2 weeks to 6 months postpartum.

Most women (up to 80%) experience some mild let-down of mood in the postpartum period. For some of these (10–15%), the symptoms are more severe and similar to those usually seen in serious depression, with an increased emphasis on concerns related to the baby (obsessive thoughts about harming it or inability to care for it). When psychotic symptoms occur, there is frequently associated sleep deprivation, volatility of behavior, and manic-like symptoms. Postpartum psychosis is much less common (< 2%), often occurs within the first 2 weeks, and requires early and aggressive management. Biologic vulnerability with hormonal changes and psychosocial stressors all play a role. The chances of a second episode are about 25% and may be reduced with prophylactic treatment.

2. Dysthymia—Dysthymia is a chronic depressive disturbance. Sadness, loss of interest, and withdrawal from activities over a period of 2 or more years with a relatively persistent course is necessary for this diagnosis. Generally, the symptoms are milder but longer-lasting than those in a major depressive episode.

3. Premenstrual dysphoric disorder—Depressive symptoms occur during the late luteal phase (last 2 weeks) of the menstrual cycle. (See also chapter 18)

C. Bipolar Disorders

Bipolar disorders consist of episodic mood shifts into mania, major depression, hypomania, and mixed mood states. The ability of bipolar disorder to mimic aspects of many other coincident major mental health disorders and a high comorbidity with substance abuse can make the initial diagnosis of bipolar disorder difficult. Bipolar I is diagnosed when an individual has both depressive and manic episodes. For individuals who experience depressive and hypomanic episodes without frank mania, the diagnosis would be Bipolar II. Individuals who become manic when treated with an antidepressant for a depressive episode are often regarded as Bipolar III.

1. Mania—A manic episode is a mood change characterized by elation with hyperactivity, overinvolvement in life activities, increased irritability, flight of ideas, easy distractibility, and little need for sleep. The overenthusiastic quality of the mood and the expansive behavior initially attract others, but the irritability, mood lability with swings into depression, aggressive behavior, and grandiosity usually lead to marked interpersonal difficulties. Activities may occur that are later regretted, eg, excessive spending, resignation from a job, a hasty marriage, sexual acting out, and exhibitionistic behavior, with alienation of friends and family. Atypical manic episodes can include gross delusions, paranoid ideation of severe proportions, and auditory hallucinations usually related to some grandiose perception. The episodes begin abruptly (sometimes precipitated by life stresses) and may last from several days to months. Spring and summer tend to be the peak periods.

Generally, the manic episodes are of shorter duration than the depressive episodes. In almost all cases, the manic episode is part of a broader bipolar (manic-depressive) disorder. Patients with four or more discrete episodes of a mood disturbance in 1 year are called “rapid cyclers.” (Substance abuse, particularly cocaine, can mimic rapid cycling.) These patients have a higher incidence of hypothyroidism. Manic patients differ from patients with schizophrenia in that the former use more effective interpersonal maneuvers, are more sensitive to the social maneuvers of others, and are more able to utilize weakness and vulnerability in others to their own advantage. Creativity has been positively correlated with mood disorders, but the best work done is between episodes of mania and depression.

2. Cyclothymic disorders—These are chronic mood disturbances with episodes of depression and hypomania. The symptoms must have at least a 2-year duration and are milder than those that occur in depressive or manic episodes. Occasionally, the symptoms will escalate into a full-blown manic or depressive episode, in which case reclassification as bipolar I would be warranted.

D. Mood Disorders Secondary to Illness and Medications

Any illness, severe or mild, can cause significant depression. Conditions such as rheumatoid arthritis, multiple sclerosis, stroke, and chronic heart disease are particularly likely to be associated with depression, as are other chronic illnesses. Depression is common in cancer, as well, with a particularly high degree of comorbidity in pancreatic cancer. Hormonal variations clearly play a role in some depressions. Varying degrees of depression occur at various times in schizophrenic disorders, central nervous system disease, and organic mental states. **Alcohol dependency** frequently coexists with serious depression.

The classic model of **drug-induced depression** occurs with the use of reserpine, both in clinical settings and as a pharmacologic probe in research settings. Corticosteroids and oral contraceptives are commonly associated with affective changes. Antihypertensive medications such as methyl dopa, guanethidine, and clonidine have been associated with the development of depressive syndromes, as have digitalis and antiparkinsonism medications (eg, levodopa). Interferons are strongly associated with depressed mood as a side effect; consultation with a psychiatrist prior to prescribing these agents is indicated in cases where there is a history of depression. It is unusual for β -blockers to produce depression when given for short periods, such as in the treatment of performance anxiety. Sustained use of β -blockers for medical conditions such as hypertension may produce depression in some patients, although most individuals do not suffer this adverse effect and the data supporting this association remain inconclusive. Infrequently, disulfiram and anticholinesterase medications may be associated with symptoms of depression. All stimulant use results in a depressive syndrome when the drug is withdrawn. Alcohol, sedatives, opiates, and most of the psychedelic drugs are depressants and, paradoxically, are often used in self-treatment of depression.

► Differential Diagnosis

Since depression may be a part of any illness—either reactively or as a secondary symptom—careful attention must be given to personal life adjustment problems and the role of medications (eg, reserpine, corticosteroids, levodopa). Schizophrenia, partial complex seizures, organic brain syndromes, panic disorders, and anxiety disorders must be differentiated. Subtle thyroid dysfunction must be ruled out.

► Complications

The most important complication is **suicide**, which often includes some elements of aggression. Suicide rates in the general population vary from 9 per 100,000 in Spain to 20 per 100,000 in the United States to 58 per 100,000 in Hungary. In individuals with depression, the lifetime risk rises to 10–15%. In patients with bipolar disorder, the risk is higher, with up to 20% of individuals dying of suicide. Men tend toward successful suicide, particularly in older age groups, whereas women make more attempts with lower mortality rates. An increased suicide rate is being observed in the younger population, ages 15–35. Patients with cancer, respiratory illnesses, AIDS, and those being maintained on hemodialysis have higher suicide rates. Alcohol use is a significant factor in many suicide attempts.

There are several groups of people who make suicide attempts. One group includes those individuals with acute situational problems. These individuals may be acutely distressed by a recent breakup in a relationship or another type of disappointment. This group also includes those who may not be diagnosed as having depression but who are overwhelmed by a stressful situation often with an aspect of public humiliation (eg, the man charged with child molestation who hangs himself in his cell). A suicide attempt in such cases may be an impulsive or aggressive act not associated with significant depression. In such cases, a suicide attempt is clearly a stratagem for controlling or hurting others or an attempted escape.

Another high-risk group includes individuals with severe depression. Severe depression may be due to conditions such as medical illness (eg, AIDS, whose victims have a suicide rate over 20 times that of the general population) or comorbid psychiatric disorders (eg, panic disorders). Anxiety, panic, and fear are major findings in suicidal behavior. A patient may seem to make a dramatic improvement, but the lifting of depression may be due to the patient's decision to commit suicide. Another high-risk group are individuals with psychotic illness who tend not to verbalize their concerns, are unpredictable, and are often successful in their suicide attempt, although they make up only a small percentage of the total.

Finally, suicide is 10 times more prevalent in patients with schizophrenia than in the general population, and jumping from bridges is a more common means of attempted suicide by schizophrenics than by others. In one study of 100 “jumpers,” 47% had schizophrenia.

The immediate goal of psychiatric evaluation is to assess the current suicidal risk and the need for hospitalization versus outpatient management. Perhaps the one most useful question is to ask the person how many hours per

day he or she thinks about suicide. If it is more than 1 hour, the individual is at high risk. Further assessing the risk by inquiring about intent, plans, means, and suicide-inhibiting factors (eg, strong ties to children or the church) is essential. The intent is less likely to be truly suicidal, for example, if small amounts of poison or medication were ingested or scratching of wrists was superficial, if the act was performed in the vicinity of others or with early notification of others, or if the attempt was arranged so that early detection would be anticipated. Alcohol, hopelessness, delusional thoughts, and complete or nearly complete loss of interest in life or ability to experience pleasure are all positively correlated with suicide attempts. Other risk factors are previous attempts, a family history of suicide, medical or psychiatric illness (eg, anxiety, depression, psychosis), male sex, older age, contemplation of violent methods, a humiliating social stressor, and drug use (including long-term sedative or alcohol use), which contributes to impulsiveness or mood swings. Successful treatment of the patient at risk for suicide cannot be achieved if the patient continues to abuse drugs.

The patient's current mood status is best evaluated by direct evaluation of plans and concerns about the future, personal reactions to the attempt, and thoughts about the reactions of others. Measurement of mood is often facilitated by using a standardized instrument such as the Hamilton or Montgomery-Asberg clinician-administered rating scales or the self-administered Patient Health Questionnaire-9. Such measures allow for initial assessment as well as ongoing treatment tracking. The patient's immediate resources should also be assessed—people who can be significantly involved (most important), family support, job situation, financial resources, etc. Suicide risk can be specifically assessed using an instrument such as the Columbia-Suicide Severity Risk Scale.

If hospitalization is not indicated (eg, gestures, impulsive attempts; see above), the clinician must formulate and institute a treatment plan or make an adequate referral. (The National Suicide Prevention Lifeline, 1-800-273-8255, may be of assistance.) Medication should be dispensed in small amounts to at-risk patients. Although TCAs and SSRIs are associated with an equal incidence of suicide attempts, the risk of successful suicide is higher with TCA overdose. Guns and medications should be removed from the patient's household. Driving should be interdicted until the patient improves. The problem is often worsened by the long-term complications of the suicide attempt, eg, brain damage due to hypoxia, peripheral neuropathies caused by staying for long periods in one position causing nerve compressions, and medical or surgical problems such as esophageal strictures and tendon dysfunctions.

The reasons for **self-mutilation**, most commonly wrist cutting (but also autocastration, autoamputation, and autoenucleation, which are associated with psychoses), may be very different from the reasons for a suicide attempt. The initial treatment plan, however, should presume suicidal ideation, and conservative treatment should be initiated.

Sleep disturbances in the depressions are discussed below.

► Treatment of Depression

A. Medical

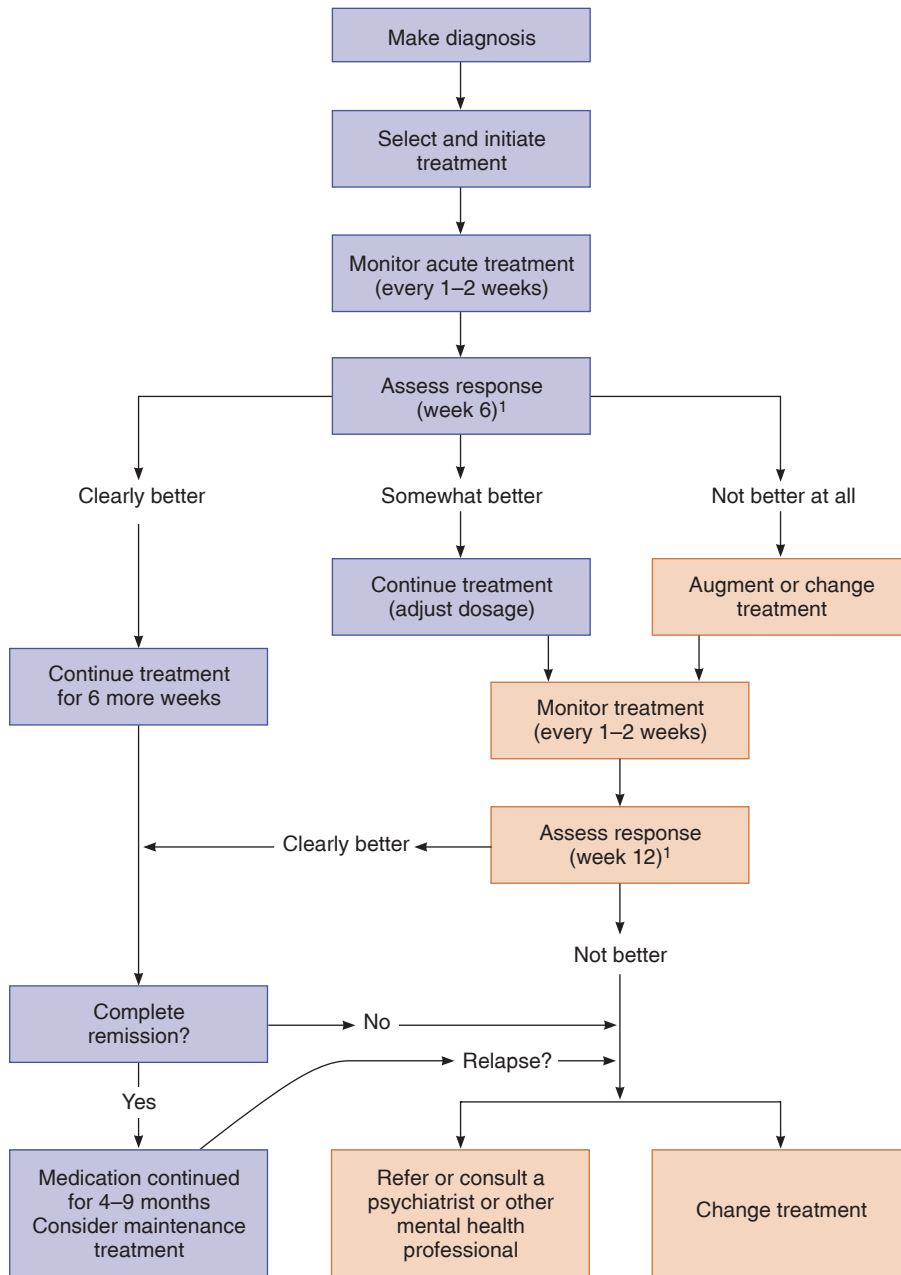

Depression associated with reactive disorders usually does not call for drug therapy and can be managed by psychotherapy and the passage of time. In severe cases—particularly when vegetative signs are significant and symptoms have persisted for more than a few weeks—antidepressant drug therapy is often effective. Drug therapy is also suggested by a family history of major depression in first-degree relatives or a past history of prior episodes.

The antidepressant medications may be conveniently classified into three groups: (1) the newer antidepressants, including the SSRIs and bupropion, duloxetine, venlafaxine, nefazodone, vilazodone, and mirtazapine, (2) the TCAs and clinically similar medications, and (3) the MAO inhibitors (see Table 25–8). These groups are described in greater detail below. ECT is effective in all types of depression and will also rapidly resolve a manic episode. It is also very effective for postpartum depression. Megavitamin treatment, acupuncture, and electrosleep are of unproved usefulness for any psychiatric condition. Repetitive transcranial magnetic stimulation has been approved by the FDA for individuals who have not responded to one trial of an antidepressant and is being evaluated for wider application but is still not covered by most insurers as a first-line treatment.

Hospitalization is necessary if suicide is a major consideration or if complex treatment modalities are required.

Medication selection is influenced by the history of previous responses if that information is available. If a relative has responded to a particular drug, this suggests that the patient may respond similarly. If no background information is available, a drug such as sertraline, 25 mg orally daily and increasing gradually up to 200 mg, or desipramine, starting with 50 mg orally and gradually increasing to 150 mg, can be selected and a *full trial* instituted. The medication trial should be monitored for worsening mood or suicidal ideation with patient assessments every 1–2 weeks until week 6. If successful, the medication should be continued for 6–12 months at the full therapeutic dose before tapering is considered. Antidepressants should usually be continued indefinitely at full dosage in individuals with a first episode of depression before the age of 20 or after the age of 50, with more than two episodes after age 40, at least one episode after age 50, or with three or more total episodes. The STAR*D trial suggests that if the response to the first medication is inadequate, the best alternatives are to switch to a second agent that may be from the same or different class of antidepressant; another option is to try augmenting the first agent with lithium (eg, 600–900 mg/d orally), buspirone (eg, 30–60 mg/d orally), or thyroid medication (eg, liothyronine, 25–50 mcg/d orally). The latter course is often taken when there has been at least a partial response to the initial drug. Dysthymia is also treated in this way. The Agency for Health Care Policy and Research has produced clinical practice guidelines that outline one algorithm of treatment decisions (Figure 25–2).

Psychotic depression should be treated with a combination of an antipsychotic such as olanzapine and an

¹Times of assessment (weeks 6 and 12) rest on very modest data. It may be necessary to revise the treatment plan earlier for patients not responding at all.

▲ **Figure 25-2.** Overview of treatment for depression. (Reproduced from Agency for Health Care Policy and Research: Depression in Primary Care. Vol. 2: Treatment of Major Depression. United States Department of Health and Human Services, 1993.)

antidepressant such as an SSRI at their usual doses. Mifepristone may have specific and early activity against psychotic depression.

Major depression with atypical features or seasonal onset can be treated with an MAO inhibitor or an SSRI with good results.

Stimulants such as dextroamphetamine (5–30 mg/d orally) and methylphenidate (10–45 mg/d orally) have enjoyed a resurgence of interest for the short-term treatment of depression in medically ill and geriatric patients. Their 50–60% efficacy rate is slightly below that of other agents. The stimulants are notable for rapid onset of action

(hours) and a paucity of side effects (tachycardia, agitation) in most patients. They are usually given in two divided doses early in the day (eg, 7 am and noon) so as to avoid interfering with sleep. These agents may also be useful as adjunctive agents in refractory depression. Although not useful in routine clinical practice, ketamine can have antidepressant properties and highlights possible therapeutic pathways.

Caution: Depressed patients may have suicidal thoughts, and the amount of drug dispensed should be appropriately controlled. It appears that in children and adolescent populations, antidepressants may be associated with some slightly increased risk of suicidality, but this diminishes by age 25. After that, antidepressants have neutral or possibly protective effects until age 65 years or older when they have protective effects. The older TCAs have a narrow therapeutic index, and one advantage of the newer medications is their wider margin of safety. Nonetheless, even with newer agents, because of the possibility of suicidality early in antidepressant treatment, close follow-up is indicated. This increase is primarily evident in individuals younger than 25 years and may be due to increased energy to act on suicidal impulses or to early agitation. In all cases of pharmacologic management of depressed states, caution is indicated until the risk of suicide is considered minimal.

1. SSRIs and atypical antidepressants—The SSRIs include fluoxetine, sertraline, paroxetine, fluvoxamine, citalopram and its enantiomer escitalopram. The chief advantages of these agents are that they do not generally cause significant cardiovascular or anticholinergic side effects, and they have much lower lethality in overdose compared to TCAs. (Notably, citalopram now carries a warning regarding QT prolongation in doses above 40 mg, and caution should be used in prescribing in patients at risk for arrhythmia. This is not the case for escitalopram.) The atypical antidepressants are bupropion, which appears to exert its effect through the dopamine neurotransmitter system; venlafaxine and duloxetine, both of which inhibit the reuptake of both serotonin and norepinephrine; nefazodone, which blocks the reuptake of serotonin but also inhibits the 5-HT₂ postsynaptic receptors; vilazodone, which inhibits the reuptake of serotonin and is a partial agonist at the 5HT_{1A} receptors; and mirtazapine, which selectively blocks presynaptic α_2 -adrenergic receptors and enhances both noradrenergic and serotonergic transmission. All of these antidepressants are effective in the treatment of depression, both typical and atypical. The SSRI medications have been effective in the treatment of panic attacks, bulimia, generalized anxiety disorder, OCD, and PTSD. They do not seem to be as clearly effective in some pain syndromes as the TCAs, although venlafaxine may have some efficacy in the treatment of neuropathic pain, and duloxetine is FDA-approved for the treatment of diabetic peripheral neuropathy and fibromyalgia.

Most of the medications in this group tend to be activating and are given in the morning so as not to interfere with sleep. Some patients, however, may have sedation, requiring that the drug be given at bedtime. This reaction occurs most commonly with paroxetine, fluvoxamine, and mirtazapine. The SSRIs can be given in once-daily dosage. Nefazodone and venlafaxine are usually given twice daily. Bupropion

and venlafaxine are available in extended-release formulations and can be given once daily. There is usually some delay in response; fluoxetine, for example, requires 2–6 weeks to act in depression, 4–8 weeks to be effective in panic disorder, and 6–12 weeks in treatment of OCD. The starting dose (10 mg) is given for 1 week before increasing to the average daily oral dose of 20 mg for depression, while OCD may require up to 80 mg daily. Some patients, particularly the elderly, may tolerate and benefit from as little as 10 mg/d or every other day. The other SSRIs have shorter half-lives and a lesser effect on hepatic enzymes, which reduces their impact on the metabolism of other medications (thus not increasing significantly the serum concentrations of other medications as much as fluoxetine). The shorter half-lives also allow for more rapid clearing if adverse side effects appear. Venlafaxine appears to be more effective with doses > 200 mg/d orally, although some individuals respond to doses as low as 75 mg/d.

The **side effects** common to all of these medications are headache, nausea, tinnitus, insomnia, and nervousness. Akathisia has been common with the SSRIs; other extrapyramidal symptoms (eg, dystonias) have occurred infrequently but particularly in withdrawal states. Because SSRIs affect platelet serotonin levels, abnormal bleeding can occur. Sertraline and citalopram appear to be the safest agents in this class when used with warfarin. Sexual side effects of erectile dysfunction, retrograde ejaculation, and dysorgasmia are very common with the SSRIs. Oral phosphodiesterase-5 inhibitors (such as sildenafil, 25–50 mg; tadalafil, 5–20 mg; or vardenafil, 10–20 mg taken 1 hour prior to sexual activity) can improve erectile dysfunction in some patients. Adjunctive bupropion (75–150 mg orally daily) may also help with restoring erectile function. Cyproheptadine, 4 mg orally prior to sexual activity, may be helpful in countering drug-induced anorgasmia. The SSRIs are strong serotonin uptake blockers and may in high dosage or in combination with MAO inhibitors, including the antiparkinsonian drug selegiline, cause a “**serotonin syndrome**.” This syndrome is manifested by rigidity, hyperthermia, autonomic instability, myoclonus, confusion, delirium, and coma. This syndrome can be a particularly troublesome problem in the elderly. Several cases of angina have been reported in association with SSRIs. However, current research indicates that SSRIs are safer agents to use than TCAs in patients with cardiac disease. A study has found that sertraline is a safe and effective antidepressant treatment in patients with acute myocardial infarction or unstable angina.

Withdrawal syndromes have been reported for the SSRIs and venlafaxine. These include dysphoric mood, agitation, and a flu-like state. These medications should be discontinued gradually over a period of weeks or months to reduce the risk of withdrawal phenomena.

Fluoxetine, fluvoxamine, sertraline, venlafaxine, and citalopram in customary antidepressant doses may increase the risk of major fetal malformation when used during pregnancy; however, the absolute risk of congenital defects is considered low. Paroxetine may be associated with a twofold increased risk of cardiac abnormalities. Postpartum developmental effects of antidepressants have been thought

to be minimal, however, this question calls for ongoing investigation. A 2010 study of depressed women in their third trimester of pregnancy, comparing those who were treated with an SSRI versus those who were untreated, suggests the SSRI may have relatively delayed gross motor development at 6 months. Peripartum effects may be a concern and are documented anecdotally in the literature. At the same time, maternal major mood disorder in pregnancy by itself carries its own risks to the mother and fetus and has been linked to low birth weight and preterm delivery. Postpartum effects of prenatal depression have not been studied. The decision to use SSRIs and other psychotropic agents during pregnancy and postpartum must be a collaborative decision based on a thorough risk-benefit analysis for each individual.

Venlafaxine is reported to be well-tolerated without significant anticholinergic or cardiovascular side effects. Nausea, nervousness, and profuse sweating appear to be the major side effects. Venlafaxine appears to have few drug-drug interactions. It does require monitoring of blood pressure because dose-related hypertension may develop in some individuals. Desvenlafaxine, a newer form of the drug, is started at its target dose of 50 mg/d orally and does not require upward titration. Duloxetine may also result in small increases in blood pressure. Common side effects include dry mouth, dizziness, and fatigue. Inhibitors of 1A2 and 2D6 may increase duloxetine levels with a risk of toxicity.

Nefazodone appears to lack the anticholinergic effects of the TCAs and the agitation sometimes induced by SSRIs. Nefazodone should not be given with terfenadine, astemizole, or cisapride. (Terfenadine, astemizole, and cisapride are not commercially available in the United States.) Because nefazodone inhibits the liver's cytochrome P450 3A4 isoenzymes, concurrent use of these medications can lead to serious QT prolongation, ventricular tachycardia, or death. Through the same mechanism of enzyme inhibition, nefazodone can elevate cyclosporine levels sixfold to tenfold. Nefazodone has been given an FDA warning because it has been implicated in liver failure in rare cases. Pretreatment and ongoing monitoring of liver enzymes are indicated.

Mirtazapine is thought to enhance central noradrenergic and serotonergic activity with minimal sexual side effects compared with the SSRIs. Its action as a potent antagonist of histaminergic receptors may make it a useful agent for patients with depression and insomnia. It is also an effective antiemetic due to its antagonism of the 5-HT₃ receptor. Its most common adverse side effects include somnolence, increased appetite, weight gain, lipid abnormalities, and dizziness. There have been reports of agranulocytosis in 2 of 2796 patients. Although it is metabolized by P450 isoenzymes, it is not an inhibitor of this system. It is given in a single oral dose at bedtime starting at 15 mg and increasing in 15-mg increments every week or every other week up to 45 mg.

2. Tricyclic antidepressants (TCAs) and clinically similar medications—TCAs were the mainstay of drug therapy for depression for many years. They have also been effective in panic disorders, pain syndromes, and anxiety states. Specific ones have been effective in OCD

(clomipramine), enuresis (imipramine), psychotic depression (amoxapine), and reduction of craving in cocaine withdrawal (desipramine).

TCAs are characterized more by their similarities than by their differences. There is a lag in clinical response for up to several weeks, largely the result of anticholinergic side effects that prevent rapid increase in dosage. They tend to affect both serotonin and norepinephrine reuptake; some medications act mainly on the former and others principally on the latter neurotransmitter system. Individuals receiving the same dosages vary markedly in therapeutic drug levels achieved (elderly patients require smaller doses), and determination of plasma drug levels is helpful when clinical response has been disappointing. Nortriptyline is usually effective when plasma levels are between 50 and 150 ng/mL; imipramine at plasma levels of 200–250 ng/mL; and desipramine at plasma levels of 100–250 ng/mL. High blood levels are not more effective than moderate levels and may be counterproductive (eg, delirium, seizures). Patients with gastrointestinal side effects benefit from plasma level monitoring to assess absorption of the drug. Most TCAs can be given in a single dose at bedtime, starting at fairly low doses (eg, nortriptyline 25 mg orally) and increasing by 25 mg every several days as tolerated until the therapeutic response is achieved (eg, nortriptyline, 100–150 mg) or to maximum dose if necessary (eg, nortriptyline, 150 mg). The most common cause of treatment failure is an inadequate trial. A full trial consists of giving maximum daily dosage for at least 6 weeks. Because of marked anticholinergic and sedating side effects, clomipramine is started at a low dose (25 mg/d orally) and increased slowly in divided doses up to 100 mg/d, held at that level for several days, and then gradually increased as necessary up to 250 mg/d. Any of the TCA-like medications should be started at very low doses (eg, 10–25 mg/d) and increased slowly in the treatment of panic disorder.

The TCAs have anticholinergic side effects to varying degrees (amitriptyline 100 mg is equivalent to atropine 5 mg). One must be particularly wary of the effect in elderly men with prostatic hyperplasia. The anticholinergic effects also predispose to other medical problems such as constipation, heat stroke, or dental problems from xerostomia. Orthostatic hypotension is fairly common, is not dose-dependent and may not remit with time on medication; this may predispose to falls and hip fractures in the elderly. Cardiac effects of the TCAs are functions of the anticholinergic effect, direct myocardial depression (quinidine-like effect), and interference with adrenergic neurons. These factors may produce altered rate, rhythm, and contractility, particularly in patients with preexisting cardiac disease, such as bundle-branch or bifascicular block. Electrocardiographic changes range from benign ST segment and T wave changes and sinus tachycardia to a variety of complex and serious arrhythmias, the latter requiring a change in medication. Because TCAs have class I antiarrhythmic effects, they should be used with caution in patients with ischemic heart disease, arrhythmias, or conduction disturbances. SSRIs or the atypical antidepressants are better initial choices for this population. TCAs lower

the seizure threshold so this is of particular concern in patients with a propensity for seizures (eg, previous head injury, alcohol withdrawal). Loss of libido and erectile, ejaculatory, and orgasmic dysfunction are fairly common and can compromise compliance. Trazodone rarely causes priapism (1 in 9000), but when it occurs, it requires treatment within 12 hours (epinephrine 1:1000 injected into the corpus cavernosum). Delirium, agitation, and mania are infrequent complications of the TCAs but can occur. Sudden discontinuation of some of these medications can produce “cholinergic rebound,” manifested by headaches and nausea with abdominal cramps. Overdoses of TCAs are often serious because of the narrow therapeutic index and quinidine-like effects (see Chapter 38).

3. Monoamine oxidase inhibitors—The MAO inhibitors are generally used as third-line medications for depression (after a failure of SSRIs, TCAs, or the atypical antidepressants) because of the dietary and other restrictions required (see below and Table 25–7). They should be considered third-line medications for refractory panic disorder as well as depression; however, this hierarchy has become more flexible since MAO inhibitor skin patches (selegiline) have become available. They deliver the MAO inhibitor to the bloodstream bypassing the gastrointestinal tract so that dietary restrictions are not necessary in the lowest dosage strength (6 mg/24 h).

Oral MAO inhibitors are administered in gradual stepwise dosage and may be given in the morning or evening, depending upon their effect on sleep. They tend to take effect in a fairly low dosage range (Table 25–8). Blood levels are not congruent with therapeutic response.

The MAO inhibitors commonly cause symptoms of orthostatic hypotension (which may persist) and sympathomimetic effects of tachycardia, sweating, and tremor. Nausea, insomnia (often associated with intense afternoon drowsiness), and sexual dysfunction are common. Trazodone, 25–75 mg orally at bedtime, may ameliorate the MAO-induced insomnia. Central nervous system effects include agitation and toxic psychoses. Dietary limitations (see Table 25–7) and abstinence from drug products containing phenylpropanolamine, phenylephrine, meperidine, dextromethorphan, and pseudoephedrine are mandatory for MAO-A type inhibitors (those marketed for treatment of depression), since the reduction of available MAO leaves the patient vulnerable to exogenous amines (eg, tyramine in foodstuffs).

Treatment for a resultant hypertensive crisis has been the same as for pheochromocytoma (see Chapter 26), but

there have been reports of success with nifedipine, 10 mg chewed and placed under the tongue, normalizing blood pressure in 1–5 minutes. The restrictions on the proscribed foodstuffs and sympathomimetic medications are in effect during treatment and for 2–3 weeks after cessation of therapy. Termination of therapy with MAO inhibitors may be associated with anxiety, agitation, cognitive slowing, and headache. Very gradual withdrawal and short-term benzodiazepine therapy will ameliorate symptoms.

4. Switching and combination therapy—If the therapeutic response has been poor after an adequate trial with the chosen drug, the diagnosis should be reassessed. Assuming that the trial has been adequate and the diagnosis is correct, a trial with a second drug is appropriate. In switching from one group to another, an adequate “wash-out time” must be allowed. This is critical in certain situations—eg, in switching from an MAO inhibitor to a TCA, allow 2–3 weeks between stopping one drug and starting another; in switching from an SSRI to an MAO inhibitor, allow 4–5 weeks. In switching within groups—eg, from one TCA to another (amitriptyline to desipramine, etc)—no washout time is needed, and one can rapidly decrease the dosage of one drug while increasing the other. In clinical practice, adjunctive treatment with lithium, buspirone, or thyroid hormone may be helpful in depression. The adjunctive use of low-dose atypical antipsychotics such as aripiprazole, olanzapine, and risperidone in the treatment of patients with refractory depression is supported by research. The side effect risk is the same as when treating psychosis. The FDA has approved aripiprazole for this purpose. Adding an atypical agent requires monitoring body mass index, lipids, and glucose. Combining two antidepressants, or adding an antipsychotic to an antidepressant, requires caution and is usually reserved for clinicians who feel comfortable managing this or after psychiatric consultation.

5. Maintenance and tapering—When clinical relief of symptoms is obtained, medication is continued for 12 months in the effective maintenance dosage, which is the dosage required in the acute stage. The full dosage should be continued indefinitely when the individual has a first episode before age 20 or after age 50, is over age 40 with two episodes, at least one episode after age 50, or has had three episodes at any age. Major depression should often be considered a chronic disease. If the medication is being tapered, it should be done gradually over several months, monitoring closely for relapse.

6. Drug interactions—Interactions with other medications are listed in Table 25–9.

7. Electroconvulsive therapy—ECT causes a generalized central nervous system seizure (peripheral convulsion is not necessary) by means of electric current. The key objective is to exceed the seizure threshold, which can be accomplished by a variety of means. The mechanism of action is not known, but it is thought to involve major neurotransmitter responses at the cell membrane. Electrical current insufficient to cause a seizure produces no therapeutic benefit.

ECT is the most effective (about 70–85%) treatment of severe depression—particularly the delusions and agitation

Table 25-7. Principal dietary restrictions in MAOI use.

1. Cheese, except cream cheese and cottage cheese and fresh yogurt
2. Fermented or aged meats such as bologna, salami
3. Broad bean pods such as Chinese bean pods
4. Liver of all types
5. Meat and yeast extracts
6. Red wine, sherry, vermouth, cognac, beer, ale
7. Soy sauce, shrimp paste, sauerkraut

MAOI, monoamine oxidase inhibitor.

³200 mg twice daily.

⁴Wellbutrin XL is a once-daily form of bupropion. Bupropion is still available as immediate release, and, if used, no single dose should exceed 150 mg.

SSRIs, serotonin selective reuptake inhibitors.

Table 25-9. Antidepressant drug interactions with other medications.

Drug	Effects
Tricyclic and other non-MAOI antidepressants	
Antacids	Decreased absorption of antidepressants
Anticoagulants	Increased hypoprothrombinemic effect
Cimetidine	Increased antidepressant blood levels and psychosis
Clonidine	Decreased antihypertensive effect
Digitalis	Increased incidence of heart block
Disulfiram	Increased antidepressant blood levels
Guanethidine	Decreased antihypertensive effect
Haloperidol	Increased antidepressant levels
Insulin	Decreased blood sugar
Lithium	Increased lithium levels with fluoxetine
Methyl dopa	Decreased antihypertensive effect
Other anticholinergic medications	Marked anticholinergic responses
Phenytoin	Increased blood levels
Procainamide	Decreased ventricular conduction
Procarbazine	Hypertensive crisis
Propranolol	Increased hypotension
Quinidine	Decreased ventricular conduction
Rauwolfia derivatives	Increased stimulation
Sedatives	Increased sedation
Sympathomimetic medications	Increased vasopressor effect
Terfenadine, ¹ astemizole, ¹ cisapride ¹	Torsades de pointes
MAOIs	
Antihistamines	Increased sedation
Belladonna-like medications	Increased blood pressure
Dextromethorphan	Same as meperidine
Guanethidine	Decreased blood pressure
Insulin	Decreased blood sugar
Levodopa	Increased blood pressure
Meperidine	Increased agitation, seizures, coma, death
Methyl dopa	Decreased blood pressure
Pseudoephedrine	Hypertensive crisis (increased blood pressure)
Reserpine	Increased blood pressure and temperature
Succinylcholine	Increased neuromuscular blockade
Sulfonylureas	Decreased blood sugar
Sympathomimetic medications	Increased blood pressure

¹Terfenadine, astemizole, and cisapride are not commercially available in the United States.

MAOIs, monoamine oxidase inhibitors.

commonly seen with depression in the elderly. It is indicated when medical conditions preclude the use of antidepressants, nonresponsiveness to these medications, and extreme suicidality. Comparative controlled studies of ECT in severe depression show that it is more effective than pharmacotherapy. It is also effective in the manic disorders and psychoses during pregnancy (when medications may be contraindicated). It has not been shown to be helpful in chronic schizophrenic disorders, and it is generally not used in acute schizophrenic episodes unless medications are not effective and it is urgent that the psychosis be controlled (eg, a catatonic stupor complicating an acute medical condition).

The most common side effects are memory disturbance and headache. Memory loss or confusion is usually related to the number and frequency of ECT treatments and proper oxygenation during treatment. Unilateral ECT is associated with less memory loss than bilateral ECT. Some memory loss is occasionally permanent, but most memory faculties return to full capacity within several weeks. There have been reports that lithium administration concurrent with ECT resulted in greater memory loss.

Increased intracranial pressure is a serious contraindication. Other problems such as cardiac disorders, aortic aneurysms, bronchopulmonary disease, and venous thrombosis are relative contraindications and must be evaluated in light of the severity of the medical problem versus the need for ECT. Serious complications arising from ECT occur in < 1 in 1000 cases. Most of these problems are cardiovascular or respiratory in nature (eg, aspiration of gastric contents). Poor patient understanding and lack of acceptance of the technique by the public are the biggest obstacles to the use of ECT.

8. Phototherapy—Phototherapy is used in major depression with seasonal onset. It consists of exposure (at a 3-foot distance) to a light source of 2500 lux for 2 hours daily. Light visors are an adaptation that provides greater mobility and an adjustable light intensity. The dosage varies, with some patients requiring morning and night exposure. One effect is alteration of biorhythm through melatonin mechanisms.

9. Experimental treatments—In preliminary studies, transcranial magnetic stimulation appears to be effective in nonpsychotic depression. Its use in this condition has been approved by the FDA for individuals who have not responded to an antidepressant. It is usually delivered in a course of 16–20 sessions over 1 month. Vagal nerve stimulation has shown some promise in extremely refractory cases and is approved by the FDA but has not been approved by many insurers.

B. Psychological

It is seldom possible to engage an individual in penetrating psychotherapeutic endeavors during the acute stage of a severe depression. While medications may be taking effect, a supportive approach to strengthen existing coping mechanisms and appropriate consideration of the patient's continuing need to function at work, to engage in recreational activities, etc, are necessary as the severity of the

depression lessens. If the patient is not seriously depressed, it is often quite appropriate to initiate intensive psychotherapeutic efforts, since flux periods are a good time to effect change. A catharsis of repressed anger and guilt may be beneficial. Therapy during or just after the acute stage may focus on coping techniques, with some practice of alternative choices. Depression-specific psychotherapies help improve self-esteem, increase assertiveness, and lessen dependency. Interpersonal psychotherapy for depression has shown efficacy in the treatment of acute depression, helping patients master interpersonal stresses and develop new coping strategies. Cognitive behavioral therapy for depression addresses patients' patterns of negative thoughts, called cognitive distortions, that lead to feelings of depression and anxiety. Treatment usually includes homework assignments such as keeping a journal of cognitive distortions and of positive responses to them. The combination of drug therapy plus interpersonal psychotherapy or cognitive behavioral therapy is more effective than either modality alone. It is usually helpful to involve the spouse or other significant family members early in treatment. Mindfulness-based cognitive therapy has reduced relapse rates in several randomized controlled trials. In two studies, it was as effective as maintenance medication in preventing relapse. This therapy incorporates meditation and teaches patients to distance themselves from depressive thinking. It may be a preferable alternative for individuals who wish to have an alternative to long-term medications to stay free of depressive episodes.

C. Social

Flexible use of appropriate social services can be of major importance in the treatment of depression. Since alcohol is often associated with depression, early involvement in alcohol treatment programs such as Alcoholics Anonymous can be important to future success (see Alcohol Dependency and Abuse, below). The structuring of daily activities during severe depression is often quite difficult for the patient, and loneliness is often a major factor. The help of family, employer, or friends is often necessary to mobilize the patient who experiences no joy in daily activities and tends to remain uninvolved and to deteriorate. Insistence on sharing activities will help involve the patient in simple but important daily functions. In some severe cases, the use of day treatment centers or support groups of a specific type (eg, mastectomy groups) is indicated. It is not unusual for a patient to have multiple legal, financial, and vocational problems requiring legal and vocational assistance.

D. Behavioral

When depression is a function of self-defeating coping techniques such as passivity, the role-playing approach can be useful. Behavioral techniques, including desensitization, may be used in problems such as phobias where depression is a by-product. When depression is a regularly used interpersonal style, behavioral counseling to family members or others can help in extinguishing the behavior in the patient. Behavioral activation, a technique of motivating depressed patients to begin engaging in pleasurable activities, has been shown to be a useful depression-specific psychotherapy.

► Treatment of Mania

Acute manic or hypomanic symptoms will respond to lithium or valproic acid after several days of treatment, but it is increasingly common to use atypical neuroleptics as adjunctive treatment or monotherapy. High-potency benzodiazepines (eg, clonazepam) may also be useful adjuncts in managing acute cases. Some schizoaffective disorders and some cases of so-called schizophrenia are probably atypical bipolar affective disorder, for which lithium treatment may be effective.

A. Neuroleptics

Acute manic symptoms of agitation and psychosis may be treated initially with the atypical antipsychotic olanzapine, (eg, 5–20 mg orally), risperidone (2–3 mg orally), or aripiprazole (15–30 mg) in conjunction with a benzodiazepine if indicated. Alternatively, when behavioral control is immediately necessary, olanzapine in an injectable form (2.5–10 mg intramuscularly) or haloperidol, 5–10 mg orally or intramuscularly repeated as needed until symptoms subside, may be used. The dosage of the neuroleptic may be gradually reduced after lithium or another mood stabilizer is started (see below). Olanzapine is approved as a maintenance treatment for bipolar disorder.

B. Clonazepam

Clonazepam can be an alternative or adjunct to a neuroleptic in controlling acute behavioral symptoms. Clonazepam has the advantage of causing no extrapyramidal side effects. Although 1–2 mg orally every 4–6 hours may be effective, up to 16 mg/d may be necessary.

C. Lithium

As a prophylactic drug for bipolar affective disorder, lithium significantly decreases the frequency and severity of both manic and depressive attacks in about 70% of patients. A positive response is more predictable if the patient has a low frequency of episodes (no more than two per year with intervals free of psychopathology). A positive response occurs more frequently in individuals who have blood relatives with a diagnosis of manic or hypomanic attacks. Patients who swing rapidly back and forth between manic and depressive attacks (at least four cycles per year) usually respond poorly to lithium prophylaxis initially, but some improve with continued long-term treatment. Carbamazepine (see below) has been used with success in this group.

In addition to its use in manic states, lithium is sometimes useful in the prophylaxis of recurrent unipolar depressions (perhaps undiagnosed bipolar disorder). Lithium may ameliorate nonspecific aggressive behaviors and dyscontrol syndromes. The dosages are the same as used in bipolar disorder. Most patients with bipolar disease can be managed long-term with lithium alone, although some will require continued or intermittent use of a neuroleptic, antidepressant, or carbamazepine. An excellent resource for information is the Lithium Information Center, Madison Institute of Medicine, 7617

Mineral Point Road, Suite 300, Madison, WI 53717-1914, <http://www.miminc.org/aboutlithinfoctr.html>.

Before treatment, the clinical workup should include a medical history and physical examination; complete blood count; T4, thyroid-stimulating hormone, blood urea nitrogen (BUN), serum creatinine, and serum electrolyte determinations; urinalysis; and electrocardiography (in patients over age 45 or with a history of cardiac disease).

1. Dosage—The common starting dosage of lithium carbonate is 300 mg orally two or three times daily, with trough blood levels measured after 5 days of treatment. In a small minority of patients, a slow release form or units of different dosage may be required. Lithium citrate is available as a syrup. The dosage is that required to maintain blood levels in the therapeutic range. For acute attacks, this ranges from 1 to 1.5 mEq/L. Although there is controversy about the optimal long-term maintenance dose, many clinicians reduce the acute level to 0.6–1 mEq/L in order to reduce side effects. The dose required to meet this need will vary in different individuals. For acute mania, doses of 1200–1800 mg/d are generally recommended. Augmentation of antidepressants is usually achieved with half of these doses. Once-a-day dosage is acceptable, but most patients have less nausea when they take the drug in divided doses with meals.

Lithium is readily absorbed, with peak serum levels occurring within 1–3 hours and complete absorption in 8 hours. Half of the total body lithium is excreted in 18–24 hours (95% in the urine). Blood for lithium levels should be drawn 12 hours after the last dose. Serum levels should be measured 5–7 days after initiation of treatment and changes in dose. For maintenance treatment, lithium levels should be monitored initially every 1–2 months but may be measured every 6–12 months in stable, long-term patients. Levels should be monitored more closely when there is any condition that causes volume depletion (eg, diarrhea, dehydration, use of diuretics).

2. Side effects—Mild gastrointestinal symptoms (take lithium with food and in divided doses), fine tremors (treat with propranolol, 20–60 mg/d orally, only if persistent), slight muscle weakness, and some degree of somnolence are early side effects that are usually transient. Moderate polyuria (reduced renal responsiveness to ADH) and polydipsia (associated with increased plasma renin concentration) are often present. Potassium administration can blunt this effect, as may once-daily dosing of lithium. Weight gain (often a result of calories in fluids taken for polydipsia) and leukocytosis not due to infection are fairly common.

Other side effects include goiter (3%; often euthyroid), hypothyroidism (10%; concomitant administration of lithium and iodide or lithium and carbamazepine enhances the hypothyroid and goitrogenic effect of either drug), changes in the glucose tolerance test toward a diabetes-like curve, nephrogenic diabetes insipidus (usually resolving about 8 weeks after cessation of lithium therapy), nephrotic syndrome, edema, folate deficiency, and pseudotumor cerebri (ophthalmoscopy is indicated if there are complaints of headache or blurred vision). A metallic taste, hair

loss, and Raynaud phenomenon have been reported in a few cases. Thyroid and kidney function should be checked at 3- to 4-month intervals. Most of these side effects subside when lithium is discontinued; when residual side effects exist, they are usually not serious. Most clinicians treat lithium-induced hypothyroidism (more common in women) with thyroid hormone while continuing lithium therapy. Hypercalcemia and elevated parathyroid hormone levels occur in some patients. Electrocardiographic abnormalities (principally T wave flattening or inversion) may occur during lithium administration but are not of major clinical significance. Sinoatrial block may occur, particularly in the elderly. Other medications that prolong intraventricular conduction, such as TCAs, must be used cautiously in conjunction with lithium. Lithium impairs ventilatory function in patients with airway obstruction. Lithium alone does not have a significant effect on sexual function, but when combined with benzodiazepines (clonazepam in most symptomatic patients) it causes sexual dysfunction in about 50% of men. Lithium may precipitate or exacerbate psoriasis in some patients.

Patients receiving long-term lithium therapy may have cogwheel rigidity and, occasionally, other extrapyramidal signs. Lithium potentiates the parkinsonian effects of haloperidol. Long-term lithium therapy has also been associated with a relative lowering of the level of memory and perceptual processing (affecting compliance in some cases). Some impairment of attention and emotional reactivity has also been noted. Lithium-induced delirium with therapeutic lithium levels is an infrequent complication usually occurring in the elderly and may persist for several days after serum levels have become negligible. Encephalopathy has occurred in patients receiving combined lithium and neuroleptic therapy and in those who have cerebrovascular disease, thus requiring careful evaluation of patients who develop neurotoxic signs at subtoxic blood levels.

Some reports have suggested that the long-term use of lithium may have adverse effects on kidney function (with interstitial fibrosis, tubular atrophy, or nephrogenic diabetes insipidus). Persistent polyuria should require an investigation of the kidney's ability to concentrate urine. A rise in serum creatinine levels is an indication for in-depth evaluation of kidney function and consideration of alternative treatments if the individual can tolerate a change. Incontinence has been reported in women, apparently related to changes in bladder cholinergic-adrenergic balance.

Prospective studies suggest that the overall risk imposed by lithium in pregnancy may be overemphasized. However, lithium exposure in early pregnancy does increase the frequency of congenital anomalies, especially Ebstein and other major cardiovascular anomalies. For women who take psychotropic medications who become pregnant, the decision to make a change in medication is complex and requires informed consent regarding the relative risks to the patient and fetus. Indeed, the risk of untreated bipolar disorder carries its own risks for pregnancy. Formula feeding should be considered in mothers taking lithium, since concentration in breast milk is one-third to half that in serum.

Frank toxicity usually occurs at blood lithium levels > 2 mEq/L. Because sodium and lithium are reabsorbed at the same loci in the proximal renal tubules, any sodium loss (diarrhea, use of diuretics, or excessive perspiration) results in increased lithium levels. Symptoms and signs include vomiting and diarrhea, the latter exacerbating the problem since more sodium is lost and more lithium is absorbed. Other symptoms and signs, some of which may not be reversible, include tremors, marked muscle weakness, confusion, dysarthria, vertigo, choreoathetosis, ataxia, hyperreflexia, rigidity, lack of coordination, myoclonus, seizures, opisthotonos, and coma. Toxicity is more severe in the elderly, who should be maintained on slightly lower serum levels. Lithium overdosage may be accidental or intentional or may occur as a result of poor monitoring.

Patients with massive ingestions of lithium or blood lithium levels > 2.5 mEq/L should be treated with induced emesis and gastric lavage. If kidney function is normal, osmotic and saline diuresis increases renal lithium clearance. Urinary alkalization is also helpful, since sodium bicarbonate decreases lithium reabsorption in the proximal tubule, as does acetazolamide. Aminophylline potentiates the diuretic effect by increasing the clearance of lithium. Medications affecting the distal loop have no effect on lithium reabsorption. Blood lithium levels > 2.5 mEq/L (confirmed by cerebrospinal fluid lithium levels) should be considered an indication for hemodialysis.

Compliance with lithium therapy is adversely affected by the loss of some hypomanic experiences valued by the patient. These include social extroversion and a sense of heightened enjoyment in many activities such as sex and business dealings, often with increased productivity in the latter.

3. Drug interactions—Patients receiving lithium should use diuretics with caution and only under close medical supervision. The thiazide diuretics cause increased lithium reabsorption from the proximal renal tubules, resulting in increased serum lithium levels (Table 25–10), and adjustment of lithium intake must be made to compensate for this. Reduce lithium dosage by 25–40% when the patient is receiving 50 mg of hydrochlorothiazide daily. Potassium-sparing diuretics (spironolactone, amiloride, triamterene) may also increase serum lithium levels and require careful monitoring of lithium levels. Loop diuretics (furosemide, ethacrynic acid, bumetanide) do not appear to alter serum lithium levels. Concurrent use of lithium and angiotensin-converting enzyme inhibitors requires a 50–75% reduction in lithium intake to achieve therapeutic lithium levels.

D. Valproic Acid

Valproic acid (divalproex) is an antiseizure drug whose activity is at least partially related to GABA neurotransmission. It is a first-line treatment for mania because it has a broader index of safety than lithium. This issue is particularly important in AIDS or other medically ill patients prone to dehydration or malabsorption with wide swings in serum lithium levels. Valproic acid has also been used effectively in panic disorder and migraine headache. Treatment is often started at a dose of 750 mg/d orally in divided doses, and dosage is then titrated to achieve therapeutic

Table 25–10. Lithium interactions with other medications.

Drug	Effects
ACE inhibitors	↑ Lithium levels
Fluoxetine	↑ Lithium levels
Ibuprofen	↑ Lithium levels
Indomethacin	↑ Lithium levels
Methyl dopa	Rigidity, mutism, fascicular twitching
Osmotic diuretics (urea, mannitol)	↑ Lithium excretion
Phenylbutazone	↑ Lithium levels
Potassium-sparing diuretics (spironolactone, amiloride, triamterene)	↑ Lithium levels
Sodium bicarbonate	↑ Lithium excretion
Succinylcholine	↑ Duration of action of succinylcholine
Theophylline, aminophylline	↑ Lithium excretion
Thiazide diuretics	↑ Lithium levels
Valproic acid	↓ Lithium levels
COX-2 inhibitors	↑ Lithium levels

ACE, angiotensin-converting enzyme; COX-2, cyclooxygenase-2.

serum levels. Oral loading in acutely manic bipolar patients in an inpatient setting (initiated at a dosage of 20 mg/kg/d) can safely achieve serum therapeutic levels in 2–3 days. Concomitant use of aspirin may increase valproate levels, carbamazepine or phenytoin may decrease valproate levels, while warfarin levels may be elevated by valproate. Gastrointestinal symptoms and weight gain are the main side effects. Liver function tests, complete blood counts, glucose levels, and weight should be monitored at 2 weeks, 4 weeks, and at 3 months initially and annually or more frequently thereafter based on clinical judgment. Significant teratogenic effects are a concern so pregnancy should be ruled out prior to initiation.

E. Carbamazepine

Carbamazepine, an antiseizure drug that stabilizes the activity of cell membranes, has been used with increasing frequency in the treatment of bipolar patients who cannot be satisfactorily treated with lithium (nonresponsive, excessive side effects, or rapid cycling). It is often effective at 800–1600 mg/d orally. It has also been used in the treatment of resistant depressions, alcohol withdrawal, and hallucinations (in conjunction with neuroleptics) and in patients with behavioral dyscontrol or panic attacks. It suppresses some phases of kindling (see Stimulants) and has been used to treat residual symptoms in previous stimulant abusers (eg, PTSD with impulse control problems). Dose-related side effects include sedation and ataxia. Dosages

start at 400–600 mg orally daily and are increased slowly to therapeutic levels. Skin rashes and a mild reduction in white count are common. SIADH occurs rarely. Non-steroidal anti-inflammatory medications (except aspirin), the antibiotics erythromycin and isoniazid, the calcium channel blockers verapamil and diltiazem (but not nifedipine), fluoxetine, propoxyphene, and cimetidine all increase carbamazepine levels. Carbamazepine can be effective in conjunction with lithium, although there have been reports of reversible neurotoxicity with the combination. Carbamazepine stimulates hepatic microsomal enzymes and so tends to decrease levels of haloperidol and oral contraceptives. It also lowers T_4 , free T_4 , and T_3 levels. Cases of fetal malformation (particularly spina bifida) have been reported along with growth deficiency and developmental delay. Liver tests and complete blood counts should be monitored in patients taking carbamazepine. Genetic studies suggest that screening for the HLA-B1502 allele in the Han Chinese population and the HLA-A3101 allele in northern Europeans may help target individuals more susceptible to a serious rash. **Oxcarbazepine**, a derivative of carbamazepine, does not appear to induce its own metabolism and is associated with fewer drug interactions, although it may impose a higher risk of hyponatremia. FDA-approved for partial seizures, oxcarbazepine may have efficacy in acute mania. It appears to be a safer alternative to carbamazepine due to its lower risk of hepatotoxicity.

F. Lamotrigine

Lamotrigine is thought to inhibit neuronal sodium channels and the release of the excitatory amino acids, glutamate and aspartate. It is FDA approved for long-term maintenance of bipolar disorder. Two double-blind studies support its efficacy in the treatment of acute bipolar depression as adjunctive therapy or as monotherapy. Its metabolism is inhibited by coadministration of valproic acid—doubling its half-life—and accelerated by hepatic enzyme-inducing agents such as carbamazepine. More frequent mild side effects include headache, dizziness, nausea, and diplopia. Rash occurring in 10% of patients is an indication for immediate cessation of dosing, since lamotrigine has been associated with Stevens-Johnson syndrome (1:1000) and, rarely, toxic epidermal necrolysis. Dosing starts at 25–50 mg/d orally and is titrated upward slowly to decrease the likelihood of rash. Slower titration and a lower total dose are indicated for patients taking valproic acid.

► Prognosis

Reactive depressions are usually time-limited, and the prognosis with treatment is good if a pathologic pattern of adjustment does not intervene. Major affective disorders frequently respond well to a full trial of drug treatment.

Mania and bipolar disorder have a good prognosis with adequate treatment, although patient adherence to treatment is often quite challenging.

SLEEP DISORDERS

Sleep consists of two distinct states as shown by electroencephalographic studies: (1) REM (rapid eye movement) sleep, also called dream sleep, D state sleep, paradoxical sleep, and (2) NREM (non-REM) sleep, also called S stage sleep, which is divided into stages 1, 2, 3, and 4 and is recognizable by different electroencephalographic patterns. Stages 3 and 4 are “delta” sleep. Dreaming occurs mostly in REM and to a lesser extent in NREM sleep.

Sleep is a cyclic phenomenon, with four or five REM periods during the night accounting for about one-fourth of the total night's sleep (1.5–2 hours). The first REM period occurs about 80–120 minutes after onset of sleep and lasts about 10 minutes. Later REM periods are longer (15–40 minutes) and occur mostly in the last several hours of sleep. Most stage 4 (deepest) sleep occurs in the first several hours.

Age-related changes in normal sleep include an unchanging percentage of REM sleep and a marked decrease in stage 3 and stage 4 sleep, with an increase in wakeful periods during the night. These normal changes, early bedtimes, and daytime naps play a role in the increased complaints of insomnia in older people. Variations in sleep patterns may be due to circumstances (eg, “jet lag”) or to idiosyncratic patterns (“night owls”) in persons who perhaps because of different “biologic rhythms” habitually go to bed late and sleep late in the morning. Creativity and rapidity of response to unfamiliar situations are impaired by loss of sleep. There are also rare individuals who have chronic difficulty in adapting to a 24-hour sleep-wake cycle (desynchronization sleep disorder), which can be resynchronized by altering exposure to light.

The three major sleep disorders are discussed below.

1. Dyssomnias (Insomnia)

► Classification & Clinical Findings

Patients may complain of difficulty getting to sleep or staying asleep, intermittent wakefulness during the night, early

morning awakening, or combinations of any of these. Transient episodes are usually of little significance. Stress, caffeine, physical discomfort, daytime napping, and early bedtimes are common factors.

Psychiatric disorders are often associated with persistent insomnia. **Depression** is usually associated with fragmented sleep, decreased total sleep time, earlier onset of REM sleep, a shift of REM activity to the first half of the night, and a loss of slow wave sleep—all of which are non-specific findings. In **manic disorders**, sleeplessness is a cardinal feature and an important early sign of impending mania in bipolar cases. Total sleep time is decreased, with shortened REM latency and increased REM activity. Sleep-related panic attacks occur in the transition from stage 2 to stage 3 sleep in some patients with a longer REM latency in the sleep pattern preceding the attacks.

Abuse of alcohol may cause or be secondary to the sleep disturbance. There is a tendency to use alcohol as a means of getting to sleep without realizing that it disrupts the normal sleep cycle. Acute alcohol intake produces a decreased sleep latency with reduced REM sleep during the first half of the night. REM sleep is increased in the second half of the night, with an increase in total amount of slow wave sleep (stages 3 and 4). Vivid dreams and frequent awakenings are common. Chronic alcohol abuse increases stage 1 and decreases REM sleep (most medications delay or block REM sleep), with symptoms persisting for many months after the individual has stopped drinking. Acute alcohol or other sedative withdrawal causes delayed onset of sleep and REM rebound with intermittent awakening during the night.

Heavy smoking (more than a pack a day) causes difficulty falling asleep—apparently independently of the often associated increase in coffee drinking. Excess intake near bedtime of caffeine, cocaine, and other stimulants (eg, over-the-counter cold remedies) causes decreased total sleep time—mostly NREM sleep—with some increased sleep latency.

Sedative-hypnotics—specifically, the benzodiazepines, which are the most commonly prescribed medications to promote sleep—tend to increase total sleep time, decrease sleep latency, and decrease nocturnal awakening, with variable effects on NREM sleep. Withdrawal causes just the opposite effects and results in continued use of the drug for the purpose of preventing withdrawal symptoms. Antidepressants decrease REM sleep (with marked rebound on withdrawal in the form of nightmares) and have varying effects on NREM sleep. The effect on REM sleep correlates with reports that REM sleep deprivation produces improvement in some depressions.

Persistent insomnias are also related to a wide variety of medical conditions, particularly delirium, pain, respiratory distress syndromes, uremia, asthma, thyroid disorders, and nocturia due to benign prostatic hyperplasia. Sleep apnea and restless leg movement are described below. Adequate analgesia and proper treatment of medical disorders will reduce symptoms and decrease the need for sedatives.

► Treatment

In general, there are two broad classes of treatment for insomnia, and the two may be combined: psychological

(cognitive-behavioral) and pharmacologic. In situations of acute distress, such as a grief reaction, pharmacologic measures may be most appropriate. With primary insomnia, however, initial efforts should be psychologically based. This is particularly true in the elderly to avoid the potential adverse reactions of medications. The elderly population is at risk for complaints of insomnia because sleep becomes lighter and more easily disrupted with aging. Medical disorders that become more common with age may also predispose to insomnia.

A. Psychological

Psychological strategies should include educating the patient regarding good **sleep hygiene**: (1) Go to bed only when sleepy. (2) Use the bed and bedroom only for sleeping and sex. (3) If still awake after 20 minutes, leave the bedroom, pursue a restful activity (such as a bath or meditation), and only return when sleepy. (4) Get up at the same time every morning regardless of the amount of sleep during the night. (5) Discontinue caffeine and nicotine, at least in the evening if not completely. (6) Establish a daily exercise regimen. (7) Avoid alcohol as it may disrupt continuity of sleep. (8) Limit fluids in the evening. (9) Learn and practice relaxation techniques. (10) Establish a bedtime ritual and a routine time for going to sleep. A 2009 study suggests that cognitive behavioral therapy for insomnia was as effective as zolpidem with benefits sustained 1 year after treatment.

B. Medical

When the above measures are insufficient, medications may be useful. Lorazepam (0.5 mg orally nightly), temazepam (7.5–15 mg orally nightly) and the nonbenzodiazepine hypnotics, zolpidem (5–10 mg orally nightly), and zaleplon (5–10 mg orally nightly), are often effective for the elderly population and can be given in larger doses—twice what is prescribed for the elderly—in younger patients. A nonbenzodiazepine hypnotic, eszopiclone (2–3 mg orally), is similar in action to zolpidem and zaleplon but dissimilar in that it is not restricted to short-term use. A lower dose of 1 mg is indicated in the elderly or those with hepatic impairment. It is important to note that short-acting agents like triazolam or zolpidem may lead to amnesic episodes if used on a daily ongoing basis. Longer-acting agents such as flurazepam (half-life of > 48 hours) may accumulate in the elderly and lead to cognitive slowing, ataxia, falls, and somnolence. In general, it is appropriate to use medications for short courses of 1–2 weeks. The medications described above have largely replaced barbiturates as hypnotic agents because of their greater safety in overdose and their lesser hepatic enzyme induction effects. Antihistamines such as diphenhydramine (25 mg orally nightly) or hydroxyzine (25 mg orally nightly) may also be useful for sleep, as they produce no pharmacologic dependency; their anticholinergic effects may, however, produce confusion or urinary symptoms in the elderly. Trazodone, an atypical antidepressant, is a non-habit-forming, effective sleep medication in lower than antidepressant doses (25–150 mg orally at bedtime). Priapism is a rare side effect

requiring emergent treatment. Ramelteon, 8 mg orally at bedtime, is a melatonin receptor agonist that helps with sleep onset and does not appear to have abuse potential. It appears to be safe for ongoing use without the development of tolerance.

Triazolam has achieved popularity as a hypnotic drug because of its very short duration of action. However, because it has been associated with dependency, transient psychotic reactions, anterograde amnesia, and rebound anxiety, it has been removed from the market in several European countries. If used, it must be prescribed only for short periods of time.

2. Hypersomnias (Disorders of Excessive Sleepiness)

► Classification & Clinical Findings

A. Sleep Apnea

This disorder is characterized by cessation of breathing for at least 30 episodes (each lasting about 10 seconds) during the night. There are two types: obstructive and central. (See Chapter 9.)

B. Narcolepsy

Narcolepsy consists of a tetrad of symptoms: (1) Sudden, brief (about 15 minutes) sleep attacks that may occur during any type of activity; (2) cataplexy—sudden loss of muscle tone involving specific small muscle groups or generalized muscle weakness that may cause the person to slump to the floor, unable to move, often associated with emotional reactions and sometimes confused with seizure disorder; (3) sleep paralysis—a generalized flaccidity of muscles with full consciousness in the transition zone between sleep and waking; and (4) hypnagogic hallucinations, visual or auditory, which may precede sleep or occur during the sleep attack. The attacks are characterized by an abrupt transition into REM sleep—a necessary criterion for diagnosis. The disorder begins in early adult life, affects both sexes equally, and usually levels off in severity at about 30 years of age.

REM sleep behavior disorder, characterized by motor dyscontrol and often violent dreams during REM sleep, may be related to narcolepsy.

C. Kleine-Levin Syndrome

This syndrome, which occurs mostly in young men, is characterized by hypersomnic attacks three or four times a year lasting up to 2 days, with hyperphagia, hypersexuality, irritability, and confusion on awakening. It has often been associated with antecedent neurologic insults. It usually remits after age 40.

D. Periodic Limb Movement Disorder (Formerly Called Nocturnal Myoclonus)

Periodic lower leg movements occur only during sleep with subsequent daytime sleepiness, anxiety, depression, and cognitive impairment. Restless leg syndrome includes movements while awake as well.

E. Shift Work Sleep Disorder

Shift work sleep disorder occurs when there is excessive fatigue as a consequence of work occurring during the normal sleep period.

► Treatment

Narcolepsy can be managed by daily administration of a stimulant such as dextroamphetamine sulfate, 10 mg orally in the morning, with increased dosage as necessary. Modafinil is a schedule IV medication FDA-approved for treating the excessive daytime fatigue of narcolepsy as well as for shift work sleep disorder. Usual dosing is 200 mg orally each morning. Its mechanism of action is unknown, yet it is thought to be less of an abuse risk than stimulants that are primarily dopaminergic. Common side effects include headache and anxiety; however, modafinil appears to be generally well tolerated. Modafinil may reduce the efficacy of cyclosporine, oral contraceptives, and other medications by inducing their hepatic metabolism. Imipramine, 75–100 mg orally daily, has been effective in treatment of cataplexy but not narcolepsy.

Periodic limb movement disorder and REM sleep behavior disorder can be treated with clonazepam with variable results. There is no treatment for Kleine-Levin syndrome.

Treatment of sleep apnea is discussed in Chapter 9.

3. Parasomnias (Abnormal Behaviors during Sleep)

These disorders are fairly common in children and less so in adults.

► Classification & Clinical Findings

A. Sleep Terror

Sleep terror (pavor nocturnus) is an abrupt, terrifying arousal from sleep, usually in preadolescent boys although it may occur in adults as well. It is distinct from sleep panic attacks. Symptoms are fear, sweating, tachycardia, and confusion for several minutes, with amnesia for the event.

B. Nightmares

Nightmares occur during REM sleep; sleep terrors in stage 3 or stage 4 sleep.

C. Sleepwalking

Sleepwalking (somnambulism) includes ambulation or other intricate behaviors while still asleep, with amnesia for the event. It affects mostly children aged 6–12 years, and episodes occur during stage 3 or stage 4 sleep in the first third of the night and in REM sleep in the later sleep hours. Sleepwalking in elderly people may be a feature of dementia. Idiosyncratic reactions to drugs (eg, marijuana, alcohol) and medical conditions (eg, partial complex seizures) may be causative factors in adults.

D. Enuresis

Enuresis is involuntary micturition during sleep in a person who usually has voluntary control. Like other parasomnias,

it is more common in children, usually in the 3–4 hours after bedtime, but is not limited to a specific stage of sleep. Confusion during the episode and amnesia for the event are common.

► Treatment

Treatment for sleep terrors is with benzodiazepines (eg, diazepam, 5–20 orally mg at bedtime), since it will suppress stage 3 and stage 4 sleep. Somnambulism responds to the same treatment for the same reason, but simple safety measures should not be neglected. Enuresis may respond to imipramine, 50–100 mg orally at bedtime, although desmopressin nasal spray (an ADH preparation) has increasingly become the treatment of choice for nocturnal enuresis. Behavioral approaches (eg, bells that ring when the pad gets wet) have also been successful.

DISORDERS OF AGGRESSION

Aggression and violence are symptoms rather than diseases, and most frequently they are not associated with an underlying medical condition. Clinicians are unable to predict dangerous behavior with greater than chance accuracy. Depression, schizophrenia, personality disorders, mania, paranoia, temporal lobe dysfunction, and organic mental states may be associated with acts of aggression. Impulse control disorders are characterized by physical abuse (usually of the aggressor's domestic partner or children), by pathologic intoxication, by impulsive sexual activities, and by reckless driving. Anabolic steroid usage by athletes has been associated with increased tendencies toward violent behavior.

In the United States, a significant proportion of all violent deaths are alcohol-related. The ingestion of even small amounts of alcohol can result in pathologic intoxication that resembles an acute organic mental condition. Amphetamines, crack cocaine, and other stimulants are frequently associated with aggressive behavior. Phencyclidine is a drug commonly associated with violent behavior that is occasionally of a bizarre nature, partly due to lowering of the pain threshold. Domestic violence and rape are much more widespread than previously recognized. Awareness of the problem is to some degree due to increasing recognition of the rights of women and the understanding by women that they do not have to accept abuse. Acceptance of this kind of aggressive behavior inevitably leads to more, with the ultimate aggression being murder—20–50% of murders in the United States occur within the family. Police are called for more domestic disputes than all other criminal incidents combined. Children living in such family situations frequently become victims of abuse.

Features of individuals who have been subjected to long-term physical or sexual abuse are as follows: trouble expressing anger, staying angry longer, general passivity in relationships, feeling “marked for life” with an accompanying feeling of deserving to be victimized, lack of trust, and dissociation of affect from experiences. They are prone to express their psychological distress with somatization symptoms, often pain complaints. They may also have symptoms related to posttraumatic stress, as discussed above. The clinician should be suspicious about the origin of any injuries not fully explained, particularly if such incidents recur.

► Treatment

A. Psychological

Management of any violent individual includes appropriate psychological maneuvers. Move slowly, talk slowly with clarity and reassurance, and evaluate the situation. Strive to create a setting that is minimally disturbing, and eliminate people or things threatening to the violent individual. Do not threaten or abuse, and do not touch or crowd the person. Allow no weapons in the area (an increasing problem in hospital emergency departments). Proximity to a door is comforting to both the patient and the examiner. Use a negotiator the violent person can relate to comfortably. Food and drink are helpful in defusing the situation (as are cigarettes for those who smoke). Honesty is important. Make no false promises, bolster the patient's self-esteem, and continue to engage the subject verbally until the situation is under control. This type of individual does better with strong external controls to replace the lack of inner controls over the long term. Close probationary supervision and judicially mandated restrictions can be most helpful. There should be a major effort to help the individual avoid drug use (eg, Alcoholics Anonymous). Victims of abuse are essentially treated as any victim of trauma and, not infrequently, have evidence of PTSD.

B. Pharmacologic

Pharmacologic means are often necessary whether or not psychological approaches have been successful. This is particularly true in the agitated or psychotic patient. The drug of choice in psychotic aggressive states is haloperidol, 5–10 mg intramuscularly every hour until symptoms are alleviated. Benzodiazepine sedatives (eg, diazepam, 5 mg orally or intravenously every several hours) can be used for mild to moderate agitation, but an antipsychotic drug is preferred for management of the seriously violent and psychotic patient. Chronic aggressive states, particularly in retardation and brain damage (rule out causative organic conditions and medications such as anticholinergic medications in amounts sufficient to cause confusion), have been ameliorated with risperidone, 0.5–2 mg/d orally, propranolol, 40–240 mg/d orally, or pindolol, 5 mg twice daily orally (pindolol causes less bradycardia and hypotension than propranolol). Carbamazepine and valproic acid are effective in the treatment of aggression and explosive disorders, particularly when associated with known or suspected brain lesions. Lithium and SSRIs are also effective

for some intermittent explosive outbursts. Buspirone (10–45 mg/d orally) is helpful for aggression, particularly in mentally retarded patients.

C. Physical

Physical management is necessary if psychological and pharmacologic means are not sufficient. It requires the active and visible presence of an adequate number of personnel (five or six) to reinforce the idea that the situation is under control despite the patient's lack of inner controls. Such an approach often precludes the need for actual physical restraint. When adequate personnel are not available, however, two people shielded by a mattress (single-bed size) can usually corner and subdue the patient without injury to anyone. Seclusion rooms and restraints should be used only when necessary (ambulatory restraints are an alternative), and the patient must then be observed at frequent intervals. Design of corridors and seclusion rooms is important. Narrow corridors, small spaces, and crowded areas exacerbate the potential for violence in an anxious patient.

D. Other Interventions

The treatment of victims (eg, battered women) is challenging and often complicated by their reluctance to leave the situation. Reasons for staying vary, but common themes include the fear of more violence because of leaving, the hope that the situation may ameliorate (in spite of steady worsening), and the financial aspects of the situation, which are seldom to the woman's advantage. Concerns for the children often finally compel the woman to seek help. An early step is to get the woman into a therapeutic situation that provides the support of others in similar straits. Al-Anon is frequently a valuable asset and quite appropriate when alcohol is a factor. The group can support the victim while she gathers strength to consider alternatives without being paralyzed by fear. Many cities now offer temporary emergency centers and counseling. Use the available resources, attend to any medical or psychiatric problems, and maintain a compassionate interest. Some states now require physicians to report injuries caused by abuse or suspected abuse to police authorities.

SUBSTANCE USE DISORDERS (DRUG DEPENDENCY, DRUG ABUSE)

The term "drug dependency" is used in a broad sense here to include both addictions and habituations. It involves the triad of compulsive drug use referred to as drug addiction, which includes: (1) a **psychological dependence** or craving

and the behavior involved in procurement of the drug; (2) **physiologic dependence**, with withdrawal symptoms on discontinuance of the drug; and (3) **tolerance**, ie, the need to increase the dose to obtain the desired effects. Drug dependency is a function of the amount of drug used and the duration of usage. The amount needed to produce dependency varies with the nature of the drug and the idiosyncratic nature of the user. The frequency of use is usually daily, and the duration is inevitably > 2–3 weeks. Polydrug abuse is very common. Transgenerational continuity of drug abuse is also common.

There is accumulating evidence that an impairment syndrome exists in many former (and current) drug users. It is believed that drug use produces damaged neurotransmitter receptor sites and that the consequent imbalance produces symptoms that may mimic other psychiatric illnesses. "**Kindling**"—repeated stimulation of the brain—renders the individual more susceptible to focal brain activity with minimal stimulation. Stimulants and depressants can produce kindling, leading to relatively spontaneous effects no longer dependent on the original stimulus. These effects may be manifested as mood swings, panic, psychosis, and occasionally overt seizure activity. The imbalance also results in frequent job changes, marital problems, and generally erratic behavior. Patients with PTSD frequently have treated themselves with a variety of drugs. Chronic abusers of a wide variety of drugs exhibit cerebral atrophy on CT scans, a finding that may relate to the above symptoms. Early recognition is important, mainly to establish realistic treatment programs that are chiefly symptom-directed.

The clinician faces three problems with substance abuse: (1) the prescribing of substances such as sedatives, stimulants, or opioids that might produce dependency; (2) the treatment of individuals who have already abused drugs, most commonly alcohol; and (3) the detection of illicit drug use in patients presenting with psychiatric symptoms. The usefulness of urinalysis for detection of drugs varies markedly with different drugs and under different circumstances (pharmacokinetics is a major factor). Water-soluble drugs (eg, alcohol, stimulants, opioids) are eliminated in a day or so. Lipophilic substances (eg, barbiturates, tetrahydrocannabinol) appear in the urine over longer periods of time: several days in most cases, 1–2 months in chronic marijuana users. Sedative drug determinations are quite variable, amount of drug and duration of use being important determinants. False-positives can be a problem related to ingestion of some legitimate medications (eg, phenytoin for barbiturates, phenylpropanolamine for amphetamines, chlorpromazine for opioids) and some foods (eg, poppy seeds for opioids, coca leaf tea for cocaine). Manipulations can alter the legitimacy of the testing. Dilution, either in vivo or in vitro, can be detected by checking urine specific gravity. Addition of ammonia, vinegar, or salt may invalidate the test, but odor and pH determinations are simple. Hair analysis can determine drug use over longer periods, particularly sequential drug-taking patterns. The sensitivity and reliability of such tests are considered good, and the method may be complementary to urinalysis.

ALCOHOL DEPENDENCY & ABUSE (Alcoholism)

ESSENTIALS OF DIAGNOSIS

Major criteria:

- ▶ Physiologic dependence as manifested by evidence of withdrawal when intake is interrupted.
- ▶ Tolerance to the effects of alcohol.
- ▶ Evidence of alcohol-associated illnesses, such as alcoholic liver disease, cerebellar degeneration.
- ▶ Continued drinking despite strong medical and social contraindications and life disruptions.
- ▶ Impairment in social and occupational functioning.
- ▶ Depression.
- ▶ Blackouts.

Other signs:

- ▶ Alcohol stigmas: alcohol odor on breath, alcoholic facies, flushed face, scleral injection, tremor, ecchymoses, peripheral neuropathy.
- ▶ Surreptitious drinking.
- ▶ Unexplained work absences.
- ▶ Frequent accidents, falls, or injuries of vague origin; in smokers, cigarette burns on hands or chest.
- ▶ Laboratory tests: elevated values of liver function tests, mean corpuscular volume, serum uric acid, and triglycerides.

▶ General Considerations

Alcoholism (also known as alcohol dependence) is a syndrome consisting of two phases: at-risk drinking and alcohol addiction. At-risk drinking is the repetitive use of alcohol, often to alleviate anxiety or solve other emotional problems. Alcohol addiction is a true addiction, similar to that which occurs following the repeated use of other sedative-hypnotics, and is characterized by recurrent use of alcohol despite disruption in social roles (family and work), alcohol-related legal problems, and taking safety risks by oneself and with others. The National Institute on Alcohol Abuse and Alcoholism formally defines at-risk drinking as more than 4 drinks per day or 14 drinks per week for men or more than 3 drinks per day or 7 drinks per week for women. These individuals are at an increased risk for developing or are developing alcohol addiction. Alcohol and other drug abuse patients have a much higher prevalence of lifetime psychiatric disorders. While male-to-female ratios in alcoholic treatment agencies remain at 4:1,

there is evidence that the rates are converging. Women delay seeking help, and when they do they tend to seek it in medical or mental health settings. Adoption and twin studies indicate some genetic influence. Ethnic distinctions are important—eg, 40% of Japanese have aldehyde dehydrogenase deficiency and are more susceptible to the effects of alcohol. Depression is often present and should be evaluated carefully. The majority of suicides and intrafamily homicides involve alcohol. Alcohol is a major factor in rapes and other assaults.

There are several screening instruments that may help identify alcoholism. One of the most useful is the CAGE questionnaire (see Table 1–7).

▶ Clinical Findings

A. Acute Intoxication

The signs of alcoholic intoxication are the same as those of overdose with any other central nervous system depressant: drowsiness, errors of commission, psychomotor dysfunction, disinhibition, dysarthria, ataxia, and nystagmus. For a 70-kg person, an ounce of whiskey, a 4- to 6-oz glass of wine, or a 12-oz bottle of beer (roughly 15, 11, and 13 grams of alcohol, respectively) may raise the level of alcohol in the blood by 25 mg/dL. For a 50-kg person, the blood alcohol level would rise even higher (35 mg/dL) with the same consumption. Blood alcohol levels below 50 mg/dL rarely cause significant motor dysfunction (the legal limit for driving under the influence is commonly 80 mg/dL). Intoxication as manifested by ataxia, dysarthria, and nausea and vomiting indicates a blood level > 150 mg/dL, and lethal blood levels range from 350 to 900 mg/dL. In severe cases, overdose is marked by respiratory depression, stupor, seizures, shock syndrome, coma, and death. Serious overdoses are frequently due to a combination of alcohol with other sedatives.

B. Withdrawal

There is a wide spectrum of manifestations of alcoholic withdrawal, ranging from anxiety, decreased cognition, and tremulousness through increasing irritability and hyperreactivity to full-blown delirium tremens. Symptoms of mild withdrawal, including tremor, elevated vital signs, and anxiety, begin within about 8 hours after the last drink and usually have passed by day 3. Generalized seizures occur within the first 24–38 hours and are more prevalent in persons who have a history of withdrawal syndromes. Delirium tremens is an acute organic psychosis that is usually manifest within 24–72 hours after the last drink (but may occur up to 7–10 days later). It is characterized by mental confusion, tremor, sensory hyperacuity, visual hallucinations (often of snakes, bugs, etc), autonomic hyperactivity, diaphoresis, dehydration, electrolyte disturbances (hypokalemia, hypomagnesemia), seizures, and cardiovascular abnormalities. The acute withdrawal syndrome is often completely unexpected and occurs when the patient has been hospitalized for some unrelated problem and presents as a diagnostic problem. Suspect alcohol withdrawal in every unexplained delirium. The mortality rate from delirium tremens has steadily decreased with early diagnosis and improved treatment.

In addition to the immediate withdrawal symptoms, there is evidence of persistent longer-term ones, including sleep disturbances, anxiety, depression, excitability, fatigue, and emotional volatility. These symptoms may persist for 3–12 months, and in some cases they become chronic.

C. Alcoholic (Organic) Hallucinosis

This syndrome occurs either during heavy drinking or on withdrawal and is characterized by a paranoid psychosis without the tremulousness, confusion, and clouded sensorium seen in withdrawal syndromes. The patient appears normal except for the auditory hallucinations, which are frequently persecutory and may cause the patient to behave aggressively and in a paranoid fashion.

D. Chronic Alcoholic Brain Syndromes

These encephalopathies are characterized by increasing erratic behavior, memory and recall problems, and emotional instability—the usual signs of organic brain injury due to any cause. Wernicke-Korsakoff syndrome due to thiamine deficiency may develop with a series of episodes. Wernicke encephalopathy consists of the triad of confusion, ataxia, and ophthalmoplegia (typically sixth nerve). Early recognition and treatment with thiamine can minimize damage. One of the possible sequelae is Korsakoff psychosis, characterized by both anterograde and retrograde amnesia, with confabulation early in the course. Early recognition and treatment of the alcoholic with intravenous thiamine and B complex vitamins can minimize damage.

E. Laboratory Findings

Ethanol may contribute to the presence of an otherwise unexplained osmolar gap. There may also be elevated liver function tests, increased serum uric acid and triglycerides, and decreased serum potassium and magnesium. The most definitive biologic marker for chronic alcoholism is carbohydrate deficient transferrin, which can detect heavy use (60 mg/d over 7–10 days) with high specificity. Two other tests that may provide clues to an alcohol problem are γ -glutamyl transpeptidase measurement (levels > 30 units/L are suggestive of heavy drinking) and mean corpuscular volume (> 95 fL in men and > 100 fL in women). If both are elevated, a serious drinking problem is likely. Use of other recreational drugs with alcohol skews and negates the significance of these tests. High-density lipoprotein cholesterol elevations combined with elevated γ -glutamyl transpeptidase concentrations also can help identify heavy drinkers.

► Differential Diagnosis

The differential diagnosis of alcoholism is essentially between primary alcoholism (when no other major psychiatric diagnosis exists) and secondary alcoholism (when alcohol is used as self-medication for major underlying psychiatric problems such as schizophrenia or affective disorder). The differentiation is important, since the latter group requires treatment for the specific psychiatric problem. In primary and secondary alcoholism, at-risk drinking can be distinguished from alcohol addiction by taking a careful psychiatric history and evaluating the degree to

which recurrent drinking impacts the social role functioning and physical safety of the individual.

The differential diagnosis of alcohol withdrawal includes other sedative withdrawals and other causes of delirium. Acute alcoholic hallucinosis must be differentiated from other acute paranoid states such as amphetamine psychosis or paranoid schizophrenia. The history and laboratory test results are the most important features in differentiating chronic organic brain syndromes due to alcohol from those due to other causes. The form of the brain syndrome is of little help—eg, chronic brain syndromes from lupus erythematosus may be associated with confabulation similar to that resulting from long-standing alcoholism.

► Complications

The medical, economic, and psychosocial problems of alcoholism are staggering. The central and peripheral nervous system complications include chronic brain syndromes, cerebellar degeneration, cardiomyopathy, and peripheral neuropathies. Direct effects on the liver include cirrhosis, esophageal varices, and eventual hepatic failure. Indirect effects include protein abnormalities, coagulation defects, hormone deficiencies, and an increased incidence of liver neoplasms.

Fetal alcohol syndrome includes one or more of the following developmental defects in the offspring of alcoholic women: (1) low birth weight and small size with failure to catch up in size or weight, (2) mental retardation, with an average IQ in the 60s, and (3) a variety of birth defects, with a large percentage of facial and cardiac abnormalities. The fetuses are very quiet in utero, and there is an increased frequency of breech presentations. There is a higher incidence of delayed postnatal growth and behavior development. The risk is appreciably higher the more alcohol ingested by the mother each day. Cigarette and marijuana smoking as well as cocaine use can produce similar effects on the fetus.

► Treatment of At-Risk Drinking

A. Psychological

The most important consideration for the clinician is to suspect the problem early and take a nonjudgmental attitude, although this does not mean a passive one. The problem of **denial** must be faced, preferably with significant family members at the first meeting. This means dealing from the beginning with any enabling behavior of the spouse or other significant people. Enabling behavior allows the alcoholic to avoid facing the consequences of his or her behavior.

There must be an emphasis on the things that can be done. This approach emphasizes the fact that the clinician cares and strikes a positive and hopeful note early in treatment. Valuable time should not be wasted trying to find out why the patient drinks; come to grips early with the immediate problem of how to stop the drinking. Although total abstinence should be the ultimate goal, a harm reduction model indicates that gradual progress toward abstinence can be a useful treatment stratagem.

Motivational interviewing, a model of counseling that addresses both the patient's ambivalence and motivation for change, may contribute to reduced consumption over time.

B. Social

Get the patient into Alcoholics Anonymous and the spouse into Al-Anon. Success is usually proportionate to the utilization of Alcoholics Anonymous, religious counseling, and other resources. The patient should be seen frequently for short periods and charged an appropriate fee.

Do not underestimate the importance of religion, particularly since the alcoholic is often a dependent person who needs a great deal of support. Early enlistment of the help of a concerned religious adviser can often provide the turning point for a personal conversion to sobriety.

One of the most important considerations is the patient's job—fear of losing a job is one of the most powerful motivations for giving up drink. The business community has become painfully aware of the problem, with the result that about 70% of the Fortune 500 companies offer programs to their employees to help with the problem of alcoholism. In the latter case, some specific recommendations to employers can be offered: (1) Avoid placement in jobs where the alcoholic must be alone, eg, as a traveling buyer or sales executive. (2) Use supervision but not surveillance. (3) Keep competition with others to a minimum. (4) Avoid positions that require quick decision-making on important matters (high-stress situations). In general, commitment to abstinence and avoidance of situations that might be conducive to drinking are most predictive of a good outcome.

C. Medical

Hospitalization is not usually necessary. It is sometimes used to dramatize a situation and force the patient to face the problem of alcoholism, but generally it should be used for medical indications.

Because of the many medical complications of alcoholism, a complete physical examination with appropriate laboratory tests is mandatory, with special attention to the liver and nervous system. Use of sedatives as a replacement for alcohol is not desirable. The usual result is concomitant use of sedatives and alcohol and worsening of the problem. Lithium is not helpful in the treatment of alcoholism.

Disulfiram (250–500 mg/d orally) has been used for many years as an aversive drug to discourage alcohol use. Disulfiram inhibits alcohol dehydrogenase, causing toxic reactions when alcohol is consumed. The results have generally been of limited effectiveness and depend on the motivation of the individual to be compliant.

Naltrexone, an opiate antagonist, in a dosage of 50 mg orally daily, has been helpful in lowering relapse rates over the 3–6 months after cessation of drinking, apparently by lessening the pleasurable effects of alcohol. One study suggests that naltrexone is most effective when given during periods of drinking in combination with therapy that supports abstinence but accepts the fact that relapses occur. Naltrexone is FDA-approved for maintenance therapy. Studies indicate that it reduces alcohol craving when used as part of a comprehensive treatment program. Acamprosate (333–666 mg orally three times daily) helps reduce craving and maintain abstinence, and can be continued even during periods of relapse.

D. Behavioral

Conditioning approaches historically have been used in some settings in the treatment of alcoholism, most commonly as a type of aversion therapy. For example, the patient is given a drink of whiskey and then a shot of apomorphine, and proceeds to vomit. In this way a strong association is built up between the drinking and vomiting. Although this kind of treatment has been successful in some cases, after appropriate informed consent, many people do not sustain the learned aversive response.

▶ Treatment of Hallucinosis & Withdrawal

A. Medical

1. Alcoholic hallucinosis—Alcoholic hallucinosis, which can occur either during or on cessation of a prolonged drinking period, is not a typical withdrawal syndrome and is handled differently. Since the symptoms are primarily those of a psychosis in the presence of a clear sensorium, they are handled like any other psychosis: hospitalization (when indicated) and adequate amounts of antipsychotic medications. Haloperidol, 5 mg orally twice a day for the first day or so, usually ameliorates symptoms quickly, and the drug can be decreased and discontinued over several days as the patient improves. It then becomes necessary to deal with the chronic alcohol abuse, which has been discussed.

2. Withdrawal symptoms—The onset of withdrawal symptoms is usually 8–12 hours and the peak intensity of symptoms is 48–72 hours after alcohol consumption is stopped. Providing adequate central nervous system depressants (eg, benzodiazepines) is important to counteract the excitability resulting from sudden cessation of alcohol intake. The choice of a specific sedative is less important than using adequate doses to bring the patient to a level of moderate sedation, and this will vary from person to person. Mild dependency requires “drying out.” In some instances for outpatients, a short course of tapering long-acting benzodiazepines—eg, diazepam, 20 mg orally daily initially, decreasing by 5 mg daily—may be a useful adjunct. In moderate to severe withdrawal, hospitalize the patient and use diazepam orally in a dosage of 5–10 mg hourly depending on the clinical need as judged by withdrawal symptoms, including nausea, tremor, autonomic hyperactivity, agitation; tactile, visual, and auditory hallucinations; and disorientation. This type of symptom-driven medication regimen for withdrawal appears to reduce total benzodiazepine usage over fixed-dose schedules. Antipsychotic medications should not be used. Monitoring of vital signs and fluid and electrolyte levels is essential for the severely ill patient.

In very severe withdrawal, intravenous administration is necessary. After stabilization, the amount of diazepam required to maintain a sedated state may be given orally every 8–12 hours. If restlessness, tremulousness, and other signs of withdrawal persist, the dosage is increased until moderate sedation occurs. The dosage is then gradually reduced by 20% every 24 hours until withdrawal is complete. This usually requires a week or so of treatment. Clonidine, 5 mcg/kg orally every 2 hours, or the patch

formulation of appropriate dosage strength, suppresses cardiovascular signs of withdrawal and has some anxiolytic effect. Carbamazepine, 400–800 mg daily orally, compares favorably with benzodiazepines for alcohol withdrawal.

Atenolol, as an adjunct to benzodiazepines, can reduce symptoms of alcohol withdrawal. The daily oral atenolol dose is 100 mg when the heart rate is above 80 beats per minute and 50 mg for a heart rate between 50 and 80 beats per minute. Atenolol should not be used when bradycardia is present.

Meticulous examination for other medical problems is necessary. Alcoholic hypoglycemia can occur with low blood alcohol levels (see Chapter 27). Alcoholics commonly have liver disease and associated clotting problems and are also prone to injury—and the combination all too frequently leads to undiagnosed subdural hematoma.

Phenytoin does not appear to be useful in managing alcohol withdrawal seizures *per se*. Sedating doses of benzodiazepines are effective in treating alcohol withdrawal seizures. Thus, other anticonvulsants are not usually needed unless there is a preexisting seizure disorder.

A general diet should be given, and vitamins in high doses: thiamine, 50 mg intravenously initially, then intramuscularly on a daily basis; pyridoxine, 100 mg/d; folic acid, 1 mg/d; and ascorbic acid, 100 mg twice a day. Intravenous glucose solutions should not be given prior to thiamine for fear of precipitating Wernicke syndrome. Thiamine is necessary as a ketolase enzyme cofactor. Concurrent administration of vitamins is satisfactory, and hydration should be meticulously assessed on an ongoing basis.

Chronic brain syndromes secondary to a long history of alcohol intake are not clearly responsive to thiamine and vitamin replenishment. Attention to the social and environmental care of this type of patient is paramount.

B. Psychological and Behavioral

The comments in the section on problem drinking apply here also; these methods of treatment become the primary consideration after successful treatment of withdrawal or alcoholic hallucinosis. Psychological and social measures should be initiated in the hospital prior to discharge. This increases the possibility of continued post-hospitalization treatment.

OTHER DRUG & SUBSTANCE DEPENDENCIES

1. Opioids

While the terms “opioids” and “narcotics” both refer to a group of drugs with actions that mimic those of morphine, the term “opioids” is used when discussing medications

prescribed in a controlled manner by a clinician, and the term “narcotics” is used to connote illicit drug use. The group includes natural derivatives of opium (opiates), synthetic surrogates (opioids), and a number of polypeptides, some of which have been discovered to be natural neurotransmitters. The principal narcotic of abuse is heroin (metabolized to morphine), which is not used as a legitimate medication. The other common opioids are prescription medications that differ in milligram potency, duration of action, and agonist and antagonist capabilities (see Chapter 5). All of the opioid analgesics can be reversed by the opioid antagonist naloxone.

The clinical symptoms and signs of mild narcotic intoxication include changes in mood, with feelings of euphoria; drowsiness; nausea with occasional emesis; needle tracks; and miosis. The incidence of snorting and inhaling heroin (“smoking”) is increasing, particularly among cocaine users. This coincides with a decrease in the availability of methaqualone (no longer marketed) and other sedatives used to temper the cocaine “high” (see discussion of cocaine under Stimulants, below). Overdosage causes respiratory depression, peripheral vasodilation, pinpoint pupils, pulmonary edema, coma, and death.

Dependency is a major concern when continued use of opioids occurs, although withdrawal causes only moderate morbidity (similar in severity to a bout of “flu”). Addicted patients sometimes consider themselves more addicted than they really are and may not require a withdrawal program. Grades of withdrawal are categorized from 0 to 4: grade 0 includes craving and anxiety; grade 1, yawning, lacrimation, rhinorrhea, and perspiration; grade 2, previous symptoms plus mydriasis, piloerection, anorexia, tremors, and hot and cold flashes with generalized aching; grades 3 and 4, increased intensity of previous symptoms and signs, with increased temperature, blood pressure, pulse, and respiratory rate and depth. In withdrawal from the most severe addiction, vomiting, diarrhea, weight loss, hemoconcentration, and spontaneous ejaculation or orgasm commonly occur. Complications of heroin administration include infections (eg, pneumonia, septic emboli, hepatitis, and HIV infection from using nonsterile needles), traumatic insults (eg, arterial spasm due to drug injection, gangrene), and pulmonary edema.

Treatment for overdosage (or suspected overdosage) is naloxone, 2 mg intravenously. If an overdose has been taken, the results are dramatic and occur within 2 minutes. Since the duration of action of naloxone is much shorter than that of the opioids, the patient must be under close observation. Hospitalization, supportive care, repeated naloxone administration, and observation for withdrawal from other drugs should be maintained for as long as necessary.

Treatment for withdrawal begins if grade 2 signs develop. If a withdrawal program is necessary, use methadone, 10 mg orally (use parenteral administration if the patient is vomiting), and observe. If signs (piloerection, mydriasis, cardiovascular changes) persist for > 4–6 hours, give another 10 mg; continue to administer methadone at 4- to 6-hour intervals until signs are not present (rarely > 40 mg of methadone in 24 hours). Divide the total amount of drug required over the first 24-hour period by 2

and give that amount every 12 hours. Each day, reduce the total 24-hour dose by 5–10 mg. Thus, a moderately addicted patient initially requiring 30–40 mg of methadone could be withdrawn over a 4- to 8-day period. Clonidine, 0.1 mg orally several times daily over a 10- to 14-day period, is both an alternative and an adjunct to methadone detoxification; it is not necessary to taper the dose. Clonidine is helpful in alleviating cardiovascular symptoms but does not significantly relieve anxiety, insomnia, or generalized aching. There is a protracted abstinence syndrome of metabolic, respiratory, and blood pressure changes over a period of 3–6 months.

Opioid antagonists (eg, naltrexone) can also be used successfully for treatment of the patient who has been free of opioids for 7–10 days. Naltrexone blocks the narcotic “high” of heroin when 50 mg is given orally every 24 hours initially for several days and then 100 mg is given every 48–72 hours. A monthly injectable form of naltrexone has become available and may enhance compliance. Liver disorders are a major contraindication. Buprenorphine, a partial agonist, has become a mainstay of office-based treatment of opiate dependency. Its use requires certified training.

Alternative strategies for the treatment of opioid withdrawal have included rapid and ultrarapid detoxification techniques. However, recent data do not support the use of either method. Methadone maintenance programs are of some value in chronic recidivism. Under carefully controlled supervision, the narcotic addict is maintained on fairly high doses of methadone (40–120 mg/d) that satisfy craving and block the effects of heroin to a great degree.

2. Sedatives (Anxiolytics)

See Anxiety Disorders, this chapter.

3. Psychedelics

About 6000 species of plants have psychoactive properties. All of the common psychedelics (LSD, mescaline, psilocybin, dimethyltryptamine, and other derivatives of phenylalanine and tryptophan) can produce similar behavioral and physiologic effects. An initial feeling of tension is followed by emotional release such as crying or laughing (1–2 hours). Later, perceptual distortions occur, with visual illusions and hallucinations, and occasionally there is fear of ego disintegration (2–3 hours). Major changes in time sense and mood lability then occur (3–4 hours). A feeling of detachment and a sense of destiny and control occur (4–6 hours). Of course, reactions vary among individuals, and some of the drugs produce markedly different time frames. Occasionally, the acute episode is terrifying (a “bad trip”), which may include panic, depression, confusion, or psychotic symptoms. Preexisting emotional problems, the attitude of the user, and the setting where the drug is used affect the experience.

Treatment of the acute episode primarily involves protection of the individual from erratic behavior that may lead to injury or death. A structured environment is usually sufficient until the drug is metabolized. In severe cases, antipsychotic medications with minimal side effects (eg, haloperidol, 5 mg intramuscularly) may be given every

several hours until the individual has regained control. In cases where “flashbacks” occur (mental imagery from a “bad trip” that is later triggered by mild stimuli such as marijuana, alcohol, or psychic trauma), a short course of an antipsychotic drug—eg, olanzapine, 5–10 mg/d, or risperidone, 2 mg/d, initially, and up to 20 mg/d and 6 mg/d, respectively—is usually sufficient. Lorazepam, 1–2 mg orally or intramuscularly every 2 hours as needed for acute agitation, may be a useful adjunct. An occasional patient may have “flashbacks” for much longer periods and require small doses of neuroleptic medications over the longer term.

4. Phencyclidine

Phencyclidine (PCP, angel dust, peace pill, hog), developed as an anesthetic agent, first appeared as a street drug deceptively sold as tetrahydrocannabinol (THC). Because it is simple to produce and mimics to some degree the traditional psychedelic drugs, PCP has become a common deceptive substitute for LSD, THC, and mescaline. It is available in crystals, capsules, and tablets to be inhaled, injected, swallowed, or smoked (it is commonly sprinkled on marijuana).

Absorption after smoking is rapid, with onset of symptoms in several minutes and peak symptoms in 15–30 minutes. Mild intoxication produces euphoria accompanied by a feeling of numbness. Moderate intoxication (5–10 mg) results in disorientation, detachment from surroundings, distortion of body image, combativeness, unusual feats of strength (partly due to its anesthetic activity), and loss of ability to integrate sensory input, especially touch and proprioception. Physical symptoms include dizziness, ataxia, dysarthria, nystagmus, retracted upper eyelid with blank stare, hyperreflexia, and tachycardia. There are increases in blood pressure, respiration, muscle tone, and urine production. Usage in the first trimester of pregnancy is associated with an increase in spontaneous abortion and congenital defects. Severe intoxication (20 mg or more) produces an increase in degree of moderate symptoms, with the addition of seizures, deepening coma, hypertensive crisis, and severe psychotic ideation. The drug is particularly long-lasting (several days to several weeks) owing to high lipid solubility, gastroenteric recycling, and the production of active metabolites. Overdosage may be fatal, with the major causes of death being hypertensive crisis, respiratory arrest, and convulsions. Acute rhabdomyolysis has been reported and can result in myoglobinuric kidney failure.

Differential diagnosis involves the whole spectrum of street drugs, since in some ways phencyclidine mimics sedatives, psychedelics, and marijuana in its effects. Blood and urine testing can detect the acute problem.

Treatment is discussed in Chapter 38.

5. Marijuana

Cannabis sativa, a hemp plant, is the source of marijuana. The parts of the plant vary in potency. The resinous exudate of the flowering tops of the female plant (hashish, charas) is the most potent, followed by the dried leaves and flowering shoots of the female plant (bhong) and the resinous mass from small leaves of inflorescence (ganja). The least potent

parts are the lower branches and the leaves of the female plant and all parts of the male plant. Mercury may be a contaminant in marijuana grown in volcanic soil. The drug is usually inhaled by smoking. Effects occur in 10–20 minutes and last 2–3 hours. “Joints” of good quality contain about 500 mg of marijuana (which contains approximately 5–15 mg of tetrahydrocannabinol with a half-life of 7 days). Marijuana soaked in formaldehyde and dried (“AMP”) has produced unusual effects, including autonomic discharge and severe though transient cognitive impairment.

With moderate dosage, marijuana produces two phases: mild euphoria followed by sleepiness. In the acute state, the user has an altered time perception, less inhibited emotions, psychomotor problems, impaired immediate memory, and conjunctival injection. High doses produce transient psychotomimetic effects. No specific treatment is necessary except in the case of the occasional “bad trip,” in which case the person is treated in the same way as for psychedelic usage. Marijuana frequently aggravates existing mental illness and adversely affects motor performance.

Studies of long-term effects have conclusively shown abnormalities in the pulmonary tree. Laryngitis and rhinitis are related to prolonged use, along with chronic obstructive pulmonary disease. Electrocardiographic abnormalities are common, but no chronic cardiac disease has been linked to marijuana use. Long-term usage has resulted in depression of plasma testosterone levels and reduced sperm counts. Abnormal menstruation and failure to ovulate have occurred in some women. Cognitive impairments are common. Health care utilization for a variety of health problems is increased in long-term marijuana smokers. Sudden withdrawal produces insomnia, nausea, myalgia, and irritability. Psychological effects of long-term marijuana usage are still unclear. Urine testing is reliable if samples are carefully collected and tested. Detection periods span 4–6 days in short-term users and 20–50 days in long-term users.

6. Stimulants: Amphetamines & Cocaine

Stimulant abuse is quite common, either alone or in combination with abuse of other drugs. The stimulants include illicit drugs such as methamphetamine (“speed”)—one variant is a smokable form called “ice,” which gives an intense and fairly long-lasting high—and methylphenidate and dextroamphetamine, which are under prescription control. Street availability of amphetamines remains high. Moderate usage of any of the stimulants produces hyperactivity, a sense of enhanced physical and mental capacity, and sympathomimetic effects. The clinical picture of acute stimulant intoxication includes sweating, tachycardia, elevated blood pressure, mydriasis, hyperactivity, and an acute brain syndrome with confusion and disorientation. Tolerance develops quickly, and, as the dosage is increased, hypervigilance, paranoid ideation (with delusions of parasitosis), stereotypy, bruxism, tactile hallucinations of insect infestation, and full-blown psychoses occur, often with persecutory ideation and aggressive responses. Stimulant withdrawal is characterized by depression with symptoms of hyperphagia and hypersomnia.

People who have used stimulants chronically (eg, anorexigenics) occasionally become sensitized (“**kindling**”) to future use of stimulants. In these individuals, even small amounts of mild stimulants such as caffeine can cause symptoms of paranoia and auditory hallucinations.

Cocaine is a stimulant. It is a product of the coca plant. The derivatives include seeds, leaves, coca paste, cocaine hydrochloride, and the free base of cocaine. Cocaine hydrochloride is the salt and the most commonly used form. Free base, a purer (and stronger) derivative called “**crack**,” is prepared by simple extraction from cocaine hydrochloride.

There are various modes of use. Coca leaf chewing involves toasting the leaves and chewing with alkaline material (eg, the ash of other burned leaves) to enhance buccal absorption. One achieves a mild high, with onset in 5–10 minutes and lasting for about an hour. Intranasal use is simply snorting cocaine through a straw. Absorption is slowed somewhat by vasoconstriction (which may eventually cause tissue necrosis and septal perforation); the onset of action is in 2–3 minutes, with a moderate high (euphoria, excitement, increased energy) lasting about 30 minutes. The purity of the cocaine is a major determinant of the high. Intravenous use of cocaine hydrochloride or “free-base” is effective in 30 seconds and produces a short-lasting, fairly intense high of about 15 minutes’ duration. The combined use of cocaine and ethanol results in the metabolic production of cocaethylene by the liver. This substance produces more intense and long-lasting cocaine-like effects. Smoking freebase (volatilized cocaine because of the lower boiling point) acts in seconds and results in an intense high lasting several minutes. The intensity of the reaction is related to the marked lipid solubility of the freebase form and produces by far the most severe medical and psychiatric symptoms.

Cardiovascular collapse, arrhythmias, myocardial infarction, and transient ischemic attacks have been reported. Seizures, strokes, migraine symptoms, hyperthermia, and lung damage may occur, and there are several obstetric complications, including spontaneous abortion, abruptio placentae, teratogenic effects, delayed fetal growth, and prematurity. Cocaine can cause anxiety, mood swings, and delirium, and chronic use can cause the same problems as other stimulants (see above).

Clinicians should be alert to cocaine use in patients presenting with unexplained nasal bleeding, headaches, fatigue, insomnia, anxiety, depression, and chronic hoarseness. Sudden withdrawal of the drug is not life-threatening but usually produces craving, sleep disturbances, hyperphagia, lassitude, and severe depression (sometimes with suicidal ideation) lasting days to weeks.

Treatment is imprecise and difficult. Since the high is related to blockage of dopamine reuptake, the dopamine agonist bromocriptine, 1.5 mg orally three times a day, alleviates some of the symptoms of craving associated with acute cocaine withdrawal. Other dopamine agonists such as apomorphine, levodopa, and amantadine are under study for this purpose. Carbamazepine may be a useful adjunct in treating symptoms of alcohol withdrawal, and desipramine in moderate doses has been useful in helping maintain abstinence in the early stages of treatment.

Treatment of psychosis is the same as that of any psychosis: antipsychotic medications in dosages sufficient to alleviate the symptoms. Any medical symptoms (eg, hyperthermia, seizures, hypertension) are treated specifically. These approaches should be used in conjunction with a structured program, most often based on the Alcoholics Anonymous model. Hospitalization may be required if self-harm or violence toward others is a perceived threat (usually indicated by paranoid delusions).

7. Caffeine

Caffeine, along with nicotine and alcohol, is one of the most commonly used drugs worldwide. About 10 billion pounds of coffee (the richest source of caffeine) are consumed yearly throughout the world. Tea, cocoa, and cola drinks also contribute to an intake of caffeine that is often astoundingly high in a large number of people. Low to moderate doses (30–200 mg/d) tend to improve some aspects of performance (eg, vigilance). The approximate content of caffeine in a (180-mL) cup of beverage is as follows: brewed coffee, 80–140 mg; instant coffee, 60–100 mg; decaffeinated coffee, 1–6 mg; black leaf tea, 30–80 mg; tea bags, 25–75 mg; instant tea, 30–60 mg; cocoa, 10–50 mg; and 12-oz cola drinks, 30–65 mg. A 2-oz chocolate candy bar has about 20 mg. Some herbal teas (eg, “morning thunder”) contain caffeine. Caffeine-containing analgesics usually contain approximately 30 mg per unit. Symptoms of caffeinism (usually associated with ingestion of over 500 mg/d) include anxiety, agitation, restlessness, insomnia, a feeling of being “wired,” and somatic symptoms referable to the heart and gastrointestinal tract. It is common for a case of caffeinism to present as an anxiety disorder. It is also common for caffeine and other stimulants to precipitate severe symptoms in compensated schizophrenic and manic-depressive patients. Chronically depressed patients often use caffeine drinks as self-medication. This diagnostic clue may help distinguish some major affective disorders. Withdrawal from caffeine (> 250 mg/d) can produce headaches, irritability, lethargy, and occasional nausea.

8. Miscellaneous Drugs, Solvents

The principal over-the-counter drugs of concern have been phenylpropanolamine and an assortment of antihistaminic agents, frequently in combination with a mild analgesic promoted as cold remedies. Medications containing phenylpropanolamine have been removed from sale in the United States due to an FDA ban. The major problem in use of phenylpropanolamine relates to its side effects as a stimulant, including precipitation of anxiety states, increased blood pressure effects, auditory and visual hallucinations, paranoid ideation, and occasionally delirium. Aggressiveness and some loss of impulse control were reported as well as sleep disturbances even with small doses.

Antihistamines usually produce some central nervous system depression—thus their use as over-the-counter sedatives. Practically all of the so-called sleep aids are antihistamines. The mixture of antihistamines with alcohol usually exacerbates the central nervous system effects. Scopolamine and bromides have generally been removed from over-the-counter products.

The abuse of laxatives sometimes can lead to electrolyte disturbances that may contribute to the manifestations of a delirium. The greatest use of laxatives tends to be in the elderly and in those with eating disorders, both of whom are the most vulnerable to physiologic changes.

Anabolic steroids are being abused by people who wish to increase muscle mass for cosmetic reasons or for greater strength. In addition to the medical problems, the practice is associated with significant mood swings, aggressiveness, and paranoid delusions. Alcohol and stimulant use is higher in these individuals. Withdrawal symptoms of steroid dependency include fatigue, depressed mood, restlessness, and insomnia.

Amyl nitrite has been used as an “orgasm expander.” The changes in time perception, “rush,” and mild euphoria caused by the drug prompted its nonmedical use, and popular lore concerning the effects of inhalation just prior to orgasm has led to increased use. Subjective effects last from 5 seconds to 15 minutes. Tolerance develops readily, but there are no known withdrawal symptoms. Abstinence for several days reestablishes the previous level of responsiveness. Long-term effects may include damage to the immune system and respiratory difficulties.

Sniffing of solvents and inhaling of gases (including aerosols) produce a form of inebriation similar to that of the volatile anesthetics. Agents include gasoline, toluene, petroleum ether, lighter fluids, cleaning fluids, paint thinners, and solvents that are present in many household products (eg, nail polish, typewriter correction fluid). Typical intoxication states include euphoria, slurred speech, hallucinations, and confusion, and with high doses, acute manifestations are unconsciousness and cardiorespiratory depression or failure; chronic exposure produces a variety of symptoms related to the liver, kidney, bone marrow, or heart. Lead encephalopathy can be associated with sniffing leaded gasoline. In addition, studies of workers chronically exposed to jet fuel showed significant increases in neuroathenic symptoms, including fatigue, anxiety, mood changes, memory difficulties, and somatic complaints. These same problems have been noted in long-term solvent abuse.

The so-called designer drugs are synthetic substitutes for commonly used recreational drugs and are produced in small, clandestine laboratories. The most common designer drugs have been methyl analogues of fentanyl and have been used as heroin substitutes. MDMA (methylenedioxymethamphetamine), an amphetamine derivative sometimes called “ecstasy,” is also a designer drug with high abuse potential and neurotoxicity. Often not detected by standard toxicology screens, these substances can present a vexing problem for clinicians faced with symptoms from a totally unknown cause.

DELIRIUM & OTHER COGNITIVE DISORDERS (FORMERLY: ORGANIC BRAIN SYNDROME)

ESSENTIALS OF DIAGNOSIS

- ▶ Transient or permanent brain dysfunction.
- ▶ Cognitive impairment to varying degrees.
- ▶ Impaired recall and recent memory, inability to focus attention, random psychomotor activity such as stereotypy, and problems in perceptual processing, often with psychotic ideation.
- ▶ Emotional disorders frequently present: depression, anxiety, irritability.
- ▶ Behavioral disturbances: impulse control, sexual acting-out, attention deficits, aggression, and exhibitionism.

▶ General Considerations

The organic problem may be a primary brain disease or a secondary manifestation of some general disorder. All of

the cognitive disorders show some degree of impaired thinking depending on the site of involvement, the rate of onset and progression, and the duration of the underlying brain lesion. Emotional disturbances (eg, depression) are often present as significant comorbidities. The behavioral disturbances tend to be more common with chronicity, more directly related to the underlying personality or central nervous system vulnerability to drug side effects, and not necessarily correlated with cognitive dysfunction.

The causes of cognitive disorders are listed in Table 25–11.

▶ Clinical Findings

The manifestations are many and varied and include problems with orientation, short or fluctuating attention span, loss of recent memory and recall, impaired judgment, emotional lability, lack of initiative, impaired impulse control, inability to reason through problems, depression (worse in mild to moderate types), confabulation (not limited to alcohol organic brain syndrome), constriction of intellectual functions, visual and auditory hallucinations, and delusions. Physical findings will naturally vary according to the cause. The electroencephalogram usually shows generalized slowing in delirium.

Table 25–11. Etiology of delirium and other cognitive disorders.

Disorder	Possible Causes
Intoxication	Alcohol, sedatives, bromides, analgesics (eg, pentazocine), psychedelic drugs, stimulants, and household solvents.
Drug withdrawal	Withdrawal from alcohol, sedative-hypnotics, corticosteroids.
Long-term effects of alcohol	Wernicke-Korsakoff syndrome.
Infections	Septicemia; meningitis and encephalitis due to bacterial, viral, fungal, parasitic, or tuberculous organisms or to central nervous system syphilis; acute and chronic infections due to the entire range of microbiologic pathogens.
Endocrine disorders	Thyrotoxicosis, hypothyroidism, adrenocortical dysfunction (including Addison disease and Cushing syndrome), pheochromocytoma, insulinoma, hypoglycemia, hyperparathyroidism, hypoparathyroidism, panhypopituitarism, diabetic ketoacidosis.
Respiratory disorders	Hypoxia, hypercapnia.
Metabolic disturbances	Fluid and electrolyte disturbances (especially hyponatremia, hypomagnesemia, and hypercalcemia), acid-base disorders, hepatic disease (hepatic encephalopathy), kidney failure, porphyria.
Nutritional deficiencies	Deficiency of vitamin B ₁ (beriberi), vitamin B ₁₂ (pernicious anemia), folic acid, nicotinic acid (pellagra); protein-calorie malnutrition.
Trauma	Subdural hematoma, subarachnoid hemorrhage, intracerebral bleeding, concussion syndrome.
Cardiovascular disorders	Myocardial infarctions, cardiac arrhythmias, cerebrovascular spasms, hypertensive encephalopathy, hemorrhages, embolisms, and occlusions indirectly cause decreased cognitive function.
Neoplasms	Primary or metastatic lesions of the central nervous system, cancer-induced hypercalcemia.
Seizure disorders	Ictal, interictal, and postictal dysfunction.
Collagen-vascular and immunologic disorders	Autoimmune disorders, including systemic lupus erythematosus, Sjögren syndrome, and AIDS.
Degenerative diseases	Alzheimer disease, Pick disease, multiple sclerosis, parkinsonism, Huntington chorea, normal pressure hydrocephalus.
Medications	Anticholinergic medications, antidepressants, H ₂ -blocking agents, digoxin, salicylates (long-term use), and a wide variety of other over-the-counter and prescribed medications.

A. Delirium

Delirium (acute confusional state) is a transient global disorder of attention, with clouding of consciousness, usually a result of systemic problems (eg, medications, hypoxemia). Onset is usually rapid. The mental status fluctuates (impairment is usually least in the morning), with varying inability to concentrate, maintain attention, and sustain purposeful behavior. There is a marked deficit of short-term memory and recall. Anxiety and irritability are common. Amnesia is retrograde (impaired recall of past memories) and anterograde (inability to recall events after the onset of the delirium). Orientation problems follow the inability to retain information. Perceptual disturbances (often visual hallucinations) and psychomotor restlessness with insomnia are common. Autonomic changes include tachycardia, dilated pupils, and sweating. The average duration is about 1 week, with full recovery in most cases. Delirium can coexist with dementia. Delirium may be hypoactive, hyperactive, or mixed. “Sundowning”—mild to moderate delirium at night—is more common in patients with preexisting dementia and may be precipitated by hospitalization, medications, and sensory deprivation.

Terminal delirium occurs commonly at the end of life. The delirium may be related to multiple medical causes, including organ failure, and may be unrecognized. Treatment must be based on a careful evaluation of the underlying etiology and the risks and benefits of available medical and nonmedical interventions.

B. Dementia

(See Chapters 4 and 24.) Dementia is characterized by chronicity and deterioration of selective mental functions. Specific cognitive assessment must be performed, since many patients are able to cover a deficit in routine conversation. The Mini-Mental State Examination produces a numerical score with up to 30 points given for correct answers to questions (likely organic < 27 points).

In all types of dementia, loss of impulse control (sexual and language) is common. The tenuous level of functioning makes the individual most susceptible to minor physical and psychological stresses. **Pseudodementia** is a term applied to depressed patients who appear to be demented. These patients are often identifiable by their tendency to complain about memory problems vociferously rather than try to cover them up. They usually say they cannot complete cognitive tasks but with encouragement can often do so. They can be considered to have depression-induced reversible dementia that remits when the depression resolves.

C. Amnestic Syndrome

This is a memory disturbance without delirium or dementia. It is usually associated with thiamine deficiency and chronic alcohol use (eg, Korsakoff syndrome). There is an impairment in the ability to learn new information or recall previously learned information.

D. Substance-Induced Hallucinosis

This condition is characterized by persistent or recurrent hallucinations (usually auditory) without the other symptoms

usually found in delirium or dementia. Alcohol or hallucinogens are often the cause. There does not have to be any other mental disorder, and there may be complete spontaneous resolution.

E. Personality Changes Due to a General Medical Condition (Formerly Organic Personality Syndrome)

This syndrome is characterized by emotional lability and loss of impulse control along with a general change in personality. Cognitive functions are preserved. Social inappropriateness is common. Loss of interest and lack of concern with the consequences of one's actions are often present. The course depends on the underlying cause (eg, frontal lobe contusion may resolve completely).

► Differential Diagnosis

The differential diagnosis consists mainly of schizophrenia and the other psychoses, which are sometimes confused with cognitive disorders and are often accompanied by psychotic symptoms.

► Complications

Chronicity may result from delayed correction of the defect, eg, subdural hematoma, low-pressure hydrocephalus. Accidents secondary to impulsive behavior and poor judgment are a major consideration. Secondary depression and impulsive behavior not infrequently lead to suicide attempts. Medications—particularly sedatives—may worsen thinking abilities and contribute to the overall problems.

► Treatment

A. Medical

Delirium should be considered a syndrome of acute brain dysfunction analogous to acute kidney failure. The first aim of treatment is to identify and correct the etiologic medical problem. Evaluation should consist of a comprehensive physical examination including a search for neurologic abnormalities, infection, or hypoxia. Routine laboratory tests may include serum electrolytes, serum glucose, BUN, serum creatinine, liver function tests, thyroid function tests, arterial blood gases, complete blood count, serum calcium, phosphorus, magnesium, vitamin B₁₂, folate, blood cultures, urinalysis, and cerebrospinal fluid analysis. Discontinue medications that may be contributing to the problem (eg, analgesics, corticosteroids, cimetidine, lidocaine, anticholinergic medications, central nervous system depressants, mefloquine). Do not overlook any possibility of reversible organic disease. Electroencephalography, CT, and MRI evaluations of the brain may be helpful in diagnosis. Ideally, the patient should be monitored without further medications while the evaluation is carried out. There are, however, two indications for medication in delirious states: behavioral control (eg, pulling out lines) and subjective distress (eg, pronounced fear due to hallucinations). If these indications are present, medications may be used. If there is any

hint of alcohol or substance withdrawal (the most common cause of delirium in the general hospital), a benzodiazepine such as lorazepam (1–2 mg every hour) can be given parenterally. If there is little likelihood of withdrawal syndrome, haloperidol is often used in doses of 1–10 mg every hour. Given intravenously under ECG monitoring, it appears to impose slight risk of extrapyramidal side effects. In addition to the medication, a pleasant, comfortable, nonthreatening, and physically safe environment with adequate nursing or attendant services should be provided. Once the underlying condition has been identified and treated, adjunctive medications can be tapered.

Treatment of the behavioral manifestations of the **dementia syndrome** usually involve trying to positively reinforce healthy behaviors and not reinforcing maladaptive behaviors (such as aggression). Arranging the physical environment to maximize autonomy as much as feasible and promote regularity of routine, helps the individual cope with their limited intellectual reserves. Simple, direct statements are more easily comprehended by these individuals. Understanding how their decreased cognitive function limits their abilities is important. For example, one elderly man in a residential apartment kept complaining that someone was stealing his ice cream at night. Realizing that he was unable to recall eating it himself, his “delusion” made a certain sense. Once his caregivers understood this, they were able to be more compassionate in listening to his complaints and less worried about an ice cream burglar.

Aggressiveness and rage states in dementia can be reduced with lipophilic β -blockers (eg, propranolol, metoprolol) in moderate doses. Since the serotonergic system has been implicated in arousal conditions, medications that affect serotonin have been found to be of some benefit in aggression and agitation. Included in this group are lithium, trazodone, buspirone, and clonazepam. Dopamine blockers (eg, the neuroleptic medications such as haloperidol) have been used for many years to attenuate aggression. Atypical neuroleptics may have a role in selected geriatric patients; however, there are reports of increased mortality in some studies related to the use of atypical neuroleptics (equaling the elevated mortality of the typical agents) in this population. There are also reports of reduced agitation in Alzheimer disease from carbamazepine, 100–400 mg/d orally (with slow increase as needed). Emotional lability in some cases responds to small doses of imipramine (25 mg orally one to three times per day) or fluoxetine (5–20 mg/d orally); depression, which often occurs early in the course of Alzheimer dementia, responds to the usual doses of antidepressant medications, preferably those with the least anticholinergic side effects (eg, SSRIs and MAO inhibitors).

Ergotoxine alkaloids (ergoloid mesylates: Hydergine, others) have been studied with mixed results; improvement in ambulatory self-care and depressed mood has been noted, but there has been no improvement of cognitive functioning on any standardized tests. Stimulant medications (eg, methylphenidate) do not change cognitive function but can improve affect and mood, which helps the caretakers cope with the problem.

B. Social

Substitute home care, board and care, or convalescent home care may be most useful when the family is unable to care for the patient. The setting should include familiar people and objects, lights at night, and a simple schedule. Counseling may help the family to cope with problems and may help keep the patient at home as long as possible. Information about local groups can be obtained from the Alzheimer's Disease and Related Disorders Association, 70 East Lake Street, Suite 600, Chicago, IL 60601. Volunteer services, including homemakers, visiting nurses, and adult protective services, may be helpful in maintaining the patient at home.

C. Behavioral

Behavioral techniques include operant responses that can be used to induce positive behaviors, eg, paying attention to the patient who is trying to communicate appropriately, and extinction by ignoring inappropriate responses. Patients with Alzheimer disease can learn skills and retain them but do not recall the circumstances in which they were learned.

D. Psychological

Formal psychological therapies are not usually helpful and may make things worse by taxing the patient's limited cognitive resources.

► Prognosis

The prognosis is good for recovery of mental functioning in delirium when the underlying condition is reversible. For most dementia syndromes, the prognosis is for gradual deterioration, although new drug treatments may prove helpful.

PSYCHIATRIC PROBLEMS ASSOCIATED WITH HOSPITALIZATION & ILLNESS

► Diagnostic Categories

A. Acute Problems

1. Delirium with psychotic features secondary to the medical or surgical problem, or compounded by effect of treatment.
2. Acute anxiety, often related to ignorance and fear of the immediate problem as well as uncertainty about the future.

3. Anxiety as an intrinsic aspect of the medical problem (eg, hyperthyroidism).
4. Denial of illness, which may present during acute or intermediate phases of illness.

B. Intermediate Problems

1. Depression as a function of the illness or acceptance of the illness, often associated with realistic or fantasied hopelessness about the future.
2. Behavioral problems, often related to denial of illness and, in extreme cases, causing the patient to leave the hospital against medical advice.

C. Recuperative Problems

1. Decreasing cooperation as the patient sees that improvement and compliance are not compelled.
2. Readjustment problems with family, job, and society.

► General Considerations

A. Acute Problems

1. “Intensive care unit psychosis”—The stressful ICU environment may be a cause of delirium. Critical care unit factors include sleep deprivation, increased arousal, mechanical ventilation, and social isolation. Other causes include those common to delirium and require vigorous investigation (see Delirium, above).

2. Presurgical and postsurgical anxiety states—Such problems are common and commonly ignored. Presurgical anxiety is very common and is principally a fear of death (many surgical patients make out their wills). Patients may be fearful of anesthesia (improved by the preoperative anesthesia interview), the mysterious operating room, and the disease processes that might be uncovered by the surgeon. Such fears frequently cause people to delay examinations that might result in earlier surgery and a greater chance of cure.

The opposite of this is **surgery proneness**, the quest for surgery to escape from overwhelming life stresses. Polysurgery patients may be classified as having factitious disorders. Dynamic motivations include the need to get medical care as a way of getting dependency needs met, the desire to outwit authority figures, unconscious guilt, or a masochistic need to suffer. Frequent surgery may also be related to a somatoform disorder, particularly body dysmorphic disorder (an obsession that a body part is disfigured). More apparent reasons may include an attempt to get relief from pain and a lifestyle that has become almost exclusively medically oriented, with all of the risks entailed in such an endeavor.

Postsurgical anxiety states are usually related to pain, procedures, and loss of body image. Acute pain problems are quite different from chronic pain disorders (see Chronic Pain Disorders, this chapter); the former are readily handled with adequate analgesic medication (see Chapter 5). Alterations in body image, as with amputations, ostomies, and mastectomies, often raise concerns about relationships with others.

3. Iatrogenic problems—These usually pertain to medications, complications of diagnostic and treatment procedures, and impersonal and unsympathetic staff behavior. Polypharmacy is often a factor. Patients with unsolved diagnostic problems are at higher risk. They are desirous of relief, and the quest engenders more diagnostic procedures with a higher incidence of complications. The upset patient and family may be very demanding. Excessive demands usually result from anxiety. Such behavior is best handled with calm and measured responses.

B. Intermediate Problems

1. Prolonged hospitalization—Prolonged hospitalization presents unique problems in certain hospital services, eg, burn units, orthopedic services, and tuberculosis wards. The acute problems of the severely burned patient are discussed in Chapter 37. The problems often are behavioral difficulties related to length of hospitalization and necessary procedures. For example, in burn units, pain is a major problem in addition to anxiety about procedures. Disputes with staff are common and often concern pain medication or ward privileges. Some patients regress to infantile behavior and dependency. Staff members must agree about their approach to the patient in order to ensure the smooth functioning of the unit.

Denial of illness may present in some patients. Intervention by an authority figure (eg, immediate work supervisor) may help the patient accept treatment and eventually abandon the coping mechanism of denial.

2. Depression—Mood disorders ranging from mild adjustment disorder to major depressive disorder frequently occur during prolonged hospitalizations. A key to the diagnosis of depression in the medical setting is the individual's loss of self-esteem; they often think of themselves as worthless and are guilt ridden. Therapeutic medications (eg, corticosteroids) may be a factor. Depression can contribute to irritability and overt anger. Severe depression can lead to anorexia, which further complicates healing and metabolic balance. It is during this period that the issue of disfigurement arises—relief at survival gives way to concern about future function and appearance.

C. Recuperative Problems

1. Anxiety—Anxiety about return to the posthospital environment can cause regression to a dependent position. Complications increase, and staff forbearance again is tested. Anxiety occurring at this stage usually is handled more easily than previous behavior problems.

2. Posthospital adjustment—Adjustment difficulties after discharge are related to the severity of the deficits and the use of outpatient facilities (eg, physical therapy, rehabilitation programs, psychiatric outpatient treatment). Some patients may experience posttraumatic stress symptoms (eg, from traumatic injuries or even from necessary medical treatments). Lack of appropriate follow-up can contribute to depression in the patient, who may feel that he or she is making poor progress and may have thoughts of “giving up.” Reintegration into work, educational, and

social endeavors may be slow. Life is simply much more difficult when one is disfigured, disabled, or disenfranchised.

► Clinical Findings

The symptoms that occur in these patients are similar to those discussed in previous sections of this chapter, eg, delirium, stress and adjustment disorders, anxiety, and depression. Behavior problems may include lack of cooperation, increased complaints, demands for medication, sexual approaches to nurses, threats to leave the hospital, and actual signing out against medical recommendations. The underlying personality structure of the individual is a major factor in coping styles (eg, the compulsive individual increases indecision, the hysterical individual increases dramatic behavior).

► Differential Diagnosis

Delirium and dementia (including cases associated with HIV infection and drug abuse) must always be ruled out, since they often present with symptoms resembling anxiety, depression, or psychosis. Personality disorders existing prior to hospitalization often underlie the various behavior problems, but particularly the management problems.

► Complications

Prolongation of hospitalization causes increased expense, deterioration of patient-staff relationships, and increased probabilities of iatrogenic and legal problems. The possibility of increasing posthospital treatment problems is enhanced.

► Treatment

A. Medical

The most important consideration by far is to have one clinician in charge, a clinician whom the patient trusts and who is able to oversee multiple treatment approaches (see Somatoform Disorders, above). In acute problems, attention must be paid to metabolic imbalance, alcohol withdrawal, and previous drug use—prescribed, recreational, or over-the-counter. Adequate sleep and analgesia are important in the prevention of delirium. When absolute behavioral control is urgently needed, agents such as propofol, dexmedetomidine, opioids, and midazolam have been used.

Many clinicians are attuned to the early detection of the surgery-prone patient. Plastic and orthopedic surgeons are at particular risk. Appropriate consultations may help detect some problems and mitigate future ones.

Postsurgical anxiety states can be alleviated by personal attention from the surgeon. Anxiety is not so effectively lessened by ancillary medical personnel, whom the patient perceives as lesser authorities, until after the clinician has reassured the patient. Inappropriate use of “as needed” analgesia places an unfair burden on the nurse. “Patient-controlled analgesia” can improve pain control, decrease anxiety, and minimize side effects.

Depression should be recognized early. If severe, it may be treated by antidepressant medications (see Antidepressant Medications, above). High levels of anxiety can be lowered with judicious use of anxiolytic agents. Unnecessary medications tend to reinforce the patient's impression that there must be a serious illness or medication would not be required.

B. Psychological

Prepare the patient and family for what is to come. This includes the types of units where the patient will be quarantined, the procedures that will be performed, and any disfigurements that will result from surgery. Repetition improves understanding. The nursing staff can be helpful, since patients frequently confide a lack of understanding to a nurse but are reluctant to do so to the physician.

Denial of illness is frequently a block to acceptance of treatment. This too should be handled with family members present (to help the patient face the reality of the situation) in a series of short interviews (for reinforcement). Dependency problems resulting from long hospitalization are best handled by focusing on the changes to come as the patient makes the transition to the outside world. Key figures are teachers, vocational counselors, and physical therapists. Challenges should be realistic and practical and handled in small steps.

Depression is usually related to the loss of familiar hospital supports, and the outpatient therapists and counselors help to lessen the impact of the loss. Some of the impact can be alleviated by anticipating, with the patient and family, the signal features of the common depression to help prevent the patient from assuming a permanent sick role (invalidism).

Suicide is always a concern when a patient is faced with despair. An honest, compassionate, and supportive approach will help sustain the patient during this trying period.

C. Behavioral

Prior desensitization can significantly allay anxiety about medical procedures. A “dry run” can be done to reinforce the oral description. Cooperation during acute problem periods can be enhanced by the use of appropriate reinforcers such as a favorite nurse or helpful family member. People who are positive reinforcers are even more helpful during the intermediate phases when the patient becomes resistant to the seemingly endless procedures (eg, debridement of burned areas).

Specific situations (eg, psychological dependency on the respirator) can be corrected by weaning with appropriate reinforcers (eg, watching a favorite movie on a DVD player when disconnected from the ventilator). Behavioral approaches should be used in a positive and optimistic way for maximal reinforcement.

Relaxation techniques and attentional distraction can be used to block side effects of a necessary treatment (eg, nausea in cancer chemotherapy).

D. Social

A change in environment requires adaptation. Because of the illness, admission and hospitalization may be more easily handled than discharge. Reintegration into society

can be difficult. In some cases, the family is a negative influence. A pre-discharge evaluation must be made to determine whether the family will be able to cope with the physical or mental changes in the patient. Working with the family while the patient is in the acute stage may presage a successful transition later on.

Development of a new social life can be facilitated by various self-help organizations (eg, the stoma club). Sharing problems with others in similar circumstances eases the return to a social life, which may be quite different from that prior to the illness.

► Prognosis

The prognosis is good in all patients who have reversible medical and surgical conditions. It is guarded when there

is serious functional loss that impairs vocational, educational, or societal possibilities—especially in the case of progressive and ultimately life-threatening illness.

26

DISEASES OF THE HYPOTHALAMUS & PITUITARY GLAND

ANTERIOR HYPOPITUITARISM

ESSENTIALS OF DIAGNOSIS

- ▶ Partial or complete deficiency of one or any combination of anterior pituitary hormones.
- ▶ **Adrenocorticotropic hormone deficiency:** reduced adrenal secretion of cortisol, testosterone, and epinephrine; aldosterone secretion remains intact.
- ▶ **Growth hormone (GH) deficiency:** short stature in children; asthenia, obesity, and increased cardiac mortality in adults.
- ▶ **Prolactin deficiency:** inhibition of postpartum lactation.
- ▶ **Thyroid-stimulating hormone (TSH) deficiency:** secondary hypothyroidism.
- ▶ **Luteinizing hormone (LH) and follicle-stimulating hormone (FSH) deficiency:** hypogonadism and infertility in men and women.

General Considerations

Hypopituitarism can be caused by either hypothalamic or pituitary dysfunction. Patients with hypopituitarism may have single or multiple hormonal deficiencies (Table 26–1). When one hormonal deficiency is discovered, others may be present.

1. Hypopituitarism caused by mass lesions—Lesions in the hypothalamus, pituitary stalk, or pituitary can cause hypopituitarism. Pituitary adenomas are usually sporadic but are sometimes part of multiple endocrine neoplasia type 1 (MEN 1). Pituitary tumors that arise in MEN 1 usually secrete prolactin (63%), GH (9%), or both (10%) and are more aggressive than sporadic adenomas. Pituitary tumors rarely cause diabetes insipidus.

Other types of mass lesions include granulomas (eg, granulomatosis with polyangiitis [formerly Wegener granulomatosis], tuberculosis), Rathke cleft cysts, apoplexy, metastatic carcinomas, aneurysms, and brain tumors (craniopharyngioma, meningioma, dysgerminoma, glioma, chondrosarcoma, chordoma of the clivus). Autoimmune hypophysitis, postpartum pituitary necrosis (Sheehan syndrome), eclampsia–preeclampsia, sickle cell disease, and African trypanosomiasis are rare causes. Langerhans cell histiocytosis usually presents in youth with diabetes insipidus or hypopituitarism; osteolytic bone lesions are noted on radiographs.

2. Hypopituitarism without mass lesions—This may be congenital in syndromes such as septo-optic dysplasia (de Morsier syndrome). Congenital hypopituitarism also develops in patients with *PROPI* and other gene mutations. Hypopituitarism may also be caused by cranial radiation, surgery, encephalitis, hemochromatosis, or autoimmunity. It may also occur after coronary artery bypass grafting. At least one pituitary hormone deficiency develops in about 25–30% of survivors of moderate to severe traumatic brain injury (Glasgow Coma Scale \leq 13/15) and in about 55% of survivors of aneurysmal subarachnoid hemorrhage. Some degree of hypopituitarism occurs in one-third of ischemic stroke patients, most commonly GH deficiency and hypogonadotropic hypogonadism. Mitotane, given for adrenal cortical carcinoma, can suppress TSH secretion and cause reversible secondary hypothyroidism. Therapy with exogenous corticosteroids (parenteral, oral, inhaled, or topical) can suppress adrenocorticotropic hormone (ACTH) secretion and causes functional isolated secondary adrenal insufficiency.

Congenital isolated hypogonadotropic hypogonadism can be caused by various gene mutations that control the production or release of gonadotropin-releasing hormone (GnRH), LH, or FSH. **Congenital adrenal hypoplasia** (see below) is one cause of isolated hypogonadotropic **hypogonadism**. It may be autosomal recessive or X-linked; the X-linked form is caused by a mutation in the *DAX 1* gene. Adrenal insufficiency, caused by failure to form the adrenal cortex, can present during infancy or childhood in boys with *DAX 1* gene mutations. **Prader-Willi syndrome**

Table 26-1. Pituitary hormones.

Anterior pituitary
Growth hormone (GH) ¹
Prolactin (PRL)
Adrenocorticotropic hormone (ACTH)
Thyroid-stimulating hormone (TSH)
Luteinizing hormone (LH) ²
Follicle-stimulating hormone (FSH)
Posterior pituitary
Arginine vasopressin (AVP) ³
Oxytocin

¹GH closely resembles human placental lactogen (hPL).

²LH closely resembles human chorionic gonadotropin (hCG).

³AVP is identical with antidiuretic hormone (ADH).

(see below) is a genetic disorder where genes on the paternal chromosome 15 are deleted or unexpressed. The incidence of this disorder is 1:15,000; both sexes are affected equally. **Kallmann syndrome** (see below) is caused by various gene mutations that impair the development or migration of GnRH-synthesizing neurons from the olfactory bulb to the hypothalamus. Kallmann syndrome is usually sporadic but may be familial and inherited as X-linked recessive (*Kal 1*), autosomal dominant (*Kal 2, 3, 4, 5, or 6*), or autosomal recessive (*Kal 3, 4, or 6*). Kallmann syndrome has an incidence of 1:10,000 males and 1:50,000 females.

► Clinical Findings

A. Symptoms and Signs

1. Gonadotropin deficiency—Also known as hypogonadotropic hypogonadism, gonadotropin deficiency is caused by insufficiencies in LH and FSH, which cause hypogonadism and infertility. **Congenital gonadotropin deficiency** is characterized by partial or complete lack of pubertal development. (See discussion of primary amenorrhea.) Patients with **Kallmann syndrome** have hypogonadism and anosmia or hyposmia. Half of these patients have unilateral renal agenesis. Some patients with Kallmann syndrome may also exhibit cryptorchidism, micropenis, color blindness, sensorineural deafness, cerebellar ataxia, cognitive problems, bimanual synkinesis, cleft lip or palate, or high-arched palate. Some affected women have menarche followed by secondary amenorrhea.

Patients with **congenital adrenal hypoplasia** have congenital normosmic idiopathic hypogonadotropic hypogonadism. Boys with congenital adrenal hypoplasia who survive beyond childhood usually do not enter puberty as a result of their hypogonadotropic hypogonadism. However, hypogonadotropic hypogonadism and subtle signs of adrenal failure can present in adulthood in males with partial loss-of-function mutations in *DAX 1*. Patients with **Prader-Willi syndrome** have variable features of both gonadotropin deficiency and primary gonadal dysfunction; boys have cryptorchidism. Other features of Prader-Willi syndrome can include mental retardation, short stature, hyperflexibility, autonomic dysregulation, cognitive impairment, and hyperphagia with obesity.

Acquired gonadotropin deficiency is characterized by the loss of axillary, pubic, and body hair. This occurs gradually but becomes particularly prominent in patients who are also hypoadrenal. Men may note diminished beard growth. Libido is diminished. Women have amenorrhea; men note decreased erections. Most patients are infertile. Androgen deficiency predisposes patients to osteopenia and muscle atrophy. (See sections on male hypogonadism and secondary amenorrhea.) Advancing age, obesity, and poor health also cause partial male hypogonadism. (See Male Hypogonadism.)

2. TSH deficiency—TSH deficiency causes hypothyroidism with manifestations such as fatigue, weakness, weight change, and hyperlipidemia. Bexarotene is a retinoid chemotherapeutic agent that suppresses TSH secretion and circulating levels of T₄ and T₃, thereby inducing reversible secondary hypothyroidism. (See Hypothyroidism and Myxedema.)

3. ACTH deficiency—This results in diminished cortisol secretion (see Adrenocortical Hypofunction). Symptoms may include weakness, fatigue, weight loss, and hypotension. Patients with partial ACTH deficiency continue to have some cortisol secretion and may not have symptoms until stressed by illness or surgery. Adrenal mineralocorticoid secretion continues, so manifestations of adrenal insufficiency in hypopituitarism are usually less striking than in bilateral adrenal gland destruction (Addison disease); hyponatremia may occur, especially when ACTH and TSH deficiencies are both present.

4. GH deficiency—When GH deficiency is congenital, it presents with hypoglycemia in infancy and short stature in childhood. GH deficiency in adulthood tends to cause mild to moderate central obesity, increased systolic blood pressure, increased low-density lipoprotein (LDL) cholesterol, and reduced cardiac output. Affected patients may also have reduced muscle and bone mass, reduced physical and mental energy, impaired concentration and memory, and depression. **Laron syndrome** is an autosomal recessive disorder that is mainly associated with mutations in GH receptor gene. This causes resistance to GH and severe insulin-like growth factor-I (IGF-I) deficiency, resulting in short stature (dwarfism). Affected individuals have a prominent forehead, depressed nasal bridge, small mandible, and central obesity. They may have recurrent hypoglycemic seizures. Partial resistance to GH may cause some cases of idiopathic short stature without features of Laron syndrome.

5. Combined pituitary hormone deficiency and panhypopituitarism—The conditions refer to a deficiency of several or all pituitary hormones. Combined pituitary hormone deficiency gradually develops in patients with *PROP 1* gene mutations, usually presenting with short stature and growth failure due to GH and TSH deficiency; lack of pubertal development occurs due to deficiencies in FSH and LH. ACTH-cortisol deficiency also gradually develops in patients with *PROP 1* gene mutations; these patients typically require corticosteroid replacement therapy by age 18 years. In addition to the

manifestations noted above, patients with long-standing hypopituitarism tend to have dry, pale, finely textured skin. The face has fine wrinkles and an apathetic countenance.

6. Other manifestations—Hypothalamic damage can cause obesity and cognitive impairment. Local tumor effects can cause headache or optic nerve compression with visual field impairment.

B. Laboratory Findings

The fasting blood glucose may be low. Hyponatremia is often present due to hypothyroidism or hypoadrenalism. Hyperkalemia usually does not occur, since aldosterone production is not affected.

For men, an accurate serum total testosterone measurement must be obtained. For older men, free testosterone is best measured by calculation, using accurate assays for testosterone and sex hormone binding globulin. Serum gonadotropins (FSH and LH) are obtained if the serum testosterone is low in order to distinguish primary hypogonadism from pituitary dysfunction.

The free thyroxine (FT₄) level is low, and TSH is usually not elevated. However, hypothyroidism with a paradoxically increased serum TSH has been reported in some patients with hypothalamic hypopituitarism. Plasma levels of sex steroids (testosterone and estradiol) are low or low normal, as are the serum gonadotropins. Elevated prolactin (PRL) levels are found in patients with prolactinomas, acromegaly, and hypothalamic disease.

ACTH deficiency usually causes functional atrophy of the adrenal cortex within 2 weeks of pituitary destruction. Therefore, the diagnosis of secondary hypoadrenalism can usually be confirmed with cosyntropin testing. For the cosyntropin test, patients should be either taking no corticosteroids or a short-acting corticosteroid (such as hydrocortisone), which is held after midnight on the morning of the test. At 8 AM, blood is drawn for serum cortisol, ACTH, and dehydroepiandrosterone (DHEA); then 0.25 mg of cosyntropin (synthetic ACTH₁₋₂₄) is administered intramuscularly or intravenously. Another blood sample is obtained 45 minutes after the cosyntropin injection to remeasure serum cortisol levels. A stimulated serum cortisol of < 20 mcg/dL (550 nmol/mL) indicates adrenal insufficiency. With gradual pituitary damage and early in the course of ACTH deficiency, patients can have a stimulated serum cortisol of ≥ 20 mcg/dL but a baseline 8 AM serum cortisol < 5 mcg/dL (137.5 nmol/L), which is suspicious for adrenal insufficiency. Serum DHEA levels are usually low in patients with adrenal deficiency, helping confirm the diagnosis. A baseline ACTH level is low or normal in secondary hypoadrenalism, distinguishing it from primary adrenal disease. For patients with symptoms of secondary adrenal insufficiency (hyponatremia, hypotension, pituitary tumor) but borderline cosyntropin testing, treatment can be instituted empirically. The cosyntropin test may be repeated at a later date. Insulin tolerance testing and metyrapone testing are usually unnecessary.

Deficiency of epinephrine occurs with secondary adrenal insufficiency, since high local concentrations of cortisol are required to induce the production of the enzyme

phenylethanolamine *N*-methyltransferase (PNMT) in the adrenal medulla that catalyzes the conversion of norepinephrine to epinephrine.

The diagnosis of GH deficiency is difficult since normal GH secretion is pulsatile and serum GH levels are nearly undetectable for most of the day. Also, adults normally tend to produce less GH as they age. Therefore, GH deficiency is often inferred by symptoms of GH deficiency in the presence of pituitary destruction or other pituitary hormone deficiencies. GH deficiency is present in 96% of patients with three or more other pituitary hormone deficiencies. GH stimulates the production of IGF-I. Unfortunately, serum IGF-I is not sensitive for GH deficiency since IGF-I levels are in the normal range in about 50% of adults with GH deficiency. Low serum IGF-I levels are not specific for GH deficiency; however, a very low level of IGF-I (< 84 mcg/L) is indicative of GH deficiency, except in conditions that naturally suppress serum IGF-I (eg, malnutrition, prolonged fasting, oral estrogen, hypothyroidism, uncontrolled diabetes mellitus, liver failure). In GH deficiency, exercise-stimulated serum GH levels remain at < 5 ng/mL and usually fail to rise; however, by age 40 years, most normal adults have lost their GH response to exercise.

Provocative GH-stimulation tests are commonly used but are poor tests for GH deficiency. The insulin hypoglycemia test is now rarely used. Other GH stimulation tests require the administration of intravenous arginine and growth hormone-releasing hormone (GHRH) and oral clonidine or carbidopa/levodopa (combination) in patients pretreated with propranolol or estrogen. However, these tests do not discriminate well between normal individuals and patients with presumed GH deficiency (patients with three or more other pituitary hormone deficiencies). Also, normal overweight adults (body mass index [BMI] ≥ 25 kg/m²) typically have blunted peak GH levels after arginine-GHRH administration.

Despite the limitations of intravenous GHRH/arginine stimulation testing, some insurance companies insist that patients have an abnormal test before covering the costs of GH replacement therapy. However, the latter test has a sensitivity of only 66% for GH deficiency. Therefore, when patients have a serum IGF-I < 84 mcg/L or three other pituitary hormone deficiencies, the likelihood of GH deficiency is so high that symptomatic patients should have a therapeutic trial of GH therapy.

The differential diagnosis of GH deficiency is congenital GH resistance with deficiency of IGF-I; at its worst, IGF-I deficiency results in Laron dwarfism that is resistant to GH therapy.

Patients with hypopituitarism without an established etiology should be screened for hemochromatosis with a serum iron and transferrin saturation or ferritin since hemochromatosis can cause hypopituitarism.

C. Imaging

MRI provides the best visualization of pituitary and hypothalamic tumors. Thickening of the pituitary stalk can be caused by sarcoidosis or hypophysitis.

► Differential Diagnosis

The failure to enter puberty may simply reflect delayed puberty, also known as constitutional delay in growth and puberty. Reversible hypogonadotropic hypogonadism may occur with serious illness, malnutrition, anorexia nervosa, or morbid obesity. Men typically develop partial secondary hypogonadism with aging. The clinical situation and the presence of normal adrenal and thyroid function allow ready distinction from hypopituitarism. Profound hypogonadotropic hypogonadism develops in men who receive GnRH analog therapy (leuprolide) for prostate cancer; it usually persists following cessation of therapy. Hypogonadotropic hypogonadism usually develops in patients receiving opioid therapy, including high-dose methadone or long-term intrathecal infusion of opioids; both GH deficiency and secondary adrenal insufficiency occur in 15% of such patients. Secondary adrenal insufficiency may persist for many months following high-dose corticosteroid therapy.

Severe illness causes functional suppression of TSH and T_4 . Hyperthyroxinemia reversibly suppresses TSH. Administration of triiodothyronine (Cytomel) suppresses TSH and T_4 . Bexarotene, used to treat cutaneous T cell lymphoma, suppresses TSH secretion, resulting in temporary central hypothyroidism. Corticosteroids or megestrol treatment reversibly suppresses endogenous ACTH and cortisol secretion.

GH deficiency normally occurs with aging. Physiologic GH deficiency that develops in obese patients may return to normal with sufficient weight loss.

► Complications

Among patients with craniopharyngiomas, diabetes insipidus is found in 16% preoperatively and in 60% postoperatively. Hyponatremia often presents abruptly during the first 2 weeks following pituitary surgery. Visual field impairment may occur. Hypothalamic damage may result in morbid obesity as well as cognitive and emotional problems. Conventional radiation therapy results in an increased incidence of small vessel ischemic strokes and second tumors.

Patients with untreated hypoadrenalism and a stressful illness may become febrile and die in shock and coma.

Adults with GH deficiency have experienced an increased cardiovascular morbidity. Rarely, acute hemorrhage may occur in large pituitary tumors, manifested by rapid loss of vision, headache, and evidence of acute pituitary failure (pituitary apoplexy) requiring emergency decompression of the sella.

► Treatment

Transsphenoidal removal of pituitary tumors will sometimes reverse hypopituitarism. Postoperative hyponatremia often occurs; serum sodium must be checked frequently for 2 weeks after pituitary surgery. Hypogonadism due to PRL excess usually resolves during treatment with dopamine agonists. Endocrine substitution therapy must be given before, during and, often, permanently after such procedures.

GH-secreting tumors may respond to octreotide (see section on acromegaly). Radiation therapy with x-ray,

gamma knife, or heavy particles may be necessary but increases the likelihood of hypopituitarism.

The mainstay of substitution therapy for pituitary insufficiency remains lifetime hormone replacement.

A. Corticosteroids

Hydrocortisone tablets, 15–35 mg/d orally in divided doses, should be given. Most patients do well with 10–20 mg in the morning and 5–15 mg in the late afternoon. Patients with partial ACTH deficiency (basal morning serum cortisol above 8 mg/dL [220 mmol/L]) require hydrocortisone replacement in lower doses of about 5 mg orally twice daily. Some patients feel better taking prednisone, 3–7.5 mg/d orally. A mineralocorticoid is rarely needed. To determine the optimal corticosteroid replacement dosage, it is necessary to monitor patients carefully for manifestations of overreplacement (Cushing syndrome) or underreplacement. A serum white blood cell count (WBC) with a relative differential can be useful, since a relative neutrophilia and lymphopenia can indicate overreplacement with corticosteroid, and vice versa. Additional corticosteroids must be given during states of stress, eg, during infection, trauma, or surgical procedures. For mild illness, corticosteroid doses are doubled or tripled. For trauma or surgical stress, hydrocortisone is given in doses of 50 mg intramuscularly or intravenously every 6 hours and then reduced to normal doses as the stress subsides. Patients with adrenal insufficiency are advised to wear a medical alert bracelet describing their condition and treatment.

Patients with secondary adrenal insufficiency due to treatment with corticosteroids at supraphysiologic doses require their usual daily dose of corticosteroid during surgery and acute illness; supplemental hydrocortisone is not usually required.

B. Thyroid

Levothyroxine is given to correct hypothyroidism only after the patient is assessed for cortisol deficiency or is already receiving corticosteroids. (See Hypothyroidism.) The typical maintenance dose is about 1.6 mcg/kg body weight. However, dosage requirements vary widely, averaging 125 mcg daily with a range of 25–300 mcg daily. The optimal replacement dose of thyroxine for each patient must be carefully assessed clinically on an individual basis. Serum FT_4 levels usually need to be in the high-normal range for adequate replacement. Assessment of serum TSH is useless for monitoring patients, since levels are always low with TSH deficiency.

C. Sex Hormones

Hypogonadotropic hypogonadism often develops in patients with hyperprolactinemia; it may be reversed with treatment of the hyperprolactinemia. (See Hyperprolactinemia.)

Androgen replacement is discussed in the section on male hypogonadism. Estrogen replacement is discussed in the section on female hypogonadism. Patients with idiopathic hypogonadotropic hypogonadism, who have received several years of hormone replacement therapy

(HRT), may have a trial off hormonal therapy to assess whether spontaneous sexual maturation may have occurred.

Women with hypopituitarism and secondary adrenal insufficiency whose serum DHEA levels are < 400 ng/mL may be treated with compounded DHEA in doses of about 25–50 mg/d orally. DHEA therapy tends to increase pubic and axillary hair and may modestly improve libido, alertness, stamina, and overall psychological well being after 6 months of therapy.

To improve spermatogenesis, human chorionic gonadotropin (hCG) (equivalent to LH) may be given at a dosage of 2000–3000 units intramuscularly three times weekly and testosterone replacement is discontinued. The dose of hCG is adjusted to normalize serum testosterone levels. After 6–12 months of hCG treatment, if the sperm count remains low, hCG injections are continued along with injections of FSH: follitropin- β (synthetic recombinant FSH) or urofollitropins (urine-derived FSH). An alternative for patients with an intact pituitary (eg, Kallmann syndrome) is the use of leuprolide (GnRH analog) by intermittent subcutaneous infusion. With either treatment, testicular volumes double within 5–12 months, and spermatogenesis occurs in most cases. With persistent treatment and the help of intracytoplasmic sperm injection for some cases, the total pregnancy success rate is about 70%. Clomiphene, 25–50 mg orally daily, can sometimes stimulate a man's own pituitary gonadotropins (when his pituitary is intact), thereby increasing testosterone and sperm production.

For fertility induction in females, ovulation may be induced with clomiphene, 50 mg daily for 5 days every 2 months. Follitropins and hCG can induce multiple births and should be used only by those experienced with their administration. (See Hypogonadism.)

D. Human Growth Hormone (hGH)

Symptomatic adults with severe GH deficiency (serum IGF-I < 85 mcg/L) may be treated with a subcutaneous recombinant human growth hormone (rhGH) injection starting at a dosage of about 0.2 mg/d (0.6 international units/d), administered three or four times weekly. The dosage of rhGH is increased every 2–4 weeks by increments of 0.1 mg (0.3 international units) until side effects occur or a sufficient salutary response and a normal serum IGF-I level are achieved. A sustained-release injectable suspension of depot GH is available (Nutropin Depot). It can be given twice monthly and is therefore more convenient than standard rhGH preparations. In a study of 20 Brazilian GH-deficient adults, depot GH, given in doses of 13.5 mg subcutaneously twice monthly over 6 months, improved body morphology and lipid profiles but was associated with an increase in carotid plaque. If the desired effects (eg, improved energy and mentation, reduction in visceral adiposity) are not seen within 3–6 months at maximum tolerated dosage, rhGH therapy is discontinued.

During pregnancy, rhGH may be safely administered to women with hypopituitarism at their usual pregestational dose during the first trimester, tapering the dose

during the second trimester, and discontinuing rhGH during the third trimester.

Oral estrogen replacement reduces hepatic IGF-I production. Therefore, prior to commencing rhGH therapy, oral estrogen is changed to a transdermal or transvaginal estradiol.

Side effects of rhGH therapy may include peripheral edema, hand stiffness, arthralgias, myalgias, headache, pseudotumor cerebri, gynecomastia, carpal tunnel syndrome, tarsal tunnel syndrome, hypertension, and proliferative retinopathy. Side effects are more common in older patients, those with greater weight and higher BMI, and those with adult-onset GH deficiency. Such symptoms usually remit promptly after a sufficient reduction in dosage. Excessive doses of rhGH could cause acromegaly; patients receiving long-term therapy require careful clinical monitoring. Serum IGF-I levels should be kept in the normal range and periodic determinations of serum IGF-I levels are helpful in guiding therapeutic dosing.

GH should not be administered during critical illness since, in one study, administration of very high doses of rhGH to patients in an intensive care unit was shown to increase overall mortality. There is no role for GH replacement in the somatopause of aging.

IGF-I (mecasermin) is available to treat patients with Laron syndrome.

E. Other Treatment

Selective transsphenoidal resection of pituitary adenomas can often restore normal pituitary function. Cabergoline, bromocriptine, or quinagolide may reverse the hypogonadism seen in hyperprolactinemia. (See Disorders of Prolactin Secretion.) Disseminated Langerhans cell histiocytosis may be treated with bisphosphonates to improve bone pain; treatment with 2-chlorodeoxyadenosine (cladribine) has been reported to produce remissions.

► Prognosis

The prognosis depends on the primary cause. Hypopituitarism resulting from a pituitary tumor may be reversible with dopamine agonists or with careful selective resection of the tumor. Spontaneous recovery from hypopituitarism associated with pituitary stalk thickening has been reported. Patients can also recover from functional hypopituitarism, eg, hypogonadism due to starvation or severe illness, suppression of ACTH by corticosteroids, or suppression of TSH by hyperthyroidism. Spontaneous reversal of isolated idiopathic hypogonadotropic hypogonadism occurs in about 10% of patients after several years of hormone replacement therapy.

Functionally, most patients with hypopituitarism do very well with hormone replacement. Men with infertility who are treated with hCG/FSH or GnRH are likely to resume spermatogenesis if they have a history of sexual maturation, descended testicles, and a baseline serum inhibin level over 60 pg/mL. Women under age 40 years, with infertility due to hypogonadotropic hypogonadism, can usually have successful induction of ovulation.

DIABETES INSIPIDUS

ESSENTIALS OF DIAGNOSIS

- ▶ Antidiuretic hormone (ADH) deficiency causes central diabetes insipidus with polyuria (2–20 L/d) and polydipsia.
- ▶ Hyponatremia occurs if fluid intake is inadequate.

▶ General Considerations

Diabetes insipidus is an uncommon disease characterized by an increase in thirst and the passage of large quantities of urine of low specific gravity (usually < 1.006 with ad libitum fluid intake). The urine is otherwise normal. It is caused by a deficiency of vasopressin or resistance to vasopressin.

Primary central diabetes insipidus (without an identifiable lesion noted on MRI of the pituitary and hypothalamus) accounts for about one-third of all cases of diabetes insipidus. Many such cases appear to be due to autoimmunity against hypothalamic arginine vasopressin (AVP)-secreting cells; pituitary stalk thickening can often be detected on pituitary MRI scanning. The cause may also be genetic. Familial diabetes insipidus occurs as a dominant genetic trait with symptoms developing at about 2 years of age. Diabetes insipidus also occurs in Wolfram syndrome, a rare autosomal recessive disorder that is also known by

the acronym DIDMOAD (diabetes insipidus, type 1 diabetes mellitus, optic atrophy, and deafness). DIDMOAD manifestations usually present in childhood but may not occur until adulthood, along with depression and cognitive problems. Diabetes insipidus can also occur in the preleukemic phase of acute myelogenous leukemia associated with myelodysplasia. **Secondary central diabetes insipidus** is due to damage to the hypothalamus or pituitary stalk by tumor, hypophysitis, anoxic encephalopathy, surgical or accidental trauma, infection (eg, encephalitis, tuberculosis, syphilis), sarcoidosis, or multifocal Langerhans cell (eosinophilic) granulomatosis (“histiocytosis X”). Metastases to the pituitary are more likely to cause diabetes insipidus (33%) than are pituitary adenomas (1%).

Vasopressinase-induced diabetes insipidus may be seen in the last trimester of pregnancy and in the puerperium. A circulating enzyme destroys native vasopressin; however, synthetic desmopressin is unaffected. **Nephrogenic diabetes insipidus** is a disorder caused by a defect in the kidney tubules that interferes with water reabsorption. These patients have normal secretion of vasopressin, and the polyuria is unresponsive to it. **Congenital nephrogenic diabetes insipidus** is present from birth and is due to defective expression of renal vasopressin V2 receptors or vasopressin-sensitive water channels. It occurs as a familial X-linked trait; adults often have hyperuricemia as well. **Acquired forms of vasopressin-resistant diabetes insipidus** are usually less severe and are seen in pyelonephritis, renal amyloidosis, myeloma, potassium depletion, Sjögren syndrome, sickle cell anemia, or chronic hypercalcemia. The disorder may occur also as a corticosteroid effect or as an acute side effect of diuretics. Certain drugs (eg, demeclocycline, lithium, foscarnet, or methicillin) may induce nephrogenic diabetes insipidus. The recovery from acute tubular necrosis may also be associated with transient nephrogenic diabetes insipidus. (See Kidney Disorders.)

▶ Clinical Findings

A. Symptoms and Signs

The symptoms of the disease are intense thirst, especially with a craving for ice water, and polyuria, the volume of ingested fluid varying from 2 L to 20 L daily, with correspondingly large urine volumes. Partial diabetes insipidus presents with less intense symptoms and should be suspected in patients with unremitting enuresis. Most patients with diabetes insipidus are able to maintain fluid balance by continuing to ingest large volumes of water. However, diabetes insipidus may present with hypernatremia and dehydration in patients without free access to water, or with a damaged hypothalamic thirst center and altered thirst sensation. Diabetes insipidus is aggravated by administration of high-dose corticosteroids, which increases renal free water clearance. Vasopressin-induced diabetes insipidus during pregnancy is often associated with oligohydramnios, preeclampsia, or hepatic dysfunction.

B. Laboratory Findings

The diagnosis of diabetes insipidus as a cause of polyuria or hypernatremia requires clinical judgment. There is no

single diagnostic laboratory test. Evaluation for diabetes insipidus should include an accurate 24-hour urine collection that is measured for volume and creatinine. A urine volume of < 2 L/24 h (in the absence of hypernatremia) essentially rules out diabetes insipidus. Serum is assayed for glucose, urea nitrogen, calcium, potassium, sodium, and uric acid. Hyperuricemia occurs in many patients with diabetes insipidus, since reduced vasopressin stimulation of the renal V1 receptor causes a reduction in the renal tubular clearance of urate.

A supervised “vasopressin challenge test” may be given: Desmopressin acetate is given in an initial dose of 0.05–0.1 mL (5–10 mcg) intranasally (or 1 mcg subcutaneously or intravenously), with measurement of urine volume for 12 hours before and 12 hours after administration. Serum sodium must be obtained immediately in the event of symptoms of hyponatremia. The dosage of desmopressin is doubled if the response is marginal. Patients with central diabetes insipidus notice a distinct reduction in thirst and polyuria; serum sodium stays normal except in some salt-losing conditions.

In **nonfamilial central diabetes insipidus**, MRI of the pituitary and hypothalamus and of the skull is done to look for mass lesions. The pituitary stalk may be thickened, which may be a manifestation of Langerhans cell histiocytosis, sarcoidosis, or lymphocytic hypophysitis. When **nephrogenic diabetes insipidus** is a diagnostic consideration, measurement of serum vasopressin is done during modest fluid restriction; typically, the vasopressin level is high.

► Differential Diagnosis

Central diabetes insipidus must be distinguished from polyuria caused by psychogenic polydipsia, diabetes mellitus, Cushing syndrome or corticosteroid treatment, lithium, hypercalcemia, hypokalemia, and the nocturnal polyuria of Parkinson disease. It must also be distinguished from vasopressinase-induced diabetes insipidus and nephrogenic diabetes insipidus.

► Complications

If water is not readily available, the excessive output of urine will lead to severe dehydration. Patients with an impaired thirst mechanism are very prone to hypernatremia, particularly since they usually also have impaired mentation and forget to take their desmopressin. All the complications of the primary disease may eventually become evident. In patients who are receiving desmopressin acetate therapy, there is a danger of induced water intoxication.

► Treatment

Mild cases of diabetes insipidus require no treatment other than adequate fluid intake. Reduction of aggravating factors (eg, corticosteroids, which directly increase renal free water clearance) will improve polyuria.

Desmopressin acetate is the treatment of choice for central diabetes insipidus. It is also useful in diabetes insipidus associated with pregnancy or the puerperium, since desmopressin is resistant to degradation by the circulating vasopressinase.

Desmopressin is given orally in a starting dose of 0.05 mg twice daily and increased to a maximum of 0.4 mg every 8 hours, if required. Oral desmopressin is particularly useful for patients with sinusitis from the nasal preparation. Gastrointestinal symptoms, asthenia, and mild increases in hepatic enzymes can occur with the oral preparation.

The nasal preparation (100 mcg/mL solution) is given every 12–24 hours as needed for thirst and polyuria. It may be administered via metered-dose nasal inhaler containing 0.1 mL/spray or via a plastic calibrated tube. The starting dose is 0.05–0.1 mL every 12–24 hours, and the dose is then individualized according to response. Nasal desmopressin may cause nasal irritation.

Desmopressin can also be given intravenously, intramuscularly, or subcutaneously in doses of 1–4 mcg every 12–24 hours as needed to treat thirst or hypernatremia.

Desmopressin may cause hyponatremia, which is uncommon if minimum effective doses are used and the patient allows thirst to occur periodically. Desmopressin can sometimes cause emotional changes, such as depression or agitation and there is an increased risk of suicide among patients starting desmopressin treatment. Erythromelalgia occurs rarely. All desmopressin preparations, including tablets, are subject to heat degradation and should be refrigerated.

Both central and nephrogenic diabetes insipidus respond partially to hydrochlorothiazide, 50–100 mg/d orally (with potassium supplement or amiloride). Nephrogenic diabetes insipidus may respond to combined treatments of indomethacin-hydrochlorothiazide, indomethacin-desmopressin, or indomethacin-amiloride. Indomethacin, 50 mg orally every 8 hours, is effective in acute cases.

Psychotherapy is required for most patients with psychogenic polydipsia. Thioridazine and lithium are best avoided if psychiatric drug therapy is needed, since they cause polyuria.

► Prognosis

Central diabetes insipidus appearing after pituitary surgery usually remits after days to weeks but may be permanent if the upper pituitary stalk is cut.

Chronic central diabetes insipidus is ordinarily more an inconvenience than a dire medical condition. Treatment with desmopressin allows normal sleep and activity. Hypernatremia can occur, especially when the thirst center is damaged, but diabetes insipidus does not otherwise reduce life expectancy, and the prognosis is that of the underlying disorder.

ACROMEGALY & GIGANTISM

ESSENTIALS OF DIAGNOSIS

- ▶ Pituitary tumor.
- ▶ Excessive growth of hands, feet, jaw, and internal organs; or gigantism before closure of epiphyses.
- ▶ Amenorrhea, headaches, visual field loss, weakness.
- ▶ Soft, doughy, sweaty handshake.
- ▶ Elevated IGF-I.
- ▶ Serum GH not suppressed following oral glucose.

▶ General Considerations

GH exerts much of its growth-promoting effects by stimulating the release of IGF-I from the liver and other tissues.

Acromegaly is nearly always caused by a pituitary adenoma. These tumors may be locally invasive, particularly into the cavernous sinus. Less than 1% are malignant. Most are macroadenomas (over 1 cm in diameter). Acromegaly is usually sporadic but may rarely be familial. The disease may also be associated with endocrine tumors of the parathyroids or pancreas (MEN 1). Acromegaly may also be seen in McCune–Albright syndrome and as part of Carney syndrome (atrial myxoma, acoustic neuroma, lentiginos, adrenal hypercortisolism). Acromegaly is rarely caused by ectopic secretion of GHRH or GH secreted by a lymphoma, hypothalamic tumor, bronchial carcinoid, or pancreatic tumor.

▶ Clinical Findings

A. Symptoms and Signs

Excessive GH causes tall stature and gigantism if it occurs in youth, before closure of epiphyses. Afterward, acromegaly develops. The term “acromegaly,” meaning extremity enlargement, seriously understates the manifestations. The hands enlarge and a doughy, moist handshake is characteristic. The fingers widen, causing patients to enlarge their rings. Carpal tunnel syndrome is common. The feet also grow, particularly in shoe width. Facial features coarsen since the bones and sinuses of the skull enlarge; hat size increases. The mandible becomes more prominent, causing prognathism and malocclusion. Tooth spacing widens. Older photographs of the patient can be a useful comparison.

Macroglossia occurs, as does hypertrophy of pharyngeal and laryngeal tissue; this causes a deep, coarse voice and sometimes makes intubation difficult. Obstructive sleep apnea may occur. A goiter may be noted. Hypertension (50%) and cardiomegaly are common. At diagnosis, about 10% of acromegalic patients have overt heart failure, with a dilated left ventricle and a reduced ejection fraction. Weight gain is typical, particularly of muscle and bone. Insulin resistance is usually present and frequently causes diabetes mellitus (30%). Arthralgias and degenerative arthritis occur. Overgrowth of vertebral bone can cause

spinal stenosis. Colon polyps are common, especially in patients with skin papillomas. The skin may also manifest hyperhidrosis, thickening, cystic acne, skin tags, and areas of acanthosis nigricans.

GH-secreting pituitary tumors usually cause some degree of hypogonadism, either by cosecretion of PRL or by direct pressure upon normal pituitary tissue. Decreased libido and erectile dysfunction are common. Women with acromegaly may experience irregular menses or amenorrhea; those who become pregnant have an increased risk of gestational diabetes and hypertension. Secondary hypothyroidism sometimes occurs; hypoadrenalism is unusual. Headaches are frequent. Temporal hemianopia may occur as a result of the optic chiasm being impinged by a suprasellar growth of the tumor.

B. Laboratory Findings

For screening purposes, a random serum IGF-I can be obtained. If it is normal for age, acromegaly is ruled out. For further evaluation, the patient should be fasting for at least 8 hours (except for water), not acutely ill, and should not have exercised on the day of testing. Assay for the following: IGF-I (increased to over five times normal in most acromegalic patients), PRL (cosecreted by many GH-secreting tumors), glucose (diabetes is common in acromegaly), liver enzymes and blood urea nitrogen (BUN) (liver failure or kidney disease can misleadingly elevate GH), serum calcium (to screen for hyperparathyroidism), serum inorganic phosphorus (frequently elevated), serum free T_4 , and TSH (secondary hypothyroidism is common in acromegaly; primary hypothyroidism may increase PRL; hyperthyroidism may occur as a result of excess TSH).

Glucose syrup (75 g) is then administered orally, and serum GH is measured 60 minutes afterward; acromegaly is excluded if the serum GH is < 1 ng/mL (immunoradiometric assay [IRMA] or chemiluminescent assays). For ultrasensitive GH assays, GH should be suppressed to < 0.3 ng/mL to exclude acromegaly. The serum IGF-I and glucose-suppressed GH are usually complementary tests; however, disparities between GH and IGF-I levels occur in up to 30% of patients.

C. Imaging

MRI shows a pituitary tumor in 90% of acromegalic patients. These tumors ordinarily involve the sella and cavernous sinus; rare ectopic tumors may arise in the sphenoid bone. MRI is generally superior to CT scanning, especially in the postoperative setting. Radiographs of the skull may show an enlarged sella and thickened skull. Radiographs may also show tufting of the terminal phalanges of the fingers and toes. A lateral view of the foot shows increased thickness of the heel pad.

▶ Differential Diagnosis

Active acromegaly must be distinguished from familial coarse features, large hands and feet, and isolated prognathism and from inactive (“burned-out”) acromegaly in which there has been a spontaneous remission due to infarction of the pituitary adenoma. GH-induced gigantism

must be differentiated from familial tall stature and from aromatase deficiency. (See Osteoporosis.)

Misleadingly high serum GH levels can be caused by exercise or eating just prior to the test; acute illness or agitation; liver failure or kidney disease; malnourishment; diabetes mellitus; or concurrent treatment with estrogens, β -blockers, or clonidine. During normal adolescence, serum IGF-I is usually elevated and GH may fail to be suppressed.

► Complications

Complications include hypopituitarism, hypertension, glucose intolerance or frank diabetes mellitus, cardiac enlargement, and cardiac failure. Carpal tunnel syndrome may cause thumb weakness and thenar atrophy. Arthritis of hips, knees, and spine can be troublesome. Cord compression may be seen. Visual field defects may be severe and progressive. Acute loss of vision or cranial nerve palsy may occur if the tumor undergoes spontaneous hemorrhage and necrosis (pituitary apoplexy). Colon polyps are more likely to develop in patients with acromegaly.

► Treatment

Pituitary microsurgery is the treatment of choice for patients with acromegaly. Many patients have an apparent surgical cure and a remission in all clinical symptoms but continue to have a mildly elevated serum GH or IGF-I postoperatively. If no residual tumor is apparent on MRI, the patient may elect to be monitored closely, rather than embark on adjuvant medical therapy that is expensive and carries its own risks (see below).

A. Pituitary Microsurgery

Endoscopic transnasal, transsphenoidal pituitary microsurgery removes the adenoma while preserving anterior pituitary function in most patients. Surgical remission is achieved in about 70% of patients followed over 3 years. GH levels fall immediately; diaphoresis and carpal tunnel syndrome often improve within a day after surgery. Transsphenoidal surgery is usually well tolerated, but complications occur in about 10% of patients, including infection, cerebrospinal fluid leak, and hypopituitarism. Transsphenoidal pituitary surgery may be difficult in patients with McCune–Albright syndrome because of fibrous dysplasia of the skull base.

Fluid and electrolyte disturbances occur in most patients postoperatively. Diabetes insipidus can occur within 2 days postoperatively but is usually mild and self-correcting. Hyponatremia can occur abruptly 4–13 days postoperatively in 21% of patients; symptoms may include nausea, vomiting, headache, malaise, or seizure. It is treated with fluid restriction and salt supplements. It is prudent to monitor serum sodium levels postoperatively. Dietary salt supplements for 2 weeks postoperatively may help prevent this complication.

Corticosteroids are administered perioperatively and tapered to replacement doses over 1 week; hydrocortisone is discontinued and cosyntropin stimulation test is performed about 6 weeks after surgery. At that time, a serum T_4 can be checked (to screen for secondary hypothyroidism) and the patient is screened for secondary hypogonadism (see above).

B. Medications

Patients who do not have a clinical or biochemical remission after surgery may be treated with a dopamine agonist (eg, cabergoline), somatostatin analogs, pegvisomant, or a combination of these medications. **Cabergoline** may be used first, since it is an oral medication. Cabergoline therapy is most successful for tumors that secrete both PRL and GH but can also be effective for patients with normal serum PRL levels. Therapy with cabergoline will shrink one-third of such tumors by more than 50%. The initial dose is 0.25 mg orally twice weekly, which is gradually increased to a maximum dosage of 1 mg twice weekly, if tolerated by the patient based on serum GH and IGF-I levels. Side effects of cabergoline include nausea, fatigue, constipation, abdominal pain, and dizziness. Long-term therapy with dopamine agonists (cabergoline, bromocriptine, or pergolide) for pituitary tumors has not caused the cardiac valve problems that can occur when much higher doses are used for Parkinson disease.

Octreotide and **lanreotide** are somatostatin analogs that are given by subcutaneous injection. Octreotide (Sandostatin LAR depot) is given at a dose of 20–40 mg intragluteally monthly. Lanreotide acetate (Somatuline Depot) is given by subcutaneous intragluteal injection at a dosage of 60–120 mg monthly. Whichever preparation is used, the dosage can be adjusted to achieve serum GH levels under 2 ng/mL. Such long-acting somatostatin analogs can achieve serum GH levels under 2 ng/mL in 79% of patients and normal serum IGF-I levels in 53% of patients. Headaches often improve, and tumor shrinkage of about 30% may be expected. Acromegalic patients with pretreatment serum GH levels exceeding 20 ng/mL are less likely to respond to octreotide or lanreotide therapy. Side effects are experienced by about one-third of patients and include injection site pain, loose acholic stools, abdominal discomfort, or cholelithiasis. All somatostatin analogs are expensive and must be continued indefinitely or until other treatment has been effective.

Pegvisomant is a GH receptor antagonist that blocks hepatic IGF-I production. Pegvisomant therapy produces symptomatic relief and normalizes serum IGF-I levels in over 90% of patients. The starting dosage is 10 mg subcutaneously daily. The maintenance dosage can be increased by 5–10 mg every 4–6 weeks, based on serum IGF-I levels and liver transaminase levels; the maximum dosage is 40 mg subcutaneously daily. Pegvisomant does not shrink GH-secreting tumors. Patients need to be monitored carefully with visual field examinations, GH levels, and MRI scanning of the pituitary. Side effects of pegvisomant, including hepatitis and liver injury, have occurred in a patient with Gilbert syndrome. Other adverse effects include edema, flulike syndrome, nausea, and hypertension. Lipohypertrophy can occur at injection sites, so injection sites must be diligently rotated and inspected. In acromegalic diabetics, hypoglycemic drugs are reduced to avoid hypoglycemia during pegvisomant therapy. The effectiveness of pegvisomant is reduced by coadministration of opioids. Pegvisomant is detected in some GH assays, which could overestimate serum GH levels. Pegvisomant is extremely expensive.

C. Stereotactic Radiosurgery

Acromegalic patients who have not had a complete remission with transsphenoidal surgery or medical therapy may be treated with **stereotactic radiosurgery** administered by gamma knife, heavy particle radiation, or adapted linear accelerator. Gamma knife radiosurgery is preferred, since it has become more widely available and normalization of serum IGF-I has been reported in up to 80% of treated patients. Radiosurgery precisely radiates the pituitary tumor in a single session and reduces radiation to the normal brain. However, it cannot be used for pituitary tumors with suprasellar extension due to the risk of damaging the optic chiasm. Radiosurgery can be used for pituitary tumors invading the cavernous sinus, since cranial nerves III, IV, V, and VI are less susceptible to radiation damage. Radiosurgery can also be used for patients who have not responded to conventional radiation therapy. Following any pituitary radiation therapy, patients are advised to take lifelong daily low-dose aspirin because of the increased risk of small-vessel stroke.

► Prognosis

Patients with acromegaly have increased morbidity and mortality from cardiovascular disorders and progressive acromegalic symptoms. Those who are treated and have a random serum GH under 1.0 ng/mL or a glucose-suppressed serum GH under 0.4 ng/mL with a normal age-adjusted serum IGF-I level have reduced morbidity and mortality. Transsphenoidal pituitary surgery is successful in 80% of patients with tumors < 2 cm in diameter and GH levels < 50 ng/mL. Extrasellar extension of the pituitary tumor, particularly cavernous sinus invasion, reduces the likelihood of surgical cure.

Adjuvant medical therapy has been quite successful in treating patients who are not cured by pituitary surgery. Postoperatively, normal pituitary function is usually preserved. Soft tissue swelling regresses but bone enlargement is permanent. Hypertension frequently persists despite successful surgery. Conventional radiation therapy (alone) produces a remission in about 40% of patients by 2 years and 75% of patients by 5 years after treatment. Gamma knife or cyberknife radiosurgery reduces GH levels an average of 77%, with 20% of patients having a full remission after 12 months. Patients with pituitary adenomas that abut the optic chiasm can be treated with cyberknife radiosurgery, controlling tumor growth and preserving vision in most patients. Heavy particle pituitary radiation produces a remission in about 70% of patients by 2 years and 80% of patients by 5 years. Radiation therapy eventually produces some degree of hypopituitarism in most patients. Conventional radiation therapy may cause some degree of organic brain syndrome and predisposes to small strokes. Patients must receive lifelong follow-up, with regular monitoring of serum GH and IGF-I levels. Serum GH levels over 5 ng/mL and rising IGF-I levels usually indicate a recurrent tumor.

Hypopituitarism may occur, due to the tumor itself, pituitary surgery, or radiation therapy. Hypopituitarism may develop years following radiation therapy, so patients must have regular clinical monitoring of their pituitary function.

HYPERPROLACTINEMIA

ESSENTIALS OF DIAGNOSIS

- **Women:** Oligomenorrhea, amenorrhea; galactorrhea; infertility.
- Prolactin normally elevated during pregnancy.
- **Men:** Hypogonadism; decreased libido and erectile dysfunction; infertility.
- Elevated serum PRL.
- CT scan or MRI often demonstrates pituitary adenoma.

► General Considerations

Non-gestational elevations in serum PRL can be caused by numerous conditions (Table 26–2). PRL-secreting pituitary tumors are more common in women than in men and are usually sporadic but may rarely be familial as part of MEN 1. Most are microadenomas (< 1 cm in diameter) that do not grow even with pregnancy or oral contraceptives. However, some giant prolactinomas (over 3 cm in diameter) can spread into the cavernous sinuses and suprasellar areas; rarely, they may erode the floor of the sella to invade the sinuses.

► Clinical Findings

A. Symptoms and Signs

Hyperprolactinemia may result in hypogonadotropic hypogonadism and reduced fertility. Men usually have erectile dysfunction and diminished libido; gynecomastia sometimes occurs but rarely with galactorrhea. Women may note oligomenorrhea or amenorrhea, although some women continue to menstruate normally. Galactorrhea, defined as lactation in the absence of nursing, is common. During pregnancy, clinically significant enlargement of a microprolactinoma (diameter < 1 cm) occurs in < 3%;

Table 26–2. Causes of hyperprolactinemia.

Physiologic Causes	Pharmacologic Causes	Pathologic Causes
Exercise	Amoxapine	Acromegaly
Idiopathic	Amphetamines	Chronic chest wall stimulation
Macroprolactinemia (“big prolactin”)	Anesthetic agents	(postthoracotomy, postmastectomy, herpes zoster, breast problems, chest acupuncture, nipple rings, etc)
Pregnancy	Antipsychotics (conventional and atypical)	Cirrhosis
Puerperium	Butyrophenones	Hypothalamic disease
Sleep (REM phase)	Cimetidine and ranitidine (not famotidine or nizatidine)	Hypothyroidism
Stress (trauma, surgery)	Estrogens	Kidney disease (especially with zinc deficiency)
Suckling	Hydroxyzine	Multiple sclerosis
	Methyldopa	Optic neuromyelitis
	Metoclopramide	Pituitary stalk section
	Opioids	Prolactin-secreting tumors
	Nicotine	Pseudocyesis (false pregnancy)
	Phenothiazines	Spinal cord lesions
	Protease inhibitors	Systemic lupus erythematosus
	Progestins	
	Reserpine	
	Risperidone	
	Selective serotonin reuptake inhibitors	
	Testosterone	
	Tricyclic antidepressants	
	Verapamil	

clinically significant enlargement of a macroprolactinoma (diameter ≥ 1 cm) occurs in about 30%.

Pituitary prolactinomas may cosecrete GH and cause acromegaly (see above). Large tumors may cause headaches, visual symptoms, and pituitary insufficiency.

Aside from pituitary tumors, some women secrete an abnormal form of prolactin that appears to cause peripartum cardiomyopathy (see Chapter 10). Suppression of prolactin secretion with dopamine agonists can reverse the cardiomyopathy.

B. Laboratory Findings

Evaluate for conditions known to cause hyperprolactinemia, particularly pregnancy (serum hCG), hypothyroidism (serum FT₄ and TSH), kidney disease (BUN and serum creatinine), cirrhosis (liver function tests) and hyperparathyroidism (serum calcium). Men are evaluated for hypogonadism with determinations of serum total and free testosterone, LH, and FSH. Women who have amenorrhea are assessed for hypogonadism with determinations of serum estradiol, LH, and FSH. Patients with pituitary macroadenomas (> 3 cm in diameter) should have PRL measured on serial dilutions of serum, since IRMA assays may otherwise report falsely low titers, the “high-dose hook effect.” Patients with macroprolactinomas or manifestations of possible hypopituitarism should be evaluated for

hypopituitarism as described above. An assay for macroprolactinemia should be considered for patients with hyperprolactinemia who are relatively asymptomatic and have no apparent cause for hyperprolactinemia.

C. Imaging

Patients with hyperprolactinemia not induced by drugs, hypothyroidism, or pregnancy should be examined by pituitary MRI. Small prolactinomas may thus be demonstrated, but clear differentiation from normal variants is not always possible. In the event that a woman with a macroprolactinoma becomes pregnant and elects not to take dopamine agonists during her pregnancy, MRI is usually not performed since the normal pituitary grows during pregnancy. However, if visual-field defects or other neurologic symptoms develop in a pregnant woman, a limited MRI study should be done, focusing on the pituitary without gadolinium contrast.

► Differential Diagnosis

The causes of hyperprolactinemia are shown in Table 26–2. Chronic nipple stimulation, nipple piercing, augmentation or reduction mammoplasty, and mastectomy may stimulate PRL secretion. The pituitary tumor of acromegaly can cosecrete GH and PRL. Hyperprolactinemia may also be idiopathic. Increased pituitary size is a normal variant in young women. About 10% of hyperprolactinemic patients are found to be secreting macroprolactin, a relatively inactive “big prolactin”; pituitary MRI is normal in 78% of cases.

The differential diagnosis for galactorrhea includes the small amount of breast milk that can be expressed from the nipple in many parous women that is not cause for concern. Nipple stimulation from nipple rings, chest surgery, or acupuncture can cause galactorrhea; serum PRL levels may be normal or minimally elevated. Some women can have galactorrhea with normal serum PRL levels and no discernible cause (idiopathic). Normal breast milk may be various colors besides white. Bloody galactorrhea requires an evaluation for breast malignancy.

► Treatment

Medications known to increase PRL should be stopped if possible. Hyperprolactinemia due to hypothyroidism is corrected by thyroxine.

Women with microprolactinomas who have amenorrhea or are desirous of contraception may safely take oral contraceptives or estrogen replacement—there is minimal risk of stimulating enlargement of the microadenoma. Patients with infertility and hyperprolactinemia may be treated with a dopamine agonist in an effort to improve fertility. Women with amenorrhea who elect to receive no treatment have an increased risk of developing osteoporosis; such women require periodic bone densitometry.

Pituitary macroprolactinomas (> 10 mm in diameter) have a higher risk of progressive growth, particularly during treatment with estrogen or testosterone replacement therapy or during pregnancy. Therefore, patients with macroprolactinomas should not be treated with sex HRT unless they are in remission with dopamine agonist medication or surgery. Pregnant women with macroprolactinomas

should continue to receive treatment with dopamine agonists throughout the pregnancy to prevent tumor growth. If dopamine agonists are not used during pregnancy in a woman with a macroprolactinoma, visual-field testing is required each trimester. During pregnancy, measurement of prolactin is not useful surveillance for tumor growth due to the fact that prolactin increases greatly during normal pregnancy.

A. Dopamine Agonists

Dopamine agonists are the initial treatment of choice for patients with giant prolactinomas and those with hyperprolactinemia desiring restoration of normal sexual function and fertility. Cabergoline is usually the best tolerated ergot-derived dopamine agonist. The beginning dosage is 0.25 mg orally once weekly for 1 week, then 0.25 mg twice weekly for the next week, then 0.5 mg twice weekly. Further dosage increases may be required monthly, based on serum PRL levels, up to a maximum of 1.5 mg twice weekly. Bromocriptine (1.25–20 mg/d orally) is an alternative drug. Women who experience nausea with oral preparations may find relief with deep vaginal insertion of cabergoline or bromocriptine tablets; vaginal irritation sometimes occurs. Quinagolide (Norprolac; not available in the United States) is a non-ergot-derived dopamine agonist for patients intolerant or resistant to ergot-derived medications; the starting dosage is 0.075 mg/d orally, increasing as needed and tolerated to a maximum of 0.6 mg/d. Patients whose tumor is resistant to one dopamine agonist may be switched to another in an effort to induce a tolerable remission.

Dopamine agonists are given at bedtime to minimize side effects of fatigue, nausea, dizziness, and orthostatic hypotension. These symptoms usually improve with dosage reduction and continued use. Erythromelalgia is rare. Dopamine agonists can cause a variety of psychiatric side effects that are not dose related and may take weeks to resolve once the dopamine agonist is discontinued. Therefore, dopamine agonists should be used judiciously in psychiatric patients whose antipsychotic medications have caused hyperprolactinemia. Long-term therapy with dopamine agonists (cabergoline, bromocriptine, or pergolide) for pituitary tumors has not caused the cardiac valve problems that can occur when much higher doses are used for Parkinson disease.

With dopamine agonist treatment, 90% of patients with prolactinomas experience a fall in serum PRL to 10% or less of pretreatment levels; about 80% of treated patients achieve a normal serum PRL level. Shrinkage of a pituitary adenoma occurs early, but the maximum effect may take up to a year. Nearly half of prolactinomas—even massive tumors—shrink more than 50%. Such shrinkage of giant prolactinomas can result in spinal fluid rhinorrhea. Discontinuing therapy after months or years usually results in the reappearance of hyperprolactinemia and galactorrhea-amenorrhea. After 2 years of cabergoline therapy, the percentage of patients who maintain a normal serum prolactin after withdrawal of the drug are as follows: 32% with idiopathic hyperprolactinemia, 21% with microprolactinomas, and 16% with macroprolactinomas.

Because dopamine agonists usually restore fertility promptly, many pregnancies have resulted; no teratogenicity

has been noted with any of the dopamine agonists. However, women with microadenomas may have treatment withdrawn during pregnancy. Macroadenomas may enlarge significantly during pregnancy; if therapy is withdrawn, such patients must be monitored clinically with serum PRL determinations and with computer-assisted visual fields. Women with macroprolactinomas who have responded to dopamine agonists may safely receive oral contraceptive agents as long as they continue receiving therapy.

B. Surgical Treatment

Transsphenoidal pituitary surgery may be urgently required for large tumors undergoing apoplexy or those severely compromising visual fields. It is also used electively for patients who do not tolerate or respond to dopamine agonists. Pituitary transsphenoidal surgery is generally well-tolerated, with a surgical mortality rate of < 0.5%. Complications, such as cerebrospinal fluid leakage, meningitis, stroke, or visual loss, occur in about 3% of cases; sinusitis, nasal septal perforation, or infection complicates about 6.5% of surgeries. Postoperative hyponatremia occurs quite commonly, and it is advisable to monitor serum sodium levels for the first 2 weeks postoperatively. For pituitary microprolactinomas, skilled neurosurgeons are successful in normalizing prolactin in 87% of patients; the 10-year recurrence rate is 13%. Pituitary function can be preserved in over 95% of cases. However, the surgical success rate for macroprolactinomas is much lower, and the complication rates are higher. Craniotomy is rarely indicated, since even large tumors can usually be decompressed via the transsphenoidal approach.

Fluid and electrolyte disturbances occur in most patients postoperatively. Diabetes insipidus can occur within 2 days postoperatively but is usually mild and self-correcting. Hyponatremia can occur abruptly 4–13 days postoperatively in 21% of patients; symptoms may include nausea, vomiting, headache, malaise, or seizure. It is treated with fluid restriction and salt supplements. It is prudent to monitor serum sodium levels postoperatively. Dietary salt supplements for 2 weeks postoperatively may help prevent this complication.

C. Radiation Therapy

Radiation therapy is reserved for patients with macroadenomas that are growing despite treatment with dopamine agonists. A single gamma knife or cyberknife treatment is preferable for certain patients whose optic chiasm is clear of tumor, since it is generally safer and more convenient than conventional radiation therapy. Conventional radiation therapy must be given over 5 weeks and carries a high risk of eventual hypopituitarism. Other possible side effects include some degree of memory impairment and an increased long-term risk of second tumors and small vessel ischemic strokes. After radiation therapy, patients are advised to take low-dose aspirin daily for life to reduce their stroke risk.

D. Chemotherapy

Some patients with aggressive pituitary macroadenomas or carcinomas are not surgical candidates and do not respond to dopamine agonists or radiation therapy. Temozolomide

may be administered, 150–200 mg/m² orally daily for 5 days of each 28-day cycle; after three cycles, treatment efficacy is determined by prolactin measurement and MRI scanning. A minority of such patients respond to temozolomide.

DISEASES OF THE THYROID GLAND

THYROID TESTING

Assays for FT₄, total triiodothyronine (T₃), and free triiodothyronine (FT₃) have largely supplanted measurements

of total T₄, resin T₃ uptake (RT₃U), and free thyroxine index (FT₄I). It is particularly important to determine “free” serum levels (FT₄ and FT₃) in conditions associated with high circulating levels of thyroxine-binding globulin, such as during therapy with oral estrogen. Ultrasensitive assays for serum TSH have largely replaced older TSH assays. Table 26–3 shows the appropriate use of thyroid tests.

HYPOTHYROIDISM & MYXEDEMA

ESSENTIALS OF DIAGNOSIS

- ▶ Weakness, fatigue, cold intolerance, constipation, weight change, depression, menorrhagia, hoarseness.
- ▶ Dry skin, bradycardia, delayed return of deep tendon reflexes.
- ▶ Anemia, hyponatremia, hyperlipidemia.
- ▶ FT₄ level is usually low.
- ▶ TSH elevated in primary hypothyroidism.

▶ General Considerations

Hypothyroidism is common, affecting over 1% of the general population and about 5% of individuals over age

Table 26–3. Appropriate use of thyroid tests.

	Test	Comment
Screening	Serum thyroid-stimulating hormone (TSH) (sensitive assay) Free thyroxine (FT ₄)	Most sensitive test for primary hypothyroidism and hyperthyroidism Excellent test
For hypothyroidism	Serum TSH Antithyroglobulin and antithyroperoxidase antibodies	High in primary and low in secondary hypothyroidism Elevated in Hashimoto thyroiditis
For hyperthyroidism	Serum TSH (sensitive assay) Triiodothyronine (T ₃) or free triiodothyronine (FT ₃) ¹²³ I uptake and scan Antithyroglobulin and antimicrosomal antibodies Thyroid-stimulating immunoglobulin; TSH receptor antibody (TSH-R Ab [stim])	Suppressed except in TSH-secreting pituitary tumor or pituitary hyperplasia (rare) Elevated Increased uptake; diffuse versus “hot” areas on scan Elevated in Graves disease Usually (65%) positive in Graves disease
For thyroid nodules	Fine-needle aspiration (FNA) biopsy ¹²³ I uptake and scan ^{99m} Tc scan Ultrasonography	Best diagnostic method for thyroid cancer Cancer is usually “cold”; less reliable than FNA biopsy Vascular versus avascular Useful to assist FNA biopsy. Useful in assessing the risk of malignancy (multinodular goiter or pure cysts are less likely to be malignant). Useful to monitor nodules and patients after thyroid surgery for carcinoma.

60 years. Thyroid hormone deficiency affects almost all body functions. The degree of severity ranges from mild and unrecognized hypothyroid states to striking myxedema. The fluid retention seen in myxedema is caused by the interstitial accumulation of hydrophilic mucopolysaccharides, which leads to lymphedema. Hyponatremia is the result of impaired renal tubular sodium reabsorption due to reductions in Na^+ - K^+ -ATPase.

Hypothyroidism may be due to failure or resection of the thyroid gland itself or deficiency of pituitary TSH (see Hypopituitarism, above). The condition must be distinguished from the functional hypothyroidism that occurs in severe nonthyroidal illness, which does not require treatment with thyroxine (see Euthyroid Sick Syndrome).

Maternal hypothyroidism during pregnancy results in offspring with IQ scores that are an average 7 points lower than those of euthyroid mothers.

Goiter may be present with thyroiditis, iodide deficiency, genetic thyroid enzyme defects, drug goitrogens (lithium, iodide, propylthiouracil or methimazole, phenylbutazone, sulfonamides, amiodarone, interferon- α , interferon- β , interleukin-2), food goitrogens in iodide-deficient areas (eg, turnips, cassavas) or, rarely, peripheral resistance to thyroid hormone or infiltrating diseases (eg, cancer, sarcoidosis). A hypothyroid phase occurs in subacute (de Quervain) viral thyroiditis following initial hyperthyroidism. Hashimoto thyroiditis is the most common cause of hypothyroidism (see Thyroiditis section).

Goiter is usually absent when hypothyroidism is due to destruction of the gland by surgery, radiation therapy (to the head, neck, chest, and shoulder region), or ^{131}I . Chemotherapy can reduce thyroid function, causing hypothyroidism. Sunitinib, a protein-tyrosine kinase inhibitor used to treat gastrointestinal stromal malignancies, causes transient primary hypothyroidism in about 50% of treated patients.

Amiodarone, because of its high iodine content, causes clinically significant hypothyroidism in about 15–20% of patients who receive it. Hypothyroidism occurs most often in patients with preexisting autoimmune thyroiditis and in patients who are not iodine-deficient. The T_4 level is normal or low, and the TSH is elevated, usually over 20 ng/dL. Another 17% of patients have milder elevations of TSH and are asymptomatic. Low-dose amiodarone is less likely to cause hypothyroidism. Cardiac patients with amiodarone-induced symptomatic hypothyroidism are treated with just enough thyroxine to relieve symptoms. Hypothyroidism usually resolves over several months if amiodarone is discontinued. Hypothyroidism may also develop in patients with a high iodine intake from other sources, especially if they have underlying lymphocytic thyroiditis.

Hepatitis C is associated with an increased risk of autoimmune thyroiditis, with 21% of affected patients having antithyroid antibodies and 13% having hypothyroidism. The risk of thyroid dysfunction is even higher when patients are treated with interferon. Interferon- α and interferon- β treatment can induce thyroid dysfunction (usually hypothyroidism, sometimes hyperthyroidism) in 6% of patients. Spontaneous resolution occurs in over 50% of cases once interferon is discontinued.

► Clinical Findings

A. Symptoms and Signs

1. Common manifestations—Mild hypothyroidism often escapes detection without screening (ie, serum TSH). Common symptoms of hypothyroidism include weight gain, fatigue, lethargy, depression, weakness, dyspnea on exertion, arthralgias or myalgias, muscle cramps, menorrhagia, constipation, dry skin, headache, paresthesias, carpal tunnel syndrome, cold intolerance, and Raynaud syndrome. Physical findings can include bradycardia; diastolic hypertension; thin, brittle nails; thinning of hair; peripheral edema; puffy face and eyelids; and skin pallor or yellowing (carotenemia). Delayed relaxation of deep tendon reflexes may be present. Patients often have a palpably enlarged thyroid (goiter) that arises due to elevated serum TSH levels or the underlying thyroid pathology, such as Hashimoto thyroiditis.

2. Less common manifestations—Less common symptoms of hypothyroidism include diminished appetite and weight loss, hoarseness, decreased sense of taste and smell, and diminished auditory acuity. Some patients may complain of dysphagia or neck discomfort. Although most menstruating women have menorrhagia, some women have scant menses or amenorrhea. Physical findings may include thinning of the outer halves of the eyebrows; thickening of the tongue; hard pitting edema; and effusions into the pleural and peritoneal cavities as well as into joints. Galactorrhea may also be present. Cardiac enlargement (“myxedema heart”) and pericardial effusions may occur. Psychosis (myxedema madness) can occur from severe hypothyroidism or from toxicity of other drugs whose metabolism is slowed in hypothyroidism. Hypothermia and stupor or myxedema coma, which is often associated with infection (especially pneumonia), may develop in patients with severe hypothyroidism. Pituitary enlargement due to hyperplasia of TSH-secreting cells, which is reversible following thyroid therapy, may be seen in long-standing hypothyroidism.

Some hypothyroid patients with Hashimoto thyroiditis have symptoms that are not due to hypothyroidism but rather to other autoimmune disease. Some autoimmune conditions that occur more commonly in patients with Hashimoto thyroiditis include Addison disease, hypoparathyroidism, diabetes mellitus, pernicious anemia, Sjögren syndrome, vitiligo, biliary cirrhosis, and celiac disease.

Celiac disease occurs in at least 5% of patients with hypothyroidism due to Hashimoto thyroiditis. Affected patients often have weight loss and gastrointestinal symptoms. However, many patients with celiac disease have minimal gastrointestinal symptoms but may have systemic manifestations such as fatigue, depression, osteoporosis or osteomalacia, iron deficiency anemia, short stature, delayed puberty, amenorrhea, or reduced fertility. Intestinal malabsorption may cause vitamin deficiencies with bruising due to vitamin K deficiency, hyperkeratosis due to vitamin A deficiency, bone pain due to vitamin D deficiency, or neuropathy and ataxia due to vitamin E or vitamin B_{12} deficiency.

B. Laboratory Findings

Hypothyroidism is a common disorder and thyroid function tests should be obtained for any patient with the non-specific symptoms or signs of hypothyroidism. The single best screening test for hypothyroidism is the serum TSH (Table 26–3). Serum TSH is increased with primary hypothyroidism but is low or normal with pituitary insufficiency. The FT₄ may be low or low-normal. Other laboratory abnormalities may often be seen: increased serum LDL cholesterol, triglycerides, lipoprotein (a), liver enzymes, and creatine kinase; increased serum PRL; and hyponatremia, hypoglycemia, and anemia (with normal or increased mean corpuscular volume). Semen analysis shows an increase in abnormal sperm morphology. In patients with autoimmune thyroiditis, titers of antibodies against thyroperoxidase and thyroglobulin are high; serum antinuclear antibodies (ANA) may be present and are not usually indicative of lupus.

The normal range for ultrasensitive TSH levels is generally stated to be 0.4–4.0 mU/L. However, the normal range of TSH varies with age such that newborns have a much higher normal range; children and elderly patients have a mildly higher normal range. Over 95% of normal adults have serum TSH concentrations under 3.0 mU/L. There is a high risk of finding antithyroid antibodies in patients with serum TSH in the upper range of normal, but most such patients are asymptomatic. TSH may be mildly elevated in some euthyroid individuals, especially elderly women (10% incidence). Such patients with normal FT₄ levels are considered to have “subclinical hypothyroidism,” but can have subtle manifestations of hypothyroidism (eg, fatigue, depression, hyperlipidemia) that may improve with thyroid hormone replacement. Patients who are completely asymptomatic with a mildly elevated serum TSH and normal serum FT₄ do not require levothyroxine replacement; in fact, mildly decreased thyroid function was associated with familial longevity in the Leiden Longevity Study. About 18% of patients with subclinical hypothyroidism later become definitely hypothyroid; many such patients have Hashimoto thyroiditis.

C. Imaging

Radiologic imaging is usually not necessary for patients with hypothyroidism. However, on CT or MRI, a goiter may be noted in the neck or in the mediastinum (retrosternal goiter). An enlarged thymus is frequently seen in the mediastinum in cases of autoimmune thyroiditis. In primary hypothyroidism with elevated serum TSH levels, MRI of the head will frequently show an enlargement of the pituitary gland from thyrotrophe hyperplasia; such enlargement can be mistaken for a pituitary tumor.

► Differential Diagnosis

Many clinical manifestations of hypothyroidism (see above) are common in the general population without thyroid illness. The differential diagnoses are the conditions and drugs that can cause aberrations in laboratory tests, resulting in a low serum T₄ or T₃ or high serum TSH in

Table 26–4. Factors that may cause aberrations in laboratory tests that may be mistaken for primary hypothyroidism.¹

Low Serum T ₄ or T ₃	High Serum TSH
Laboratory error	Laboratory error
Acute psychiatric problems	Autoimmune disease (assay interference)
Cirrhosis	Heterophile antibodies
Nephrotic syndrome	Anti-mouse antibodies
Familial thyroid-binding globulin deficiency	Strenuous exercise (acute)
Severe illness	Sleep deprivation (acute)
Drugs	Recovery from nonthyroidal illness (transient)
Androgens	Acute psychiatric admissions (14% transient)
Asparaginase	Elderly—especially women (10%, mild elevations)
Carbamazepine	
Chloral hydrate	
Corticosteroids	
Diclofenac (T ₃)	
Didanosine	
Fenclofenac	
5-Fluorouracil	
Halofenate	
Mitotane	
Naproxen (T ₃)	
Nicotinic acid	
Oxcarbazepine	
Phenobarbital	
Phenytoin (total T ₄ may be as low as 2 mcg/dL)	
Salicylates—large doses (T ₃ and T ₄)	
Sertraline	
Stavudine	
T ₃ therapy (T ₄)	

¹True primary hypothyroidism may coexist.

T₄, levothyroxine; T₃, triiodothyronine; TSH, thyroid-stimulating hormone.

the absence of hypothyroidism (Table 26–4). The pituitary is often quite enlarged in primary hypothyroidism, due to reversible hyperplasia of TSH-secreting cells; the concomitant hyperprolactinemia seen in hypothyroidism can lead to the mistaken diagnosis of a TSH-secreting or PRL-secreting pituitary adenoma.

Euthyroid sick syndrome should be considered in patients with abnormal thyroid function tests (eg, low serum T₄ and low levels of FT₄) without thyroid disease; conditions that can result in this syndrome include severe illness, caloric deprivation, or major surgery. Patients who have undergone major surgery may have accelerated peripheral metabolism of serum T₄ to reverse T₃ (rT₃). Furthermore, in most patients who are critically ill, there is a circulating inhibitor of thyroid hormone binding to serum thyroxine-binding proteins (TBPs). This causes the RT₃U to be misleadingly low, causing the computed FT₄I to be very low. The presence of a very low serum T₄ in severe nonthyroidal illness indicates a poor prognosis. Serum TSH tends to be suppressed in severe nonthyroidal illness, making the diagnosis of concurrent primary hypothyroidism quite difficult, although the presence of a goiter suggests the diagnosis.

The clinician must decide whether such severely ill patients (with a low serum T_4 but no elevated TSH) might have hypothyroidism due to pituitary insufficiency. Patients without symptoms of prior brain lesion or hypopituitarism are very unlikely to suddenly develop hypopituitarism during an unrelated illness. Patients with diabetes insipidus, hypopituitarism, or other signs of a central nervous system lesion may be given T_4 empirically.

True secondary hypothyroidism due to direct dopamine suppression of TSH-secreting cells may develop in patients receiving prolonged dopamine infusions.

Certain antiseizure medications cause low serum FT_4 levels by accelerating hepatic conversion of T_4 to T_3 ; serum TSH levels are normal.

► Complications

Cardiac complications may occur as a result of preexistent coronary artery disease and congestive heart failure, which may be exacerbated by levothyroxine therapy. Patients with severe hypothyroidism have an increased susceptibility to bacterial pneumonia. Megacolon has been described in long-standing hypothyroidism. Organic psychoses with paranoid delusions may occur (“myxedema madness”). Rarely, adrenal crisis may be precipitated by thyroid therapy. Hypothyroidism is a rare cause of infertility, which may respond to thyroid medication. Pregnancy in a woman with untreated hypothyroidism often results in miscarriage. Sellar enlargement and even well-defined TSH-secreting tumors may develop in untreated cases. These tumors decrease in size after replacement therapy is instituted.

Myxedema crisis refers to severe, life-threatening hypothyroidism. The manifestations of hypothyroidism are present and more severe. Affected patients have impaired cognition, ranging from confusion to somnolence to coma (myxedema coma). Convulsions and abnormal central nervous system signs may occur. Patients have severe hypothermia, hypoventilation, hyponatremia, hypoglycemia, and hypotension. Rhabdomyolysis and acute kidney injury may occur. Myxedema coma is most often seen in elderly women who have had a stroke or who have stopped taking their thyroxine medication. It is often induced by an underlying infection; cardiac, respiratory, or central nervous system illness; cold exposure; or drug use. The mortality rate from myxedema coma is high. Myxedematous patients are unusually sensitive to opioids and average doses may result in death. Patients with severe myxedema may have hyponatremia that is severe and refractory to treatment.

► Treatment

Before therapy with thyroid hormone is commenced, the hypothyroid patient requires at least a clinical assessment for adrenal insufficiency and angina, for which the patient would require evaluation and treatment.

A. Beginning Treatment for Hypothyroidism

Levothyroxine is the preferred preparation for treating hypothyroid patients. However, patients (as a group) receiving levothyroxine replacement do not have the same sense of well-being as their peers. In response, some clinicians

prescribe mixed T_4/T_3 preparations such as Armour thyroid, but levothyroxine alone renders patients clinically euthyroid as long as it is given in sufficient doses (see below).

Otherwise healthy young and middle-age adults with hypothyroidism may be treated initially with levothyroxine in doses of 25–75 mcg orally daily. The lower doses are used for very mild hypothyroidism, while higher doses are given for more symptomatic hypothyroidism. Women who are pregnant with significant hypothyroidism may begin therapy with levothyroxine at higher doses of 100–150 mcg orally daily. The levothyroxine dosage may be increased according to clinical response and serum TSH, initially trying to keep the serum TSH level between 0.4 mU/L and 2.0 mU/L. The levothyroxine dose required to render patients clinically euthyroid varies considerably, with higher doses required during pregnancy and with certain medications (see below). Since food interferes slightly with the absorption of levothyroxine, it is advisable to take levothyroxine with water in the morning after an overnight fast. The selected time should become a regular daily habit for the patient. After beginning daily administration, significant increases in serum T_4 levels are seen within 1–2 weeks, and near-peak levels are seen within 3–4 weeks.

Patients with coronary disease or those who are over age 60 years are treated with smaller initial doses of levothyroxine, 25–50 mcg orally daily; higher initial doses may be used if such patients are severely hypothyroid. The dose can be increased by 25 mcg every 1–3 weeks until the patient is euthyroid. Patients with hypothyroidism and known ischemic heart disease may begin thyroxine therapy following restoration of coronary perfusion by coronary artery angioplasty or bypass.

Myxedema crisis requires larger initial doses of levothyroxine intravenously, since myxedema itself can interfere with levothyroxine intestinal absorption. Levothyroxine sodium 400 mcg is given intravenously as a loading dose, followed by 50–100 mcg intravenously daily; the lower dose is given to patients with suspected coronary insufficiency. In patients with myxedema coma, liothyronine (T_3 , Triostat) can be given intravenously in doses of 5–10 mcg every 8 hours for the first 48 hours. The hypothermic patient is warmed only with blankets, since faster warming can precipitate cardiovascular collapse. Patients with hypercapnia require intubation and assisted mechanical ventilation. Infections must be detected and treated aggressively. Patients in whom concomitant adrenal insufficiency is suspected are treated with hydrocortisone, 100 mg intravenously, followed by 25–50 mcg every 8 hours.

B. Monitoring & Optimizing Treatment of Hypothyroidism

Every hypothyroid patient requires regular clinical assessments that must include interim histories and physical examinations. Clinical judgment is critical to determine the optimal levothyroxine dose for each patient. Laboratory assays supplement clinical judgment. An elevated serum TSH usually indicates the need for a higher dose of levothyroxine (see below). Unfortunately, normal serum TSH and FT_4 levels do not accurately determine that the patient is euthyroid (see below). The patient should be prescribed sufficient levothyroxine to restore a clinically euthyroid state,

while maintaining the serum T_3 within the reference range. For most patients with hypothyroidism, a stable maintenance dose of levothyroxine can usually be found.

Levothyroxine doses may need to be titrated upward after patients commence taking medications that increase the hepatic metabolism of levothyroxine (eg, carbamazepine, phenobarbital, primidone, phenytoin, rifabutin, rifampin, sunitinib, and imatinib [Gleevec]). Amiodarone can cause an increase or decrease in thyroxine dose requirements, making it necessary to closely monitor serum TSH and adjust the thyroxine dosage accordingly in these patients. Malabsorption of thyroxine can be caused by coadministration of binding substances, such as iron preparations (including iron found in multivitamins), fiber, raloxifene, sucralfate, aluminum hydroxide antacids, sevelamer, orlistat, calcium and magnesium supplements, and soy milk or soy protein supplements. Bile acid-binding resins, such as cholestyramine and colestevam, can bind T_4 and impair its absorption even when administered 5 hours before the T_4 . Proton pump inhibitors reduce gastric acidity, which interferes slightly with the absorption of levothyroxine. Gastrointestinal disorders can interfere with thyroxine absorption, including celiac disease, inflammatory bowel disease, lactose intolerance, *Helicobacter pylori* gastritis, and atrophic gastritis.

Different thyroxine preparations vary in their bioavailability by up to 14%. Such differences in the bioavailability of different T_4 formulations may have a subtle but significant clinical impact. It is therefore recommended that patients always continue to take the same brand name of thyroxine or the same manufacturer's generic thyroxine. There is no standardized optimal dose of levothyroxine, so each patient's dose must be based on careful clinical assessment. Although serum TSH levels can be helpful in determining optimal dosing, it is important to consider clinical response and to not rely entirely on serum TSH levels to determine the patient's optimal thyroxine dosage.

Women with hypothyroidism typically require increased doses of T_4 during therapy with oral estrogen as well as during pregnancy (see below). Conversely, T_4 dosage requirements for women often decrease with delivery, cessation of oral estrogen, and menopause.

1. During pregnancy—Administering adequate levothyroxine to a hypothyroid woman is critical. The fetus is at least partially dependent on maternal T_4 for central nervous system development—particularly in the second trimester. It is therefore important to carefully monitor hypothyroid women with serum TSH (FT_4I or FT_4 concentrations in hypopituitarism) determinations every 4–6 weeks and to increase T_4 replacement progressively as required (see Chapter 19).

There is considerable individual variation in the requirement for additional T_4 replacement during pregnancy. An increase in levothyroxine requirement has been noted as early as the fifth week of pregnancy. Therefore, for women receiving replacement thyroxine, it is prudent to increase levothyroxine dosages by approximately 30% as soon as pregnancy is confirmed. By mid pregnancy, women require an average of 47% increase in their levothyroxine dosage.

The increased T_4 dosage requirements during pregnancy are believed to be due to several factors: (1) Rising estrogen

levels during pregnancy increase thyroxine binding globulin (TBG) serum concentrations, reducing FT_4 levels. (2) Placental deiodinase promotes the turnover of T_4 . (3) Supplemental iron and prenatal multivitamins containing iron can bind to oral T_4 and reduce its intestinal absorption. Similarly, supplemental calcium can also reduce T_4 absorption. Therefore, it is important that patients take their T_4 replacement at least 4 hours before or after such dietary supplements. Postpartum, T_4 replacement requirements ordinarily return to prepregnancy levels.

Serum TSH levels normally drop while FT_4I rises during the first trimester of pregnancy. This probably results from high levels of hCG (with structural homology to TSH) that stimulates thyroid hormone production. Most women with a low serum TSH in the first trimester are euthyroid. Serum FT_4I is helpful in evaluating the thyroid status of pregnant women, particularly in the first trimester. Following delivery, levothyroxine dose requirements decline.

2. Elevated serum TSH levels—This usually indicates underreplacement with levothyroxine. However, before increasing the T_4 dosage, it is important to confirm that the patient is indeed taking the medication as directed and does not have angina. It is also important to consider the following: A high TSH in a patient receiving standard replacement doses of T_4 may indicate malabsorption of levothyroxine due to concurrent administration with binding substances (see above) or with food (instead of fasting). Malabsorption of T_4 can also occur in short bowel syndrome; therapy with medium chain triglyceride oil may improve absorption. Impaired absorption of T_4 can also be caused by diarrhea of any cause or malabsorption due to concurrent celiac disease (sprue), regional enteritis, liver disease, or pancreatic exocrine insufficiency. Serum TSH may be elevated transiently in acute psychiatric illness and during recovery from nonthyroidal illness. Autoimmune disease can cause false elevations of TSH by interfering with the assay. A high TSH can also be caused by thyrotropin-secreting pituitary tumors. TSH may be increased by phenothiazines and atypical antipsychotics.

3. Normal serum TSH levels—Patients are treated with sufficient levothyroxine to achieve normal serum TSH levels of 0.4–2.0 mU/L. Patients who continue to feel hypothyroid despite a normal serum TSH may have a suboptimal serum T_3 ; they may respond well to higher replacement doses of levothyroxine.

4. Low or suppressed serum TSH levels—Serum TSH levels (using a sensitive assay) that are below the reference range (0.4–4.0 mU/L) are considered “low” (0.04–0.4 mU/L) or “suppressed” (≤ 0.03 mU/L). It has generally been assumed that since TSH is a sensitive test for hyperthyroidism in Graves disease, a low serum TSH in patients taking levothyroxine reliably indicates overreplacement; that assumption is proving incorrect. Certainly, if a patient taking levothyroxine has a suppressed serum TSH and manifestations of hyperthyroidism, the dosage of levothyroxine must be reduced. However, many patients with low serum TSH levels exhibit no symptoms of hyperthyroidism. For such patients, it is important to determine whether hypopituitarism or severe nonthyroidal illness is present, which can result

in low serum TSH levels without hyperthyroidism. TSH can also be reduced by certain medications, such as nonsteroidal anti-inflammatory drugs; opioids; nifedipine; verapamil; and high-dose, short-term administration of corticosteroids. Absent such conditions, a clinically euthyroid patient with a suppressed serum TSH should be given a lower dosage of levothyroxine. Patients who exhibit hypothyroid symptoms on the reduced dosage of levothyroxine may have the higher dose resumed.

Some hypothyroid patients receiving levothyroxine have hypothyroid-type symptoms, particularly persistent fatigue or weight gain, despite having low serum TSH levels. Such patients require careful assessment for concurrent illnesses such as adrenal insufficiency, hypogonadism, anemia, celiac disease, or depression. If such conditions are not present or are treated and hypothyroid-type symptoms persist despite low-normal or low TSH levels, a serum T_3 level (FT_3 in pregnancy and women receiving oral estrogens) is often helpful. If the serum T_3 level is low or low normal, the patient may benefit from an increase in levothyroxine dosage; if a definite clinical benefit is achieved, the higher dose is continued. Patients with a low serum TSH (0.04–0.4 mU/L) on replacement levothyroxine do not have any long-term increased risk of cardiovascular disease, dysrhythmias, or fractures. However, patients with suppressed serum TSH (≤ 0.03 mU/L) do have an increased risk of such side effects and long-term monitoring for atrial arrhythmias and osteoporosis is recommended.

► Prognosis

Hypothyroidism caused by interferon- α resolves within 17 months of stopping the drug in 50% of patients. Patients with mild hypothyroidism caused by Hashimoto thyroiditis have a remission rate of 11%. With early treatment of hypothyroidism, striking transformations take place both in appearance and mental function. Return to a normal state is usually the rule, but relapses will occur if treatment is interrupted. On the whole, response to thyroid treatment is most satisfactory. However, untreated hypothyroid patients with myxedema crisis have a mortality rate approaching 100%. Even with optimal treatment, patients with myxedema crisis have a mortality rate of 20–50%.

HYPERTHYROIDISM (THYROTOXICOSIS)

ESSENTIALS OF DIAGNOSIS

- Sweating, weight loss or gain, anxiety, palpitations, loose stools, heat intolerance, irritability, fatigue, weakness, menstrual irregularity.
- Tachycardia; warm, moist skin; stare; tremor.
- In Graves disease: goiter (often with bruit); ophthalmopathy.
- Suppressed TSH in primary hyperthyroidism; increased T_4 , FT_4 , T_3 , FT_3 .

► General Considerations

The term “thyrotoxicosis” refers to the clinical manifestations associated with serum levels of T_4 or T_3 that are excessive for the individual (hyperthyroidism). Serum TSH levels are suppressed in primary hyperthyroidism. However, certain drugs and conditions can affect laboratory tests and lead to the erroneous diagnosis of hyperthyroidism in euthyroid individuals (Table 26–5). The causes of hyperthyroidism are many and diverse, as described below.

A. Graves Disease

Graves disease (known as Basedow disease in Europe) is the most common cause of thyrotoxicosis. It is an autoimmune disorder affecting the thyroid gland, characterized by an increase in synthesis and release of thyroid hormones. Graves disease is much more common in women than in men (8:1), and its onset is usually between the ages of 20 and 40 years. It may be accompanied by infiltrative ophthalmopathy (Graves exophthalmos) and, less commonly, by infiltrative dermopathy (pretibial myxedema). The thymus gland is typically enlarged and serum ANA levels are usually elevated, reflecting the underlying autoimmunity. Graves disease has a familial tendency, and many patients have a family history of Graves disease or hypothyroidism from Hashimoto thyroiditis. Histocompatibility studies have shown an association with group HLA-B8 and HLA-DR3. The pathogenesis of the hyperthyroidism of Graves disease involves the formation of autoantibodies that bind to the TSH receptor in thyroid cell membranes and stimulate the gland to hyperfunction. Such antibodies are called thyroid-stimulating immunoglobulins (TSI) or TSH receptor antibodies (TSHrAb).

Dietary iodine supplementation can trigger Graves disease. An increased incidence of Graves disease occurs in countries that have embarked on national programs to fortify commercial salt with potassium iodide; the increase in Graves disease lasts about 4 years. Similarly, patients being treated with potassium iodide or amiodarone (which contains iodine) have an increased risk of developing Graves disease.

Patients with Graves disease have an increased risk of other systemic autoimmune disorders. Affected patients are at increased risk for Sjögren syndrome, pernicious anemia,

Laboratory error	Laboratory error
Collecting serum in vial with gel barrier for T ₃	Autonomous thyroid or thyroid nodule
Acute psychiatric problems (30%)	Acute corticosteroid administration
Acute medical illness (eg, acute intermittent porphyria)	Elderly euthyroid
AIDS (increased thyroid-binding globulin)	Nonthyroidal illness (severe)
Autoimmunity	Pregnancy (especially with morning sickness)
Hepatitis: acute or chronic active	hCG-secreting trophoblastic tumors
Primary biliary cirrhosis	Drugs
Pregnancy (especially with morning sickness)	Thyroid hormone
Hyperemesis gravidarum	Amphetamines
Familial thyroid-binding abnormalities	Dopamine
Familial generalized resistance to thyroid (Refetoff syndrome)	Dopamine agonists
Drugs	Calcium channel blockers (nifedipine, verapamil)
Amiodarone	
Amphetamines	
Clofibrate	
Estrogens (oral)	
Heparin (dialysis method)	
Heroin	
Thyroid hormone therapy	
Methadone	
Perphenazine	
Tamoxifen	

¹True clinical hyperthyroidism may coexist.

hCG, human chorionic gonadotropin; NSAIDs, nonsteroidal anti-inflammatory drugs; T₄, levothyroxine; T₃, triiodothyronine; TSH, thyroid-stimulating hormone.

Addison disease, alopecia areata, vitiligo, celiac disease, autoimmune diabetes mellitus type 1, hypoparathyroidism, myasthenia gravis, and cardiomyopathy.

B. Toxic Multinodular Goiter and Thyroid Adenomas

Autonomous toxic adenomas of the thyroid may be single (Plummer disease) or multiple (toxic multinodular goiter).

Jod-Basedow disease, or iodine-induced hyperthyroidism, may occur in patients with multinodular goiters after intake of large amounts of iodine in the diet or in the form of radiographic contrast materials or drugs, especially amiodarone. This condition is not associated with infiltrative ophthalmopathy or dermopathy.

C. Subacute (de Quervain) Thyroiditis

Subacute thyroiditis typically presents with a moderately enlarged, tender thyroid, and hyperthyroidism. It is thought to be due to a viral infection. If the gland is nontender, the disorder is called “silent thyroiditis.” Hyperthyroidism is

followed by hypothyroidism. Patients taking lithium may rarely experience thyrotoxicosis due to silent thyroiditis. Symptoms mimic a manic episode such that the diagnosis is often missed.

D. Thyrotoxicosis Factitia

Thyrotoxicosis factitia is due to ingestion of excessive amounts of exogenous thyroid hormone. Isolated epidemics of thyrotoxicosis have been caused by consumption of ground beef contaminated with bovine thyroid gland.

E. Struma Ovarii

Thyroid tissue is contained in about 3% of ovarian dermoid tumors and teratomas. This thyroid tissue may autonomously secrete thyroid hormone due to a toxic nodule or in concert with the woman's thyroid gland in Graves disease or toxic multinodular goiter.

F. Pituitary Tumor

TSH hypersecretion by the pituitary may be caused by a tumor or thyrotrophe cell hyperplasia and is a rare cause of hyperthyroidism. Serum TSH is elevated or normal in the presence of true thyrotoxicosis. Pituitary hyperplasia may be detected on MRI scan as pituitary enlargement without a discrete adenoma being visible. This condition appears to be due to a diminished feedback effect of T₄ upon the pituitary. Some cases are familial. Prolonged untreated hypothyroidism causes pituitary enlargement due to thyrotrophe hyperplasia; thyrotrophe tumors are rare.

G. Thyroiditis

Hashimoto thyroiditis may cause transient hyperthyroidism during the initial destructive phase. This is also seen in some patients receiving interferon- α , interferon- β , and interleukin-2. Postpartum thyroiditis refers to Hashimoto thyroiditis that occurs in the first 6 months after delivery. It is common, occurring postpartum in 5–10% of women in the United States. Hyperthyroidism results from the release of stored thyroid hormone following damage to the thyroid. Thyroiditis and hyperthyroidism can also develop in patients receiving sunitinib chemotherapy.

H. Pregnancy and Trophoblastic Tumors

The prevalence of hyperthyroidism in pregnancy—most commonly due to Graves disease—is about 0.2%. Struma ovarii is rare. Newborns have an increased risk of intrauterine growth retardation, prematurity, and transient thyrotoxicosis from transplacental transfer of thyrotropin receptor antibody (TRAb).

Although hCG generally has a low affinity for the thyroid's TSH receptors, very high serum levels of hCG may cause sufficient receptor activation to cause thyrotoxicosis. Mild gestational hyperthyroidism may occur during the first 4 months of pregnancy, when hCG levels are very high. Pregnant women are more likely to have thyrotoxicosis and hyperemesis gravidarum if they have high serum levels of asialo-hCG, a subfraction of hCG with greater affinity for TSH receptors.

High levels of hCG can also cause thyrotoxicosis in some cases of molar pregnancy, choriocarcinoma, and testicular malignancies.

I. Thyroid Carcinoma

Metastatic functioning thyroid carcinoma is a rare cause of thyrotoxicosis. Hyperthyroidism can be induced by recombinant human thyroid-stimulating hormone (rhTSH) that is given prior to radioiodine therapy or scanning. (See Thyroid Cancer section.)

J. Iodine-Induced Hyperthyroidism

Iodine-induced hyperthyroidism is also known as Jod-Basedow disease. The recommended iodine intake for nonpregnant adults is 150 mcg/d. Higher iodine intake can precipitate hyperthyroidism, particularly in patients with nodular goiters, autonomous thyroid nodules, or asymptomatic Graves disease. Iodine-induced hyperthyroidism also occurs in patients with no detectable underlying thyroid disorder. Common sources of excess iodine include intravenous iodinated radiocontrast dye, certain foods (eg, kelp, nori), topical iodinated antiseptics (eg, povidine iodine), and medications (eg, potassium iodide or amiodarone). Intravenous iodinated radiocontrast dye can also precipitate thyrotoxicosis by inducing a destructive subacute thyroiditis that may be painful and is similar to type 2 amiodarone-induced thyrotoxicosis.

K. Amiodarone-Induced Thyrotoxicosis

Amiodarone is a widely used antiarrhythmic drug. The half-life of amiodarone and its metabolites is about 100 days. By weight, amiodarone is 37% iodine and thyroid dysfunction develops in about 15–20% of patients taking amiodarone. In the United States, amiodarone-induced thyrotoxicosis develops in about 3% of patients taking the drug; the incidence of amiodarone-induced thyrotoxicosis is higher in Europe and in iodine-deficient geographic areas (20%). Hyperthyroidism can occur 4 months to 3 years after initiation of amiodarone and may develop several months after amiodarone has been discontinued.

Type 1 amiodarone-induced thyrotoxicosis is caused by active elaboration of excessive thyroid hormone and may occur by either of two mechanisms: (1) Free iodine may cause toxic multinodular goiter in iodine-deficient patients with preexisting autonomous thyroid nodules. Thyroid radioactive iodine (RAI) uptake ranges from low to high. (2) Excessive free iodine can trigger an immunologic attack on the thyroid; this may cause Graves disease, commonly with diffuse thyroid enlargement and antithyroid peroxidase antibodies (70%). Color flow Doppler sonography shows increased vascularity and blood flow velocity. Thyroidal radioiodine uptake may be low, normal, or increased.

Type 2 amiodarone-induced thyrotoxicosis is caused by destructive thyroiditis, which releases stored thyroid hormone from damaged cells; hyperthyroidism can last 1–3 months and may be followed by hypothyroidism. On ultrasound, the thyroid gland is normal in size, and on color flow Doppler sonography there is no increase in vascularity. Thyroidal radioiodine uptake is usually very low (< 3%).

► Clinical Findings

A. Symptoms and Signs

Thyrotoxicosis due to any cause produces many different manifestations of variable intensity among different individuals. Patients may complain of nervousness, restlessness, heat intolerance, increased sweating, pruritus, fatigue, weakness, muscle cramps, frequent bowel movements, or weight change (usually loss). There may be palpitations or angina pectoris. Women frequently report menstrual irregularities.

Signs of thyrotoxicosis also include fine resting finger tremors, moist warm skin, fever, hyperreflexia, fine hair, and onycholysis. Chronic thyrotoxicosis may cause osteoporosis. Clubbing and swelling of the fingers (acropachy) develop in a small number of patients.

In patients with Graves disease, physical examination usually reveals a diffusely enlarged thyroid, frequently asymmetric, often with a bruit. However, some patients have no palpable thyroid enlargement. The thyroid gland in subacute thyroiditis is usually moderately enlarged and tender. In patients with toxic multinodular goiter, the thyroid usually has palpable nodules.

Cardiopulmonary manifestations of thyrotoxicosis commonly include a forceful heartbeat, premature atrial contractions, and sinus tachycardia. Patients often have exertional dyspnea. Atrial fibrillation or atrial tachycardia occurs in about 8% of patients with thyrotoxicosis, more commonly in men, the elderly, and those with ischemic or valvular heart disease. The ventricular response from the atrial fibrillation may be difficult to control. Thyrotoxicosis itself can cause a thyrotoxic cardiomyopathy, and the onset of atrial fibrillation can precipitate congestive heart failure. Echocardiogram reveals pulmonary hypertension in 49% of patients with hyperthyroidism; of these, 71% have pulmonary artery hypertension while 29% have pulmonary venous hypertension. Hemodynamic abnormalities and pulmonary hypertension are reversible with restoration of euthyroidism.

Graves eye manifestations, which can occur with hyperthyroidism of any etiology, include upper eyelid retraction (Dalrymple sign), lid lag with downward gaze (von Graefe sign), and a staring appearance (Kocher sign). **Ophthalmopathy** is clinically apparent in 20–40% of patients with Graves disease and type 1 amiodarone-induced thyrotoxicosis, but in no other conditions causing hyperthyroidism. It usually consists of conjunctival edema (chemosis), conjunctivitis, and mild exophthalmos (proptosis). About 5–10% of patients experience more severe exophthalmos, with the eye being pushed forward by increased retro-orbital fat and eye muscles that have been thickened by lymphocytic infiltration. Such patients can experience diplopia from extraocular muscle entrapment. There may be weakness of upward gaze (Stellwag sign). The optic nerve may be compressed in severe cases, causing progressive loss of color vision, visual fields, and visual acuity. Corneal drying may occur with inadequate lid closure. Eye changes may sometimes be asymmetric or unilateral. The severity of the eye disease is not closely correlated with the severity of the thyrotoxicosis. Some patients with Graves ophthalmopathy are clinically euthyroid.

Exophthalmometry should be performed on all patients with Graves disease to document their degree of exophthalmos and detect progression of orbitopathy. The protrusion of the eye beyond the orbital rim is measured with a prism instrument (Hertel exophthalmometer). Maximum normal eye protrusion varies between kindreds and races, being about 22 mm for blacks, 20 mm for whites, and 18 mm for Asians.

The differential diagnosis for Graves ophthalmopathy includes diplopia caused by coexistent **ocular myasthenia gravis**, which is more common in Graves disease and is usually mild, often with selective eye involvement. Acetylcholinesterase receptor antibody (AChR Ab) levels are elevated in only 36% of such patients, and a thymoma is present in 9%. Orbital lymphoma can also masquerade as Graves ophthalmopathy.

Graves dermopathy (pretibial myxedema) occurs in about 3% of patients with Graves disease, usually in the pretibial region. It is more common in patients with high levels of serum thyroid-stimulating immunoglobulin and in those with severe Graves ophthalmopathy. Glycosaminoglycans accumulation and lymphoid infiltration occur in affected skin, which becomes erythematous with a thickened, rough texture. Elephantiasis of the legs is a rare complication.

Thyroid acropachy is an extreme and unusual manifestation of Graves disease. It presents with digital clubbing, swelling of fingers and toes, and a periosteal reaction of extremity bones. It is ordinarily associated with ophthalmopathy and thyroid dermopathy. Most patients are smokers. The presence of thyroid acropachy is an indication of the severity of the autoimmunity; most patients have high serum titers of thyroid-stimulating immunoglobulin. Patients with thyroid acropachy are at greater risk for having concurrent Graves dermopathy and severe ophthalmopathy. However, acropachy itself does not usually cause clinical complaints.

Tetany is a rare presenting feature. In hyperthyroidism, the renal excretion of magnesium is increased and hypomagnesemia is common. Severe magnesium depletion causes hypoparathyroidism that can result in hypocalcemia.

Hyperthyroidism during pregnancy shares many of the features of normal pregnancy: tachycardia, warm skin, heat intolerance, increased sweating, and a palpable thyroid. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease. However, there is an increased risk of thyroid storm, preeclampsia–eclampsia, congestive heart failure, premature delivery, and abruptio placentae. TSI (or TSHrAb) crosses the placenta; if maternal serum TSI (or TSHrAb) levels reach > 500% in the third trimester, the risk of transient neonatal Graves disease in the newborn is increased.

Hypokalemic periodic paralysis occurs in about 15% of Asian or Native American men with thyrotoxicosis. It usually presents abruptly with symmetric flaccid paralysis (and few thyrotoxic symptoms), often after intravenous dextrose, oral carbohydrate, or vigorous exercise. Attacks last 7–72 hours.

B. Laboratory Findings

Serum FT_4 , T_3 , FT_3 , T_4 , thyroid resin uptake, and FT_4 index are all usually increased. Sometimes the FT_4 level may be

normal but with an elevated serum T_3 (T_3 toxicosis). Serum T_3 can be misleadingly elevated when blood is collected in tubes using a gel barrier, which causes certain immunoassays (eg, Immulite but not AxSYM analyzers) to report serum total T_3 levels that are falsely elevated in 24% of normal patients. Serum T_4 or T_3 can be elevated in other nonthyroidal conditions (Table 26–5).

Serum TSH is suppressed in hyperthyroidism, except in the very rare cases of pituitary inappropriate secretion of thyrotropin. Serum TSH may be misleadingly low in other nonthyroidal conditions (Table 26–5). The term “**subclinical hyperthyroidism**” is used to describe asymptomatic individuals with a low serum TSH but normal serum levels of FT_4 and T_3 ; progression to symptomatic thyrotoxicosis occurs at a rate of 1–2% per year in patients without a goiter and at a rate of 5% per year in patients with a multinodular goiter.

Hyperthyroidism can cause other laboratory abnormalities, including hypercalcemia, increased alkaline phosphatase, anemia, and decreased granulocytes. Hypokalemia and hypophosphatemia occur in thyrotoxic periodic paralysis.

Problems of diagnosis occur in patients with acute psychiatric disorders; about 30% of these patients have elevated serum T_4 levels without clinical thyrotoxicosis. The TSH is not usually suppressed, distinguishing psychiatric disorder from true hyperthyroidism. T_4 levels return to normal gradually.

In **Graves disease**, serum TSI (or TSHrAb) is usually detectable (65%). Antithyroglobulin or antithyroperoxidase antibodies are usually elevated but are nonspecific. Serum ANA and anti-double-stranded DNA antibodies are also usually elevated without any evidence of lupus erythematosus or other collagen-vascular disease.

With **subacute thyroiditis**, patients often have an increased erythrocyte sedimentation rate (ESR) but antithyroid antibodies are usually not present in the plasma, and tests for TSI (or TSHrAb) are negative. Patients with **iodine-induced hyperthyroidism** also have undetectable serum TSI (or TSHrAb), an absence of serum antithyroperoxidase antibodies, and an elevated urinary iodine concentration. In **thyrotoxicosis factitia**, serum thyroglobulin levels are low, distinguishing it from other causes of hyperthyroidism.

With **hyperthyroidism during pregnancy**, women have an elevated FT_4 while the TSH is suppressed. However, apparent lack of full TSH suppression can be seen due to misidentification of hCG as TSH in certain assays. Although the total T_4 is elevated in most pregnant women, values over 20 mcg/dL are encountered only in hyperthyroidism. The T_3 resin uptake, which is low in normal pregnancy because of high TBG concentration, is normal or high in thyrotoxic persons. Pregnancy can have a beneficial effect on the thyrotoxicosis of Graves disease, with decreasing antibody titers and decreasing FT_4 levels as the pregnancy advances.

Since high levels of T_4 and FT_4 are normally seen in patients taking **amiodarone**, suppressed TSH (sensitive assay) must be present along with a greatly elevated T_4 (> 20 mcg/dL) or T_3 (> 200 ng/dL) in order to diagnose hyperthyroidism. (**Note:** Hypothyroidism occurs in an additional 6% of patients receiving amiodarone after

2–39 weeks of therapy.) In **type 1 amiodarone-induced thyrotoxicosis**, the presence of proptosis, thyroid-stimulating immunoglobulin is diagnostic. In **type 2 amiodarone-induced thyrotoxicosis**, serum levels of interleukin-6 (IL-6) are usually quite elevated.

C. Imaging

RAI should never be administered to pregnant women. In others, RAI scanning and uptake may be helpful to determine the cause for hyperthyroidism. RAI uptake and scanning is not necessary for patients with obvious Graves disease who have elevated serum thyroid-stimulating immunoglobulin or associated Graves ophthalmopathy. Women with hyperthyroidism due to Graves disease should ideally have the RAI scan extended to include the pelvis in order to screen for concomitant struma ovarii (rare). A high RAI uptake is seen in **Graves disease** and **toxic nodular goiter**. Patients with **type 1 amiodarone-induced thyrotoxicosis** have RAI uptake that is usually detectable but typically below the normal range, although some patients may have elevated RAI uptake. A low RAI uptake is characteristic of **subacute thyroiditis** and iodine-induced hyperthyroidism. Low RAI uptake is also seen with interleukin-2 therapy and after neck surgery for hyperparathyroidism. In **type 2 amiodarone-induced thyrotoxicosis**, thyroid RAI uptake is usually below 3%.

Thyroid ultrasound can be helpful in patients with hyperthyroidism, particularly in patients with palpable thyroid nodules. **Color flow Doppler sonography** is helpful to distinguish type 1 amiodarone-induced thyrotoxicosis, with its increased blood flow velocity and vascularity, from type 2 amiodarone-induced thyrotoxicosis (reduced vascularity).

MRI and CT scanning of the orbits are the imaging methods of choice to visualize Graves ophthalmopathy affecting the extraocular muscles. Imaging is required only in severe or unilateral cases or in euthyroid exophthalmos that must be distinguished from orbital pseudotumor, tumors, and other lesions.

► Differential Diagnosis

True thyrotoxicosis must be distinguished from those conditions that elevate serum T_4 and T_3 or suppress serum TSH without affecting clinical status (see Table 26–5).

Some states of hypermetabolism without thyrotoxicosis—notably severe anemia, leukemia, polycythemia, and cancer—rarely cause confusion. Pheochromocytoma is often associated with hypermetabolism, tachycardia, weight loss, and profuse sweating. Acromegaly may also produce tachycardia, sweating, and thyroid enlargement. Appropriate laboratory tests will easily distinguish these entities.

Cardiac disease (eg, atrial fibrillation, angina) refractory to treatment suggests the possibility of underlying (“apathetic”) hyperthyroidism. Other causes of ophthalmoplegia (eg, myasthenia gravis) and exophthalmos (eg, orbital tumor, pseudotumor) must be considered. Thyrotoxicosis must also be considered in the differential diagnosis of muscle weakness and osteoporosis. Diabetes mellitus and Addison disease may coexist with thyrotoxicosis.

► Complications

Hypercalcemia, osteoporosis, and nephrocalcinosis may occur. Decreased libido, erectile dysfunction, diminished sperm motility, and gynecomastia may be noted in men with hyperthyroidism. Other complications include cardiac arrhythmias and heart failure, thyroid crisis, ophthalmopathy, dermatopathy, and thyrotoxic hypokalemic periodic paralysis (see below).

► Treatment

A. Graves Disease

The treatment of Graves disease involves a choice of methods rather than a method of choice.

1. Propranolol—Propranolol is generally used for symptomatic relief until the hyperthyroidism is resolved. It effectively relieves the tachycardia, tremor, diaphoresis, and anxiety that occur with hyperthyroidism due to any cause. It is the initial treatment of choice for thyroid storm. The periodic paralysis seen in association with thyrotoxicosis is also effectively treated with β -blockade. It has no effect on thyroid hormone secretion. Treatment is usually begun with propranolol ER 60 mg orally once or twice daily, with dosage increases every 2–3 days to a maximum daily dose of 320 mg. Propranolol ER is initially given every 12 hours for patients with severe hyperthyroidism, due to accelerated metabolism of the propranolol; it may be given once daily as hyperthyroidism improves.

2. Thiourea drugs—Methimazole or propylthiouracil is generally used for young adults or patients with mild thyrotoxicosis, small goiters, or fear of isotopes. Carbimazole is another thiourea that is converted to methimazole in vivo and is available outside the United States. Elderly patients usually respond particularly well. These drugs are also useful for preparing hyperthyroid patients for surgery and elderly patients for RAI treatment. The drugs do not permanently damage the thyroid and are associated with a lower chance of posttreatment hypothyroidism (compared with RAI or surgery). When thiourea therapy is discontinued, there is a high recurrence rate for hyperthyroidism (about 50%). A better likelihood of long-term remission is seen in patients with small goiters or mild hyperthyroidism and those requiring small doses of thiourea. Patients whose thyroperoxidase and thyroglobulin antibodies remain high after 2 years of therapy have been reported to have only a 10% rate of relapse. Thiourea therapy may be continued long-term for patients who are tolerating it well.

Agranulocytosis occurs in about 0.3% of patients taking methimazole and about 0.4% of patients taking propylthiouracil. Agranulocytosis usually occurs in the first 60 days of therapy, and it develops in a few patients after 5 months of therapy. There is a genetic tendency to develop agranulocytosis with thiourea therapy; if a close relative has had this adverse reaction, other therapies should be considered for the patient. Patients are warned that if a sore throat or febrile illness develops, they should seek medical attention and have a WBC determined immediately. The agranulocytosis is generally reversible; recovery is not

improved by filgrastim (granulocyte colony-stimulating factor [G-CSF]). Periodic surveillance of the WBC during treatment has been advocated, but the onset of agranulocytosis is generally abrupt.

Other side effects common to thiourea drugs include pruritus, allergic dermatitis, nausea, and dyspepsia. Antihistamines may control mild pruritus without discontinuation of the drug. Since the two thiourea drugs are similar, patients who have had a major allergic reaction from one should not be given the other.

Primary hypothyroidism may occur. The patient may become clinically hypothyroid for 2 weeks or more before TSH levels rise, having been suppressed by the preceding hyperthyroidism. Therefore, the patient's changing thyroid status is best monitored clinically and with serum levels of FT₄. Rapid growth of the goiter usually occurs if prolonged hypothyroidism is allowed to develop; the goiter may sometimes become massive but usually regresses rapidly with reduction or cessation of thiourea therapy or with thyroid hormone replacement.

A. METHIMAZOLE—Methimazole is generally preferred over propylthiouracil since methimazole is more convenient to use and is less likely to cause fulminant hepatic necrosis. Methimazole therapy is also less likely to cause ¹³¹I treatment failure. Rare complications peculiar to methimazole include serum sickness, cholestatic jaundice, loss of taste, alopecia, nephrotic syndrome, and hypoglycemia. Methimazole is given orally in initial doses of 30–60 mg once daily. Some patients with very mild hyperthyroidism may respond well to smaller initial doses of methimazole (10–20 mg daily). Methimazole may also be administered twice daily to reduce the likelihood of gastrointestinal upset. Methimazole use in pregnancy has been associated with a possibly increased risk of fetal anomalies such as aplasia cutis, esophageal atresia, and coanal atresia. However, methimazole may be used if the patient cannot tolerate propylthiouracil (see below). If methimazole is used during pregnancy or breastfeeding, the dose should not exceed 20 mg daily. The dosage is reduced as manifestations of hyperthyroidism resolve and as the FT₄ level falls toward normal. For patients who have elected to receive ¹³¹I therapy, methimazole is discontinued 4 days prior to receiving the ¹³¹I and is resumed at a lower dose 3 days afterwards to avoid recurrence of hyperthyroidism. About 4 weeks after ¹³¹I therapy, methimazole may be discontinued if the patient is euthyroid.

B. PROPYLTHIOURACIL—Propylthiouracil has been the drug of choice during breastfeeding since it is not concentrated in the milk as much as methimazole. Propylthiouracil is also favored during pregnancy, possibly causing fewer problems in the newborn. Rare complications peculiar to propylthiouracil include arthritis, lupus, aplastic anemia, thrombocytopenia, and hypoprothrombinemia. Acute hepatitis occurs rarely and is treated with prednisone but may progress to liver failure. Propylthiouracil is given orally in initial doses of 300–600 mg daily in four divided doses. The dosage and frequency of administration are reduced as symptoms of hyperthyroidism resolve and the FT₄ level approaches normal. During pregnancy, the dose of propylthiouracil is kept below 200 mg/d to avoid goitrous

hypothyroidism in the infant; the patient may be switched to methimazole in the second trimester.

3. Iodinated contrast agents—These agents provide effective temporary treatment for thyrotoxicosis of any cause. Iopanoic acid (Telepaque) or ipodate sodium (Bilivist, Oragrafin) is given orally in a dosage of 500 mg twice daily for 3 days, then 500 mg once daily. These agents inhibit peripheral 5'-monodeiodination of T₄, thereby blocking its conversion to active T₃. Within 24 hours, serum T₃ levels fall an average of 62%. For patients with Graves disease, methimazole is begun first to block iodine organification; the next day, ipodate sodium or iopanoic acid may be added. The iodinated contrast agents are particularly useful for patients who are very symptomatically thyrotoxic (see Thyroid Storm). They offer a therapeutic option for patients with T₄ overdosage, subacute thyroiditis, and amiodarone-induced thyrotoxicosis and for those intolerant to thioureas and for newborns with thyrotoxicosis (due to maternal Graves disease). Treatment periods of 8 months or more are possible, but efficacy tends to wane with time. In Graves disease, thyroid RAI uptake may be suppressed during treatment but typically returns to pretreatment uptake by 7 days after discontinuation of the drug, allowing ¹³¹I treatment.

4. Radioactive iodine (¹³¹I, RAI)—The administration of ¹³¹I is an excellent method of destroying overactive thyroid tissue (either diffuse or toxic nodular goiter). There are ample data to conclude that patients who are treated with RAI in adulthood do not have an increased risk of subsequent thyroid cancer, leukemia, or other malignancies. Similarly, individuals who were treated with RAI as teenagers have not shown any increased risk of malignancy in a 36-year retrospective study. Children born to parents previously treated with ¹³¹I show normal rates of congenital abnormalities.

Because fetal radiation is harmful, *RAI should not be given to pregnant women*. A sensitive pregnancy test (serum β-hCG) should be obtained on all women of reproductive age prior to ¹³¹I therapy.

Most patients may receive ¹³¹I while being symptomatically treated with propranolol ER, which is then reduced in dosage as hyperthyroxinemia resolves. However, some patients (those with coronary disease, the elderly, or those with severe hyperthyroidism) are usually rendered euthyroid with a thiouracil drug (see above) while the dosage of propranolol is reduced. A higher rate of ¹³¹I treatment failure has been reported in patients with Graves disease who have been receiving methimazole or propylthiouracil. However, therapy with ¹³¹I will usually be effective if the methimazole is discontinued at least 4 days before RAI therapy and if the therapeutic dosage of ¹³¹I is adjusted (upward) according to RAI uptake on the pretherapy scan. Prior to ¹³¹I therapy, patients are instructed against receiving intravenous iodinated contrast or ingesting large quantities of dietary iodine, but severe restriction of dietary iodine is not usually necessary.

Following ¹³¹I treatment for hyperthyroidism, Graves ophthalmopathy appears or worsens in 15% of patients (23% in smokers and 6% in nonsmokers) and improves in

none, whereas during treatment with methimazole, ophthalmopathy worsens in 3% and improves in 2% of patients. Among patients receiving prednisone following ^{131}I treatment, preexistent ophthalmopathy worsens in none and improves in 67%. Therefore, patients with Graves ophthalmopathy who are to be treated with radioiodine should be considered for prophylactic prednisone (20–40 mg/d) for 2 months following administration of ^{131}I , particularly in patients who have severe orbital involvement.

Smoking increases the risk of having a flare in ophthalmopathy following ^{131}I treatment and also reduces the effectiveness of prednisone treatment. Therefore, patients who smoke are strongly encouraged to quit prior to ^{131}I treatment.

FT_4 levels may sometimes drop within 2 months after ^{131}I treatment, but then rise again to thyrotoxic levels, at which time thyroid RAI uptake is low. This phenomenon is caused by a release of stored thyroid hormone from injured thyroid cells and does not indicate a treatment failure. In fact, serum FT_4 then falls abruptly to hypothyroid levels.

There is a high incidence of hypothyroidism in the months to years after ^{131}I , even when small doses are given. Patients with Graves disease treated with ^{131}I also have an increased lifetime risk of developing hyperparathyroidism, particularly when radioiodine therapy was administered in childhood or adolescence. Lifelong clinical follow-up is mandatory, with measurements of serum TSH, FT_4 , and calcium when indicated.

5. Thyroid surgery—Thyroidectomy may be performed for pregnant women whose thyrotoxicosis is not controlled with low doses of thioureas, and for women who desire to become pregnant in the very near future. Surgery is also an option for nodular goiters, when there is a suspicion for malignancy.

The Hartley–Dunhill operation is the procedure of choice for patients with Graves disease having surgery; this operation consists of a total resection of one lobe and a subtotal resection of the other lobe, leaving about 4 g of thyroid tissue. Subtotal thyroidectomy of both lobes is often used, but ultimately results in a 9% recurrence rate for hyperthyroidism. Total thyroidectomy of both lobes poses an increased risk of hypoparathyroidism and damage to the recurrent laryngeal nerves.

Patients are ordinarily rendered euthyroid preoperatively with a thiourea drug. Iodate sodium or iopanoic acid (500 mg orally twice daily) may be used in addition to a thiourea to accelerate the decline in serum T_3 . Propranolol ER is given orally at initial doses of 60–80 mg twice daily and increased every 2–3 days until the heart rate is < 90 beats per minute. Propranolol is continued until the serum T_3 (or free T_3) is normal preoperatively. Thyroid vascularity is reduced by preoperative treatment with either iodate sodium or iopanoic acid (500 mg twice orally daily for 3 days) or iodine (eg, Lugol solution, two or three drops orally daily for several days). If a patient undergoes surgery while thyrotoxic, larger doses of propranolol are given perioperatively to reduce the likelihood of thyroid crisis.

Morbidity includes possible damage to the recurrent laryngeal nerve, with resultant vocal cord paralysis. If both recurrent laryngeal nerves are damaged, airway obstruction

may develop, and the patient may require intubation and tracheostomy. Hypoparathyroidism also occurs, which means that calcium levels must be checked postoperatively. When a competent, experienced neck surgeon performs a thyroidectomy, surgical complications are uncommon. Thyroid surgery should be performed as an inpatient, with at least an overnight observational period.

B. Toxic Solitary Thyroid Nodules

Toxic solitary thyroid nodules are usually benign but may rarely be malignant. If a nonsurgical therapy is elected, the nodule should be evaluated with a fine-needle aspiration biopsy (FNA). Hyperthyroidism caused by a single hyperfunctioning thyroid nodule may be treated symptomatically with propranolol ER and methimazole or propylthiouracil, as in Graves disease (see above). Patients who tolerate methimazole well may elect to continue it for long-term therapy. The dose of methimazole should be adjusted to keep the TSH slightly suppressed, so the risk of TSH-stimulated growth of the nodule is reduced. For patients under age 40 years and for healthy older patients, surgery is usually recommended; patients are made euthyroid with a thiourea preoperatively and given several days of iodine, ipodate sodium, or iopanoic acid before surgery as in Graves disease (see above). Transient postoperative hypothyroidism resolves spontaneously. Permanent hypothyroidism occurs in about 14% of patients by 6 years after surgery. Patients with a toxic solitary nodule who are over age 40 years or in poor health may be offered ^{131}I therapy. If the patient has been receiving methimazole preparatory to ^{131}I , the TSH should be kept slightly suppressed in order to reduce the uptake of ^{131}I by the normal thyroid. Nevertheless, permanent hypothyroidism occurs in about one-third of patients after 8 years of ^{131}I therapy. The nodule remains palpable in 50% and may grow in 10% of patients after ^{131}I .

C. Toxic Multinodular Goiter

Hyperthyroidism caused by a toxic multinodular goiter may also be treated with propranolol ER and methimazole, as in Graves disease. Methimazole does reverse hyperthyroidism, but there is a 95% recurrence rate if it is stopped. Definitive treatment for large multinodular goiters is surgery, prior to which patients are rendered euthyroid. Surgery is particularly indicated to relieve pressure symptoms or for cosmetic indications. Patients with toxic multinodular goiter are prepared for surgery the same as those with Graves disease. Patients who are to receive ^{131}I treatment are rendered nearly euthyroid with methimazole, which is stopped at least 4 days before RAI treatment. Meanwhile, the patient follows a low-iodine diet; this is done to enhance the thyroid gland's uptake of RAI, which may be relatively low in this condition (compared to Graves disease). Relatively high doses of ^{131}I are usually required; recurrent thyrotoxicosis and hypothyroidism are common, so patients must be monitored closely. Peculiarly, in about 5% of patients with diffusely nodular toxic goiter, the administration of ^{131}I therapy may induce Graves disease. Also, Graves eye disease has occurred rarely following ^{131}I therapy for multinodular goiter.

D. Subacute (de Quervain) Thyroiditis

Patients with hyperthyroidism due to subacute thyroiditis are treated symptomatically with oral propranolol ER at initial doses of about 60–80 mg twice daily and increased every 2–3 days until the heart rate is < 90 beats per minute. Iodate sodium or iopanoic acid, 500 mg orally daily, promptly corrects elevated T_3 levels and is continued for 15–60 days until the serum FT_4 level normalizes. The condition subsides spontaneously within weeks to months. Thioureas are ineffective, since thyroid hormone production is actually low in this condition. RAI is ineffective, since the thyroid's iodine uptake is low. Since periods of hypothyroidism may occur following the initial inflammatory episode, patients should have close clinical follow-up, with serum FT_4 measurement when necessary. Prompt treatment of the transient hypothyroidism may reduce the incidence of recurrent thyroiditis. Pain can usually be managed with non-aspirin nonsteroidal anti-inflammatory drugs.

E. Hashimoto Thyroiditis (Hashitoxicosis)

Rarely, hyperthyroidism develops as a result of release of stored thyroid hormone during severe Hashimoto thyroiditis. Serum thyroperoxidase or thyroglobulin antibodies are usually high, but RAI uptake is low, thus distinguishing it from Graves disease. This is especially common in postpartum women, in whom it may be transient. Treatment is with propranolol ER. Iodate sodium or iopanoic acid may also be used as described above. Patients are monitored carefully for the development of hypothyroidism and treated.

F. Hyperthyroidism during Pregnancy and Lactation

There may be a slightly increased risk of fetal anomalies associated with methimazole in the first trimester. Therefore, pregnant women with hyperthyroidism are treated with propylthiouracil in the first trimester and then may be switched to methimazole. Either thiourea should be given in the smallest dose possible, permitting mild subclinical hyperthyroidism to occur since it is usually well tolerated. Both propylthiouracil and methimazole cross the placenta and can induce hypothyroidism, with fetal TSH hypersecretion and goiter. Thyroid hormone administration to the mother does not prevent hypothyroidism in the fetus, since T_4 and T_3 do not freely cross the placenta. Fetal hypothyroidism is rare if the mother's hyperthyroidism is controlled with small daily doses of propylthiouracil (50–150 mg/d orally) or methimazole (5–15 mg/d orally). Thyroidectomy is reserved for women who are allergic or resistant to antithyroid drugs (usually due to noncompliance) or who have very large goiters. Fetal ultrasound at 32 weeks gestation can visualize any fetal goiter, so fetal thyroid dysfunction can be diagnosed and treated.

Both methimazole and propylthiouracil are secreted in breast milk, but not in amounts that affect the infant's thyroid hormone levels. No adverse reactions to these drugs (eg, rash, hepatic dysfunction, leukopenia) have been reported in breast-fed infants. Recommended doses are 20 mg orally daily or less for methimazole and 450 mg

orally daily or less for propylthiouracil. It is recommended that the medication be taken just after breast-feeding.

G. Treatment of Other Causes of Hyperthyroidism

Patients with thyrotoxicosis from **thyrotrope pituitary hyperplasia** are treated with propranolol ER as described above. Definitive treatment is with RAI or thyroid surgery. Patients with thyrotoxicosis caused by a **thyrotrope pituitary adenoma** are treated with propranolol ER and methimazole, followed by transsphenoidal resection of the pituitary tumor, when possible.

Patients with **type 1 amiodarone-induced thyrotoxicosis** usually require propranolol ER. Therapy with ^{131}I may be successful in some patients with sufficient RAI uptake. If radioiodine therapy is not an option (due to insufficient RAI uptake), treatment with methimazole is begun. If radioiodine is administered, methimazole may be started several days afterward. After two doses of methimazole, iopanoic acid or sodium ipodate may be added to the regimen to further block conversion of T_4 to T_3 ; the recommended dosage for each is 500 mg orally twice daily for 3 days, followed by 500 mg once daily until thyrotoxicosis is resolved. If iopanoic acid or sodium ipodate is not available, the alternative is potassium perchlorate; it is given in doses of ≤ 1000 mg daily (in divided doses) for a course not to exceed 30 days in order to avoid the complication of aplastic anemia. Amiodarone may be withdrawn but this does not have a significant therapeutic effect for several months. Thyroidectomy is reserved for resistant cases.

Patients with **type 2 amiodarone-induced thyrotoxicosis** usually require propranolol ER. Prednisone is given at an initial dose of about 0.5–0.7 mg/kg; that dose of prednisone is continued for about 2 weeks and then slowly tapered and finally withdrawn after about 3 months. Iopanoic acid or ipodate sodium may also be used (see above). Withdrawal of amiodarone is not usually necessary. Methimazole is ineffective. Thyroidectomy is rarely required, since the condition is transient. Most patients become euthyroid within 30–40 days, except in cases of very severe thyrotoxicosis.

Some cases of **amiodarone-induced thyrotoxicosis** cannot be strictly categorized as either type 1 or type 2. Such patients usually have negligible radioiodine uptake, so treatment is usually commenced with propranolol ER and a 1-month trial of methimazole. Iopanoic acid or ipodate sodium can be added to methimazole as noted above. Prednisone is given for severe thyrotoxicosis or when methimazole fails to correct the thyrotoxicosis. Amiodarone is discontinued, when feasible.

H. Treatment of Complications

1. Graves ophthalmopathy—The risk of having a “flare” of ophthalmopathy following ^{131}I treatment for hyperthyroidism is about 6% for nonsmokers and 23% for smokers. Graves ophthalmopathy can also be aggravated by thiazolidinediones (eg, pioglitazone, rosiglitazone); these oral diabetic agents should be avoided or withdrawn in patients with Graves disease. Patients with mild ophthalmopathy

may be treated with selenium 100 mcg orally twice daily, which slows the progression of the disease. For acute, progressive exophthalmos, intravenous methylprednisolone, begun promptly, is superior to oral prednisone, possibly due to improved compliance. Methylprednisolone is given intravenously, 500 mg weekly for 6 weeks, then 250 mg weekly for 6 weeks. If oral prednisone is chosen for treatment, it must be given promptly in daily doses of 40–60 mg/d orally, with dosage reduction over several weeks. Higher initial prednisone doses of 80–120 mg/d are used when there is optic nerve compression. Prednisone alleviates acute eye symptoms in 64% of nonsmokers, but only 14% of smokers respond well.

Progressive active exophthalmos may be treated with retrobulbar radiation therapy using a supervoltage linear accelerator (4–6 MeV) to deliver 20 Gy over 2 weeks to the extraocular muscles, avoiding the cornea and lens. Prednisone in high doses is given concurrently. Patients who respond well to orbital radiation include those with signs of acute inflammation, recent exophthalmos (< 6 months), or optic nerve compression. Patients with chronic proptosis and orbital muscle restriction respond less well. Retrobulbar radiation does not cause cataracts or tumors; however, it can cause radiation-induced retinopathy (usually subclinical) in about 5% of patients overall, mostly in diabetics.

For severe cases, orbital decompression surgery may save vision, though diplopia often persists postoperatively. General eye protective measures include wearing glasses to protect the protruding eye and taping the lids shut during sleep if corneal drying is a problem. Methylcellulose drops and gels (“artificial tears”) may also help. Tarsorrhaphy or canthoplasty can frequently help protect the cornea and provide improved appearance. Hypothyroidism and hyperthyroidism must be treated promptly.

2. Cardiac complications—

A. SINUS TACHYCARDIA—Treatment consists of treating the thyrotoxicosis. A β -blocker (as described above) such as propranolol is used in the interim unless there is an associated cardiomyopathy.

B. ATRIAL FIBRILLATION—Hyperthyroidism must be treated immediately (see above). Other drugs, including digoxin, β -blockers, anticoagulants, may be required. Electrical cardioversion is unlikely to convert atrial fibrillation to normal sinus rhythm while the patient is thyrotoxic. Spontaneous conversion to normal sinus rhythm occurs in 62% of patients with return of euthyroidism, but that likelihood decreases with age. Following conversion to euthyroidism, there is a 60% chance that atrial fibrillation will recur, despite normal thyroid function tests. Those with persistent atrial fibrillation may have elective cardioversion 4 months after resolution of hyperthyroidism.

(1) **Digoxin**—Digoxin is used to slow a fast ventricular response to thyrotoxic atrial fibrillation; it must be used in larger than normal doses because of increased clearance and an increased number of cardiac cellular sodium pumps requiring inhibition. Digoxin doses are reduced as hyperthyroidism is corrected.

(2) **β -Blockers**— β -Blockers may also reduce the ventricular rate, but they must be used with caution—particularly

in patients with cardiomegaly or signs of heart failure—since their negative inotropic effect may precipitate congestive heart failure. Therefore, an initial trial of a short-duration β -blocker should be considered, such as esmolol intravenously. If a β -blocker is used, doses of digoxin must be reduced.

(3) **Anticoagulants**—Anticoagulation is indicated in the following situations: left atrial enlargement on echocardiogram, global left ventricular dysfunction, recent congestive heart failure, hypertension, recurrent atrial fibrillation, or a history of previous thromboembolism. The doses of warfarin required in thyrotoxicosis are smaller than normal because of an accelerated plasma clearance of vitamin K–dependent clotting factors. Higher warfarin doses are usually required as hyperthyroidism subsides.

C. HEART FAILURE—Heart failure due to thyrotoxicosis may be caused by extreme tachycardia, cardiomyopathy, or both. Very aggressive treatment of the hyperthyroidism is required in either case (see Thyroid Crisis, below). The tachycardia from atrial fibrillation is treated with digoxin as above. Intravenous furosemide is typically required. Oral spironolactone or eplerenone may be helpful. If tachycardia appears to be the main cause of the failure, β -blockers are administered cautiously as described above.

Congestive heart failure may occur as a result of low-output dilated cardiomyopathy in the setting of hyperthyroidism. It is uncommon and may be caused by an idiosyncratic severe toxic effect of hyperthyroidism upon certain hearts. Cardiomyopathy may occur at any age and without preexisting cardiac disease. β -Blockers and calcium channel blockers are avoided. Emergency treatment may include afterload reduction, diuretics, digoxin, and other inotropic agents while the patient is being rendered euthyroid. Heart failure usually persists despite correction of hyperthyroidism.

D. APATHETIC HYPERTHYROIDISM—Apathetic hyperthyroidism may present with angina pectoris. Treatment is directed at reversing the hyperthyroidism as well as providing standard antianginal therapy. Coronary angioplasty or bypass grafting can often be avoided by prompt diagnosis and treatment.

3. Thyroid crisis or “storm”—This disorder, rarely seen today, is an extreme form of thyrotoxicosis that may be triggered by stressful illness, thyroid surgery, or RAI administration. Its manifestations often include marked delirium, severe tachycardia, vomiting, diarrhea, dehydration and very high fever. The mortality rate is high.

A thiourea drug is given (eg, methimazole, 15–25 mg orally every 6 hours or propylthiouracil, 150–250 mg orally every 6 hours). Iodate sodium (500 mg/d orally) can be helpful if begun 1 hour after the first dose of thiourea. Iodide is given 1 hour later as Lugol solution (10 drops three times daily orally) or as sodium iodide (1 g intravenously slowly). Propranolol is given (cautiously in the presence of heart failure; see above) in a dosage of 0.5–2 mg intravenously every 4 hours or 20–120 mg orally every 6 hours. Hydrocortisone is usually given in doses of 50 mg orally every 6 hours, with rapid dosage reduction as the clinical situation improves. Aspirin is avoided since it

displaces T_4 from TBG, raising FT_4 serum levels. Definitive treatment with ^{131}I or surgery is delayed until the patient is euthyroid.

4. Hyperthyroidism from postpartum thyroiditis—

Propranolol ER is given during the hyperthyroid phase followed by levothyroxine during the hypothyroidism phase (see Thyroiditis, below).

5. Graves dermopathy—Treatment involves application of a topical corticosteroid (eg, fluocinolone) with nocturnal plastic occlusive dressings.

6. Thyrotoxic hypokalemic periodic paralysis—Sudden symmetric flaccid paralysis, along with hypokalemia and hypophosphatemia can occur with hyperthyroidism. There are often few classic signs of thyrotoxicosis. It is most prevalent in Asian and Native Americans with hyperthyroidism and is 30 times more common in men than women. Therapy with oral propranolol, 3 mg/kg, normalizes the serum potassium and phosphate levels and reverses the paralysis within 2–3 hours. No intravenous potassium or phosphate is ordinarily required. Intravenous dextrose and oral carbohydrate aggravate the condition and are to be avoided. Therapy is continued with propranolol, 60–80 mg orally every 8 hours (or sustained-action propranolol ER daily at equivalent daily dosage), along with a thiourea drug such as methimazole to treat the hyperthyroidism.

► Prognosis

Graves disease may rarely subside spontaneously, particularly when it is mild or subclinical. Graves disease that presents in early pregnancy has a 30% chance of spontaneous remission before the third trimester. The ocular, cardiac, and psychological complications can become serious and persistent even after treatment. Permanent hypoparathyroidism and vocal cord palsy are risks of surgical thyroidectomy. Recurrences are common following thiourea therapy but also occur after low-dose ^{131}I therapy or subtotal thyroidectomy. With adequate treatment and long-term follow-up, the results are usually good. However, despite treatment for their hyperthyroidism, women experience an increased long-term risk of death from thyroid disease, cardiovascular disease, stroke, and fracture of the femur. Posttreatment hypothyroidism is common. It may occur within a few months or up to several years after RAI therapy or subtotal thyroidectomy. Malignant exophthalmos has a poor prognosis unless treated aggressively.

Subclinical hyperthyroidism refers to a condition in which asymptomatic individuals have a low serum TSH and normal FT_4 and T_3 . Most such patients do well without treatment. In one series, clinical hyperthyroidism developed in only one of seven patients after 2 years. In most patients, the serum TSH may revert to normal within 2 years. Most such patients do not have accelerated bone loss. However, if a baseline bone density shows significant osteopenia, bone densitometry may be performed periodically. In persons over age 60 years, serum TSH is very low (< 0.1 mU/L) in 3% and mildly low (0.1–0.4 mU/L) in 9%. The chance of developing atrial fibrillation is 2.8% yearly in elderly patients with very low TSH and 1.1% yearly in those with mildly low TSH. Asymptomatic persons with

very low TSH are monitored closely but are not treated unless atrial fibrillation or other manifestations of hyperthyroidism develop.

THYROIDITIS

ESSENTIALS OF DIAGNOSIS

- ▶ **Acute and subacute forms:** thyroid gland swelling, sometimes causing pressure symptoms.
- ▶ **Chronic form:** thyroid gland may or may not be enlarged with rubbery firmness.
- ▶ Thyroid function tests variable.
- ▶ Serum antithyroperoxidase and antithyroglobulin antibody levels usually elevated in Hashimoto thyroiditis.

► General Considerations

Thyroiditis may be classified as follows: (1) chronic lymphocytic thyroiditis due to autoimmunity (also called Hashimoto thyroiditis), (2) subacute thyroiditis, (3) suppurative thyroiditis, and (4) Riedel thyroiditis.

Hashimoto thyroiditis is an autoimmune condition and the most common thyroid disorder in the United States. B-lymphocytes invade the thyroid gland, such that the condition is also known as **chronic lymphocytic thyroiditis**. Detectable levels of antithyroid antibodies are usually present: antithyroperoxidase (antimitochondrial) antibodies or antithyroglobulin antibodies, or both. Elevated serum levels of antithyroid antibodies are found in 3% of men and 13% of women. Women over the age of 60 years have a 25%

incidence of elevated serum levels of antithyroid antibodies. However, only a small subset of individuals with elevated antithyroid antibody levels ever develops thyroid dysfunction. One percent of the population has serum antithyroid antibody titers > 1:6400 and they are at particular risk for thyroid dysfunction. The incidence of Hashimoto thyroiditis varies by kindred, race, and by sex; in persons older than 12 years of age in the United States, elevated levels of antithyroid antibodies are found in 14.3% of whites, 10.9% of Mexican-Americans, and 5.3% of blacks.

Hashimoto thyroiditis tends to be familial and is six times more common in women than in men. Its frequency is increased by dietary iodine supplementation. Certain drugs (amiodarone, interferon- α , interferon- β , interleukin-2, G-CSF) frequently induce thyroid autoantibodies. Childhood or occupational exposure to head-neck external beam radiation increases the lifetime risk of Hashimoto thyroiditis. Subclinical thyroiditis is extremely common, as evidenced in autopsy series that have found focal thyroiditis in about 40% of women and 20% of men.

Hashimoto thyroiditis often progresses to hypothyroidism, which may be linked to thyrotropin receptor-blocking antibodies, detected in 10% of patients with Hashimoto thyroiditis. Hypothyroidism is more likely to develop in smokers than in nonsmokers, possibly due to the thiocyanates in cigarette smoke. High serum levels of thyroid peroxidase antibody also predict progression from subclinical hypothyroidism to symptomatic hypothyroidism. Although the hypothyroidism is usually permanent, up to 11% of patients experience a remission after several years. There are two possible causes for such remissions: (1) the Hashimoto thyroiditis may improve spontaneously; and (2) thyroid-stimulating immunoglobulin is produced in sufficient quantities to overwhelm the destructive effects of concurrent Hashimoto thyroiditis, causing the thyroid to produce more thyroid hormone. Rarely, if the thyroid gland goes on to produce *excessive* thyroid hormone, the result is an autoimmune hyperthyroidism (see Graves disease).

Hashimoto thyroiditis is sometimes associated with other endocrine deficiencies as part of polyglandular autoimmunity (PGA). Adults with type 2 PGA are prone to autoimmune thyroiditis, diabetes mellitus type 1, autoimmune gonadal failure, hypoparathyroidism, and adrenal insufficiency (see Adrenal Insufficiency). Thyroiditis is associated with other autoimmune conditions, such as pernicious anemia, Sjögren syndrome, vitiligo, inflammatory bowel disease, and celiac disease. The incidence of celiac disease in patients with Hashimoto thyroiditis is about 5%. Hashimoto thyroiditis is very rarely associated with other autoimmune conditions such as myocarditis, hypophysitis, alopecia areata, encephalitis, primary pulmonary hypertension, or membranous nephropathy. Women with gonadal dysgenesis (Turner syndrome) have a 15% incidence of significant thyroid dysfunction by age 40 years. Thyroiditis is also commonly seen in patients with hepatitis C.

Painless postpartum thyroiditis refers to autoimmune thyroiditis that occurs soon after delivery in 7.2% of women. There is some evidence that the autoimmunity may be triggered by the accumulation of fetal cells in the maternal thyroid during pregnancy, a condition known as

microchimerism. Women in whom postpartum thyroiditis develops have a 70% chance of recurrence after subsequent pregnancies. It occurs most commonly in women who have high levels of thyroid peroxidase antibody in the first trimester of pregnancy or immediately after delivery. It is also more common in women with other autoimmunity or a family history of Hashimoto thyroiditis.

Painless sporadic thyroiditis is thought to be a subacute form of Hashimoto thyroiditis that is similar to painless postpartum thyroiditis (see above), except that it is not related to pregnancy. It accounts for about 1% of cases of thyrotoxicosis.

Subacute thyroiditis—also called de Quervain thyroiditis, granulomatous thyroiditis, and giant cell thyroiditis—is relatively common. It is believed to be caused by a viral infection and often follows an upper respiratory tract infection. Its incidence peaks in the summer. It accounts for up to 5% of clinical thyroid disease and young and middle-aged women are most commonly affected.

Suppurative thyroiditis refers to a nonviral infection of the thyroid gland. It is usually bacterial. However, mycobacterial, fungal, and parasitic infections can occur, particularly in immunosuppressed individuals. Suppurative thyroiditis is quite rare, since the thyroid is resistant to infection, largely due to its high iodine content. It tends to affect patients with preexistent thyroid disease. Congenital pyriform sinus fistulas are a cause for recurrent suppurative thyroiditis in otherwise normal individuals.

Riedel thyroiditis is also called invasive fibrous thyroiditis, Riedel struma, woody thyroiditis, ligneous thyroiditis, and invasive thyroiditis. It is the rarest form of thyroiditis and is found most frequently in middle-aged or elderly women. It is usually a manifestation of a multifocal systemic fibrosis syndrome.

► Clinical Findings

A. Symptoms and Signs

In **Hashimoto thyroiditis**, the thyroid gland is usually diffusely enlarged, firm, and finely nodular. One thyroid lobe may be asymmetrically enlarged, raising concerns about neoplasm. Although patients may complain of neck tightness, pain and tenderness are not usually present. About 10% of cases are atrophic, the gland being fibrotic, particularly in elderly women.

Systemic manifestations are mostly related to ambient levels of thyroid hormone. However, depression and chronic fatigue are more common in such patients, even after correction of hypothyroidism. About one-third of patients have mild dry mouth (xerostomia) or dry eyes (keratoconjunctivitis sicca) of an autoimmune nature related to Sjögren syndrome. It may be associated with myasthenia gravis, which is usually of mild severity, mainly affecting the extraocular muscles and having a relatively low incidence of detectable AChR Ab or thymic disease. Associated celiac disease can produce fatigue or depression, often in the absence of gastrointestinal symptoms.

Postpartum thyroiditis is typically manifested by hyperthyroidism that begins 1–6 months after delivery and persists for only 1–2 months. Then, hypothyroidism tends to develop in affected women beginning 4–8 months after delivery.

Thyrotoxic symptoms in **painless sporadic thyroiditis** are usually mild; a small, nontender goiter may be palpated in about 50% of such patients. High serum thyroid peroxidase antibody concentrations are found in only 50% of such patients. The course is similar to painless postpartum thyroiditis.

Subacute thyroiditis presents with an acute, usually painful enlargement of the thyroid gland, often with dysphagia. The pain may radiate to the ears. Patients usually have a low-grade fever and fatigue. The manifestations may persist for weeks or months and may be associated with malaise. If there is no pain, it is called **silent thyroiditis**. Thyrotoxicosis develops in 50% of affected patients and tends to last for several weeks. Subsequently, hypothyroidism develops that lasts 4–6 months. Normal thyroid function typically returns within 12 months, but persistent hypothyroidism develops in 5% of patients.

Patients with **suppurative thyroiditis** usually are febrile and have severe pain, tenderness, redness, and fluctuation in the region of the thyroid gland. In **Riedel thyroiditis**, thyroid enlargement is often asymmetric; the gland is stony hard and adherent to the neck structures, causing signs of compression and invasion, including dysphagia, dyspnea, pain, and hoarseness. Related conditions include retroperitoneal fibrosis, fibrosing mediastinitis, sclerosing cervicitis, subretinal fibrosis, and biliary tract sclerosis. It may respond to therapy with tamoxifen (see Treatment).

B. Laboratory Findings

In Hashimoto thyroiditis with clinically evident disease, there are usually increased circulating levels of antithyroid peroxidase (90%) or antithyroglobulin (40%) antibodies. Antithyroid antibodies decline during pregnancy and are often undetectable in the third trimester. Once Hashimoto thyroiditis has been diagnosed, monitoring of these antibody levels is not necessary. The serum TSH level is elevated if thyroid hormone is not elaborated in adequate amounts by the thyroid gland.

Patients with Hashimoto thyroiditis have a 15% incidence of having serum antibodies associated with celiac disease (sprue, gluten-sensitive enteropathy). At least 5% of patients with Hashimoto thyroiditis are found to have clinically significant celiac disease. Although most patients with celiac disease have gastrointestinal complaints such as bloating or diarrhea, vague symptoms such as fatigue or ennui may predominate. Serum levels of IgA endomysial antibody or IgA tissue transglutaminase (tTG) antibody may be elevated. However, these antibody levels decline on a low gluten diet. Many patients with mild celiac disease have negative serology and a trial of a gluten-free diet is the most sensitive test.

In subacute thyroiditis, the ESR is markedly elevated while antithyroid antibody titers are low, distinguishing it from autoimmune thyroiditis. In **suppurative thyroiditis**, both the leukocyte count and ESR are usually elevated.

With hyperthyroidism due to Hashimoto thyroiditis or subacute thyroiditis, serum FT_4 levels tend to be proportionally higher than T_3 levels, since the hyperthyroidism is due to the passive release of stored thyroid hormone, which is predominantly T_4 ; this is in contrast to Graves disease

and toxic nodular goiter, where T_3 is relatively more elevated. Because T_4 is less active than T_3 , the hyperthyroidism seen in thyroiditis is usually less severe. Serum levels of TSH are suppressed in hyperthyroidism due to thyroiditis.

C. Imaging

Ultrasound in cases of Hashimoto thyroiditis typically shows a gland with characteristic diffuse heterogeneous density and hypoechogenicity. Ultrasonography of the thyroid helps distinguish thyroiditis from multinodular goiter or thyroid nodules that are suspicious for malignancy. It is also helpful in guiding FNA biopsy of small suspicious thyroid nodules. Color-flow Doppler ultrasonography can help distinguish thyroiditis from Graves disease, since patients with Graves disease have a hypervascular thyroid gland, whereas in thyroiditis there is normal or reduced vascularity.

RAI uptake and scan may be helpful in determining the cause of hyperthyroidism, distinguishing thyroiditis from Graves disease, since patients with subacute thyroiditis exhibit a very low RAI uptake. In patients with chronic Hashimoto thyroiditis (euthyroid or hypothyroid), RAI uptake may be normal or high with uneven uptake on the scan; scanning is not useful in making the diagnosis.

[^{18}F]Fluorodeoxyglucose positron emission tomography (^{18}F FDG-PET) scanning frequently shows diffuse thyroid uptake of isotope in cases of thyroiditis. About 3% of all ^{18}F FDG-PET scans shows such uptake. However, discrete thyroid nodules can also be discovered on ^{18}F FDG-PET scanning and are known as “thyroid PET incidentalomas,” of which 50% are malignant.

D. Fine-Needle Aspiration Biopsy

Patients with **Hashimoto thyroiditis** who have a thyroid nodule should have an ultrasound-guided FNA biopsy, since the risk of papillary thyroid cancer is about 8% in such nodules. When **suppurative thyroiditis** is suspected, an FNA biopsy with Gram stain and culture is required. FNA biopsy is usually not required for subacute thyroiditis but shows characteristic giant multinucleated cells.

► Complications

Hashimoto thyroiditis may lead to hypothyroidism or transient thyrotoxicosis. Perimenopausal women with high serum levels of antithyropoxidase antibodies have a higher relative risk of depression independently of ambient thyroid hormone levels.

Pregnant women with Hashimoto thyroiditis have an increased risk of spontaneous miscarriage in the first trimester of pregnancy. Hyperthyroidism may develop in patients with Hashimoto thyroiditis, either due to the emergence of Graves disease or due to the release of stored thyroid hormone, which is caused by inflammation. The latter condition has variably been termed “hashitoxicosis” or “painless sporadic thyroiditis;” it is known as postpartum painless thyroiditis when it occurs in women after delivery.

Patients with Hashimoto thyroiditis have an increased risk of other autoimmune conditions, such as Addison disease, hypoparathyroidism, diabetes, pernicious anemia, biliary cirrhosis, vitiligo, and celiac disease.

In the suppurative forms of thyroiditis, any of the complications of infection may occur; the subacute and chronic forms of the disease are complicated by the effects of pressure on the neck structures: dyspnea and, in Riedel struma, vocal cord palsy. Papillary thyroid carcinoma or thyroid lymphoma may rarely be associated with chronic thyroiditis and must be considered in the diagnosis of uneven painless enlargements that continue in spite of treatment; such patients require FNA biopsy.

► Differential Diagnosis

Thyroiditis must be considered in the differential diagnosis of all types of goiters, especially if enlargement is rapid. The very low RAI uptake in subacute thyroiditis with elevated T_4 and T_3 is helpful. Thyroid autoantibody tests have been of help in the diagnosis of Hashimoto thyroiditis, but the tests are not specific and may also be positive in patients with multinodular goiters, malignancy (eg, thyroid carcinoma, lymphoma), and concurrent Graves disease. The subacute and suppurative forms of thyroiditis may resemble any infectious process in or near the neck structures. Chronic thyroiditis, especially if the enlargement is uneven and if there is pressure on surrounding structures, may resemble carcinoma, and both disorders may be present in the same gland.

► Treatment

A. Hashimoto Thyroiditis

If hypothyroidism is present, levothyroxine should be given in the usual replacement doses (0.05–0.2 mg orally daily). In patients with a large goiter and normal or elevated serum TSH, an attempt is made to shrink the goiter by administering levothyroxine in doses sufficient to drive the serum TSH below the reference range while maintaining clinical euthyroidism. Suppressing doses of T_4 tend to shrink the goiter an average of 30% over 6 months. If the goiter does not regress, lower replacement doses of levothyroxine may be given. If the thyroid gland is only minimally enlarged and the patient is euthyroid, regular observation is in order, since hypothyroidism may develop subsequently—often years later. (See Hypothyroidism section.)

In one study involving 21 patients with Hashimoto thyroiditis and subclinical hypothyroidism, simvastatin (20 mg orally daily) improved thyroid function over 8 weeks, possibly by stimulating apoptosis of certain types of lymphocytes. In another study, selenium (200 mcg daily orally for 3 months) reduced the serum levels of anti-thyroperoxidase antibodies by 49% versus a 10% reduction in the placebo arm. The long-term effectiveness of simvastatin or selenium therapy on the course of Hashimoto thyroiditis is unknown.

B. Subacute Thyroiditis

All treatment is empiric and must be continued for several weeks. Recurrence is common. The drug of choice is aspirin, which relieves pain and inflammation. Thyrotoxic symptoms are treated with propranolol, 10–40 mg every 6 hours. Iodinated contrast agents cause a prompt fall in

serum T_3 levels and a dramatic improvement in thyrotoxic symptoms. Sodium ipodate (Oragrafin, Bilivist) or iopanoic acid (Telepaque) is given orally in doses of 500 mg orally daily until serum FT_4 levels return to normal. Transient hypothyroidism is treated with T_4 (0.05–0.1 mg orally daily) if symptomatic.

C. Suppurative Thyroiditis

Treatment is with antibiotics and with surgical drainage when fluctuation is marked.

D. Riedel Struma

The treatment of choice is tamoxifen, 20 mg orally twice daily, which must be continued for years. Tamoxifen can induce partial to complete remissions in most patients within 3–6 months. Its mode of action appears to be unrelated to its antiestrogen activity. Short-term corticosteroid treatment may be added for partial alleviation of pain and compression symptoms. Surgical decompression usually fails to permanently alleviate compression symptoms; such surgery is difficult due to dense fibrous adhesions, making surgical complications more likely.

► Prognosis

Hashimoto thyroiditis is occasionally associated with other autoimmune disorders (diabetes mellitus, Addison disease, pernicious anemia, etc). In general, however, patients with Hashimoto thyroiditis have an excellent prognosis, since the condition either remains stable for years or progresses slowly to hypothyroidism, which is easily treated. Although 80% of women with postpartum thyroiditis subsequently recover normal thyroid function, permanent hypothyroidism eventually develops in about 50% within 7 years. Permanent hypothyroidism is more common in women who are multiparous or who have had a spontaneous abortion. In subacute thyroiditis, spontaneous remissions and exacerbations are common; the disease process may smolder for months. Papillary thyroid carcinoma carries a relatively good prognosis when it occurs in patients with Hashimoto thyroiditis.

THYROID NODULES & MULTINODULAR GOITER

ESSENTIALS OF DIAGNOSIS

- ▶ Single or multiple thyroid nodules are commonly found with careful thyroid examinations.
- ▶ Thyroid function tests mandatory.
- ▶ Thyroid biopsy for single or dominant nodules or for a history of prior head-neck or chest-shoulder radiation.
- ▶ Ultrasound examination useful for biopsy and follow-up.
- ▶ Clinical follow-up required.

▶ General Considerations

Thyroid nodules are extremely common. In Germany, neck ultrasound screening of adults found a 20% incidence of thyroid nodules > 1 cm in diameter. Palpable nodules are found in 5% of women and 1% of men in iodine-sufficient areas of the world. Palpable thyroid nodules are even more common in iodine-deficient geographic areas (see Iodine Deficiency Disorder & Endemic Goiter). Each year in the United States, about 275,000 thyroid nodules are detected by palpation, of which 10% are malignant. Palpable thyroid nodules are increasingly prevalent with age. On high-resolution thyroid ultrasound, about 50% of palpable “solitary nodules” are found to be just one nodule in a multinodular goiter.

In recent years, an increased general use of scanning (CT, MRI, ultrasound, PET) has led to an increased rate of incidentally detecting nonpalpable thyroid nodules. In fact, thyroid ultrasound detects thyroid nodules in about 20% of randomly screened healthy adults.

Although 90% of thyroid nodules are benign, the presence of a thyroid nodule ≥ 1 cm diameter warrants follow-up and further testing for function and malignancy. An occasional nodule < 1 cm diameter requires follow-up if it has high-risk characteristics on ultrasound or if the patient has had prior head-neck radiation therapy. Thyroid nodules that are incidentally discovered on ^{18}F -FDG-PET scanning have a 33% risk for being malignant and definitely require biopsy.

Most patients with a thyroid nodule are euthyroid, but there is a high incidence of hypothyroidism or hyperthyroidism. Goiter may be caused by numerous conditions, including multinodular goiter, iodine deficiency, pregnancy (in areas of iodine deficiency), Graves disease, Hashimoto thyroiditis, subacute thyroiditis, or infections. About 90% of thyroid nodules are benign adenoma, colloid nodule, or cyst but may sometimes be a primary thyroid malignancy or (less frequently) a metastatic neoplasm. Patients with multiple thyroid nodules have the same overall risk of thyroid cancer as patients with solitary nodules. The risk of a thyroid nodule being malignant is higher among patients with a history of head-neck radiation, total body radiation for bone marrow transplantation, exposure

to radioactive fallout as a child or teen, a family history of thyroid cancer or a thyroid cancer syndrome (eg, Cowden syndrome, multiple endocrine neoplasia type 2, familial polyposis, Carney syndrome), or a personal history of another malignancy. The risk of malignancy is also higher if there is hoarseness or vocal fold paralysis, and if the thyroid nodule is large, adherent to the trachea or strap muscles, or associated with lymphadenopathy. The presence of Hashimoto thyroiditis does not reduce the risk of malignancy; a nodule of ≥ 1 cm in a gland with thyroiditis carries an 8% chance of malignancy.

▶ Clinical Findings

Table 26–6 illustrates the approach to the evaluation of thyroid nodules based on the index of suspicion for malignancy.

A. Symptoms and Signs

Most small thyroid nodules cause no symptoms. They may sometimes be detected only by having the patient swallow during careful inspection and palpation of the thyroid.

A thyroid nodule or multinodular goiter can grow to become visible and of concern to the patient. Particularly large nodular goiters can become a cosmetic embarrassment. Nodules can grow large enough to cause discomfort, hoarseness, or dysphagia. Retrosternal large multinodular goiters can cause dyspnea due to tracheal compression. Large substernal goiters may cause superior vena cava syndrome, manifested by facial erythema and jugular vein distention that progress to cyanosis and facial edema when both arms are kept raised over the head (Pemberton sign).

Depending on their cause, goiters and thyroid nodules may be associated with hypothyroidism (Hashimoto thyroiditis, endemic goiter) or hyperthyroidism (Graves disease, toxic nodular goiter, subacute thyroiditis, and thyroid cancer with metastases).

B. Laboratory Findings

A serum TSH level (sensitive assay) should be obtained for all patients with a thyroid nodule. Patients with a subnormal serum TSH must have further assessment for hyperthyroidism and have a radionuclide thyroid scan (^{123}I or $^{99\text{m}}\text{Tc}$ pertechnetate) to determine whether the nodule is hyperfunctioning; hyperfunctioning nodules are rarely malignant. Tests for antithyroperoxidase antibodies and antithyroglobulin antibodies may also be helpful. Very high antibody levels are found in Hashimoto thyroiditis. However, thyroiditis frequently coexists with malignancy, so suspicious nodules should always be biopsied. Serum calcitonin is obtained if a medullary thyroid carcinoma is suspected in a family member with a history of familial medullary thyroid carcinoma or MEN type 2.

C. Imaging

Neck ultrasonography should be performed to measure the size of a nodule and to determine whether a palpable nodule is part of a multinodular goiter. The following ultrasound characteristics of thyroid nodules increase the

Table 26-6. Clinical evaluation of thyroid nodules.¹

Clinical Evidence	Low Index of Suspicion	High Index of Suspicion
History	Family history of goiter; residence in area of endemic goiter	Previous therapeutic radiation of head, neck, or chest; hoarseness
Physical characteristics	Older women; soft nodule; multinodular goiter	Young adults, men; solitary, firm nodule; vocal cord paralysis; enlarged lymph nodes; distant metastatic lesions
Serum factors	High titer of antithyroid antibody; hypothyroidism; hyperthyroidism	Elevated serum calcitonin
Fine-needle aspiration biopsy	Colloid nodule or adenoma	Papillary carcinoma, follicular lesion, medullary or anaplastic carcinoma
Scanning techniques		
Uptake of ¹²³ I	Hot nodule	Cold nodule
Ultrasonogram	Cystic lesion	Solid lesion
Roentgenogram	Shell-like calcification	Punctate calcification
Response to thyroxine therapy	Regression after 0.05-0.1 mg/d for 6 months or more	Increase in size

¹Clinically suspicious nodules should be evaluated with fine-needle aspiration biopsy.

likelihood of malignancy: irregular or indistinct margins, heterogenous nodule echogenicity, intranodular vascular images, microcalcifications, complex cyst, or diameter over 1 cm. Ultrasound is also useful for long-term surveillance of thyroid nodules and multinodular goiter. Ultrasonography is generally preferred over CT and MRI because of its accuracy, ease of use, and lower cost.

RAI (¹²³I or ¹³¹I) scans have limited usefulness in the evaluation of thyroid nodules. Hypofunctioning (cold) nodules have a somewhat increased risk of being malignant but most are benign. Hyperfunctioning (hot) nodules are ordinarily benign but may sometimes be malignant. RAI uptake and scanning is helpful if a patient is found to have evidence of hyperthyroidism. (See Hyperthyroidism)

CT scanning is helpful for larger thyroid nodules and multinodular goiter; it can determine the degree of tracheal compression and the degree of extension into the mediastinum.

D. Incidentally Discovered Thyroid Nodules

Thyroid nodules are frequently discovered as an incidental finding, with an incidence that depends on the imaging modality: MRI, 50%; CT, 13%; and ¹⁸FDG-PET, 2%. When such scanning detects a thyroid nodule, an ultrasound is performed to better determine the nodule's risk for malignancy and the need for FNA biopsy, and to establish a baseline for ultrasound follow-up. The malignancy risk is about 17% for nodules discovered incidentally on CT or MRI, and 25–50% for nodules discovered incidentally by ¹⁸FDG-PET. For incidentally discovered thyroid nodules of borderline concern, follow-up thyroid ultrasound in 3–6 months may be helpful; growing lesions may be biopsied or resected.

E. Fine-Needle Aspiration Biopsy

Fine-needle aspiration (FNA) biopsy is the best method to assess a thyroid nodule for malignancy. FNA biopsy can be done while patients continue taking anticoagulants or aspirin. For multinodular goiters, the four largest nodules (≥ 1 cm diameter) should be biopsied to minimize the risk of missing a malignancy. For solitary thyroid nodules, FNA biopsy is indicated for the following: (1) nodules > 5 mm diameter with a suspicious appearance on ultrasound; (2) nodules associated with abnormal cervical lymph nodes; (3) nodules ≥ 1 cm diameter that are solid or have microcalcifications; (4) mixed cystic-solid nodules ≥ 1.5 cm diameter with any suspicious features on ultrasound or ≥ 2 cm diameter with benign features on ultrasound; (5) spongiform nodules ≥ 2 cm diameter. Pure cystic nodules are benign and do not require FNA biopsy. Using ultrasound guidance for FNA biopsy improves the diagnostic accuracy for both palpable and nonpalpable thyroid nodules. The chance of an optimal tissue sampling is also improved by having an experienced clinician perform the FNA biopsy and by having the aspirate interpreted by a skilled cytopathologist.

In one review of thyroid FNA biopsies, about 70% were benign, 5% were malignant, 10% were “suspicious,” and 15% were “nondiagnostic.” Nondiagnostic, bloody, or hypocellular FNA biopsies should be repeated under ultrasound guidance; nodules that continue to have nondiagnostic cytology should be monitored closely; those that are solid or that grow should be resected.

When FNA cytology is “suspicious” for papillary thyroid carcinoma or Hürthle cell neoplasm, the risk of malignancy is 57%. When FNA cytology yields a “suspicious” follicular lesion, the overall risk of the lesion being malignant

is about 20–25%. The risk that a follicular lesion is malignant increases for patients who are much younger or older than age 50. Most patients with suspicious FNA cytology are advised to have surgery.

Cystic nodules yielding serous fluid are usually benign, but the aspirate should be submitted for cytologic testing. Cystic nodules yielding bloody fluid have a higher chance of being malignant.

False-positive thyroid FNA biopsy results occur at a rate of about 4%. False-negative thyroid FNA biopsy results also occur at an overall rate of about 4%, less commonly when performed under ultrasound guidance and interpreted by cytopathologists. False-negative results delay surgical excision and lead to an increased risk of vascular and capsular invasion by the malignancy. Some false-negative FNA biopsy results may not have actually been inaccurate, since truly benign thyroid nodules can later become malignant. Patients who have a negative thyroid FNA should have observational follow-up, ideally with both palpation and ultrasound; nodules that continue to grow should be rebiopsied or excised.

▶ Treatment

All thyroid nodules, including those that are benign, need to be monitored by regular periodic palpation and ultrasound and rebiopsied if growth occurs. A toxic multinodular goiter and hyperthyroidism, associated with the ingestion or intravenous administration of large amounts of iodine, may develop in patients with multinodular goiters. It is therefore prudent to minimize excessive dietary iodine intake and intravenous iodinated contrast. Patients found to have hyperthyroidism may have a RAI uptake and scan for additional evaluation, especially if ^{131}I is a therapeutic consideration. Patients with toxic multinodular goiters may also be treated with methimazole, propranolol, or surgery (see Hyperthyroidism section).

A. Levothyroxine Suppression Therapy

Patients with elevated levels of serum TSH are treated with levothyroxine replacement. Otherwise, for small benign thyroid nodules, levothyroxine suppression therapy is not recommended. For larger nodules (> 2 cm), if TSH levels are elevated or normal, TSH suppression with levothyroxine (starting doses of 50 mcg orally daily) can be considered. Thyroxine suppression therapy is most successful in iodine-deficient areas of the world and less successful in iodine-sufficient regions. Long-term levothyroxine suppression of TSH tends to keep nodules from enlarging, but only 20% shrink more than 50%. In one 5-year study, thyroid nodule size increased in 29% of patients treated with levothyroxine, compared to growth in 56% of nodules in patients not receiving levothyroxine. Levothyroxine suppression also reduces the emergency of new nodules: 8% with levothyroxine and 29% without levothyroxine. Levothyroxine suppression therapy is not usually given to patients with cardiac disease, since it increases the risk for angina and atrial fibrillation. Levothyroxine suppression causes a small loss of bone density, particularly in postmenopausal women if the serum TSH is suppressed to

< 0.05 mU/L. Such patients are advised to have bone density testing every 3–5 years. Levothyroxine should not be administered if the baseline TSH is low, since that is an indication of autonomous thyroid secretion, such that levothyroxine therapy will be ineffective and liable to cause clinical thyrotoxicosis.

Levothyroxine suppression needs to be carefully monitored, since it carries a 17% risk of inducing symptoms of hyperthyroidism. This can occur due to excessive levothyroxine dosing, the emergence of an autonomous or toxic nodule or Graves disease, or a reduction in thyroid binding globulin seen in early menopause or with discontinuing oral estrogen therapy. Therefore, coronary insufficiency and cardiac arrhythmias are relative contraindications to levothyroxine suppression. All patients receiving levothyroxine suppression therapy should have serum TSH levels monitored regularly, with the dose of levothyroxine adjusted to keep the serum TSH mildly suppressed between 0.2 mU/L and 0.8 mU/L. Thyroid nodules require careful clinical evaluation and thyroid palpation or ultrasound examinations about every 6 months initially. After several years of stability, yearly examinations are sufficient.

B. Potassium Iodide

Additional suppression of thyroid nodules may be obtained by adding oral potassium iodide, 150 mcg daily, to levothyroxine suppression therapy (see above) for patients with thyroid nodules ≥ 1 cm in diameter. In a German study, the addition of potassium iodide to levothyroxine further decreased thyroid nodule size over the course of 1 year. However, the study excluded children; pregnant women; non-whites; and patients with autoimmune thyroid disease, autonomous nodules, consumption of other iodine-containing medications, dermatitis herpetiformis, or iodine allergy. The long-term risk of administering potassium iodide to iodine-sufficient patients is unknown.

C. Surgery

Total thyroidectomy is required for thyroid nodules that are malignant on FNA biopsy (see Thyroid Cancer section). More limited thyroid surgery is indicated for benign nodules with indeterminate or suspicious cytologic test results, compression symptoms, discomfort, or cosmetic embarrassment. Surgery may also be used to remove hyperfunctioning “hot” thyroid adenomas or toxic multinodular goiter causing hyperthyroidism (see Hyperthyroidism section).

D. Percutaneous Ethanol Injection

Thyroid cysts can be aspirated, but cystic fluid recurs in 75% of patients. Percutaneous ethanol injection has been used to shrink pure cysts; it must often be repeated, but the success rate is 80%. Percutaneous ethanol injection can also be used to shrink benign (biopsy proven) thyroid nodules. The complication rate is about 9%, but serious or permanent complications are rare.

E. Radioiodine (^{131}I) Therapy

Radioactive ^{131}I is a treatment option for hyperthyroid patients with toxic thyroid adenomas, multinodular goiter,

or Graves disease (see Hyperthyroidism section). It may also be used to shrink benign nontoxic thyroid nodules. Thyroid nodules shrink an average of 40% by 1 year and 59% by 2 years after ^{131}I therapy. Nodules that shrink after ^{131}I therapy generally remain palpable and become firmer; they may develop unusual cytologic characteristics on FNA biopsy. ^{131}I therapy may be used to shrink large multinodular goiter but may rarely induce Graves disease. Hypothyroidism is a risk and may occur years after ^{131}I therapy, so it is advisable to assess thyroid function every 3 months for the first year, every 6 months thereafter, and immediately for symptoms of hypothyroidism or hyperthyroidism.

► Prognosis

The great majority of thyroid nodules are benign. Benign thyroid nodules may involute but usually persist or grow slowly. About 90% of thyroid nodules will increase their volume by $\geq 15\%$ over 5 years; cystic nodules are less likely to grow. Cytologically benign nodules that grow are unlikely to be malignant; in one series, only 1 of 78 rebiopsied nodules was found to be malignant. The prognosis for patients with thyroid nodules that prove to be malignant is determined by the histologic type and other factors (see below). Multinodular goiters tend to persist or grow slowly, even in iodine-deficient areas where iodine repletion usually does not shrink established goiters. Patients with very small, incidentally discovered, nonpalpable thyroid nodules do require follow-up with thyroid ultrasound every 1–2 years but are at low risk for malignancy. Nodules that are malignant have a minor effect on morbidity and mortality.

THYROID CANCER

ESSENTIALS OF DIAGNOSIS

- Painless swelling in region of thyroid.
- Thyroid function tests usually normal.
- Past history of irradiation to head and neck region may be present.
- Positive thyroid needle aspiration.

► General Considerations

The incidence of papillary and follicular (differentiated) thyroid carcinomas increases with age. The overall female:male ratio is 3:1. The yearly incidence of thyroid cancer has been increasing in the United States, with the number of cases diagnosed annually reaching 37,200, probably as a result of the wider use of CT, MRI, PET, and ultrasound that incidentally find small thyroid malignancies. Thyroid cancer mortality has been stable, accounting for about 1500 deaths in the United States annually. Thyroid microcarcinoma (≤ 10 mm diameter) is found with the surprising frequency of 35%. Clearly, most thyroid cancers remain microscopic and indolent. However, larger thyroid cancers (palpable or ≥ 1 cm in diameter) are more malignant and require treatment.

Papillary thyroid carcinoma is the most common thyroid malignancy (Table 26–7).

Pure papillary and mixed papillary-follicular carcinoma represent about 80% of all thyroid cancers. It usually presents as a single thyroid nodule, but it can arise out of a multinodular goiter. Papillary thyroid carcinoma is commonly multifocal within the gland, with other foci usually arising *de novo* rather than representing intraglandular metastases. About 10% of cases present with palpable cervical lymph node metastases from a small thyroid cancer. Papillary thyroid carcinomas tend to grow slowly and often remain confined to the thyroid and regional lymph nodes for years. However, they may become more aggressive, especially in patients over age 45 years, and most particularly in the elderly. The cancer may invade the trachea and local muscles and may spread to the lungs.

Papillary thyroid carcinoma is caused by genetic mutations or translocations. Activating mutations of the *ras* oncogene can cause benign thyroid adenomas or nodular goiter. Additional activating mutations in *BRAF* or *TRK* genes can lead to papillary carcinoma. About 45% of papillary thyroid carcinomas are caused by over expression of the *ret* oncogene by the translocation of certain gene promoters to it, producing *retPTC-1*, *retPTC-2*, or *retPTC-3*. Radiation treatments to the head and neck region tend to cause *retPTC-1*. Nuclear fallout exposure tends to cause *retPTC-3*, resulting in more aggressive papillary thyroid carcinomas. Additional loss of the *p53* tumor suppressor gene can cause progression of papillary thyroid carcinoma to anaplastic thyroid carcinoma.

Exposure to head and neck radiation therapy poses a particular threat to children who then have an increased lifetime risk of developing thyroid pathology, including papillary thyroid carcinoma; thyroid malignancy may emerge between 10 and 40 years after exposure, with a peak occurrence 20–25 years later. After an explosion at the Chernobyl Nuclear Plant in the Ukraine in 1986, the risk of developing papillary thyroid carcinoma was highest among children who were under age 5 at the time of exposure to radiation; emergence of more aggressive papillary thyroid carcinoma occurred within 6–7 years after exposure.

Papillary thyroid carcinoma can occur in familial syndromes as an autosomal dominant trait, caused by loss of various tumor suppressor genes. Such syndromes (with associated features) include familial papillary carcinoma

Table 26-7. Some characteristics of thyroid cancer.

	Papillary	Follicular	Medullary	Undifferentiated
Incidence	Most common	Common	Uncommon	Uncommon
Average age	42	50	50	57
Females	70%	72%	56%	56%
Invasion				
Juxtanodal	+++++	+	+++++	+++
Blood vessels	+	+++	+++	+++++
Distant sites	+	+++	++	+++++
¹²³ I uptake	+	++++	0	0
Mortality	+	++ to +++	+ to ++++	+++++++

(with papillary renal carcinoma); familial nonmedullary thyroid carcinoma; familial polyposis (with large intestine polyps and gastrointestinal tumors); Gardner syndrome (with small and large intestine polyps, fibromas, lipomas, osteomas); and Turcot syndrome (with large intestine polyps and brain tumors). Older patients with multinodular goiter may rarely develop a papillary thyroid carcinoma. Papillary carcinoma can sometimes undergo a late anaplastic transformation into an aggressive carcinoma.

Generally speaking, papillary carcinoma is the least aggressive thyroid malignancy. However, the tumor spreads via lymphatics within the thyroid, appearing to be multifocal in 60% of patients and involving both lobes in 30% of patients. About 80% of patients have microscopic metastases to cervical lymph nodes. Unlike other forms of cancer, patients with papillary thyroid carcinoma who have palpable lymph node metastases do not have a particularly increased mortality rate; however, their risk of local recurrence is increased.

Occult metastases to the lung occur in 10–15% of papillary thyroid cancer. About 70% of small lung metastases resolve following ¹³¹I therapy; however, larger pulmonary metastases have only a 10% remission rate.

Microscopic “micropapillary” carcinoma (≤ 1 mm and invisible even on thyroid ultrasound) is a variant of normal, being found in 24% of thyroidectomies performed for benign thyroid disease when 2-mm sections were carefully examined. It thus appears that the overwhelming majority of these microscopic foci never become clinically significant. The surgical pathology report of such a tiny papillary carcinoma that is otherwise benign does not justify aggressive follow-up or treatment because a cancer diagnosis is unwarranted and harmful. All that may be required is yearly follow-up with palpation of the neck and mild TSH suppression by thyroxine.

Follicular thyroid carcinoma and its variants (eg, Hürthle cell carcinoma) account for about 14% of thyroid malignancies; follicular thyroid carcinoma is generally more aggressive than papillary carcinoma. Rarely, some follicular carcinomas secrete enough T_4 to cause thyrotoxicosis if the tumor load becomes significant. Metastases commonly

are found in neck nodes, bones, and lungs. Most follicular thyroid carcinomas avidly absorb iodine, making possible diagnostic scanning and treatment with ¹³¹I after total thyroidectomy. The follicular histopathologic features that are associated with a high risk of metastasis and recurrence are poorly differentiated and Hürthle cell (oncocyctic) variants. The latter variants do not take up RAI.

Follicular carcinoma results from certain gene mutations or translocations. Aberrant DNA methylation, activation of the *ras* oncogene, and mutations of the *MEN1* gene can result in benign follicular adenomas. Loss of function of *PPAR γ* or the *3P* tumor suppressor gene can lead to follicular carcinoma, and additional loss of the *p53* tumor suppressor gene can produce anaplastic carcinoma.

Follicular thyroid carcinoma and adenomas develop in patients with Cowden disease, a rare autosomal dominant familial syndrome caused by loss of a tumor suppressor gene; such patients tend to have macrocephaly, multiple hamartomas, early-onset breast cancer, intestinal polyps, facial papules, and other skin and mucosal lesions.

Medullary thyroid carcinoma represents about 3% of thyroid cancers. About one-third of cases are sporadic, one-third are familial, and one-third are associated with MEN type 2. Medullary thyroid carcinoma is often caused by an activating mutation of the *ret* oncogene on chromosome 10. Mutation analysis of the *ret* oncogene exons 10, 11, 13, and 14 detects 95% of the mutations causing MEN 2A and 90% of the mutations causing familial medullary thyroid carcinoma. Patients with MEN 2B have activating mutations in exon 16 of the *ret* oncogene. These germline mutations can be detected by DNA analysis of peripheral WBCs. Therefore, discovery of a medullary thyroid carcinoma makes genetic analysis mandatory. If a gene defect is discovered, related family members must have genetic screening for that specific gene defect. When a family member with MEN 2A or familial medullary thyroid carcinoma does not have an identifiable *ret* oncogene mutation, gene carriers may still be identified using family linkage analysis. Even when no gene defect is detectable, family members should have thyroid surveillance every 6 months. Somatic mutations of the *ret* oncogene can be identified in

the tumors of 30% of patients with sporadic (nonfamilial) medullary thyroid carcinoma. (See Multiple Endocrine Neoplasia.)

Medullary thyroid carcinoma arises from parafollicular thyroid cells that can secrete calcitonin, prostaglandins, serotonin, ACTH, corticotropin-releasing hormone (CRH), and other peptides. These peptides can cause symptoms and can be used as tumor markers. Early local metastases are usually present, usually to adjacent muscle and trachea as well as to local and mediastinal lymph nodes. Eventually, late metastases may appear in the bones, lungs, adrenals, or liver. Medullary thyroid carcinoma does not concentrate iodine.

Anaplastic thyroid carcinoma represents about 2% of thyroid cancers. It usually presents in an older patient as a rapidly enlarging mass in a multinodular goiter. It is the most aggressive thyroid carcinoma and metastasizes early to surrounding nodes and distant sites. Local pressure symptoms include dysphagia or vocal cord paralysis. This tumor does not concentrate iodine.

Anaplastic thyroid carcinoma is caused by certain gene mutations, including inactivating mutations of the *p53* tumor suppressor gene, as described above for papillary and follicular thyroid carcinomas.

Other thyroid malignancies together represent about 3% of thyroid cancers. **Lymphoma** of the thyroid is more common in older women. Thyroid lymphomas are most commonly B cell lymphomas (50%) or mucosa-associated lymphoid tissue (MALT; 23%); other types include follicular, small lymphocytic, and Burkitt lymphoma and Hodgkin disease. Thyroidectomy is rarely required. **Other cancers** may sometimes metastasize to the thyroid, particularly bronchogenic, breast, and renal carcinomas and malignant melanoma.

► Clinical Findings

A. Symptoms and Signs

Thyroid carcinoma usually presents as a palpable, firm, nontender nodule in the thyroid. Most thyroid carcinomas are asymptomatic, but large thyroid cancers can cause neck discomfort, dysphagia, or hoarseness (due to pressure on the recurrent laryngeal nerve). About 3% of thyroid malignancies present with a metastasis, usually to local lymph nodes but sometimes to distant sites such as bone or lung. Palpable lymph node involvement is present in 15% of adults and 60% of youths. Metastatic functioning differentiated thyroid carcinoma can sometimes secrete enough thyroid hormone to produce thyrotoxicosis. **Anaplastic thyroid carcinoma** is more apt to be advanced at the time of diagnosis, presenting with dysphagia, hoarseness, dyspnea, and metastases to the lungs. Occasionally, such carcinomas may be discovered while they are still relatively small and localized.

Medullary thyroid carcinoma frequently causes flushing and persistent diarrhea (30%), which may be the initial clinical feature. Patients with metastases often experience fatigue as well as other symptoms. Cushing syndrome develops in about 5% of patients from secretion of ACTH or CRH. Signs of pressure or invasion of surrounding tissues

are present in anaplastic or large tumors; recurrent laryngeal nerve palsy can occur.

Lymphoma usually presents as a rapidly enlarging, painful mass arising out of a multinodular or diffuse goiter affected by autoimmune thyroiditis, with which it may be confused microscopically. About 20% of cases have concomitant hypothyroidism.

B. Laboratory Findings

(FNA biopsy is discussed above in the section on Thyroid Nodules.) Thyroid function tests are generally normal unless there is concomitant thyroiditis. Follicular carcinoma may secrete enough T_4 to suppress TSH and cause clinical hyperthyroidism.

Serum thyroglobulin is high in most metastatic papillary and follicular tumors, making this a useful marker for recurrent or metastatic disease. Caution must be exercised for the following reasons: (1) Circulating antithyroglobulin antibodies can cause erroneous thyroglobulin determinations. (2) Thyroglobulin levels may be misleadingly elevated in thyroiditis, which often coexists with carcinoma. (3) Certain thyroglobulin assays falsely report the continued presence of thyroglobulin after total thyroidectomy and tumor resection, causing undue concern about possible metastases. Therefore, unexpected thyroglobulin levels should prompt a repeat assay in another reference laboratory.

Serum calcitonin levels are usually elevated in medullary thyroid carcinoma, making this a marker for metastatic disease. However, serum calcitonin may be elevated in many other conditions, such as thyroiditis; pregnancy; azotemia; hypercalcemia; and other malignancies, including pheochromocytomas, carcinoid tumors, and carcinomas of the lung, pancreas, breast, and colon.

In patients with **medullary thyroid carcinoma**, serum calcitonin and carcinoembryonic antigen (CEA) determinations should be obtained before surgery, then regularly in postoperative follow-up: every 4 months for 5 years, then every 6 months for life. In patients with extensive metastases, serum calcitonin should be measured in the laboratory with serial dilutions. Calcitonin levels remain elevated in patients with persistent tumor but also in some patients with apparent cure or indolent disease. Therefore, rising levels of calcitonin (or CEA) are the best indication for recurrence. Serum calcitonin levels > 250 pg/mL are also an indication for recurrent or metastatic medullary thyroid carcinoma. Serum CEA levels are usually elevated with medullary carcinoma, making this a useful second marker; however, it is not specific for this carcinoma.

C. Imaging

1. Ultrasound of the neck—Ultrasound of the neck should be performed routinely on all patients with thyroid cancer for the initial diagnosis and for follow-up. Ultrasound is useful in determining the size and location of the malignancy as well as the location of any neck metastases.

2. Radioactive iodine scanning—RAI (^{131}I or ^{123}I) thyroid and whole-body scanning is used after thyroidectomy for surveillance as described below, supplanting its previous

use to determine whether a nodule was “cold” as a sign of malignancy.

3. CT and MRI scanning—CT scanning may demonstrate metastases and is particularly useful for localizing and monitoring lung metastases. However, CT scanning is less sensitive than ultrasound for detecting metastases within the neck. Iodinated contrast should never be given prior to RAI scanning or RAI therapy, since the large amounts of iodine in contrast media competitively inhibit the uptake of RAI by the thyroid, greatly reducing the effectiveness of subsequent RAI scanning and therapy. Medullary carcinoma in the thyroid, nodes, and liver may calcify, but lung metastases rarely do so. MRI is particularly useful for imaging bone metastases.

4. PET scanning—PET scanning is particularly useful for detecting thyroid cancer metastases that do not have sufficient iodine uptake to be visible on RAI scans. Metastases are best detected using ^{18}F FDG-PET whole-body scanning. The sensitivity of ^{18}F FDG-PET scanning for differentiated thyroid cancer is enhanced if the patient is hypothyroid or receiving thyrotropin, which increases the metabolic activity of differentiated thyroid cancer. Disadvantages of PET scanning include its lack of specificity for thyroid cancer as well as its expense and lack of availability in some locations. ^{18}F FDG-PET scanning has prognostic implications, since differentiated thyroid cancer metastases with low standard uptake value (SUV) scores are associated with a better prognosis.

► Differential Diagnosis

Neuroendocrine carcinomas may metastasize to the thyroid and be confused with medullary thyroid carcinoma.

False-positive ^{131}I scans are common with normal residual thyroid tissue and have been reported with Zenker diverticulum, struma ovarii, pleuropericardial cyst, gastric pull-up, and ^{131}I -contaminated bodily secretions. False-negative ^{131}I scans are common in early metastatic differentiated thyroid carcinoma but occur also in more advanced disease, including 14% of bone metastases.

► Complications

The complications vary with the type of carcinoma. Differentiated thyroid carcinomas may have local or distant metastases. One-third of medullary carcinomas may secrete serotonin and prostaglandins, producing flushing and diarrhea, and may be complicated by the coexistence of pheochromocytomas or hyperparathyroidism. The risks of radical neck surgery include permanent hypoparathyroidism and vocal cord palsy due to recurrent laryngeal nerve damage; permanent hypothyroidism is expected after thyroidectomy and should always be treated adequately.

► Treatment of Differentiated Thyroid Carcinoma

A. Surgical Treatment

Surgical removal is the treatment of choice for thyroid carcinomas. Neck ultrasound is obtained preoperatively, since

suspicious cervical lymphadenopathy is detected in about 25%. Intraoperative thyroid ultrasound by the surgeon also helps assess the extent of the tumor and lymph node involvement, altering surgical treatment in many cases. For differentiated papillary and follicular carcinoma > 1 cm diameter, total thyroidectomy is performed with limited removal of cervical lymph nodes. For medullary thyroid carcinoma, repeated neck dissections are often required.

For indeterminate nodules, surgery consists of a thyroid lobectomy for an indeterminate “follicular lesion” that is ≤ 4 cm diameter. If malignancy is diagnosed on pathology, a completion thyroidectomy is performed. For indeterminate follicular lesions > 4 cm diameter that are at higher risk for being malignant, a bilateral thyroidectomy is performed as the initial surgery. Higher risk lesions include those with a FNA biopsy that shows marked atypia or that are suspicious for papillary carcinoma and those that occur in patients with a history of radiation exposure or a family history of thyroid carcinoma.

For biopsies that are diagnostic of malignancy, surgery involves lobectomy alone for papillary thyroid carcinomas < 1 cm diameter in patients under age 45 years who have no history of head and neck irradiation and no evidence of lymph node metastasis on ultrasonography. Other patients should have a total or near total thyroidectomy. The advantage of near-total thyroidectomy for differentiated thyroid carcinoma is that multicentric foci of carcinoma are more apt to be resected. Also, there is less normal thyroid tissue to compete with cancer for ^{131}I administered later for scans or treatment. A central neck lymph node dissection is performed at the time of thyroidectomy for patients with nodal metastases that are clinically evident. A lateral neck dissection is performed for patients with biopsy-proven lateral cervical lymphadenopathy. Neck muscle resections are usually avoided for differentiated thyroid carcinoma. However, patients with the Hürthle cell variant of follicular carcinoma may benefit from a modified radical neck dissection. Metastases to the brain are best treated surgically, since treatment with radiation or RAI is ineffective. Levothyroxine is prescribed in doses of 0.05–0.1 mg orally daily immediately postoperatively (see Thyroxine Suppression and Chemotherapy, below). About 2–4 months after surgery, patients require reevaluation and often require therapy with ^{131}I (see below).

Permanent injury to one recurrent laryngeal nerve occurs in between 1–2% and 7% of patients, depending on the experience of the surgeon. Bilateral nerve palsies are rare. Temporary recurrent laryngeal nerve palsies occur in another 5% but often resolve within 6 months. After total thyroidectomy, temporary hypoparathyroidism occurs in 20% and becomes permanent in about 2%. The incidence of hypoparathyroidism may be reduced if accidentally resected parathyroids are immediately autotransplanted into the neck muscles. Thyroidectomy requires at least an overnight hospital admission, since late bleeding, airway problems, and tetany can occur. Ambulatory thyroidectomy is potentially dangerous and should not be done. Following surgery, staging (Table 26–8) should be done to help determine prognosis and to plan therapy and follow-up.

Table 26-8. Pathologic tumor-node-metastasis (pTNM) staging and tumor-related approximate survival rates for adults with appropriately treated differentiated (papillary) thyroid carcinoma based upon patient age, primary tumor size and invasiveness (T), lymph node involvement (N), and distant metastases (M).¹

Stage	Description	Five-Year Survival	Ten-Year Survival
I	Under 45: any T, any N, no M Over 45: T ≤ 1 cm, no N, no M	99%	98%
II	Under 45: any T, any N, any M Over 45: T > 1 cm limited to thyroid, no N, no M	99%	90%
III	Over 45: T > 4 cm limited to thyroid, no N, no M; or any T limited to thyroid, regional N, no M	95%	75%
IV	Over 45: T local invasion, any N, any M; or T extensive invasion, any N, no M; or any T, any N, distant M	85%	65%

¹Patients having a relatively worse prognosis include those with familial differentiated thyroid carcinoma.

In pregnant women with thyroid cancer, surgery is usually delayed until after delivery, except for fast-growing tumors that may be resected after 24 weeks gestation; there has been no difference in survival or tumor recurrence rates in women who underwent surgery during or after their pregnancy. Differentiated thyroid carcinoma does not behave more aggressively during pregnancy. But there is a higher risk of complications in pregnant women undergoing thyroid surgery, compared to nonpregnant women.

B. Thyroxine Suppression and Chemotherapy

Patients who have had a thyroidectomy for differentiated thyroid cancer must take thyroxine replacement for life. Oral thyroxine should be given in doses that suppress serum TSH without causing clinical thyrotoxicosis. An ultrasensitive TSH assay should be used; serum TSH should be suppressed below 0.1 mU/L for patients with stage II disease and below 0.05 mU/L for patients with stage III–IV disease. (See Table 26-8.) Although patients receiving thyroxine suppression therapy (TSH < 0.05 mU/L) are at risk for a lower bone density than age-matched controls, the adverse effect upon bone density and fracture risk is relatively minor for patients who remain clinically euthyroid. Nevertheless, patients receiving thyroxine suppression therapy are advised to have periodic bone densitometry.

Zoledronic acid, an intravenous bisphosphonate, has proven useful for osteolytic metastases from other solid tumors and has been used for patients with thyroid bone metastases, but its effectiveness is unknown.

Thyroid carcinomas are extraordinarily resistant to chemotherapy. Sorafenib and sunitinib are tyrosine kinase inhibitors that have shown some activity against metastatic differentiated thyroid carcinomas that are radioiodine-resistant, with partial responses in 20% and stable disease in 60%.

C. Radioactive Iodine (¹³¹I) Therapy

Differentiated thyroid cancers variably retain the normal thyroid's ability to respond to TSH, secrete thyroglobulin, and concentrate iodine. There are two reasons to treat

patients with ¹³¹I after thyroidectomy: (1) thyroid remnant ablation and (2) treatment of known or suspected thyroid cancer. ¹³¹I is usually administered 2–4 months after surgery. Treatment with ¹³¹I is repeated 9–12 months later if surveillance RAI scanning shows evidence of metastatic disease. (See Surveillance, below.)

Before starting ¹³¹I therapy, patients follow a low iodine diet for at least 2 weeks. The low iodine diet consists of avoiding the following: iodized table salt, sea salt, fish, shellfish, seaweed, commercial bread, dairy products, processed meats, canned or dried fruit, canned fruit juices, highly salted soups and snack foods, black tea, instant coffee, food coloring with Red Dye #3, egg yolks, multivitamins with iodine, or topical iodine. Patients must not be given amiodarone or intravenous radiologic contrast dyes containing iodine.

1. Thyroid remnant ablation—A small dose of 30 mCi (1110 MBq) ¹³¹I is given for “remnant ablation” of residual normal thyroid tissues after surgery for differentiated thyroid cancer. This small dose of ¹³¹I is given to patients with no lymph node involvement who are at low risk for metastases. There are several advantages for giving thyroid remnant ablation: (1) There is usually remnant normal tissue that can produce thyroglobulin (a useful tumor marker); (2) Remnant ablation using ¹³¹I may destroy microscopic deposits of cancer; (3) The post-therapy scan may visualize metastatic cancer that would otherwise have been invisible. However, ¹³¹I remnant ablation has not been useful for patients with stage I papillary thyroid carcinomas < 1 cm diameter that are unifocal or multifocal. Such very low-risk patients may have close surveillance without receiving remnant ablation.

2. Treatment of metastases—RAI therapy improves survival and reduces recurrence rates for patients with stage III–IV cancer and those with stage II cancer having gross extrathyroidal extension. RAI therapy is also given to patients with stage II cancer who have distant metastases, a primary tumor > 4 cm diameter, or primary tumors 1–4 cm diameter with lymph node metastases or other high-risk features. Brain metastases do not usually respond

to ^{131}I and are best resected or treated with gamma knife radiosurgery (Table 26–8). A post-therapy whole-body scan is performed 2–10 days after ^{131}I therapy.

Staging with RAI scanning or ^{18}F -FDG-PET/CT scanning assists dosing decisions for ^{131}I therapy. Radioiodine doses of 50–100 mCi are given to patients with large primary tumors or tumors at the surgical margin. Patients with local lymph node involvement typically receive 100 mCi of ^{131}I ; patients with more extensive neck node involvement, regional or distant metastases receive ^{131}I at a dose of 125–200 mCi (4625–7400 MBq). Unfortunately, about 35% of patients with differentiated thyroid carcinoma have poor uptake of ^{131}I into metastases. Patients with asymptomatic, stable, radioiodine-resistant metastases may be carefully monitored for tumor progression.

Some patients have elevated serum thyroglobulin levels but a negative whole-body radioiodine scan and a negative neck ultrasound. In such patients, an ^{18}F -FDG PET/CT scan is obtained. If all scans are negative, empiric therapy with ^{131}I is not useful.

Doses of ^{131}I over 100 mCi (3800 MBq) can cause gastritis, temporary oligospermia, sialadenitis, and xerostomia. RAI therapy can cause neurologic decompensation in patients with brain metastases; it is advisable to treat such patients with prednisone 30–40 mg orally daily for several days before and after ^{131}I therapy. Cumulative doses of ^{131}I over 500 mCi can cause infertility, pancytopenia (4%), and leukemia (0.3%). Pulmonary fibrosis can occur in patients with diffuse lung metastases after receiving cumulative ^{131}I activities of > 600 mCi (22 GBq). The kidneys excrete RAI, so patients receiving dialysis for kidney disease require a dosage reduction to only 20% of the usual dose of ^{131}I .

3. rhTSH-stimulated ^{131}I therapy, thyroglobulin, and scan—Recombinant human thyroid stimulating hormone (rhTSH, Thyrogen) is given to increase the sensitivity of serum thyroglobulin for residual cancer and to increase the uptake of ^{131}I into residual thyroid tissue (thyroid remnant “ablation”) or cancer. Thyrogen must be kept refrigerated and is administered according to the following protocol: Thyroxine replacement is held for 2 days before rhTSH and for 3 days afterward. rhTSH 0.9 mg is administered intragluteally (not intravenously) daily for 2 consecutive days. On the third day, blood is drawn: serum TSH is assayed to confirm that it is > 30 mU/mL; serum hCG is measured in reproductive-age women to screen for pregnancy; and serum thyroglobulin is measured as a tumor marker. RAI is then administered at the prescribed dose (see above).

Thyrogen should not be administered to patients with an intact thyroid gland because it can cause severe thyroid swelling and hyperthyroidism. Hyperthyroidism can also occur in patients with significant metastases or residual normal thyroid. Other side effects include nausea (11%) and headache (7%). Thyrotropin has caused neurologic deterioration in 7% of patients with central nervous system metastases.

4. Thyroxine-withdrawal stimulated ^{131}I therapy, thyroglobulin, and scan—Thyroxine withdrawal is sometimes used because of its lower cost, despite the discomforts of becoming hypothyroid. Thyroxine is withdrawn for

14 days and the patient is allowed to become hypothyroid; high levels of endogenous TSH stimulate the uptake of RAI and production of thyroglobulin by thyroid cancer or residual thyroid. Just prior to ^{131}I therapy, the following blood tests are obtained: serum TSH to confirm it is > 30 mU/mL, serum hCG in reproductive-age women to screen for pregnancy, serum thyroglobulin as a tumor marker. Three days after ^{131}I therapy, thyroxine therapy may be resumed at full replacement dose.

5. Side effects and contraindications—National Cancer Institute surveillance data for thousands of patients with thyroid cancer indicate that patients with differentiated thyroid cancer, treated with only surgery, have a 5% increased risk of developing a second non-thyroid malignancy (especially breast cancer). Patients with thyroid cancer who received ^{131}I therapy have a 20% increased risk of developing a second non-thyroid malignancy (especially leukemia and lymphoma). The greatest risk of second cancers appeared within 5 years of ^{131}I therapy and was most significant for younger patients.

Pregnant women may not receive RAI therapy. Women are advised to avoid pregnancy for at least 4 months following ^{131}I therapy. Men have been found to have abnormal spermatozoa for up to 6 months following ^{131}I therapy and are advised to use contraceptive methods during that time.

► Treatment of Other Thyroid Malignancies

Patients with anaplastic thyroid carcinoma are treated with local resection and radiation. Lovastatin has been demonstrated to cause differentiation and apoptosis of anaplastic thyroid carcinoma cells in vitro; however, clinical studies have not been performed. Anaplastic thyroid carcinoma does not respond to ^{131}I therapy and is resistant to chemotherapy.

Patients with thyroid MALT lymphomas have a low risk of recurrence after simple thyroidectomy. Patients with other thyroid lymphomas are best treated with external radiation therapy; chemotherapy is added for extensive lymphoma. Patients with systemic lymphomas involving the thyroid are usually treated with chemotherapy.

Patients with a *ret* protooncogene mutation should have a prophylactic total thyroidectomy, ideally by age 6 years (MEN 2A) or at age 6 months (MEN 2B). Medullary thyroid carcinoma is best treated with surgery for the primary tumor and metastases. It does not respond to ^{131}I therapy and is generally resistant to chemotherapy. In one study, vandetanib (100 mg orally once daily) produced a partial remission in 16% and stable disease in 53% of patients with locally advanced or metastatic medullary thyroid carcinoma.

A. External Radiation Therapy

External radiation may be delivered to bone metastases, especially those without radioiodine uptake. Local neck radiation therapy may also be given to patients with anaplastic thyroid carcinoma. Brain metastases can be treated with gamma knife radiosurgery.

► Surveillance

Patients with differentiated thyroid carcinoma must be observed long-term for recurrent or metastatic disease. Patients with **differentiated thyroid carcinoma** have traditionally required at least two annual consecutively negative stimulated serum thyroglobulin determinations < 1 ng/mL and normal RAI scans (if done) and neck ultrasound before they are considered to be in remission. The first surveillance occurs with stimulated postoperative serum thyroglobulin, ^{131}I therapy, and post-therapy scanning about 2–4 months after surgery. (See Treatment, above.) At 9–12 months postoperatively, patients usually receive another stimulated serum thyroglobulin and radioiodine scan. Patients with persistent RAI uptake restricted to the thyroid bed need not have repeated ^{131}I therapies if the neck ultrasound appears normal and stimulated serum thyroglobulin is < 2 ng/mL. Further radioiodine or other scans may be required for patients with more aggressive differentiated thyroid cancer, prior metastases, rising serum thyroglobulin levels, or other evidence of metastases.

1. Serum TSH suppression—Patients with differentiated thyroid cancer are treated with thyroxine doses that are sufficient to suppress the serum TSH below the normal range. For intermediate- or high-risk patients, the serum TSH should be suppressed below 0.1 mU/L, while the target TSH for low-risk patients is 0.1–0.5 mU/mL. Patients who are considered cured should nevertheless be treated with sufficient thyroxine to keep the serum TSH < 2 mU/L. Follow-up must include physical examinations and laboratory testing to ensure that patients remain clinically euthyroid with serum TSH levels in the target range. To achieve suppression of serum TSH, the required dose of thyroxine may be such that serum FT_4 levels may be slightly elevated; in that case, measurement of serum T_3 or free T_3 can be useful to ensure the patient is not frankly hyperthyroid. Thyrotoxicosis can be caused by overreplacement with thyroxine or by the growth of functioning metastases.

2. Serum thyroglobulin—Thyroglobulin is produced by normal thyroid tissue and by most differentiated thyroid carcinomas. It is only after a total or near-total thyroidectomy and ^{131}I remnant ablation that thyroglobulin becomes a useful tumor marker for patients with differentiated papillary or follicular thyroid cancer, particularly for patients who do not have serum antithyroglobulin antibodies.

Detectable thyroglobulin levels do not necessarily indicate the presence of residual or metastatic thyroid cancer. Conversely, baseline serum thyroglobulin levels are insensitive markers for disease recurrence. However, baseline or stimulated serum thyroglobulin levels ≥ 2 ng/mL indicate the need for a repeat neck ultrasound and further scanning with RAI or ^{18}F FDG-PET. If serum thyroglobulin levels remain ≥ 2 ng/mL in the presence of normal scanning, it is prudent to repeat the serum thyroglobulin in a national reference laboratory. In one series of patients with differentiated thyroid cancer following thyroidectomy, there was a 21% incidence of metastases in patients with serum thyroglobulin < 1 ng/mL (while receiving thyroxine for TSH suppression). Therefore, *baseline* serum thyroglobulin

levels are inadequately sensitive and *stimulated* serum thyroglobulin measurements should be used and *always* with neck ultrasound. The usefulness of routinely doing a radioiodine scan (see below) in low-risk patients is controversial but continues to be done in many centers during stimulation following either rhTSH or thyroid hormone withdrawal, according to described protocols.

3. Neck ultrasound—Neck ultrasound should be used in all patients with thyroid carcinoma to supplement neck palpation; it should be performed preoperatively, 3 months postoperatively, and regularly thereafter. Ultrasound is more sensitive for lymph node metastases than either CT or MRI scanning. Small inflammatory nodes may be detected postoperatively and do not necessarily indicate metastatic disease, but follow-up is necessary. Ultrasound-guided FNA biopsy should be performed on suspicious lesions.

4. Radioactive iodine (RAI: ^{131}I or ^{123}I) neck and whole-body scanning—Despite its limitations, RAI scanning has traditionally been used to detect metastatic differentiated thyroid cancer and to determine whether the cancer is amenable to treatment with ^{131}I . RAI scanning is particularly useful for high-risk patients and those with persistent antithyroglobulin antibodies that make serum thyroglobulin determinations unreliable.

The ^{131}I isotope may be used in scanning doses, given < 2 weeks before scheduled ^{131}I treatment to avoid “stunning” metastases such that they take up less of the RAI therapy dose. The radioisotope ^{123}I may also be used and does not stun tumors; it allows single-photon emission computed tomography (SPECT) to better localize metastases. Initial RAI scanning is typically performed about 2–4 months following surgery for differentiated thyroid carcinoma. Whole-body scanning should be performed for at least 30 minutes for at least 140,000 counts and spot views of the neck should be obtained for at least 35,000 counts.

About 65% of metastases are detectable by RAI scanning, but only after optimal preparation: Patients should ideally have a total or near-total thyroidectomy, since any residual normal thyroid competes for RAI with metastases, which are less avid for iodine. It is reasonable to perform a rhTSH-stimulated scan and thyroglobulin level 2–3 months after the initial neck surgery; if the scan is negative and the serum thyroglobulin is < 2 ng/mL, low-risk patients may not require further scanning but should continue to be monitored with neck ultrasound and serum thyroglobulin levels every 6–12 months. For higher-risk patients, the rhTSH-stimulated thyroglobulin and RAI scan may be repeated about 1 year after surgery and then again if warranted. Serum thyroglobulin and radioiodine scanning are stimulated by either rhTSH or thyroid hormone withdrawal according to the protocols described above for ^{131}I treatment.

The combination of rhTSH-stimulated scanning and thyroglobulin levels detects a thyroid remnant or cancer with a sensitivity of 84%. However, the presence of antithyroglobulin antibodies renders the serum thyroglobulin determination uninterpretable. In about 21% of low-risk patients, rhTSH stimulates serum thyroglobulin to above 2 ng/mL; such patients have a 23% risk of local neck

metastases and a 13% risk of distant metastases. The rhTSH-stimulated radioiodine neck and whole-body scan detects only about half of these metastases because they are small or not avid for iodine. Some patients have persistent radioiodine uptake in the neck on diagnostic scanning but have no visible tumor on neck ultrasound; such patients do not require additional radioiodine therapy, especially if the serum thyroglobulin level is very low.

5. Positron emission tomography scanning— ^{18}F FDG-PET scanning is particularly useful for detecting thyroid cancer metastases in patients with a detectable serum thyroglobulin (especially serum thyroglobulin levels >10 ng/mL and rising) who have a normal whole-body RAI scan and an unrevealing neck ultrasound. The patient should be fasting at least 6 hours prior to ^{18}F FDG-PET scanning; water is allowed, but no sweetened beverages. Diabetic patients with blood sugars <200 mg/dL may be scanned. ^{18}F FDG-PET scanning can be combined with a CT scan; the resultant ^{18}F FDG-PET/CT fusion scan is 60% sensitive for detecting metastases that are not visible by other methods. This scan is less sensitive for small brain metastases. ^{18}F FDG-PET scanning detects the metabolic activity of tumor tissue; for differentiated thyroid carcinoma, this scan is more sensitive when the patient's thyroid cancer is stimulated with rhTSH (Thyrogen) as described above. One problem with ^{18}F FDG-PET scanning is its lack of specificity. False-positives can occur with benign hepatic tumors, sarcoidosis, radiation therapy, suture granulomas, reactive lymph nodes, or inflammation at surgical sites that can persist for months. False-positive uptake can also occur in muscles and brown fat.

^{18}F FDG-PET scanning predicts survival better than standard staging; the number, location, and SUV_{max} of metastases are all significant prognostic factors. (See Prognosis.) ^{18}F FDG-PET scanning is particularly sensitive for detecting medullary thyroid carcinoma metastases, and prescan thyrotropin does not improve the PET scan sensitivity for medullary thyroid carcinoma.

6. Other scanning—Thallium-201 (^{201}Tl) scans may be useful for detecting metastatic differentiated thyroid carcinoma when the ^{131}I scan is normal but serum thyroglobulin is elevated. MRI scanning is particularly useful for imaging metastases in the brain, mediastinum, or bones. CT scanning is useful for imaging and monitoring pulmonary metastases.

► Prognosis

Papillary thyroid cancer staging and survival data are shown on Table 26–8. ^{18}F FDG-PET scanning independently predicts survival, with patients having few PET-avid metastases and low SUV_{max} (highest image-pixel standardized uptake value) having a better prognosis. There is generally a good prognosis, particularly for adults under age 45 years, despite the fact that up to 40% of these patients are found to harbor lymph node metastases when extensive lymph node dissections are performed. The following characteristics imply a worse prognosis: age over 45 years, male sex, bone or brain metastases, macronodular (>1 cm) pulmonary metastases, and lack of ^{131}I uptake into metastases. Younger patients with pulmonary metastases tend to

respond better to ^{131}I therapy than do older adults. Certain papillary histologic types are associated with a higher risk of recurrence and reduced survival: tall cell, columnar cell, and diffuse sclerosing types. Brain metastases are detected in 1%; they reduce median survival to 12 months, but the patient's prognosis is improved by surgical resection. Patients with a **follicular variant of papillary carcinoma** have a prognosis somewhere between that of papillary and follicular thyroid carcinoma.

Patients with **follicular carcinoma** have a cancer mortality rate that is 3.4 times higher than patients with papillary carcinoma. The **Hürthle cell variant** of follicular carcinoma is even more aggressive. Both follicular carcinoma and its Hürthle cell variant tend to present at a more advanced stage than papillary carcinoma. However, at a given stage, the different types of differentiated thyroid carcinoma have a similar prognosis. Patients with primary tumors >1 cm in diameter who undergo limited thyroid surgery (subtotal thyroidectomy or lobectomy) have a 2.2-fold increased mortality over those having total or near-total thyroidectomies. Patients who have not received ^{131}I ablation have mortality rates that are increased twofold by 10 years and threefold by 25 years (over those who have received ablation). The risk of cancer recurrence is twofold higher in men than in women and 1.7-fold higher in multifocal than in unifocal tumors.

Patients with a normal ^{18}F FDG-PET scan have a 98% 5-year survival, while those having >10 metastases have a 20% 5-year survival. Those with a SUV_{max} of 0.1–4.6 have a 5-year survival of 85%, while those with a $\text{SUV}_{\text{max}} >13.3$ have a 5-year survival of 20%. Patients with only local metastases have a 5-year survival of 95%, while those with regional (supraclavicular, mediastinal) metastases have a 5-year survival of 70%, and those with distant metastases have a 5-year survival of 35%.

Medullary thyroid carcinoma is more aggressive than differentiated thyroid cancer but is typically fairly indolent. The overall 10-year survival rate is 90% when the tumor is confined to the thyroid, 70% for those with metastases to cervical lymph nodes, and 20% for those with distant metastases. Patients with sporadic disease usually have lymph node involvement noted at the time of diagnosis, whereas distal metastases may not be noted for years. For patients with medullary thyroid carcinoma who have metastases to lymph nodes, modified radical neck dissection is recommended. Familial cases or those associated with MEN 2A tend to be less aggressive; the 10-year survival rate is higher, in part due to earlier detection. Medullary thyroid carcinoma that is seen in MEN 2B is more aggressive, arises earlier in life, and carries a worse overall prognosis, especially when associated with a germline *M918T* mutation. The elderly tend to have more aggressive medullary thyroid carcinomas. Women with medullary thyroid carcinoma who are under age 40 years have a better prognosis. A better prognosis is also obtained in patients undergoing total thyroidectomy and neck dissection; radiation therapy reduces recurrence in patients with metastases to neck nodes. The mortality rate is increased 4.5-fold when primary or metastatic tumor tissue stains heavily for myelomonocytic antigen M-1. Conversely,

tumors with heavy immunoperoxidase staining for calcitonin are associated with prolonged survival even in the presence of significant metastases.

Anaplastic thyroid carcinoma carries a 1-year survival rate of about 10% and a 5-year survival rate of about 5%. Patients with fully localized tumors on MRI have a better prognosis.

Localized lymphoma carries a 5-year survival of nearly 100%. Those with disease outside the thyroid have a 63% 5-year survival. However, the prognosis is better for those with the MALT type. Patients presenting with stridor, pain, laryngeal nerve palsy, or mediastinal extension tend to fare worse.

IODINE DEFICIENCY DISORDER & ENDEMIC GOITER

ESSENTIALS OF DIAGNOSIS

- ▶ Common in regions with low-iodine diets.
- ▶ High rate of congenital hypothyroidism and cretinism.
- ▶ Goiters may become multinodular and enlarge.
- ▶ Most adults with endemic goiter are found to be euthyroid; however, some are hypothyroid or hyperthyroid.

▶ General Considerations

About 1 billion people are iodine deficient, having no access to iodized salt and living in areas with iodine-depleted soil. Severe iodine deficiency increases the risk of miscarriage and stillbirth. About 0.5% of live births in iodine-deficient areas have full-blown cretinism. Moderate iodine deficiency during gestation and infancy cause other manifestations of congenital hypothyroidism, such as deafness and short stature and permanently lowers a child's IQ by 10–15 points.

Populations in areas of iodine deficiency have a high incidence of goiter. One such area is Pescopagano, Italy, where 60% of adults have goiters. Hyperthyroidism (present or past) occurred in 2.9%; hypothyroidism was overt in 0.2% and subclinical in 3.8%.

Although iodine deficiency is the most common cause of endemic goiter, certain foods (eg, sorghum, millet, maize, cassava), mineral deficiencies (selenium, iron), and water pollutants can themselves cause goiter or aggravate a goiter proclivity caused by iodine deficiency. In iodine-deficient patients, smoking can induce goiter growth. Pregnancy aggravates iodine deficiency and is associated with an increase in size of thyroid nodules and the emergence of new nodules. Some individuals are particularly susceptible to goiter owing to congenital partial defects in thyroid enzyme activity.

▶ Clinical Findings

A. Symptoms and Signs

Endemic goiters may become multinodular and very large. Growth often occurs during pregnancy and may cause compressive symptoms.

Substernal goiters are usually asymptomatic but can cause tracheal compression, respiratory distress and failure, dysphagia, superior vena cava syndrome, gastrointestinal bleeding from esophageal varices, palsies of the phrenic or recurrent laryngeal nerves, or Horner syndrome. Cerebral ischemia and stroke can result from arterial compression or thyrocervical steal syndrome. Substernal goiters can rarely cause pleural or pericardial effusions. The incidence of significant malignancy is < 1%.

Some patients with endemic goiter may become hypothyroid. Others may become thyrotoxic as the goiter grows and becomes more autonomous, especially if iodine is added to the diet.

B. Laboratory Findings

The serum T₄ and TSH are generally normal. TSH falls in the presence of hyperthyroidism if a multinodular goiter has become autonomous in the presence of sufficient amounts of iodine for thyroid hormone synthesis. TSH rises with hypothyroidism. Thyroid RAI uptake is usually elevated, but it may be normal if iodine intake has improved. Serum levels of anti-thyroid antibodies are usually either undetectable or in low titers. Serum thyroglobulin is often elevated.

▶ Differential Diagnosis

Endemic goiter must be distinguished from all other forms of nodular goiter that may coexist in an endemic region (see above).

► Prevention

Adding iodine to commercial salt prevents iodine deficiency. In the United States, potassium iodide is used. Some tropical countries use potassium iodate, since it is more stable than potassium iodide in hot and humid climates. Iodized salt contains iodine at about 20 mg per kg salt. The minimum dietary requirement for iodine is about 50 mcg daily, with optimal iodine intake being 150–300 mcg daily. Iodine sufficiency is assessed by measurement of urinary iodide excretion, the target being more than 10 mcg/dL. Initiating iodine supplementation in an iodine-deficient area greatly reduces the emergence of new goiters but causes an increased frequency of hyperthyroidism during the first year.

► Treatment

The addition of potassium iodide to table salt greatly reduces the prevalence of endemic goiter and cretinism but is less effective in shrinking established goiter. Concurrent deficiencies in both vitamin A and iodine increase the risk of endemic goiter and concurrent repletion of both iodide and vitamin A reduces goiter in endemic goiter regions.

Adults with large multinodular goiter may require thyroidectomy for cosmesis, compressive symptoms, or thyrotoxicosis. Following partial thyroidectomy in iodine-deficient geographic areas, there is a high goiter recurrence rate, so near-total thyroidectomy is preferred when surgery is indicated. Certain patients may be treated with ¹³¹I for large compressive goiters.

► Complications

Dietary iodine supplementation increases the risk of autoimmune thyroid dysfunction, which may cause hypothyroidism or hyperthyroidism. Excessive iodine supplementation increases the risk of goiter. Suppression of TSH by administering thyroxine carries the risk of inducing hyperthyroidism, particularly in patients with autonomous multinodular goiters; therefore, thyroxine suppression should not be started in patients with a low TSH level. Rarely, Graves disease can develop 3–10 months after ¹³¹I treatment in patients with large multinodular goiters.

▼ DISEASES OF THE PARATHYROIDS

Parathyroid hormone (PTH) increases osteoclastic activity in bone, increases the renal tubular reabsorption of calcium, and stimulates the synthesis of 1,25-dihydroxycholecalciferol by the kidney. Meanwhile, PTH inhibits the

absorption of phosphate and bicarbonate by the renal tubule. All of these actions cause a net increase in serum calcium.

HYPOPARATHYROIDISM & PSEUDOHYPOPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- ▶ Tetany, carpopedal spasms, tingling of lips and hands, muscle and abdominal cramps, psychological changes.
- ▶ Positive Chvostek sign and Trousseau phenomenon.
- ▶ Serum calcium low; serum phosphate high; alkaline phosphatase normal; urine calcium excretion reduced.
- ▶ Low or low-normal serum PTH in presence of hypocalcemia.
- ▶ Serum magnesium may be low.

► General Considerations

Acquired hypoparathyroidism is most commonly seen following thyroidectomy, when it is usually transient but may be permanent. It may also occur after multiple parathyroidectomies. Hypoparathyroidism may occur transiently after surgical removal of a parathyroid adenoma for primary hyperparathyroidism due to suppression of the remaining normal parathyroids and accelerated remineralization of the skeleton (hungry bone syndrome). Neck irradiation may rarely cause hypoparathyroidism.

Autoimmune hypoparathyroidism may be isolated or combined with other endocrine deficiencies in polyglandular autoimmunity (PGA), which is also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED). PGA type 1 presents in childhood with at least two of the following manifestations: candidiasis, hypoparathyroidism, or Addison disease. Cataracts, uveitis, alopecia, vitiligo, or autoimmune thyroid disease may also develop. Fat malabsorption occurs in 20% of patients with PGA-1 and may present as weight loss; diarrhea; or malabsorption of vitamin D, a fat-soluble vitamin used to treat the hypoparathyroidism. The fat malabsorption may be due to a deficiency in the jejunal enteroendocrine cells that produce cholecystokinin, causing a reduction in bile acid secretion. Hypoparathyroidism can also occur in systemic lupus erythematosus, caused by antiparathyroid antibodies.

Parathyroid deficiency may also be the result of damage from heavy metals such as copper (Wilson disease) or iron (hemochromatosis, transfusion hemosiderosis), granulomas, Riedel thyroiditis, tumors, or infection.

Functional hypoparathyroidism may also occur as a result of magnesium deficiency (malabsorption, chronic alcoholism), which prevents the secretion of PTH. Correction of hypomagnesemia results in rapid disappearance

of the condition. Hypermagnesemia can also suppress PTH secretion; it may occur in patients with kidney disease who take magnesium supplements, laxatives, or antacids.

In **congenital hypoparathyroidism**, parathyroid cells have calcium-sensing receptors (CaSR) that sense the serum calcium concentration and suppress PTH secretion by way of G-protein-coupled mechanisms. Gain-of-function mutations (constitutive activation) of the *CaSR* gene suppress the parathyroid glands, resulting in hypocalcemia without elevations in serum PTH levels. Such mutations cause “autosomal dominant hypocalcemia with hypercalciuria” from deficient secretion of PTH. The prevalence of autosomal dominant hypocalcemia with hypercalciuria in the population is about 1 in 70,000, and it typically presents in infancy with hypocalcemic seizures.

Hypoparathyroidism, deafness, and renal dysplasia (HDR or Barakat) syndrome is an autosomal dominant condition caused by haploinsufficiency or mutations of the gene *GATA3*; the condition is autosomal dominant. Hypocalcemia is present from birth but may not be detected until the occurrence of mental retardation or hypocalcemic tetany. Hypoparathyroidism may also be seen in DiGeorge syndrome, along with congenital cardiac and facial anomalies; hypocalcemia usually presents with tetany in infancy, but some cases are not detected until adulthood.

Familial isolated hypoparathyroidism is caused by mutations in various genes that encode the secretion of PTH or the embryologic development of the parathyroid glands. Mutations in the *TBCE* gene cause autosomal recessive hypoparathyroidism with other phenotypic abnormalities that are known as the Kenny-Caffey syndrome or the Sanjad-Sakati syndrome. Various mutations in genes that encode mitochondria have maternal inheritance and cause hypoparathyroidism in association with other syndromes: Kearns-Sayre (ophthalmoplegia, retinopathy, cardiomyopathy, diabetes) and MELAS (mitochondrial encephalopathy, lactic acidosis, stroke).

► Clinical Findings

A. Symptoms and Signs

Acute hypoparathyroidism and hypocalcemia can occur spontaneously or may be precipitated when a patient with untreated hypoparathyroidism receives a proton pump inhibitor. Manifestations of hypocalcemia include tetany, muscle cramps, carpal spasm, irritability, altered mental status, convulsions, and stridor; tingling of the circumoral area, hands, and feet is almost always present. Symptoms of the chronic disease are lethargy, personality changes, anxiety state, blurring of vision due to premature cataracts, Parkinsonism, and mental retardation. Some patients with chronic hypocalcemia are asymptomatic, even with very low levels of serum calcium.

Chvostek sign (facial muscle contraction on tapping the facial nerve in front of the ear) is positive, and Trousseau phenomenon (carpal spasm after application of a sphygmomanometer cuff) is present. Cataracts may occur; the nails may be thin and brittle; the skin is dry and scaly, at times with fungus infection (candidiasis), and there may be loss of eyebrows; and deep tendon reflexes may be hyperactive.

Papilledema and elevated cerebrospinal fluid pressure are occasionally seen. Teeth may be defective if the onset of the disease occurs in childhood.

B. Laboratory Findings

Serum calcium is low, serum phosphate high, urinary calcium low, and alkaline phosphatase normal. Serum calcium is largely bound to albumin. In hypoalbuminemia, the serum ionized calcium may be determined, but it has had surprisingly poor clinical utility. Alternatively, the serum calcium level can be corrected for serum albumin level as follows:

$$\text{“Corrected” serum Ca}^{2+} = \text{Serum Ca}^{2+} \text{ mg/dL} + (0.8 \times [4.0 - \text{Albumin g/dL}])$$

PTH levels are low. Hypomagnesemia may exacerbate symptoms and decrease parathyroid function.

C. Imaging

Radiographs or CT scans of the skull may show basal ganglia calcifications; the bones may be denser than normal. Cutaneous calcification may occur.

D. Other Examinations

Slit-lamp examination may show early posterior lenticular cataract formation. The electrocardiogram (ECG) shows prolonged QT intervals and T wave abnormalities. Patients with chronic hypoparathyroidism tend to have increased bone mineral density, particularly in the lumbar spine.

► Complications

Acute tetany with stridor, especially if associated with vocal cord palsy, may lead to respiratory obstruction requiring tracheostomy. Pseudotumor cerebri has been reported. Congestive heart failure may rarely occur. The complications of chronic hypoparathyroidism largely depend on the duration of the disease. There may be associated autoimmunity causing sprue syndrome, pernicious anemia, or Addison disease. In long-standing cases, cataract formation and calcification of the basal ganglia are seen. Occasionally, parkinsonian symptoms or choreoathetosis develop. Ossification of the paravertebral ligaments may occur with nerve root compression; surgical decompression may be required. Seizures are common in untreated patients. Overtreatment with vitamin D and calcium may produce nephrocalcinosis and impairment of kidney function. Chronic hypocalcemia can cause heart failure.

► Differential Diagnosis

Paresthesias, muscle cramps, or tetany due to respiratory alkalosis, in which the serum calcium is normal, can be confused with hypocalcemia. In fact, hyperventilation tends to accentuate hypocalcemic symptoms.

At times hypoparathyroidism is misdiagnosed as idiopathic epilepsy, choreoathetosis, or brain tumor (on the basis of brain calcifications, convulsions, choked disks) or, more rarely, as “asthma” (on the basis of stridor and dyspnea).

In patients with hypoalbuminemia, serum levels of ionized calcium are normal.

Hypocalcemia may also be due to malabsorption of calcium, magnesium, or vitamin D; patients do not always have diarrhea. Hypocalcemia may also be caused by certain drugs: loop diuretics, plicamycin, phenytoin, alendronate, and foscarnet. In addition, hypocalcemia may be seen in cases of rapid intravascular volume expansion or due to chelation from transfusions of large volumes of citrated blood. It is also observed in patients with acute pancreatitis. Hypocalcemia may develop in some patients with certain osteoblastic metastatic carcinomas (especially breast, prostate) instead of the expected hypercalcemia. Hypocalcemia with hyperphosphatemia (simulating hypoparathyroidism) is seen in azotemia but may also be caused by large doses of intravenous, oral, or rectal phosphate preparations and by chemotherapy of responsive lymphomas or leukemias.

Hypocalcemia with hypercalciuria may be due to a familial syndrome involving a mutation in the calcium-sensing receptor; such patients have levels of serum PTH that are in the normal range, distinguishing it from hypoparathyroidism. It is transmitted as an autosomal dominant disorder. Such patients are hypercalciuric; treatment with calcium and vitamin D may cause nephrocalcinosis.

Congenital pseudohypoparathyroidism is a group of disorders characterized by resistance to PTH. There are several subtypes caused by different mutations involving the PTH receptor or its G protein or adenyl cyclase. Renal tubular resistance to PTH causes hypercalciuria with resultant hypocalcemia. PTH levels are high and the PTH receptors in bone are typically not involved, such that bony changes of hyperparathyroidism may be evident. In pseudohypoparathyroidism type 1a, patients have hypocalcemia and hyperphosphatemia with additional features known as Albright hereditary osteodystrophy: mental retardation, short stature, obesity, round face, short fourth metacarpals, ectopic bone formation, hypothyroidism, and hypogonadism. Patients without hypocalcemia but sharing the phenotypic abnormalities are said to have "pseudopseudohypoparathyroidism."

► Treatment

A. Emergency Treatment for Acute Attack (Hypoparathyroid Tetany)

This usually occurs after surgery and requires immediate treatment.

1. Airway—Be sure an adequate airway is present.

2. Intravenous calcium gluconate—Calcium gluconate, 10–20 mL of 10% solution intravenously, may be given *slowly* until tetany ceases. Ten to 50 mL of 10% calcium gluconate may be added to 1 L of 5% glucose in water or saline and administered by slow intravenous drip. The rate should be adjusted so that the serum calcium is maintained between 8 mg/dL and 9 mg/dL.

3. Oral calcium—Calcium salts should be given orally as soon as possible to supply 1–2 g of calcium daily. Liquid calcium carbonate, 500 mg/5 mL, may be especially useful. The dosage is 1–3 g calcium daily. Calcium citrate contains 21% calcium, but a higher proportion is absorbed with less gastrointestinal intolerance.

4. Vitamin D preparations—(Table 26–9.) Therapy should be started as soon as oral calcium is begun. The active metabolite of vitamin D, 1,25-dihydroxycholecalciferol (calcitriol), has a very rapid onset of action and is not long-lasting if hypercalcemia occurs. It is of great use in the treatment of acute hypocalcemia. Therapy is commenced at a dosage of 0.25 mcg orally each morning with upward dosage titration to near normocalcemia. Ultimately, doses of 0.5–2 mcg/d are usually required. Calcifediol (25-hydroxyvitamin D₃), another option for treatment, has an intermediate onset and duration of action; the usual starting dose is 20 mcg/d orally.

5. Magnesium—If hypomagnesemia is present (chronic alcoholism, malnutrition, renal loss, drugs such as cisplatin, etc), it must be corrected to treat the resulting hypocalcemia. Acutely, magnesium sulfate is given intravenously, 1–2 g every 6 hours. Long-term magnesium replacement may be given as magnesium oxide tablets (600 mg), one or two per day, or as a combined magnesium and calcium preparation (CalMag, others).

6. Transplantation of cryopreserved parathyroid tissue removed during prior surgery—Transplantation restores normocalcemia in about 23% of cases.

B. Maintenance Treatment

The goal should be to maintain the serum calcium in a slightly low but asymptomatic range (8–8.6 mg/dL). This

Table 26–9. Vitamin D preparations used in the treatment of hypoparathyroidism.

	Available Preparations	Daily Dose	Duration of Action
Ergocalciferol ergosterol, (vitamin D ₂ , Calciferol)	Capsules of 50,000 international units; 8000 international units/mL oral solution	2000–200,000 units	1–2 weeks
Cholecalciferol (vitamin D ₃)	Capsules of 50,000 international units not available commercially in United States; may be compounded	10,000–50,000 units	4–8 weeks
Calcitriol (Rocaltrol)	Capsules of 0.25 and 0.5 mcg; 1 mcg/mL oral solution; 1 mcg/mL for injection	0.25–4 mcg	½–2 weeks

will minimize the hypercalciuria that would otherwise occur and provides a margin of safety against overdosage and hypercalcemia, which may produce permanent damage to kidney function. Patients with mild, asymptomatic hypocalcemia require no therapy. For others, calcium supplementation (1 g/d) is given, along with a vitamin D preparation.

Patients with chronic hypoparathyroidism must usually be treated with some type of vitamin D (Table 26–9). Monitoring of serum calcium at regular intervals (at least every 3 months) is mandatory. **Calcitriol**, a short-acting preparation, is given in doses that range from 0.25 mcg/d to 2.0 mcg orally daily. **Ergocalciferol** (vitamin D₂) is derived from plants and is commercially available. The usual dose ranges from 25,000 to 150,000 units/d. It is a slow-acting preparation that is stored in fat, giving it a long duration of action. If toxicity develops, hypercalcemia—treatable with hydration and prednisone—may persist for weeks after it is discontinued. Despite this risk, ergocalciferol usually produces a more stable serum calcium level than do the shorter-acting preparations.

Teriparatide (Forteo) is a recombinant preparation of human PTH 1–34. Teriparatide is effective in treating patients with hypoparathyroidism when given by subcutaneous injection at an initial dose of 0.4 mcg/kg twice daily. The dose is adjusted to produce normal serum calcium levels. The disadvantages of teriparatide therapy include its extremely high cost and the necessity for injections. Furthermore, teriparatide is not approved by the US Food and Drug Administration (FDA) for this indication because prolonged high doses in rats caused osteosarcoma. Therefore, teriparatide therapy is reserved for patients with severe hypoparathyroidism that fails to respond to vitamin D.

Target serum calcium levels (albumin-corrected) should be 8.0–8.5 mg/dL; these levels are mildly low to avoid hypercalciuria. It is prudent to monitor urine calcium with “spot” urine determinations and keep the level below 30 mg/dL if possible. Hypercalciuria may respond to oral hydrochlorothiazide, usually given with a potassium supplement.

Caution: Phenothiazine drugs should be administered with caution, since they may precipitate extrapyramidal symptoms in hypocalcemic patients. Furosemide should be avoided, since it may worsen hypocalcemia.

► Prognosis

The outlook is good if the diagnosis is made promptly and treatment instituted. Any dental changes, cataracts, and brain calcifications are permanent. Periodic blood chemical evaluation is required, since changes in calcium levels may call for modification of the treatment schedule. Hypercalcemia that develops in patients with seemingly stable, treated hypoparathyroidism may be a presenting sign of Addison disease.

Despite optimal therapy, patients with hypoparathyroidism have been reported to have an overall reduced quality of life. Affected patients have a high risk of having mood and psychiatric disorders along with a reduced overall sense of well-being.

HYPERPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- Frequently detected incidentally by screening.
- Renal calculi, polyuria, hypertension, constipation, fatigue, mental changes.
- Bone pain; rarely, cystic lesions and pathologic fractures.
- Serum and urine calcium elevated; urine phosphate high with low to normal serum phosphate; alkaline phosphatase normal to elevated.
- Elevated PTH.

► General Considerations

Primary hyperparathyroidism is the most common cause of hypercalcemia, with a prevalence of 1–4 cases per 1000 persons. It occurs at all ages but most commonly in the seventh decade and in women (74%). Before age 45, the prevalence is similar in men and women.

The disease is caused by hypersecretion of PTH, usually by a single parathyroid adenoma (80%), and less commonly by hyperplasia by two or more parathyroid glands (20%), or carcinoma (\leq 1%). However, when hyperparathyroidism presents before age 30 years, there is a higher incidence of multiglandular disease (36%) and parathyroid carcinoma (5%). The size of the parathyroid adenoma correlates with the serum PTH level.

Hyperparathyroidism is familial in about 10% of cases. Parathyroid hyperplasia may arise in MEN types 1, 2A, and 2B. In MEN 1, multiglandular hyperparathyroidism is usually the initial manifestation and ultimately occurs in 90% of affected individuals. Hyperparathyroidism in MEN 2A is less frequent than in MEN 1 and is usually

milder. Familial hyperparathyroidism can also occur in the hyperparathyroidism-jaw tumor syndrome, a rare autosomal dominant familial condition in which parathyroid cystic adenomas or carcinomas are associated with ossifying fibromas of the mandible and maxilla as well as renal lesions (cysts, hamartomas, Wilms tumors). Affected individuals usually present with severe hypercalcemia as teenagers or young adults; the pathology is usually a single parathyroid adenoma. (See Table 26–17.)

Hyperparathyroidism results in the excessive excretion of calcium and phosphate by the kidneys. PTH stimulates renal tubular reabsorption of calcium; however, hyperparathyroidism causes hypercalcemia and an increase in calcium in the glomerular filtrate that overwhelms tubular reabsorption capacity, resulting in hypercalciuria. At least 5% of renal calculi are associated with this disease. Diffuse parenchymal calcification (nephrocalcinosis) is seen less commonly. Excessive PTH can cause cortical demineralization that is particularly evident at the wrist and hip; trabecular bone is usually spared as evidenced by relatively higher spinal bone density compared to the wrist. Severe, chronic hyperparathyroidism can cause diffuse demineralization, pathologic fractures, and cystic bone lesions throughout the skeleton, a condition known as **osteitis fibrosa cystica**.

In chronic kidney disease, hyperphosphatemia and decreased renal production of 1,25-dihydroxycholecalciferol ($1,25[\text{OH}]_2\text{D}_3$) initially produce a decrease in ionized calcium. The parathyroid glands are stimulated (secondary hyperparathyroidism) and may enlarge, becoming autonomous (tertiary hyperparathyroidism). The bone disease seen in this setting is known as **renal osteodystrophy**. Parathyroid hyperplasia in uremia can result in extremely high serum PTH levels that are associated with uremic vascular calcification. Hypercalcemia often occurs after kidney transplant.

Parathyroid carcinoma is a rare cause of hyperparathyroidism but is more common in patients with serum calcium levels ≥ 14.0 mcg/dL. About 50% of parathyroid carcinomas are palpable.

► Clinical Findings

A. Symptoms and Signs

In the developed world, hypercalcemia of hyperparathyroidism is typically discovered accidentally by routine chemistry panels. Many patients are asymptomatic or have mild symptoms that may be elicited only upon questioning. Parathyroid adenomas are usually so small and deeply located in the neck that they are almost never palpable; when a mass is palpated, it usually turns out to be an incidental thyroid nodule.

Symptomatic patients are said to have problems with “bones, stones, abdominal groans, psychic moans, with fatigue overtones.” The manifestations are categorized as skeletal, urinary tract, and those associated with hypercalcemia.

1. Skeletal manifestations—Hyperparathyroidism causes a loss of cortical bone and a gain of trabecular bone. Low bone density is typically most prominent at the wrist.
