The NK cell is believed to be the most important target for IL-2 therapy because depletion of this cell type can negate the protective effects of IL-2 in animal models.[4] The high doses used in cancer chemotherapy are believed to saturate completely the intermediate-affinity IL-2 receptors of NK cells.[39] In animal models, transplanted tumor micrometastases seem to regress when IL-2 is used alone or in combination with LAK cells. In human clinical trials involving advanced melanoma, the coadministration of IL-2 and LAK cells resulted in the complete regression of tumors in approximately 5% of cases, and the partial regression (>50% reduction in tumor mass) in 15% of cases. Comparative values for metastatic renal cancer were 4% and 11%. IL-2 therapy has certain inherent problems not found in classic hormone therapy. IL-2 is a short-range hormone designed to influence cells in an extremely local manner. High-dose IL-2 therapy is toxic, and complications lead to a mortality rate of approximately 4%. Adverse effects include capillary leak syndrome (resulting in edema, reduced organ perfusion, and hypotension), cardiac arrhythmias, myocardial infarction, respiratory insufficiency, mental disturbances, and increased infections.[43]

Experimentation with lower dosages has greatly influenced IL-2 immunotherapy. Lower dosages are based on the observation that 10% of NK cells express high-affinity receptors for IL-2; a 500-fold decrease in the IL-2 dose (administered as a continuous intravenous infusion) would still be sufficient to saturate all these high-affinity receptors. The low-dose regimen was found to produce a gradual, 10-fold increase in circulating NK cells without causing significant toxicity.[39] Such low-dose administration of IL-2 has also been used to increase the number of NK cells in patients with HIV infection or advanced cancer.[4,39]

Subcutaneous administration of IL-2 has been tested as an immunostimulant in individuals with asymptomatic HIV infection. This route leads to an increase in the proportion of T cells expressing IL-2Rs without increasing NK cells or viral proliferation.[39]

Interferons

There are two major classes of interferons: type 1 interferons (IFN-α, IFN-β, and IFN-ω), and type 2 interferon (IFN-γ). Type 1 interferons are produced by most nucleated cells. IFN-γ is mainly a product of TH1 T cells and activated NK cells.[20]

Type 1 interferons act by stimulating the phosphorylation of cytosolic proteins termed *signal transducers and activators of transcription (STAT)*. These STAT proteins form a complex with a specific nonphosphorylated protein; the complex enters the nucleus, binds to its designated response element on DNA, and promotes transcription.[36] Only the nonphosphorylated protein constituent actually binds to DNA.

Recombinant forms of IFN-α (interferon alfa-2a, interferon alfa-2b, interferon alfacon-1) and IFN-β (interferon beta-1a, interferon beta-1b) and a purified form from human leukocytes (interferon alfa-N3) have received approval by the FDA for use in the clinical setting, as described in Chapters 40 and 42.[35] IFN-α preparations are indicated in the treatment of numerous diseases, including hairy cell leukemia, chronic myelogenous leukemia, condyloma acuminatum, acquired immunodeficiency syndrome–related Kaposi's sarcoma, chronic hepatitis B and C, and malignant melanoma. IFN-β preparations are approved for the treatment of remitting and recurring multiple sclerosis. In addition, trials are ongoing for the use of type 1 interferons in numerous other cancers, AIDS, viral infections, papillomas, and angiogenic disorders.

IFN-γ was initially discovered as a result of its antiviral properties, but it also displays antiproliferative effects against tumors. IFN-γ is a glycosylated protein that exists exclusively as a covalently coupled homodimer. It shares very little DNA sequence homology with either IFN-α or IFN-β, and IFN-γ is more accurately classified as an interleukin. The mechanism by which IFN-γ stimulates transcription is similar, however, to that of the type 1 interferons. The resultant effects of its action include (1) stimulation of CD4+ TH1 T cells and macrophages, (2) suppression of antibody production (IFN-γ antagonizes CD4+ TH2 T cells), (3) induction of immunoglobulin class switching, (4) upregulation of MHC II expression by epithelial tumor cells and macrophages (an effect antagonized by prostaglandin E2), and (5) alteration of antigen processing by changing the mix of peptide products produced by the proteasome.[2] IFN-γ, in the form of a single polypeptide chain designated *interferon γ-1b,* is approved for managing serious infections associated with granulomatous disease and delaying the progression of malignant osteopetrosis. It is also useful in the management of rheumatoid arthritis.

TH1 and TH2 Cytokines

In later phases of specific immune responses, one function of cytokines is to regulate the nature of the immune response. TH1 cytokines help guide specific immunity against changes in intracellular, cytosolic antigens, and TH2 cytokines help direct specific immunity against changes in extracellular antigens. These TH1 and TH2 responses are mutually inhibitory: the TH1 cytokines IFN-γ and IL-12 inhibit TH2 responses, and the TH2 cytokines IL-4 and IL-10 inhibit TH1 responses. Pharmacologic regulation of the relative proportions of TH1 and TH2 cytokines may provide a way to treat diseases in which an inappropriate TH1 or TH2 response is a component of the disease process (in contrast to the problem of simply too much or too little immune response).

The types of disorders that may be amenable to cytokine intervention in these later stages include infectious diseases in which there is an inappropriate type of immune response, inflammatory autoimmune diseases, and IgE-mediated allergic diseases.[32] Lepromatous leprosy, nonhealing forms of leishmaniasis, tuberculosis, trypanosomiasis, and certain fungal diseases are infections that may be exacerbated by an inappropriately strong TH2 response. The administration of the TH1 cytokine IFN-γ, as mentioned previously, is approved for this indication.

Experimental allergic encephalomyelitis, a potential animal model for multiple sclerosis, seems to involve an overzealous TH1 response and can be transferred by T cells with the TH1 phenotype. In animals, spontaneous recovery from the disease is associated with an expansion of T cells with the TH2 phenotype; a study in humans with multiple sclerosis suggests that the administration of IFN-γ exacerbates the disease process (to the point where the research had to be terminated). Opposite effects occur with IFN-β,[41] which has FDA approval for the treatment of this form of the disease. The destruction of β-islet cells in insulin-dependent diabetes mellitus has been associated with tissue infiltration by T cells of the TH1 phenotype. For such TH1-mediated disease, it is possible that the administration of TH2 cytokines IL-4 and IL-10 may be beneficial.

IgE-mediated allergic diseases are consistent with the overactivity of TH2 T cells. Well-known examples include allergic rhinitis, immediate drug allergies, and life-threatening anaphylaxis resulting from insect stings. The successful long-term treatment of IgE-mediated allergies empirically corresponds with a shift in antibody isotypes from IgE to IgG; it is widely believed that various desensitization procedures in which the allergen is injected into the allergic host owe their success to the generation of "blocking antibodies" of the IgG subclass. Bee venom immunotherapy is a good model for such procedures; it is associated with a TH2-to-TH1 shift.[28] The TH1 cytokine profile favors production of IgG rather than IgE. In local tissues, mast cells and basophils are important sources of IL-4. Local therapies currently being explored include anti-IL-4 antibodies and IFN-α.

Short-term desensitization procedures are also available for dealing with IgE-mediated allergies. Occasionally, it may be essential to treat a patient with a certain drug despite a known allergy to that drug (e.g., using penicillin to treat an infection in an individual with a positive skin test indicative of penicillin allergy). Most individuals are not allergic to penicillin itself, but rather to antigens that form by the covalent linkage between the β-lactam ring of penicillin metabolites and certain proteins. In acute desensitization, penicillin is administered in incrementally increasing dosages over 4 to 6 hours. The goal of these therapies is not to cause a permanent reduction in antipenicillin IgE, but instead to induce rapidly a state of clinical tolerance. The actual mechanism of clinical tolerance is unclear (possible Fc receptor downregulation in mast cells); the end result is a diminished risk of anaphylaxis with only minor urticarial side effects.

DRUGS USED IN IMMUNOTHERAPY

Nonproprietary (generic) name	*Proprietary (trade) name*
Agents for active immunization	
See references 6 and 14	
Agents for passive immunization	
Botulism immunoglobulin (human)	BabyBIG
Cytomegalovirus immunoglobulin (human)	CytoGam
Hepatitis B immunoglobulin (human)	HepaGam B, HyperHEP B S/D, Nabi-HB
Immunoglobulin (human)	BayGam, Carimune NF, Flebogamma, Gamimune N, Gammagard, Octagan
Palivizumab	Synagis
Rabies immunoglobulin (human)	IMOGAM
Respiratory syncytial virus immunoglobulin (human)	RespiGam
Rho(D) immunoglobulin (human)	HyperRho S/D, RhoGAM, WinRho SDF
Tetanus immunoglobulin	HyperTET S/D
Varicella-zoster immunoglobulin	—
Antitoxins	
Antivenin (Crotalidae), polyvalent	—
Antivenin (*Latrodectus mactans*)	—
Antivenin (*Micrurus fulvius*)	—
Crotalidae polyvalent immune fab	CroFab
Rabies immunoglobulin (human)	Hyperab, Imogam
Immunostimulants	
Thymosin*	—
Levamisole*	Ergamisol
Immunomodulators	
Imiquimod	Aldera
Lenalidomide	Revlimid
Mitoxantrone	Novantrone
Thalidomide	Thalomid
Monoclonal antibodies	
See Table 41-2	
Immunosuppressants	
Abatacept	Orencia
Azathioprine	Azasan, Imuran
Basiliximab	Simulect
Cyclophosphamide	Cytoxan
Cyclosporine	Gengraf, Neoral, Sandimmune
daaclizumab	ZENAPAX
Glatiramer	Copaxone
Lymphocyte immunoglobulin, antithymocyte globulin (equine)	Atgam
Antithymocyte globulin (rabbit)	Thymoglobulin
Melphalan	Alkeran
Mercaptopurine	Purinethol
Methotrexate	Rheumatrex Dose Pack, Trexall
Muromonab-CD3	Orthoclone OKT3
Mycophenolate mofetil	CellCept
Mycophenolic acid	Myfortic
Prednisone	Sterapred
Sirolimus	Rapamune
Tacrolimus (FK506)	Prograf
Slow-acting disease-modifying antirheumatic drugs	
See Chapter 21	
Cytokines	
Aldesleukin (IL-2)	Proleukin
Anakinra	Kineret
Denileukin diftitox	Ontak
Interferon alpha-2a	Roferon-A
Interferon alpha-2b	Intron A
Interferon alpha-n3	ALFERON N
Interferon alfacon-1	Infergen
Interferon beta-1a	Avonex, Rebif
Interferon beta-1b	Betaseron, Extavia
Interferon gamma-1b	Actimmune
Peginterferon alpha-2a	Pegasys
Peginterferon alpha-2b	PEG-Intron
Hematopoietic growth factors	
See Chapter 30	
Therapy for allergic reactions	
See Chapters 22, 32, and 35

CHAPTER 42

Antineoplastic Drugs

KARL K. KWOK, LINSEY R. CURTIS, AND MARK M. SCHUBERT

The role of antineoplastic drugs in cancer treatment has greatly expanded in the past few decades. These drugs can cure numerous advanced tumors and are the treatment of choice for many widely disseminated malignancies that cannot be reached by surgery or are beyond the limits of safety of radiotherapy. They are also used as adjuncts to surgery and irradiation in the prevention of metastasis from locally treated primary tumors. Research has resulted in the development of new agents, more effective applications of existing agents, and the use of adjunctive drugs to overcome resistance and minimize drug toxicity.

The past decade has also brought about a greater depth of research and understanding of the molecular biology of cancer cell growth. Many mechanisms of growth stimulation and retardation and the actions of growth modulators have been discovered. Gene rearrangements and mutations and their resultant influences on cell growth are being elucidated. These discoveries provide many new targets for the management of abnormal cell growth, and with that have come multiple new approaches to cancer therapy and several new classes of drugs. Antineoplastic regimens that contribute to the goal of eliminating and destroying tumor cells now include traditional chemotherapeutic drugs (i.e., alkylators, antimetabolites, antibiotics, steroids, plant alkaloids, and other agents), biologic response modifiers, novel targeting agents, and agents used specifically to protect the patient from the toxic effects of these drugs. In the last few years, several newer chemotherapy drugs, such as nelarabine, ixabepilone, and others, have been introduced as the antineoplastic agents, and some older therapeutic agents, such as arsenic trioxide, and thalidomide, are experiencing a resurgence of interest in their actions.

Other newer groups of drugs used in managing cancer include specific hormonal agents, such as letrozole, anastrozole, and fulvestrant; differentiating agents, such as tretinoid; and monoclonal antibodies (MAbs), which have a variety of different targets and potential mechanisms of action. Additional groups include drugs that target signal transduction, such as imatinib mesylate; drugs that block crucial cellular receptors, including epidermal growth factor receptors (EGFRs) such as erlotinib; and drugs that inhibit angiogenesis, such as bevacizumab, a MAb that blocks vascular endothelial growth factor (VEGF). There are also groups that include proteasome inhibitors, such as bortezomib, and drugs that may enhance or remove blocks to apoptosis (programmed cell death). As the choices in therapeutic agents, combinations, and approaches increase, the ability to successfully eradicate cancer is improving.

HISTORY OF CANCER CHEMOTHERAPY

The cytotoxic effects of drugs were observed well before the turn of the twentieth century, but their usefulness in the treatment of disease was not appreciated until the mid-1940s. Chemical warfare with sulfur mustard gas in World War I resulted in shrinkage of lymph nodes and myeloid tissues in the victims. The application of these nitrogen mustard compounds for the medical treatment of Hodgkin's disease, malignant lymphomas, and chronic leukemia followed these observations but was not reported until the end of World War II. In 1944, glucocorticoids were shown to have a profound effect on the volume, structure, and function of lymphoid tissue.[17] Subsequently, this effect was used in the control of human leukemia, and since then prednisone and prednisolone have been incorporated in drug protocols designed to ablate lymphoproliferative and myeloproliferative diseases.

In 1948, Farber and colleagues[20] obtained temporary remissions in children with acute leukemia who were given the folic acid antagonist 4-aminopteroylglutamic acid (aminopterin). This specially tailored molecule was the first antimetabolite to produce unequivocally beneficial results in a human neoplastic disease.

The folate antagonist approach led to the development of competitive inhibitors of purines and pyrimidines that interfered with the synthesis of nucleic acids in rapidly multiplying neoplastic cells. Observations in animal tumor models of selective uptake of uracil by colon tumor cells resulted in the development of a "designer" antimetabolite, 5-fluorouracil.

The first antibiotic with activity against human tumors was actinomycin D. Introduced as an anticancer agent in 1952, dactinomycin (actinomycin D) is curative in many patients with Wilms' tumor and uterine choriocarcinoma. The anticancer effects of the vinca alkaloids, extracted from the periwinkle plant (*Vinca rosea*), were initially shown in animals with experimental leukemia in 1960.[40] In the same year, vinblastine was found to be valuable in the treatment of acute forms of leukemia, Hodgkin's disease, and adenocarcinoma of the colon.[35] The earliest reports of the use of carmustine, the prototype of the nitrosourea group of cytotoxic compounds, against human malignancies appeared in 1966.

In 1967, the enzyme L-asparaginase was found to produce remissions in some patients with acute leukemia. The first of the heavy metal complexes to have significant success in the treatment of human cancer was cisplatin, introduced in 1969. The 1950s and 1960s brought rapid development of new agents, and continued refinements in their use occurred in the 1970s and early 1980s with additional combination chemo-

therapy regimens and a better understanding of the cytokinetics of tumor cells and the pharmacokinetics of the drugs.[13,15] The late 1980s and early 1990s contributed several new agents, such as taxanes, topoisomerase I inhibitors, and others with measurable efficacy and decreased toxicity; biologic response modifiers such as interferon and interleukin-2; and chemoprotective agents and newer technologies for the application of these antineoplastic agents.

The late 1990s brought the commercial availability of some MAbs for the treatment of several cancers, as well as important research on the role of angiogenesis, which had started in the 1960s. Angiogenesis, which is the formation of new blood vessels, plays a role in supporting existing tumors with required nutrients and oxygen and in forming metastatic tumors. The identification of angiogenic factors such as VEGF, basic fibroblastic growth factor, and other regulators and inhibitors of angiogenesis is leading to the development of new drugs to target these factors and evaluate their role in starving cancer cells and preventing the formation of metastatic disease.[44]

Several novel strategies are being considered in clinical trials, applying newer drug entities for newly identified targets. Drugs being studied include angiogenesis factors, inhibitors of matrix metalloproteinase, and drugs that affect intracellular signaling pathways (e.g., tyrosine kinase [TK] inhibitors). Many drugs have been developed that can promote apoptosis, target cyclin-dependent kinases, and inhibit the family of enzymes that plays a role in cell cycle progression. The challenge of these clinical trials is to identify agents specific to the cancer cell process and determine the appropriate role of these agents, combined with existing therapies, in enhancing responses to cancer treatment and minimizing side effects.

PRINCIPLES OF CANCER CHEMOTHERAPY

The goal of chemotherapy is to eradicate every viable tumor cell without significantly damaging normal host tissue. Attaining this goal requires that the tumor be inherently sensitive to the chemotherapy agents, that the tumor receptor sites be exposed to adequate concentrations of active drug for sufficient periods, and that the host cells be resistant to the effects of the chemotherapy drugs. Classic chemotherapy agents are not tumor cell specific and kill all cells actively undergoing cell division. In addition to killing the abnormal or malignant cells, normal cells in the gastrointestinal tract, bone marrow, and hair follicles and other tissues are affected.

Chemotherapy drugs kill or impair susceptible tumor cells by blocking a drug-sensitive biochemical or metabolic pathway. Some, such as cell cycle phase–specific antimetabolites, act by inhibiting DNA synthesis and are most effective against rapidly dividing cells. Others, including alkylating agents, act by interfering with nucleic acid function and protein production throughout the cell division cycle and are effective against both proliferating and resting cells (Figures 42-1 and 42-2). All chemotherapy drugs are extremely cytotoxic with low margins of safety. Incorporating the current understanding of tumor biology, the patient's physiologic status, and the drug's pharmacologic features, the principles that govern the useful application of cancer chemotherapy include the following:

1. The tumor must be susceptible to the drugs selected for treatment. Not all tumors are responsive to the same agents.
2. The drugs or methods of administration must not have intolerable local or systemic toxicity that would prevent the completion of an adequate course of treatment.

3. The dosages and schedules for the drugs must be calculated to maximize the contact with the tumor cells, and the drugs must be present in sufficient concentration during the crucial periods of the cell's metabolic cycle.
4. Cancer chemotherapy is more effective when the tumor mass is small than when the tumor cell burden is high. A larger fraction of the tumor cell population is undergoing active division in a small tumor mass, and the blood supply is more plentiful, allowing for increased sensitivity and delivery of the drugs. Debulking by surgery or irradiation reduces tumor cell burden and can induce resting cell populations into active cell division, increasing the growth fraction of the tumor.
5. Anticancer drugs kill cells according to first-order kinetics. Even a drug that destroyed 99.99% of the tumor cells would leave a substantial number of tumor cells intact if the initial quantity was large. Because survival of a few or perhaps even a single malignant cell may lead to tumor regrowth, chemotherapy is generally given in cycles to maximize tumor cell reduction. The optimal interval between cycles is determined by the time required to allow for sufficient bone marrow recovery without allowing significant tumor regrowth.
6. The administration of combinations of antineoplastic drugs takes advantage of the different mechanisms of action. By using agents that act at different phases of the cell cycle, synergistic effects and an increase in the collective antitumor effect may be obtained without a concomitant increase in undesirable side effects. Combination chemotherapy may prevent or slow the development of resistant strains.
7. Cancer cells may build up resistance to a previously effective drug, which then becomes ineffective. Such resistance has been ascribed to various causes, including decreased drug penetration resulting from a reduction in tumor blood supply, drug-provoked mutations, enzyme alterations, and acquired resistance through natural selection of tumor cells insensitive to the drug. The therapeutic potential of antineoplastic drugs may be enhanced by active antitumor defense mechanisms in the host. Immunotherapy given with chemotherapy, either concurrently or sequentially, may boost the tumoricidal effect of the drugs.

CHEMOTHERAPEUTIC DRUGS

Antineoplastic Alkylating Agents

Alkylating agents (Table 42-1) are composed of six major chemical classes: (1) nitrogen mustards (chlorambucil, cyclophosphamide, estramustine, ifosfamide, mechlorethamine, and melphalan), (2) alkyl sulfonates (busulfan), (3) ethylenimines (thiotepa), (4) triazines (dacarbazine), (5) tetrazines (temozolomide), and (6) nitrosoureas (carmustine, lomustine, and streptozocin). They all share the common chemical characteristic of forming alkyl radicals, which form covalent linkages with nucleophilic moieties such as the phosphate, sulfhydryl, hydroxyl, carboxyl, amino, and imidazole groups. This radical formation allows them to react with organic compounds such as DNA and RNA and proteins essential for cell metabolism and protein synthesis. By binding these groups, they also prevent cell division by cross-linking strands of DNA.

TABLE **42-1**

Classification of Available Antineoplastic and Associated Drugs

CLASS OR TYPE OF AGENT	NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	ADVERSE EFFECTS*	STOMATITIS†	CLINICAL APPLICATIONS
Alkylating Agents					
Nitrogen mustards	Chlorambucil	Leukeran	*Myelosuppression,*‡ pulmonary fibrosis, dermatotoxicity, hepatotoxicity	0	Chronic lymphocytic leukemia, Hodgkin's disease, lymphosarcoma, ovarian cancer, seminoma
	Cyclophosphamide	Cytoxan	Immunosuppression, *myelosuppression,* dermatotoxicity, hemorrhagic cystitis, *GI enterotoxicity,* hepatotoxicity, alopecia, SIADH	+	Hodgkin's disease; lymphoma; leukemia; multiple myeloma; sarcoma; testicular, prostate, lung, breast, and ovarian carcinoma
	Estramustine	Emcyt	*Myelosuppression,* cardiovascular toxicity, GI enterotoxicity, gynecomastia	+	Prostate cancer
	Ifosfamide	Ifex	*Myelosuppression,* nausea and vomiting, *hemorrhagic cystitis,* lethargy, confusion	+	Testicular carcinoma, sarcoma, ovarian carcinoma
	Mechlorethamine	Mustargen	*Myelosuppression, nausea and vomiting,* tissue necrosis, alopecia, neurotoxicity	0	Hodgkin's disease, lymphoma, mycosis fungoides
	Bendamustine	Treanda	*Myelosuppression, nausea and vomiting, hypersensitivity reactions,* fever	0	Chronic lymphocytic leukemia
	Melphalan	Alkeran	*Myelosuppression,* GI enterotoxicity, pulmonary fibrosis, dermatotoxicity, teratogenicity, SIADH	0	Multiple myeloma, ovarian carcinoma
Alkyl sulfonate	Busulfan	Myleran	*Myelosuppression, nausea and vomiting, pulmonary fibrosis,* dermatotoxicity, cataract formation, gynecomastia	0	Chronic myelocytic leukemia, polycythemia vera
Ethylenimine derivative	Thiotepa	Thioplex	*Myelosuppression,* infertility, dermatotoxicity, nausea and vomiting	0	Carcinoma of breast, ovary, and bladder; rhabdomyosarcoma
Triazene derivative	Dacarbazine	DTIC	*Nausea and vomiting,* fever, *myelosuppression,* alopecia, hepatotoxicity, dermatotoxicity	0	Melanoma, Hodgkin's disease, sarcoma
Tetrazine derivative	Temozolomide	Temodar	*Myelosuppression, GI enterotoxicity*	+	Brain tumor, melanoma
Nitrosoureas	Carmustine	BiCNU	*Myelosuppression, GI enterotoxicity,* hepatotoxicity, nephrotoxicity, pulmonary fibrosis	0	Hodgkin's disease, brain tumor, lymphoma, melanoma, multiple myeloma
	Lomustine	CeeNu	*Myelosuppression,* GI enterotoxicity, hepatotoxicity, nephrotoxicity, pulmonary fibrosis	0	Hodgkin's disease, lung and brain tumors, multiple myeloma, melanoma
	Streptozocin	Zanosar	*Nausea and vomiting, nephrotoxicity,* hypoglycemia, hepatotoxicity, fever, myelosuppression	0	Islet cell carcinoma of the pancreas

*Myelosuppression includes a suppression of blood cell–forming elements resulting in leukopenia, thrombocytopenia, and anemia. GI enterotoxicity includes nausea, vomiting, diarrhea, and mucosal damage. Dermatotoxicity includes cutaneous toxicities such as pigmentation, rashes, erythema, and exfoliation. Neurotoxicity includes peripheral neuropathy, pain, paresthesias, altered sensorium, decrease in sensory and motor activity, and paralytic ileus. Hepatotoxicity includes liver dysfunction such as drug-induced hepatitis, transient elevation of transaminases, bile stasis, cholangitis, and veno-occlusive disease. Cardiotoxicity includes myocardial damage, congestive heart failure, and arrhythmias. Nephrotoxicity may manifest as renal insufficiency or acute renal tubular necrosis.

†Stomatitis: 0, rare; +, occasional; ++, frequent or common.

‡*Italic type* indicates a frequent or dose-limiting toxicity.

CNS, Central nervous system; *GI,* gastrointestinal; *SIADH,* syndrome of inappropriate antidiuretic hormone secretion.

Alkylating agents are not cell cycle specific, although they are most destructive to rapidly proliferating tissues and seem to cause cellular death only when the cell attempts to divide. Because they produce irreversible changes in the DNA molecule, alkylating agents are mutagenic, teratogenic, and carcinogenic in addition to being oncolytic. Alkylating agents are also radiomimetic because they produce morphologic damage in cells similar to the damage caused by radiation injury. Because most of these agents are myelosuppressive, immunosuppression and susceptibility to infection are common outcomes. They vary greatly in lipid solubility, membrane transport, and pharmacokinetic properties and differ in clinical use. The molecular structures of representative alkylating agents are shown in Figure 42-3; adverse effects and clinical applications are summarized in Table 42-1.

Nitrogen mustards

Mechlorethamine. Mechlorethamine was the first nitrogen mustard introduced in clinical practice and the progenitor of antineoplastic alkylating agents. It is still used systemically in the treatment of Hodgkin's disease; in combination with vincristine, procarbazine, and prednisone; and topically to treat mycosis fungoides. The drug is a vesicant that produces severe local tissue necrosis unless administered through a running intravenous infusion. This irritant effect is used to control intractable pleural effusions caused by intrapleural malignancies. In such instances, the drug is administered by intracavitary injection. Usually given intravenously, this drug is highly reactive and has a short stability and biologic half-life. The acute side effects of nitrogen mustard are nausea and vomiting, and these usually begin within 30 minutes after injection and persist for 8 hours.

Bendamustine hydrochloride. Bendamustine hydrochloride (Treanda) is an intravenously administered bifunctional mechlorethamine derivative with alkylator and purine antimetabolite activity. This bifunctional agent may have an advantage to overcome cross-resistance with other alkylating agents. Bendamustine has been studied in combination with rituximab in the management of patients with indolent or mantle cell lymphoma and has shown significant activity.[59] It has been approved more recently for the treatment of chronic lymphocytic leukemia and continues to be studied in many other tumor types, including breast cancer and sarcomas. The most common adverse effects (occurring 15% to 20% of the time) include neutropenia, thrombocytopenia, anemia, pyrexia, nausea, and vomiting.

Chlorambucil. Chlorambucil is given orally for chronic lymphocytic leukemia, indolent non-Hodgkin's lymphoma, carcinoma of the ovary and breast, and multiple myeloma. The drug is well absorbed and rapidly metabolized, but its route of excretion is uncertain. Chlorambucil is generally well tolerated with minimal gastrointestinal toxicity in the usual doses.

Cyclophosphamide. Cyclophosphamide is a cyclic mustard that resulted from attempts to produce an alkylating agent with greater selectivity for neoplastic tissues than the original nitrogen mustard mechlorethamine. Cyclophosphamide is a broad-spectrum agent and is valuable in induction, maintenance, and remission therapy for non-Hodgkin's lymphoma, leukemia, and prostate, lung, breast, and ovarian cancers. It is also used in high doses as part of the conditioning regimen for bone marrow transplants. Cyclophosphamide also has excellent immunosuppressive properties and is useful in severe rheumatoid arthritis, allograft rejection, and other immune disorders. The drug may be administered orally or intravenously and is metabolized to the active compounds phosphoramide mustard and acrolein by the liver. Acrolein is toxic to the bladder, producing hemorrhagic cystitis and dysuria that can be minimized by vigorous hydration and frequent bladder emptying. Cyclophosphamide is a powerful myelosuppressant manifested primarily as leukopenia.

Ifosfamide. Ifosfamide is a nitrogen mustard differing from cyclophosphamide only in the location of a chloroethyl moiety. This intravenous drug is also a prodrug that must be metabolized by the liver cytochrome P450 (CYP) system to the active

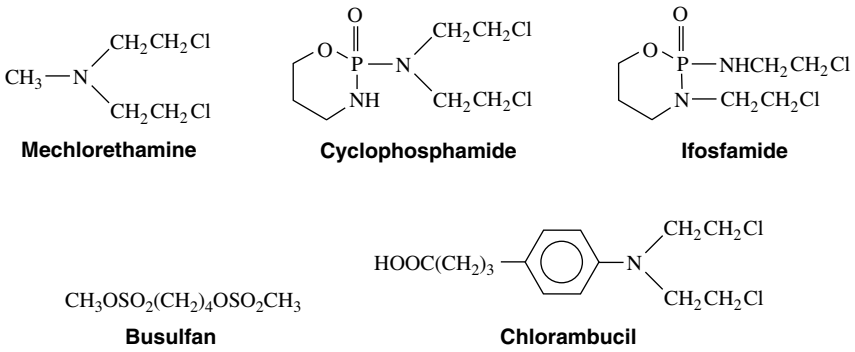

FIGURE **42-3** Structural formulas of representative alkylating agents.

alkylating agent ifosfamide mustard and other toxic metabolites (acrolein and chloroacetic acid). Ifosfamide has a broad spectrum of antineoplastic activity. Although ifosfamide has significant toxic effects, the dose-limiting toxicity of this newest alkylator is hemorrhagic cystitis. The high incidence of this toxicity requires uroprotection with adequate hydration, frequent bladder emptying, and the concurrent use of mesna, a uroprotective agent. Mesna contains a free sulfhydryl group that reacts with and inactivates the toxic metabolites.

Melphalan. Melphalan is a phenylalanine mustard that is available orally for treatment of multiple myeloma and carcinomas of the ovaries and breast. Melphalan is erratically absorbed from the gastrointestinal tract, and intravenous melphalan is available for use in high doses for bone marrow transplant conditioning regimens.

Alkyl sulfonates

Busulfan. Busulfan historically was used almost exclusively in the control of chronic myelogenous leukemia. Today, it is used mostly in high-dose conditioning regimens for bone marrow transplants. A slow-acting sulfur mustard that is well absorbed after oral administration, busulfan is rapidly cleared from the blood and excreted in the urine as inactive metabolites. It has bone marrow–suppressive effects similar to other antineoplastic alkylating drugs; however, with busulfan, the myelosuppression can be quite prolonged.

Ethylenimines

Thiotepa. Thiotepa (triethylenethiophosphoramide) is an alkylating agent that has produced favorable results in breast and ovarian cancers, lymphoma, and rhabdomyosarcoma. It is clinically used in standard doses for the treatment of superficial bladder cancer, where it is directly instilled into the bladder lumen. This agent has also been used to control malignant effusions, and high doses are used in the treatment of refractory cancer and in bone marrow transplants. After intravenous infusion, most of the drug is excreted unchanged in the urine.

Triazines

Dacarbazine. Dacarbazine (DTIC) is an artificially synthesized congener of the naturally occurring purine precursor 5-aminoimidazole-4-carboxamide. Originally developed as an antimetabolite, DTIC is N-demethylated in the liver to yield an effective alkylating derivative. After intravenous administration, the drug is extensively metabolized and renally excreted. DTIC has an elimination half-life of approximately 5 hours. The drug is most effective in the management of malignant melanoma, soft tissue sarcomas, and Hodgkin's disease. Nausea and vomiting are the predominant side effects, with an onset in the first few hours that may persist for several days. Fatal hepatic damage has occurred rarely.

Tetrazines

Temozolomide. Temozolomide is the first imidazotetrazinone derivative used in clinical practice. Similar to DTIC, temozolomide is metabolized to monomethyl 5-triazinoimidazole carboxamide (MTIC), which is ultimately converted to the cytotoxic methyldiazonium ion. Temozolomide has advantages over DTIC: it can be administered orally, and it does not require hepatic conversion to MTIC because temozolomide is spontaneously converted to the active metabolite at physiologic pH.[29] Temozolomide penetrates tissues well and is able to cross the blood-brain barrier, allowing it to be used to treat brain tumors such as astrocytoma[69] and glioblastoma multiforme, an aggressive primary brain tumor. Temozolomide has also been used to treat malignant melanoma. The major toxic effects associated with this alkylating agent include myelosuppression, nausea, vomiting, headache, and fatigue.

Nitrosoureas

Carmustine and lomustine. Two nitrosoureas, carmustine and lomustine, decompose in the body to yield reactive intermediates that act as classic alkylating agents in causing strand breaks and cross-links in DNA. They also produce isocyanates that inhibit DNA repair and RNA synthesis. Carmustine is administered intravenously, whereas lomustine is given orally. Both are rapidly metabolized and slowly excreted in the urine. Nitrosoureas are characterized by their lipophilicity and their ability to cross the blood-brain barrier. This property is useful in the treatment of brain tumors. Each typically produces a delayed bone marrow depression that becomes apparent in 3 to 6 weeks and lasts for an additional 2 to 3 weeks. Side effects include nausea and vomiting in most patients within 2 to 6 hours after administration.

Streptozocin. Streptozocin is a naturally occurring antibiotic that has a mode of action similar to that of nitrosoureas. In contrast to carmustine and lomustine, however, streptozocin does not readily cross the blood-brain barrier, and it is not strongly myelosuppressive. Streptozocin is unique in its special affinity for the islet cells of the pancreas. The drug is diabetogenic in animals and effective against metastatic insulinomas in humans. Streptozocin should be administered intravenously with care because it is a vesicant. It is one of the most emetogenic agents and requires adequate premedication with antiemetics. Potentially fatal renal toxicity and hepatotoxicity have occurred.[67]

Antimetabolite Agents

Antimetabolites bear a marked structural resemblance to folic acid and to the purine and pyrimidine bases involved in the synthesis of DNA, RNA, and certain coenzymes (Figure 42-4). They differ in molecular arrangement from the corresponding metabolite to a degree sufficient to serve as fraudu-

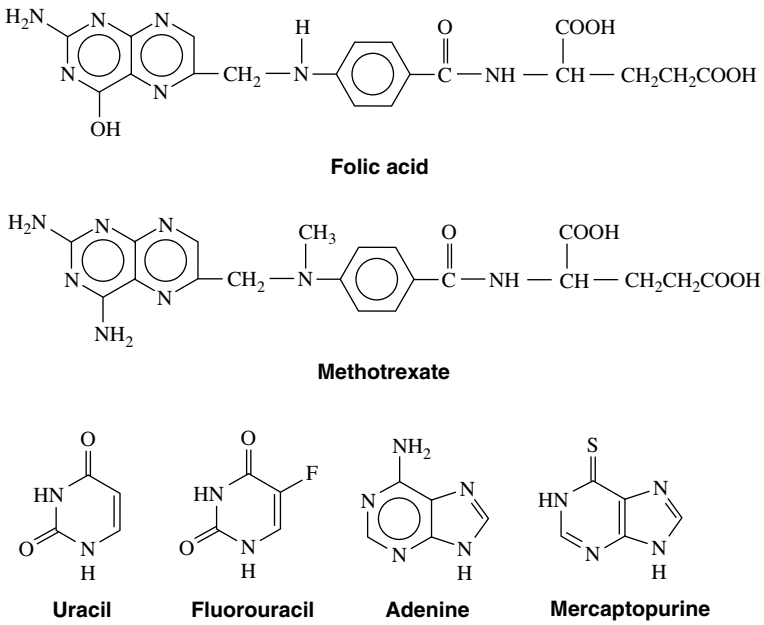

FIGURE **42-4** Structural relationships between several antimetabolites and their respective analogues.

lent substrates for biochemical reactions, either inhibiting synthetic steps or becoming incorporated into molecules and interfering with cellular function or replication. Antimetabolites characteristically exert their major effects during the S (DNA synthesis) phase of the cell cycle. This activity interferes with the growth of rapidly proliferating cells throughout the body—the bone marrow, germinal cells, hair follicles, and lining of the alimentary tract. Oral manifestations are an especially prominent feature of the toxicity of these agents. Three classes of antimetabolites exist: folic acid analogues, purine analogues, and pyrimidine analogues.

Folic acid analogues

Folic acid is an essential vitamin that is converted into metabolically active tetrahydrofolic acid by the enzyme dihydrofolate reductase. Tetrahydrofolic acid participates in the synthesis of purines, thymidylate, and ultimately nucleic acids by transferring one-carbon units to the nucleotide precursors.

Methotrexate

Methotrexate is the 4-amino, 10-methyl analogue of folic acid and a potent inhibitor of dihydrofolate reductase. This inhibition results in the decreased conversion of dihydrofolate to tetrahydrofolate and impaired synthesis of thymidylic acid and inosinic acid. Deficiencies of these acids retard DNA and RNA synthesis. Protein synthesis is also inhibited because reduced folates are cofactors in the conversion of glycine to serine and homocysteine to methionine.

Methotrexate is readily absorbed from the gastrointestinal tract and is primarily excreted in the urine. There is some enterohepatic recycling of methotrexate, which extends the elimination half-life of the drug and is responsible for most of the marrow and gastrointestinal toxicity. Methotrexate tends to distribute into "third spaces," such as ascitic, pleural, or peritoneal fluids that can potentially act as a drug reservoir. The presence of these clinical features or renal failure or both contributes to increased toxicity. Depending on the indication, methotrexate may be administered by many different routes with a variable dosing range. Administered orally, the drug is often used to treat rheumatoid arthritis and psoriasis. Intrathecal administration is used to treat central nervous system (CNS) tumors, and intra-arterial administration is used for regional therapy of head and neck cancers. Given intravenously and intramuscularly, methotrexate is a valuable therapeutic agent in some forms of leukemia, choriocarcinoma, lymphoma, sarcoma, testicular tumors, and carcinoma of the breast and lung. The drug is also used in very high doses for adjuvant and salvage therapies for osteosarcoma and leukemia.

High-dose therapy with methotrexate requires monitoring of serum blood concentrations and the use of folinic acid "rescue." The folinic acid (e.g., citrovorum factor, calcium folinate, leucovorin) bypasses the blockade of dihydrofolate reductase in normal cells and may reduce the incidence and severity of mucositis and myelosuppression. Other nontumoricidal applications of methotrexate include its use after allogeneic bone marrow transplants to prevent graft-versus-host disease, to treat systemic lupus erythematosus, and in steroid-dependent asthmatic patients to decrease asthmatic symptoms.

Methotrexate is subject to many important drug interactions. Highly plasma protein-bound drugs such as salicylates, sulfonamides, and phenytoin may displace methotrexate from its protein-binding sites and result in greater toxicity. Organic acids such as salicylate and probenecid inhibit the tubular secretion of methotrexate, resulting in increased concentrations of methotrexate and toxicity. Penicillins can also compete with methotrexate for renal tubular secretion.[32] In patients receiving large gram doses of methotrexate, the concurrent use of nonsteroidal anti-inflammatory drugs (NSAIDs) should be avoided because this drug class can also reduce renal blood flow and increase the risk of nephrotoxicity.

Dose-limiting toxic effects of methotrexate include bone marrow depression manifested by leukopenia and thrombocytopenia, which are conducive to secondary infection and hemorrhage; a very painful stomatitis with mucosal and epithelial ulceration; pharyngitis and dysphagia; esophagitis; gastroenterocolitis; and proctitis with associated watery and bloody diarrhea. Large doses can be nephrotoxic, and long-term treatment with methotrexate can lead to changes in hepatic function.

Pemetrexed disodium

Pemetrexed disodium is a new antifolate that can attack multiple enzyme targets, including dihydrofolate reductase, thy-

midylate synthase, and glycinamide ribonucleotide formyl transferase. By inhibiting the formation of precursor purine and pyrimidine nucleotide, pemetrexed prevents the formation of DNA and RNA, which are required for the growth and survival of normal cells and cancer cells. Pemetrexed is approved for treatment of malignant pleural mesothelioma and for use as a second-line agent for treatment of non–small cell lung cancer (NSCLC). Vitamin supplementation with folic acid (1 mg daily) and vitamin B_{12} (1000 μg intramuscularly every 9 weeks) helps to control the hematologic and nonhematologic toxicities.[49] Steroid treatment with dexamethasone (4 mg twice a day on the day before, the day of, and the day after pemetrexed therapy) is used to help limit skin rashes. The most common side effects are hematologic, rash, nausea, and vomiting. Occasionally, chest pain, edema, and hypertension may be seen in patients, and neuropathy and myalgias occur in 29% and 13% of patients, respectively. Stomatitis has been reported in about 20% of patients treated with pemetrexed.

Purine analogues

Historically, the most commonly used purine analogues in cancer chemotherapy have been mercaptopurine and thioguanine. Newer agents include fludarabine, pentostatin, cladribine, clofarabine, and nelarabine.

Mercaptopurine and thioguanine. The mechanisms of action of the thiopurines mercaptopurine and thioguanine have not yet been fully established. Presumably, they affect the incorporation of purine derivatives into nucleic acids. The analogues are converted in the body to the ribonucleotide form, which interferes with the conversion of inosinic acid to the nucleotides of adenine and guanine, resulting in the inhibition of DNA and RNA synthesis. They also inhibit de novo biosynthesis of purines from the small molecule precursors (glycine, formate, and phosphate), which ultimately leads to fraudulent DNA.

Orally administered mercaptopurine is readily absorbed but undergoes extensive first-pass metabolism by the liver. After intravenous injection, the plasma half-life is approximately 90 minutes. The drug is metabolized by methylation in the liver and by the hepatic enzyme xanthine oxidase. Concurrent administration with allopurinol, a xanthine oxidase inhibitor originally developed to increase the anticancer effect of mercaptopurine, requires a 50% reduction in the dose of mercaptopurine. Allopurinol is of little clinical value in this setting because it also increases the toxicity of mercaptopurine. The use of allopurinol in the treatment of gout is described in Chapter 21. Currently, mercaptopurine is used mainly for maintenance of remission in acute lymphocytic leukemia. The chief toxic effect is myelosuppression. Pulmonary fibrosis and pancreatitis may also occur. Thioguanine has activity, toxicity, and clinical applications similar to those of mercaptopurine.

Fludarabine. Fludarabine (2-fluoro-ara-AMP) is an analogue of adenosine. This injectable purine antagonist is quickly dephosphorylated in the plasma, enters the cell, and is converted to the triphosphate form. This false nucleotide inhibits ribonucleotide reductase and DNA polymerase, which results in the inhibition of DNA synthesis.[37] Fludarabine is indicated for the treatment of B-cell chronic lymphocytic leukemia in patients who have not responded to traditional therapy with an alkylating agent. Fludarabine is primarily excreted by the kidneys and has a long plasma half-life of approximately 10 hours. Transient myelosuppression and immunosuppression, with an increased risk of opportunistic infection, seems to be the major toxicity at current doses. Fludarabine has also been used for treatment of non-Hodgkin's lymphoma, hairy cell leukemia, and cutaneous T-cell lymphoma and in salvage regimens for the treatment of acute myeloid leukemia.

Pentostatin. Pentostatin is a newer antimetabolite isolated from *Streptomyces antibioticus*. This purine analogue is an inhibitor of adenosine deaminase, which converts adenosine to inosine. This inhibition apparently leads to inhibition of methylation and other reactions. Cytotoxic treatment with pentostatin results in the accumulation of deoxyadenosine 5′-triphosphate. The drug exhibits activity in nonreplicating and dividing cells. Pentostatin is quickly distributed to all body tissues after administration; the plasma half-life is 2.6 to 9.4 hours, with the major portion of the drug recovered in the urine unchanged. Pentostatin has been most active in the treatment of hairy cell leukemia; it also has activity in patients with chronic lymphocytic leukemia. Toxicity is dose-dependent, with acute renal failure and CNS side effects being the most severe.

Cladribine. Cladribine is an adenosine deaminase–resistant purine substrate analogue toxic to lymphocytes and monocytes. It is undergoing clinical trials against hematologic malignancies and is available for the treatment of hairy cell leukemia. The major limiting toxicity is myelosuppression.

Clofarabine and nelarabine

Clofarabine and nelarabine are the newest purine nucleoside antimetabolites approved for the treatment of acute lymphocytic leukemias. Clofarabine is converted intracellularly by deoxycytidine kinase to the 5′-monophosphate metabolite, then via monophosphokinases and diphosphokinases to the active 5′-triphosphate form. The clofarabine 5′-triphosphate inhibits DNA synthesis through its action on ribonucleotide reductase and DNA polymerases. Clofarabine is approved by the U.S. Food and Drug Administration (FDA) for the treatment of pediatric patients with relapsed or refractory acute lymphocytic leukemia after at least two prior treatment regimens.[24] It is also being studied for other malignancies, including the treatment of acute myeloid leukemias in adults. The principal toxicities associated with clofarabine are nausea, vomiting, hematologic toxicity, febrile neutropenia, hepatobiliary toxicity, infections, and renal toxicity. Clofarabine can also produce a syndrome manifested by the rapid development of tachypnea, tachycardia, hypotension, shock, and multiorgan failure called *systemic inflammatory response syndrome,* which is similar to a capillary leak syndrome. Cardiac effects include tachycardia and left ventricular systolic dysfunction.

Nelarabine is a prodrug of the deoxyguanosine analogue-9-beta-D-arabinofuranosylguanine (ara-G). Nelarabine is demethylated to ara-G and activated to the active 5′-triphosphate, ara-GTP. The active ara-G is incorporated into the DNA resulting in inhibition of DNA synthesis and cell death. There is a differential accumulation in T cells, and nelarabine is approved for the treatment of patients with T-cell acute lymphoblastic leukemia and lymphoma who have not responded to or have relapsed after treatment with at least two other chemotherapy regimens.[9] A major adverse effect associated with nelarabine resulting in a "black box" warning involves neurologic events that include severe somnolence, convulsions, peripheral neuropathies, and paralysis. Other adverse effects include fatigue, bone marrow suppression, gastrointestinal side effects, and some pulmonary complaints of cough and dyspnea. Rarely, patients have complained of blurred vision while receiving nelarabine. The combination of nelarabine and adenosine deaminase inhibitors such as pentostatin should be avoided because this combination may result in a decreased conversion of nelarabine to its active substrate, decreasing its efficacy and potentially changing the adverse profile of both drugs.

Pyrimidine analogues

Several pyrimidine congeners have been examined for antineoplastic activity. These drugs exert multiple effects on cellular growth and are among the most useful agents for solid tumors and leukemia.

Fluorouracil and floxuridine. The fluorinated pyrimidines fluorouracil and floxuridine are prepared by substituting a stable fluorine atom for hydrogen in position 5 of the uracil and deoxyuridine molecules. These compounds, after intracellular conversion to 5-fluoro-2′-deoxyuridine monophosphate, are potent antimetabolites that bind to and inhibit thymidylate synthetase, inhibiting formation of thymidylic acid and impairing DNA synthesis. Fluorouracil metabolism also produces a critical intermediate, 5-fluorouridine triphosphate, which is incorporated into RNA and interferes with its function. 5-Fluorodeoxyuridine triphosphate (5-FdUTP) may also be incorporated into DNA, producing single-strand breaks contributing to the cytotoxicity.[54]

Fluorouracil is used most often for treatment of gastrointestinal adenocarcinomas, breast cancer, and ovarian cancer. Activity has also been reported in bladder and prostate cancer. The drug is usually given intravenously as a bolus or short infusion or as a prolonged continuous infusion daily, over several days, or for months. Continuous infusion is advantageous because the plasma half-life of the drug is short (10 to 20 minutes), and the drug (similar to other antimetabolites) works primarily in the S phase of the cell cycle. Continuous infusion provides for prolonged exposure of the cells to the drug and the opportunity for cell populations not in the S phase to cycle into that sensitive phase. The toxicity profile of fluorouracil depends on the method of administration. Given as a continuous infusion over a 96-hour period, the dose-limiting toxicity is mucositis, whereas intravenous bolus results in bone marrow suppression. Fluorouracil can be administered topically to treat actinic keratoses and noninvasive skin cancers and, commonly, to improve efficacy of radiation therapy in head and neck cancers by working as a radiosensitizer. Folinic acid (leucovorin) has been combined with fluorouracil to enhance the inhibition of thymidylate synthetase in resistant disease.

Floxuridine, the deoxyribonucleoside of fluorouracil, exerts a more direct inhibition of thymidylate synthetase than fluorouracil. The drug must be given by continuous infusion because it is rapidly catabolized in vivo. Floxuridine administered intra-arterially is indicated for gastrointestinal adenocarcinomas metastatic to the liver and has produced beneficial results in the treatment of head and neck carcinoma, although fluorouracil is now the preferred agent. The adverse effects of fluorinated pyrimidines may be quite severe. Stomatitis, pharyngitis, dysphagia, enteritis, and diarrhea can be life-threatening. Myocardial ischemia caused by coronary artery vasospasm has been described with fluorouracil.

Capecitabine. Capecitabine (5′-deoxy-5-fluoro-N-[(pentuloxy)carbonyl]-cytidine) is a newer oral agent used in the treatment of advanced breast and colorectal cancers. Capecitabine is hydrolyzed in the liver and ultimately converted to the active drug 5-fluorouracil. Its activity profile and pharmacokinetic profile are similar to infusional fluorouracil. Side effects of capecitabine include severe diarrhea, stomatitis, and some mild nausea and vomiting. Severe hand-foot syndrome (palmar/plantar erythrodysesthesia) and other dermatologic changes have been reported.[16]

Cytarabine. Cytarabine (cytosine arabinoside) is an analogue of 2′-deoxycytidine that can inhibit DNA synthesis by inhibiting DNA polymerase activity as a result of its incorporation into DNA and the formation of fraudulent DNA. Premature DNA chain termination results. Cytarabine is primarily a cell cycle S phase–specific agent. When given intravenously, the drug is rapidly cleared from the blood by deamination in the liver, with a plasma half-life of 5 to 20 minutes. With these properties, continuous infusion is often the preferred route of administration. Cytarabine crosses the blood-brain barrier, achieving cerebrospinal fluid concentrations of 40% to 50% of those of plasma. This feature allows for the treatment of CNS disease with systemic high-dose therapy. Cytarabine may be administered intrathecally and produces high concentrations that decline slowly because of the absence of cytidine deaminase in the CNS.[1] Cytarabine is the most active single drug available for the treatment of acute myelogenous leukemia in adults, producing about a 25% incidence of complete remission. It is often used in combination with other agents. It has some modest activity against lymphomas. The major side effect is myelosuppression. High doses produce severe nausea and vomiting, severe diarrhea, cerebellar toxicity, and keratoconjunctivitis.[26]

Gemcitabine. Gemcitabine (difluorodeoxycytidine) is a newer antimetabolite useful in many experimental tumor models, with clinical responses in NSCLC and breast cancer. It is currently indicated for first-line treatment of patients with locally advanced or metastatic adenocarcinoma of the pancreas.[31] Recent trials support the use of gemcitabine in combination with cisplatin to treat metastatic NSCLC. Its dose-limiting side effect is myelosuppression characterized by thrombocytopenia. Transient febrile episodes and a flulike syndrome have been commonly reported.

Antibiotics

Numerous substances originally isolated as antibiotics have been found to exert antineoplastic activity because of their cytotoxic properties. These substances, produced naturally by various *Streptomyces* species, operate by binding with DNA to produce irreversible complexes that inhibit cell division. Various other possible mechanisms for cytotoxicity have been proposed for these agents. Antibiotics can work on cells in different phases of the cell cycle, behaving as non–phase-specific agents. Semisynthetic derivatives of some of the antibiotics are being prepared and tested clinically in an effort to reduce toxicity but retain the oncolytic potency of the parent compound.

Dactinomycin

Dactinomycin (actinomycin D) is a crystalline antibiotic composed of a phenoxazone chromophore and two cyclic peptide chains obtained as a product of fermentation by *Streptomyces parvulus*. The drug intercalates into DNA between adjacent guanine-cytosine base pairs and inhibits DNA-directed RNA synthesis. Dactinomycin is rapidly distributed into tissues and has a prolonged terminal half-life. The drug apparently is not metabolized, but is primarily excreted in the bile. Dactinomycin is the main agent for the treatment of pediatric tumors, such as Wilms' tumor, Ewing's sarcoma, and embryonal rhabdomyosarcoma, and is of considerable value in treatment of choriocarcinoma and testicular tumors. Mucositis characterized by oral ulcerations and diarrhea often necessitates limiting the dose. Extravasation from the vein causes severe tissue necrosis.

Daunorubicin

Daunorubicin is a cytotoxic anthracycline antibiotic produced by *Streptomyces peucetius* subsp. *caesius,* which is also the source of doxorubicin and idarubicin (Figure 42-5). The drug combines with DNA in an intercalative mode by slipping into the helical structure between stacked bases. Synthesis of DNA and RNA is inhibited, and preformed DNA is damaged.

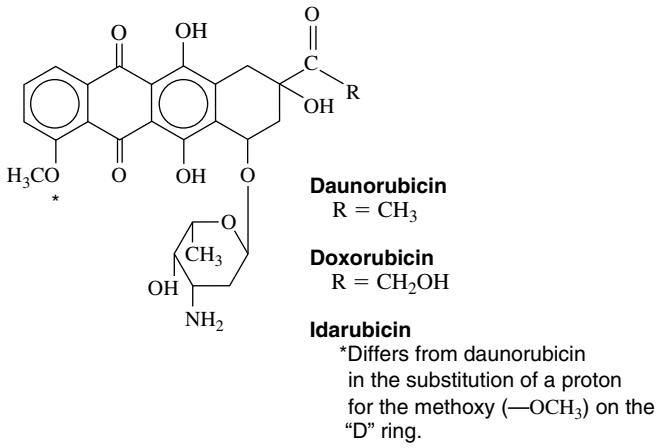

FIGURE **42-5** Structural formulas of anthracycline antibiotics. R = CH_3 for daunorubicin; R = CH_2OH for doxorubicin.

Other possible mechanisms are postulated, including metabolism to form cytotoxic free radicals, a cell membrane surface cytotoxic action, and inhibition of topoisomerase II. The killing effect of daunorubicin is at a maximum in the DNA synthesis S phase of the cell cycle, but damage is not phase specific. Experimental evidence exists for synergy between these antibiotics and drugs such as etoposide.

Daunorubicin is most useful in the treatment of acute myelogenous leukemia and acute lymphocytic leukemia. The drug is extensively tissue bound with a long elimination half-life. The major route of elimination is through biliary excretion, with some urinary excretion. Patients should be warned about red-colored urine a few days after a dose of daunorubicin. Cardiomyopathy manifested by acute congestive heart failure, acute cardiac arrhythmias, radiation recall dermatitis, and local necrosis from extravasation at the injection site are associated with cumulative doses of daunorubicin exceeding total lifetime limits of 450 to 550 mg/m^2.

Doxorubicin

Doxorubicin differs from daunorubicin by one hydroxy group (see Figure 42-5). This anthracycline glycoside acts by intercalating into DNA and shares other mechanisms of action with daunorubicin. Doxorubicin has a much broader spectrum of antineoplastic activity than daunorubicin.

Doxorubicin is a vesicant that is always given intravenously. It is rapidly cleared from the plasma and concentrated in the tissues. Urinary excretion is low, rarely accounting for more than 10% of the administered dose; in contrast, biliary excretion is high. Plasma concentrations of doxorubicin and its metabolites are markedly elevated, and the rate of elimination is greatly prolonged in the presence of severely impaired liver function.

The major toxic effects begin shortly after drug administration and last 2 to 3 days. Extravasation of the drug produces soft tissue necrosis. Myelosuppression, primarily granulocytopenia, is maximal 10 to 14 days after drug administration. Mucositis manifested mainly as soreness of the mouth with ulcerations occurs in almost all patients. Cardiomyopathy expressed as congestive heart failure becomes a serious risk in patients given a total dose exceeding 550 mg/m^2. Concurrent administration with dexrazoxane may help reduce the incidence of cardiomyopathy associated with doxorubicin therapy.[12] New liposomal encapsulated forms of doxorubicin and daunorubicin are now available. They allow for increased circulation time and the possibility of enhanced antitumor activity and decreased cardiomyopathy in the treatment of Kaposi's sarcoma related to acquired immunodeficiency syndrome (AIDS), advanced breast and ovarian cancers, and others.

Epirubicin

Epirubicin is a semisynthetic derivative of doxorubicin that has been extensively evaluated in patients with breast cancer. Epirubicin is also being evaluated for its intravesical use in superficial bladder cancer.[51] The major dose-limiting adverse effects include hematologic and cumulative dose-related cardiotoxicity. Other important side effects include mucositis, nausea and vomiting, alopecia, and local cutaneous reactions.

Idarubicin

Idarubicin is an analogue of daunorubicin lacking the methoxy group on the C4 position of the aglycone (see Figure 42-5). This antibiotic is used for the treatment of acute myelogenous leukemia, breast cancer, and some lymphomas. Oral idarubicin is not currently available. The toxicity of idarubicin seems to be less severe than the toxicity of either daunorubicin or doxorubicin, and it may have a lower risk of cardiotoxicity. Nausea, vomiting, and mucositis seem equivalent to the other anthracyclines.

Mitoxantrone

Mitoxantrone, an anthraquinone antibiotic, is a synthesized drug with antibacterial, antiviral, antiprotozoal, and immunomodulating activities. Its antineoplastic activity results from intercalation to DNA and inhibition of topoisomerase II, producing DNA strand breaks. Mitoxantrone is not phase specific. It is clinically active against breast carcinomas, acute leukemias, and lymphomas. Mitoxantrone has been approved for patients with progressive multiple sclerosis and is recognized for its potential use as first-line therapy in acute myelogenous leukemia.[39,64] Mitoxantrone exhibits less cumulative cardiotoxicity than anthracyclines. The drug can impart a blue-green color to the urine 24 hours after administration; bluish discoloration of the sclera may also occur.

Bleomycin

Bleomycin is an antibiotic complex of several glycopeptides derived from *Streptomyces verticillus*. The cytotoxic action of bleomycin has been attributed to DNA scission and fragmentation with inhibition of usual DNA repair mechanisms. RNA and protein synthesis seem to be inhibited as well. Bleomycin is rapidly cleared from the blood and concentrated in the liver, lungs, spleen, kidneys, and epithelial tissue. Approximately 80% is excreted in the urine within 24 hours. Bleomycin is cell phase specific, having its major effects on cells in the G_2 and M phases of the cell cycle.[2]

The main clinical applications of bleomycin are in the treatment of squamous cell carcinoma, testicular tumors, and lymphomas. Bleomycin is also used to treat malignant pleural effusions by direct instillation into the pleural space. The major attractive features of bleomycin include minimal nausea and vomiting, almost no myelosuppression, and lack of local tissue toxicities. This improved toxicity profile accounts for the inclusion of bleomycin into many combination chemotherapy protocols. The major dose-limiting toxicity is pulmonary, manifesting as interstitial pneumonitis that might progress to pulmonary fibrosis and fatal pulmonary insufficiency. This toxicity is associated with a cumulative dose of more than 400 U, age older than 70 years, underlying pulmonary disease, chest irradiation, and high oxygen exposure. Some reports suggest an increase in oxygen-induced pulmonary complications in patients previously treated with bleomycin. For anesthesia and postoperative periods, it is recommended that elevated inspired oxygen concentrations should be administered only when clearly indicated.

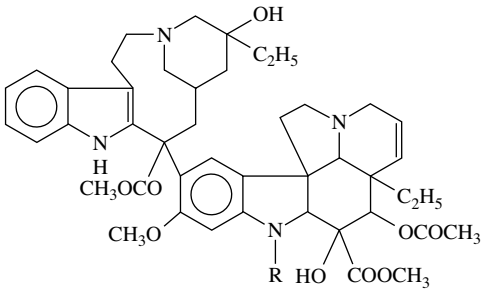

FIGURE **42-6** Structural formulas of vinca alkaloids.

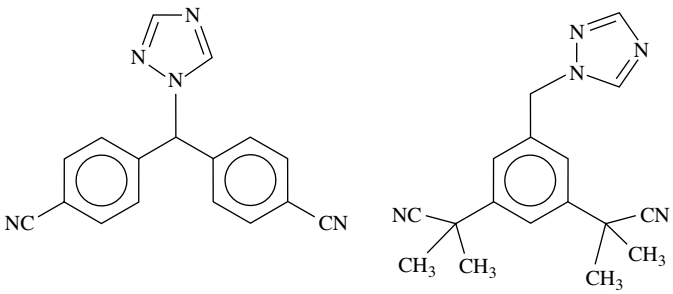

FIGURE **42-7** Structural formulas of representative nonsteroidal aromatase inhibitors.

Mitomycin

Mitomycin is derived from *Streptomyces caespitosus*. After intracellular activation, mitomycin inhibits DNA synthesis by reacting with DNA in the manner of the alkylating agents. When combined with fluorouracil or nitrosoureas, mitomycin has been effective against gastrointestinal, head and neck, breast, cervix, and lung carcinomas. Severe toxicity to the bone marrow (neutropenia and thrombocytopenia), reaching a maximum in about 3 to 4 weeks, and to the alimentary tract (nausea, vomiting, oral ulceration, and diarrhea) is the limiting factor in the use of this drug. Pulmonary toxicity and adult hemolytic uremic syndrome are dose-related.

Vinca Alkaloids

Vinblastine and vincristine

Vinblastine and vincristine, the two older alkaloids in clinical use, are derived from asymmetric dimeric compounds extracted from the shrub *Vinca rosea*; they are almost identical in structure (Figure 42-6). Vinblastine contains a methyl group and vincristine contains a formyl group attached to the nitrogen in the dihydroindole portion of the molecule. Vinorelbine, a newer third vinca alkaloid, is a semisynthetic derivative of vinblastine.[65] The antineoplastic activity of vinca alkaloids has been attributed to their capacity to arrest cell division in metaphase by binding to the microtubular protein tubulin that forms the mitotic spindle.

These drugs are metabolized in the liver and excreted mainly by the biliary and intestinal tracts. Vinblastine and vincristine are of major value in treating Hodgkin's disease and other lymphomas. Vinorelbine is used in the treatment of NSCLC and may have future roles in the treatment of other carcinomas including breast carcinoma.[68] The most common toxic manifestation of vinblastine is leukopenia. High doses induce gastrointestinal disturbances, including nausea, vomiting, diarrhea, and anorexia. Other side effects of this drug include partial alopecia, headache, paresthesias, mental depression, mild peripheral neuropathy, and phlebitis at the injection site. Vincristine produces dose-related neurotoxicity. Hyponatremia associated with the syndrome of inappropriate antidiuretic hormone secretion has been reported. Tissue damage from extravasated drug requires immediate attention. Myelosuppression and neurotoxicity manifested by decreased deep tendon reflexes seem to be dose-limiting toxic effects of vinorelbine.

Hormone Agonists and Antagonists

The role of hormonal manipulation for cancer therapy was explored in 1896, when ovariectomy was first used in the treatment of breast cancer. Because they share commonality of their steroid ring structure, adenocorticosteroids, estrogens, antiestrogens, androgens, progestational agents, and gonadotropin-releasing factors each have a role in cancer control.

Drugs affecting corticosteroid status

Prednisone, tamoxifen, and toremifene. Prednisone is widely used in combination with other antineoplastic drugs in acute and chronic lymphocytic leukemia, Hodgkin's disease, lymphoma, and multiple myeloma; it is also helpful in reducing hypercalcemia associated with bony metastases. Estrogens are useful in the treatment of advanced prostatic carcinoma and as adjunctive treatment in select patients with postmenopausal breast carcinoma. Although the mode of action is unknown, the therapeutic response in breast cancer is correlated with the presence of estrogen-binding receptor sites in the tumor. The antiestrogen tamoxifen is beneficial in patients whose adenocarcinoma of the breast depends on estrogen for growth, as shown by positive estrogen or progesterone receptor status. Tamoxifen has also been used in endometrial carcinoma and malignant melanoma. The side effects seen with this oral agent include an initial flare-up in disease activity, bone pain, or hypercalcemia; this is associated with efficacy of the medication. Additional side effects include hot flashes, sweating, nausea and vomiting, and increased risk for blood clot formation. Toremifene is a chlorinated derivative of tamoxifen and has shown a similar efficacy and tolerability profile as tamoxifen. Androgens are effective in some cases of metastatic breast cancer. Progestational agents such as megestrol are effective in metastatic endometrial, breast, and renal cell carcinoma. The pharmacologic characteristics of steroid hormones are discussed in detail in Chapters 35 and 37.

Mitotane and aminogutethimide. Adrenocortical secretion is suppressed by the agents mitotane and aminoglutethimide. Mitotane causes atrophy of the adrenal cortex by inhibiting mitochondrial function. Aminoglutethimide, an inhibitor of several CYP450 enzymes, inhibits the conversion of cholesterol to pregnenolone, reducing the synthesis of corticosteroids and the sex steroids. It also blocks the conversion of androgens to estrogens. These agents are used in patients with adrenal tumors and occasionally in breast cancer patients.[5]

Drugs affecting sex hormone status

Anastrozole and letrozole. Anastrozole and letrozole are nonsteroidal, selective aromatase inhibitors that do not reduce mineralocorticoid or glucocorticoid activity. Their structure and site of action are shown in Figures 42-7 and 42-8. These agents are indicated for use in postmenopausal women with advanced breast cancer that has progressed during therapy with tamoxifen. Randomized clinical trials comparing anastrozole and letrozole with megestrol acetate showed at least similar, if not superior, response rates and duration of response.

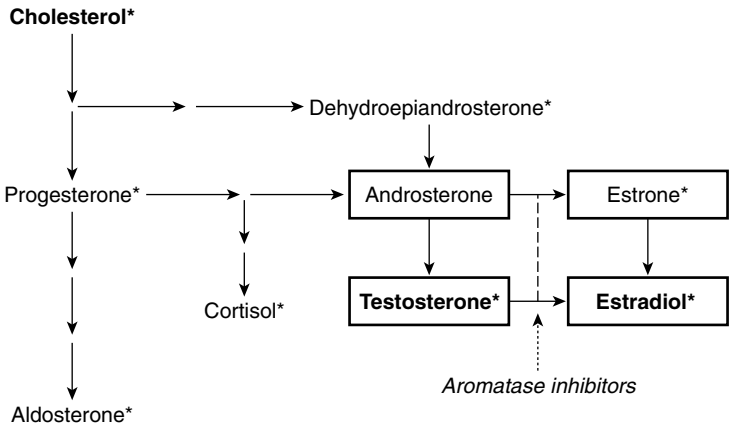

FIGURE **42-8** Aromatase inhibitor site of activity in the steroidogenic pathway. *Biologically active.

Selective aromatase inhibitors are generally well tolerated. Adverse effects include nausea, vomiting, and hot flashes. Letrozole is currently being compared with tamoxifen in studies as a first-line therapy for advanced breast cancer,[47] and letrozole is useful in preventing recurrence when used as adjuvant therapy for estrogen receptor/progesterone receptor–positive breast cancer after tamoxifen therapy. Exemestane is an orally irreversible steroidal aromatase inhibitor or inactivator. Clinical trials show its effective antitumor activity in postmenopausal breast cancer patients with similar side-effect profiles as the other aromatase inhibitors.[8]

Leuprolide and goserelin. Leuprolide (a nonapeptide) and goserelin (a decapeptide) are synthetic analogues of naturally occurring gonadotropin-releasing hormone (GnRH). They have potent GnRH-agonist properties during short-term or pulsatile therapy, but paradoxically inhibit gonadotropin secretion and suppress ovarian and testicular steroidogenesis during long-term administration. The drugs act principally on the pituitary gland in humans to limit the release of follicle-stimulating hormone and luteinizing hormone. Because of these inhibitory effects, these agents may interfere with the growth of hormone-dependent tumors. The drugs are used clinically for the palliative treatment of advanced carcinoma of the prostate and may be valuable in the control of breast cancer. They are also used to treat endometriosis. Even with continued treatment, acute flare-ups in the diseases are also possible, with pain and hypercalcemia.

Flutamide, bicalutamide, and nilutamide. Flutamide is a nonsteroidal antiandrogen that competes directly for testosterone receptor binding sites in the prostate cells. This agent, used orally for prostate cancer, can help prevent flare-ups when used with a GnRH agonist such as leuprolide. Adverse reactions include gynecomastia and decreased libido. Bicalutamide and nilutamide are nonsteroidal antiandrogen agents similar to flutamide and are used in combination with leuprolide for advanced prostate cancer. Nilutamide has rarely caused interstitial pneumonitis and affects the eyes' ability to adjust to changes from light to dark conditions, such as driving from daylight into a dark tunnel.

Enzymes

Asparaginase

Asparaginase is an enzyme that catalyzes the hydrolysis of L-asparagine to L-aspartic acid and ammonia. The therapeutic drug is one of the isozymes elaborated by *Escherichia coli*. It inhibits protein synthesis in tumor cells by depriving them of the amino acid asparagine. This drug is phase specific, with the greatest activity in the G_1 phase of the cell cycle. Timing and scheduling of asparaginase with other chemotherapy agents is important to prevent the antagonism of the effects of the other agents. Clinical use is confined presently to acute lymphocytic leukemia. The drug may produce acute anaphylaxis with hypotension, sweating, bronchospasm, and urticaria, and test doses are usually administered to help detect the possibility of a hypersensitivity reaction. Other effects in patients taking L-asparaginase include alteration in liver function and the coagulation factors resulting in either increased bleeding or increased clotting. A newer formulation of asparaginase is pegaspargase (PEG-L-asparaginase), which has polyethylene glycol covalently linked to the asparaginase to decrease immunogenicity and to prolong its half-life.

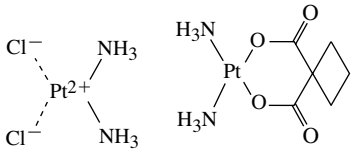

FIGURE **42-9** Structural formulas of platinum compounds.

Platinum Complexes

Cisplatin

Cisplatin (*cis*-diamminedichloroplatinum) is a heavy metal complex containing a central atom of platinum surrounded by two chloride ions and two amino groups in the cis position (Figure 42-9). The compound has biochemical properties similar to bifunctional alkylating agents in that it produces interstrand and intrastrand cross-links in DNA, inhibiting its synthesis. Cisplatin is not a cell cycle phase–specific agent. The drug has proved most effective in the treatment of carcinoma of the testis and ovary, transitional cell bladder neoplasia, and head and neck cancers. In particular, it is finding increased use as a radiosensitizer when given at a few very specific points in the provision of radiation therapy for squamous cell carcinomas of the head and neck. It also has activity in small cell lung cancer in combination with etoposide.

After intravenous injection, cisplatin is excreted primarily in the urine; the other excretory pathways are undetermined. Severe emesis is the dose-limiting toxicity. Newer antiemetic agents and protocols usually allow for the completion of therapy. Nephrotoxicity expressed as renal tubular necrosis is another major dose-limiting side effect. The agent can be ototoxic, causing initially high-frequency and later complete hearing loss, and long-term use produces peripheral neuropa-

thy. Bone marrow suppression is rare in usual doses, but high doses can cause leukopenia. Concurrent administration of amifostine with cisplatin may reduce the cumulative renal toxicity associated with repeated administration in patients with advanced carcinoma of the ovary and NSCLC. Other toxic effects associated with cisplatin in combination with other chemotherapy agents may also be reduced by pretreatment with amifostine.[42]

Carboplatin

Carboplatin is a second-generation platinum complex designed to maintain antitumor efficacy while decreasing nephrotoxicity, ototoxicity, and neurotoxic effects. The emetogenic potential of carboplatin is less than that of cisplatin. The major dose-limiting side effect is myelosuppression, with thrombocytopenia being more significant than leukopenia. Carboplatin is active in small cell lung cancer, ovarian carcinoma, and head and neck carcinomas.

Oxaliplatin

Oxaliplatin is a newer third-generation platinum derivative with a novel mechanism of action. Oxaliplatin may exert its cytotoxic effects by blocking DNA replication and transcription. It is more potent than other platinums and has activity against tumors resistant to cisplatin and carboplatin. Early trials suggest synergistic activity in colorectal cancer when used with fluorouracil.[7] Oxaliplatin has been approved more recently for the treatment of patients with advanced colorectal cancer when administered in combination with fluorouracil and leucovorin. The toxicity profile of oxaliplatin includes some unique neurotoxic effects. There is an acute and chronic presentation of the toxicity. Acute symptoms include paresthesia of the hands, feet, and perioral area; jaw tightness; and laryngopharyngeal dysesthesia. These symptoms can occur with the infusion or within hours after administration and may be triggered by exposure to cold temperatures or cold objects such as ice used for mucositis prophylaxis. Chronic symptoms of peripheral neuropathy may be aggravated by exposure to cold.

Podophyllotoxins

Etoposide

Etoposide, a semisynthetic derivative of the mandrake plant substance podophyllotoxin (Figure 42-10), is indicated for the treatment of advanced testicular cancer. It is also active against Kaposi's sarcoma, small cell lung cancer, NSCLC, and lymphomas. A cell cycle–specific drug, etoposide is unique because it is most active in the G_2 phase of the cycle. The drug seems to prevent cell division by damaging DNA, by inhibiting topoisomerase II, or by forming free radicals. Oral etoposide is commercially available and is approximately 50% bioavailable, but the drug is typically given via slow intravenous administration to avoid hypotension. Myelosuppression, nausea, and vomiting are the most common adverse effects. Etopophos is a prodrug formulation of etoposide. This formulation has greater solubility, allowing for more rapid infusion with less hypersensitivity and hypotensive reactions.[30]

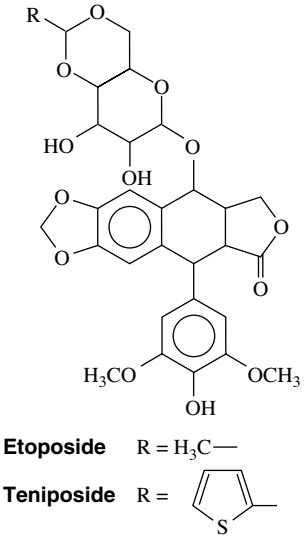

FIGURE **42-10** Structural formulas of etoposide and teniposide.

Teniposide

Teniposide is similar to etoposide, differing in the substitution of a thenylidene group for a methyl group on the carbohydrate moiety (see Figure 42-10). Although the mechanism of action is similar to that of etoposide, its cytotoxic properties are more potent. Current uses include treatment of refractory childhood leukemias and neuroblastoma. Myelosuppression is dose-limiting, and severe allergic reactions have been reported.

Camptothecins

Topotecan

Topotecan is a semisynthetic analogue of camptothecin. Camptothecin is isolated from an ornamental tree, *Camptotheca acuminata*, found in China. The mechanism of action is the inhibition of topoisomerase I, which causes single-strand breaks in DNA. The current indication for topotecan is for the treatment of metastatic ovarian carcinoma. Topotecan in combination with cytarabine is also used to treat advanced myelodysplastic syndromes and acute myelogenous leukemia.[3] The major dose-limiting side effect is myelosuppression. Irinotecan, another derivative of camptothecin, is indicated for use in colorectal carcinomas that have not responded to fluorouracil therapy. Irinotecan in combination with fluorouracil/leucovorin has been shown to increase survival in colorectal cancer patients and may become first-line therapy for this disease.[58] The major side effects of topotecan include myelosuppression and diarrhea requiring aggressive medical management.

Taxoids and Epothilones

Paclitaxel

Paclitaxel is another naturally derived product. Originally extracted from the bark of the western yew tree, *Taxus brevifolia*, paclitaxel induces polymerization and stabilization of microtubules. The development of paclitaxel has been slow because of the laborious process for extracting the active drug and the lack of success in synthesizing it because of its complex chemical structure (Figure 42-11). It is poorly soluble in water and is formulated in a Cremophor El (polyoxyethylated castor oil) and alcohol vehicle. This vehicle may contribute to the high incidence of allergic reactions to the injectable drug. These severe reactions result in dyspnea, hypotension, bronchospasm, urticaria, and erythematous rashes, and they must be managed prophylactically by premedication with steroids or H_1 and H_2 antihistamines or both and by prolonging the infusion. The antineoplastic activity of this drug is broad, and the current approved use of paclitaxel includes treatment of metastatic carcinoma of the ovaries and breast. A new formulation of paclitaxel is available that has the paclitaxel bound to albumin, which is free of toxic solvents, and may provide an improved response rate over traditional paclitaxel. Trials are ongoing to establish the role of this new class of "protein-bound particle" drugs.

Docetaxel

Docetaxel is an antineoplastic agent belonging to the taxoid family. It is a semisynthetic preparation that starts from the needles of yew plants. It works like paclitaxel by binding to free tubulin, promoting the assembly of tubulin and inhibiting its

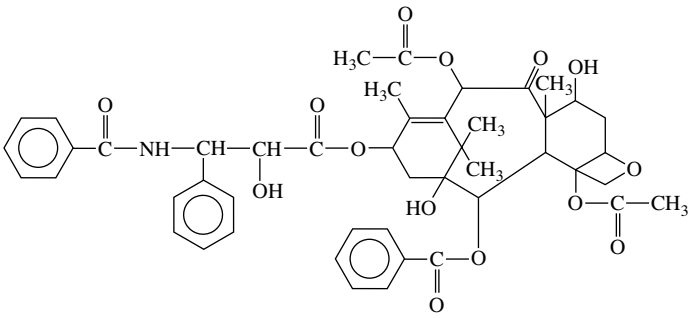

FIGURE **42-11** Structural formula of paclitaxel.

disassembly. Docetaxel is indicated for the treatment of locally advanced breast cancer. Docetaxel has moved rapidly from second-line treatment of breast cancer to current evaluations in large, adjuvant trials in breast cancer and use in NSCLC.[10,22] Docetaxel has a toxicity profile similar to that of paclitaxel, with allergic reactions requiring premedication with dexamethasone starting 1 day before therapy. Fluid retention and cutaneous toxicity occur more frequently than with paclitaxel, but there are fewer cardiac arrhythmias and myalgias.

Ixabepilone

Ixabepilone (Ixempra) is the first of the class of epothilones to be approved for use in the treatment of breast cancer. Epothilones are macrolide fermentation products of the myxobacterium *Sorangium cellulosum*. Epothilones A and B can competitively displace paclitaxel from its binding of microtubules and work by stabilizing microtubules, causing cell cycle arrest. Ixabepilone is a semisynthetic analogue of epothilone B and has been studied in paclitaxel-resistant breast cancer. It is approved for monotherapy or in combination with capecitabine for treatment of patients with metastatic or locally advanced breast cancer resistant to treatment with an anthracycline and a taxane.

A major toxicity associated with ixabepilone is grade III to IV peripheral neuropathy, seen in about 14% of patients receiving monotherapy with ixabepilone and 23% of patients receiving the combination with capecitabine. The neuropathies were generally reversible with the discontinuation of treatment. Severe neutropenia was frequently seen in patients treated with the combination of ixabepilone and capecitabine. Other adverse effects occurring in more than 20% of the patients treated include anemia, leukopenia, thrombocytopenia, fatigue, myalgia/arthralgia, nausea and vomiting, alopecia, stomatitis/mucositis, and diarrhea. Ixabepilone is being studied in numerous other resistant tumors, as are other epothilones such as patupilone, KOS-1584, and sagopilone/ZK-EPO.[66]

Other Agents

Hydroxyurea

Hydroxyurea inhibits DNA synthesis by blocking the action of ribonucleoside diphosphate reductase. Hydroxyurea is readily absorbed from the alimentary tract; tissue distribution includes the CNS. Elimination is mainly by urinary excretion. Hydroxyurea is used principally to treat busulfan-resistant chronic myelogenous leukemia and to reduce rapidly increasing peripheral blast counts in acute leukemia. Hydroxyurea is also used in sickle cell disease and for other myeloproliferative disorders such as polycythemia vera. High doses most often produce myelosuppression and megaloblastic anemia.

Procarbazine

Procarbazine, a derivative of methylhydrazine, was originally synthesized for its use as an antidepressant. It suppresses mitosis and produces chromosomal defects. It is a monoamine oxidase inhibitor that possesses teratogenic and carcinogenic properties in addition to antineoplastic activity. Procarbazine is rapidly absorbed from the alimentary tract, quickly metabolized by the liver, and excreted in the urine mainly in the form of a metabolic breakdown product. Procarbazine is most active against Hodgkin's disease and is modestly effective in other lymphomas and multiple myeloma when given in combination with alkylating agents and vinca alkaloids. Nausea and vomiting occur with high doses, and hematologic toxicity in the form of leukopenia and thrombocytopenia occurs within 3 to 4 weeks. Because procarbazine is a mild monoamine oxidase inhibitor, patients should be warned about concurrent use of tyramine-rich foods, antidepressants, CNS depressants, and other drugs that are known to interact significantly with monoamine oxidase inhibitors. Procarbazine is reported to have some degree of disulfiram-like activity, so alcoholic beverages should be avoided.

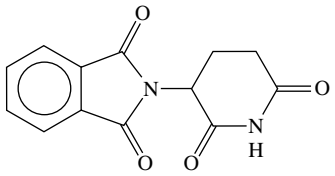

FIGURE **42-12** Structural formula of thalidomide.

Thalidomide

Thalidomide (Figure 42-12) was used in Europe and Canada in the 1950s as an anxiolytic, antiemetic, and sedative drug until it was discovered to cause major teratogenic effects. This agent was not approved for use in the United States at that time because of a potential for irreversible neurotoxicity after long-term use. In the late 1990s, thalidomide was approved by the FDA for the treatment of Hansen's disease (leprosy). Since then, many additional conditions and disease states, such as AIDS-related cachexia, rheumatoid arthritis, graft-versus-host disease, and cancers such as multiple myeloma, have been treated with thalidomide.[6] The mechanism of thalidomide activity is complex and still not well understood, but it involves two major effects: antiangiogenesis and immune system modulation.

Angiogenesis, as stated previously, is an important mechanism for tumor growth and formation of metastases. On inhibition of angiogenesis, the tumor cells starve without the necessary nutrient supply. In addition, thalidomide can inhibit tumor necrosis factor-α production, stimulate T-cell proliferation, and increase interferon and interleukin-2 release. The role of each of these mechanisms in its antineoplastic effect is unknown. The success rates in treating multiple myeloma as a single agent range from 25% to 75%. The most frequent dose-dependent adverse effects include sedation, rash, fatigue, and constipation. Thalidomide has also been shown to increase

the risk of developing thromboses, and it is recommended that patients receive anticoagulation therapy while on thalidomide. Because of the risk of birth defects, patients and physicians must be enrolled in a drug company program to be able to take or prescribe thalidomide.

Lenalidomide

Lenalidomide is a structural analogue of thalidomide that has more potent activity. It is approved for second-line treatment of multiple myeloma in combination with dexamethasone. The mechanism of action of lenalidomide is not well understood. In multiple myeloma, lenalidomide induces apoptosis in myeloma cells, inhibits the production of cytokines in the bone marrow that allow for the growth of myeloma, stimulates natural killer cell immunity against myeloma cells, decreases the binding of myeloma cells to the bone marrow stromal cells, and stimulates the action of dexamethasone. Lenalidomide in combination with dexamethasone has a response rate of 50% to 60% in multiple myeloma patients.[52] Lenalidomide is also approved for treatment of myelodysplastic syndromes. For myelodysplastic syndromes, lenalidomide is thought to inhibit tumor necrosis factor-α, inhibit angiogenesis, and have immunomodulatory effects that stimulate $CD4^+$ and $CD8^+$ cells. It has been shown to be more effective in patients with the cytogenic abnormality of deletion of chromosome 5q. Adverse effects of lenalidomide include myelosuppression, fatigue, neuropathies, constipation, and somnolence. When combined with dexamethasone, lenalidomide has an increased risk of developing deep vein thromboses and should be given with aspirin or anticoagulation therapy. Similar to thalidomide, patients taking lenalidomide and prescribing physicians must be enrolled in a program aimed at preventing birth defects.

Arsenic trioxide

Arsenic trioxide (As_2O_3) has been investigated more recently in clinical trials for treatment of acute promyelocytic leukemia in patients who relapsed after standard treatment with chemotherapy and all-*trans*-retinoic acid or after a bone marrow transplant. The rates of complete remission with low-dose arsenic were impressive in this refractory patient population. The proposed mechanisms of activity of this arsenical compound include induction of apoptosis by activation of cysteine proteases (caspases) and initiation of cytodifferentiation. The adverse effects linked to low-dose arsenic trioxide in clinical trials consisted of lightheadedness during infusion, fatigue, musculoskeletal pain, hyperglycemia, and peripheral neuropathy.[62] The frequency of oral complications from this treatment is low and includes sore throat, oral blisters, and dry mouth. A more serious but rare side effect is a presentation similar to "retinoic acid syndrome" (discussed later). This condition may be observed in patients with acute promyelocytic leukemia receiving arsenic trioxide. Cardiac side effects include QTc interval prolongation on electrocardiogram.[48]

Decitabine and azacytidine

Decitabine and azacytidine are two newer agents that work by inhibiting DNA methylation. Hypomethylation of the DNA results in the reactivation of genes that have been previously silenced in particular tumor suppressor genes. Decitabine is a deoxycycline and cytarabine nucleotide derivative that inhibits the process of DNA methyltransferase after being incorporated into the DNA, whereas azacytidine can be incorporated into DNA and RNA. Azacytidine also is a nucleotide analogue and is incorporated in place of cytidine, where it acts as a direct and irreversible inhibitor of DNA methyltransferase. Both of these agents have been approved for the treatment of myelodysplastic disorders. The major adverse effects of these drugs are myelosuppression, resulting in thrombocytopenia, neutropenia and febrile episodes, and infection. Common gastrointestinal side effects include nausea and vomiting and mucositis. Other effects include liver dysfunction and creatine elevations.[43]

Bisphosphonates

The bisphosphonates zoledronic acid and pamidronate have been used to manage hypercalcemia of malignancy and for bone pain associated with metastases arising from breast, prostate, and lung carcinomas and multiple myeloma. The use of these agents has had a favorable impact on the natural history of the disease, improving the quality of life by decreasing pain and skeletal fractures. Side effects include fevers, flulike syndromes, increases in serum creatinine and decreased renal function, and hypocalcemia. A more recently reported side effect associated with the routine use of zoledronic acid and pamidronate is the development of avascular osteonecrosis of the jaw (see Chapter 34).[38]

Differentiating Agents: Retinoids

Several classes of compounds have the potential in vitro and in vivo to have a differentiating effect on the malignant clone, inhibiting growth and proliferation. Among these compounds are the retinoids, including some commercially available and experimental agents such as isotretinoic acid (13-*cis*-retinoic acid), 9-*cis*-retinoic acid, all-*trans*-retinoic acid, bexarotene, etretinate, and the arotinoids. Retinoid effects seem to result from changes in gene expression mediated through specific intracellular receptors. There are two subfamilies of retinoid intracellular receptors: the retinoid acid receptors (RARs) and the retinoid X receptors (RXRs). These retinoid receptors each have three subtypes, designated *RARα, RARβ, RARγ,* and the corresponding *RXRα, RXRβ,* and *RXRγ.* These receptors form dimers with each other or other receptors, and each receptor subtype or combination is thought to control unique and overlapping target genes, regulating their transcription. Retinoids play crucial roles in normal development and physiologic functioning. They are also capable of inhibiting cell growth, inducing differentiation, and inducing apoptosis in various tumor cell lines.

Tretinoin

Tretinoin is the commercial formulation of all-*trans*-retinoic acid. This agent has been the most successful differentiating agent used in the treatment of acute promyelocytic leukemia. Genotypically, these leukemic clones have a characteristic translocation between the long arms of chromosome 15 and 17, which results in fusion between a gene that encodes RARα and a gene known as *pml*. The *pml*/RAR fusion protein functions as an oncogene and blocks differentiation of the myelocytes at the promyelocyte stage. Orally administered tretinoin induces differentiation and apoptosis of malignant promyelocytes. Tretinoin is metabolized in the liver and can induce its own metabolism, leading to decreased levels and clinical effects with continued administration. Tretinoin, similar to most retinoids, is teratogenic. Common side effects include dry skin, exfoliation, xerostomia, and cheilitis. A rare but potentially lethal dose-limiting toxicity is known as *retinoic acid syndrome*, which consists of fever, chest pain, dyspnea, hypoxia, pulmonary infiltrates, and pleural or pericardial effusions.[14]

Bexarotene

Bexarotene is a retinoid that selectively activates RXRs. The approved indication for bexarotene is for the treatment of cutaneous T-cell lymphoma. In vitro and animal testing suggests potential applications of bexarotene in other malignancies. This oral retinoid is hepatically metabolized and primarily eliminated through the hepatobiliary system. Bexarotene can

cause major lipid abnormalities in patients and may require monitoring and treatment. Other side effects include headache, asthenia, hypothyroidism, rash, dry skin, leukopenia, and nausea.

Other retinoids

Of all the retinoids, isotretinoic acid (13-*cis*-retinoic acid) has undergone the most extensive clinical examination. The activity of this agent alone in established cancers is limited. This agent has been used to reverse oral leukoplakia in heavy tobacco users.[36] The duration of clinical response is brief, and most patients have a relapse if the drug is stopped. Other retinoids, such as 9-*cis*-retinoic acid, which is a pan-agonist for RAR and RXR, are undergoing clinical evaluations for roles in the treatment of other tumors.

Biologic Response Modifiers

The continuing evolution of recombinant technology beginning in the early 1970s has resulted in the availability of clinical agents to modify host responses and aid in killing cancer cells by themselves and in combination with other cytotoxic agents. Known as the fourth modality of cancer therapy, biologic response modifiers are used to assist the body's natural ability to kill cancer cells or to minimize adverse effects on normal cells.

Interferons

Two types of human interferon, interferon alfa-2a and interferon alfa-2b, have been produced by recombinant DNA techniques and marketed for cancer chemotherapy. Each agent is a protein chain of 165 amino acids, differing from each other only at a single amino acid residue. A purified form of interferon-α, prepared from human plasma, is also available under the nonproprietary name of *interferon alfa-n3*.

These agents exert antiviral, immunostimulant, and antiproliferative properties by binding to specific cell membrane receptors; however, the exact mechanism of action remains to be elucidated. They are currently being used to treat hairy cell leukemia, Kaposi's sarcoma, chronic hepatitis, chronic myelogenous leukemia, melanoma, and other malignancies in combination with chemotherapy and as biologic response modifiers in other situations.[41]

Interferons are given by subcutaneous or intramuscular injection and have plasma half-lives of 4 to 8 hours. They are hydrolyzed in the kidney, and metabolites are largely reabsorbed from the glomerular filtrate. Interferons have the ability to depress the activity of the hepatic CYP450 system. Numerous side effects have been associated with their use. Most patients have a flulike syndrome with fever, chills, myalgia, fatigue, and headache. Loss of appetite is also common, and patients may have nausea, vomiting, and diarrhea. Dermatologic and CNS disturbances (e.g., ataxia, confusion) occur in a few patients.[41]

Aldesleukin

Aldesleukin (interleukin-2 [IL-2]) is a recombinant product produced by a genetically engineered *E. coli* strain. IL-2 has numerous immunoregulatory properties, including enhancement of lymphocyte mitogenesis, lymphocyte cytotoxicity, induction of killer cells (natural and lymphokine activated), and induction of interferon-γ production. IL-2 is administered by intravenous infusion and is metabolized and eliminated by the kidneys. The plasma half-life of IL-2 is short (approximately 90 minutes). Currently, IL-2 is used for the treatment of adults with metastatic renal cell carcinoma. In addition, high-dose IL-2 treatment has produced some long-lasting complete responses or partial remissions in metastatic melanoma patients. The major toxicities of IL-2 are associated with capillary leak syndrome, resulting in clinically significant hypotension, weight gain, fluid retention and accumulation, pulmonary edema, and acute renal dysfunction with oliguria or anuria. Some of the common side effects (e.g., chills and fevers) can be reduced with appropriate premedication. Pruritic rashes are common.

Oprelvekin

Interleukin-11 (IL-11) is a cytokine that occurs in vivo in many tissues, such as bone marrow, brain, kidneys, heart, lungs, spleen, uterus, and intestines. IL-11 participates in stimulating megakaryocytes and their precursors in the bone marrow. Other important growth factors and cytokines are necessary for megakaryocyte production and maturation. Interleukin-3 acts synergistically with IL-11. Oprelvekin is a recombinant IL-11 produced similarly to aldesleukin. Thrombocytopenia and neutropenia are important dose-limiting toxicities of chemotherapy that can potentially delay treatment or require reduction in the total dose delivered to the patient.

Prevention or reduction in duration and severity of bone marrow toxicity enables the patient to receive a planned chemotherapeutic regimen. IL-11 reduces bone marrow toxicity occurring during chemotherapy. As discussed later, filgrastim and sargramostim stimulate white blood cell production, but they do not have any effects on increasing platelet and red blood cell production. Oprelvekin was found to prevent severe thrombocytopenia and decrease the need for platelet transfusions in several double-blind, randomized clinical trials in cancer patients receiving highly myelosuppressive chemotherapeutic regimens. The widespread use of oprelvekin is limited, however, by its adverse effects profile and cost. Administration of oprelvekin leads to significant fluid retention, which may cause other important complications, such as peripheral edema, dilutional anemia, palpitations, dyspnea, headache, and atrial arrhythmias. Headache, myalgia, arthralgia, and fatigue are also reported frequently.

Filgrastim and sargramostim

Colony-stimulating factors represent a third group of biologic response modifiers (in addition to interferons and interleukins) that has had a clinical effect in the treatment of neoplastic disease. These agents—filgrastim (granulocyte colony-stimulating factor) and sargramostim (granulocyte-macrophage colony-stimulating factor)—are not cytotoxic. They offer the benefit of ameliorating the hematologic toxicity induced by the chemotherapeutic agents. Injected subcutaneously or intravenously, colony-stimulating factors are approved for the treatment of chemotherapy-related and transplant-related neutropenia in bone marrow transplant patients. The growth factors can shorten the overall period of neutropenia, reduce the number of febrile episodes, and decrease the need for broad-spectrum antibiotics. They are used investigationally for other clinical conditions of neutropenia. They also can mobilize stem cells into the peripheral blood for collection by cell separation for stem cell transplants after high-dose chemotherapy and radiation therapy.

The value of the growth factors may ultimately be to allow more chemotherapy to be administered, with less need for dose reductions because of side effects. Predictably, other adverse effects, such as mucositis, may become dose-limiting as dosages are escalated. Adverse effects of these agents are usually flulike symptoms, fever, chills, bone pain, and myalgia. Pleuritis and pericarditis have been reported.

Palifermin

Palifermin is a human keratinocyte growth factor and binds to the keratinocyte growth factor receptor, which results in proliferation, differentiation, and migration of epithelial cells. It is FDA approved to decrease the incidence and duration of severe oral mucositis in patients with hematologic malignan-

cies receiving myelotoxic therapy requiring hematopoietic stem cell support. This injectable growth factor is given 3 days before and 3 days after chemotherapy. In a clinical trial in autologous transplant patients, it reduced the duration of World Health Organization grade III and IV mucositis duration from 9 to 6 days and incidence from 98% to 63%. Palifermin has also been studied for use with chemotherapy agents such as fluorouracil, which can increase the risk of mucositis, and for the prevention of high-dose methotrexate–induced oral mucositis, where it may reduce the incidence, severity, and duration of the lesions.[60] Palifermin's current role is to prevent or decrease the duration of mucositis in stem cell transplant patients. It does not yet have an established role in the treatment of chemotherapy-induced mucositis.

Many other biologic response–modifying approaches are being explored in clinical trials. Levamisole, an anthelmintic agent, has a role with fluorouracil for the treatment of Dukes C colon cancer because of its immunomodulating effects. Vaccines, new cytokines, additional interleukins and colony-stimulating factors, and interferon-α all are being evaluated alone and in combination with chemotherapy to increase responses against these neoplastic diseases.

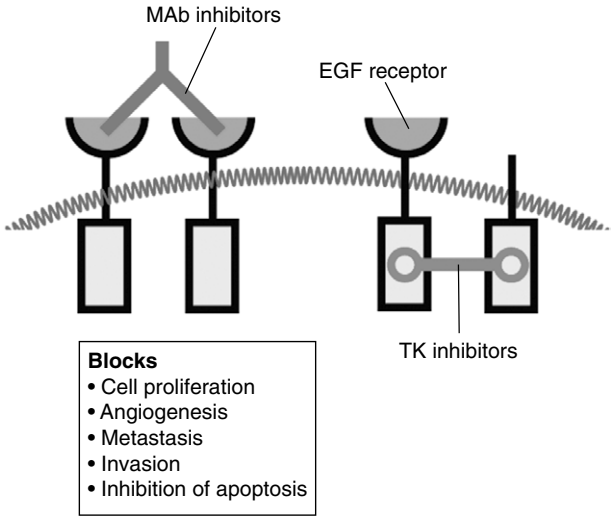

FIGURE **42-13** Inhibition of epidermal growth factor *(EGF)* receptor and resulting action on cells. *MAb,* Monoclonal antibodies; *TK,* tyrosine kinase.

TARGETED ANTINEOPLASTIC THERAPY

Researchers constantly strive to find the "magic bullet" to cure cancer. In the process of discovering new molecules with anticancer activity, the molecular mechanisms and cellular processes are better understood. The idea of targeting a specific molecular pathway in the tumor cell cycle originated from the limitations of traditional antineoplastic drugs such as nonselective toxicity, drug resistance, and suboptimal success rates. Over the past few years, new drugs have been developed that fall into the category of targeted therapy and are summarized in Table 42-2. Tyrosine kinase inhibitors, MAbs, and proteasome inhibitors target a specific receptor or pathway in malignant cells. They are used as single-agent or combination therapy to eradicate specific types of tumor cells, increase response rates, and slow the progression of cancers.

Tyrosine Kinase Inhibitors

Several TKs have been identified in malignant cells and used as targets for new drugs. The overexpression of EGFR-TK has been identified in malignant cells. This glycoprotein spans the cellular membrane and transduces extracellular stimuli into intracellular responses. An abnormally high activity of EGFR-TK has been linked to induction, growth, and metastatic potential of malignant cells. Inhibition of the EGFR-TK–mediated signaling pathway has been shown to result in suppression of tumor growth (Figure 42-13). The most effective drugs target the extracellular ligand-receptor binding or the intracellular phosphorylation step. Another TK target is the Bcr-Abl TK found in chronic myeloid leukemia. A characteristic of this type of leukemia is a translocation between two chromosomes to form the Philadelphia (Ph) chromosome. This translocation occurs at the breakpoint cluster region (*Bcr*) gene on chromosome 22 and the proto-oncogene on chromosome 9, identified by Abelson as *Abl*. This translocation forms the Bcr-Abl fusion gene, which codes for the Bcr-Abl TK. Other TKs that have been identified for targets include VEGF-TK; cKit (stem cell factor); FLT3 (FMS-like TK 3), which is related to the platelet-derived growth factor (PDGF); RAS, Src, and Raf.[18]

Erlotinib

Erlotinib is an oral agent that inhibits EGFR-TK that is approved as second-line therapy for advanced NSCLC and first-line therapy for advanced pancreatic cancer in combination with gemcitabine. Erlotinib may be combined with chemotherapy in NSCLC to increase response rates or given as monotherapy to patients with a poor performance status or who are unable to receive chemotherapy. Nonsmokers and Asian patients seem to benefit the most from erlotinib therapy.[63] In pancreatic cancer, erlotinib has been shown to inhibit EGFR activation, which inhibits signal transduction and cell proliferation. It also seems to enhance gemcitabine activity, and the combination has been shown to stabilize disease. Side effects of erlotinib include diarrhea and an acne-like skin rash that may be associated with efficacy.[57]

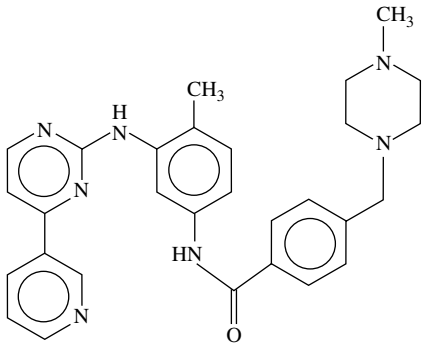

FIGURE **42-14** Structural formula of imatinib.

Imatinib

Imatinib is an oral TK inhibitor that targets Bcr-Abl in chronic myeloid leukemia and Ph^+ acute lymphocytic leukemia patients; its structure is shown in Figure 42-14. It functions by binding to the adenosine 5′-triphosphate binding site while it is in the closed state, causing signal transduction to end. The IRIS trial evaluated imatinib for first-line therapy in patients with chronic myeloid leukemia. In this trial, 87% of imatinib patients achieved a complete cytogenic response, only 7% of patients progressed to advanced disease, and there was an overall survival rate of 89% after 5 years. Because of these results, imatinib is considered first-line therapy for chronic myeloid leukemia patients. It has also proven to be successful in treating Ph^+ acute lymphocytic leukemia patients in combination with standard chemotherapy. Common toxicities

TABLE **42-2**

Targeted Therapies

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	CELLULAR TARGET	TREATMENT INDICATION	ADVERSE EFFECTS
Tyrosine Kinase Inhibitors				
Erlotinib	Tarceva	EGFR	Lung cancer, pancreatic cancer	Acneiform skin rash, diarrhea
Imatinib	Gleevec	Bcr-Abl	CML, Ph^+ ALL, GIST	Myelosuppression, peripheral edema, GI pain, nausea, bone pain, rash
Dasatinib	Sprycel	Bcr-Abl	Imatinib-resistant or imatinib-intolerant CML and Ph^+ ALL, GIST	Myelosuppression, pleural effusions, nausea and vomiting
Nilotinib	Tasigna	Bcr-Abl	Imatinib-resistant or imatinib-intolerant CML and Ph^+ ALL	Myelosuppression, hyperglycemia, increased serum lipase, QTc interval prolongation
Lapatinib	Tykerb	ErbB-1 and ErbB-2	Advanced or metastatic breast cancer	Nausea, fatigue, itching, acne, diarrhea
Sorafenib	Nexavar	VEGF, PDGFR, cKit, FLT3	Renal cell carcinoma	Diarrhea, hand-foot syndrome, hypertension, neutropenia, fatigue, hypophosphatemia
Sunitinib	Sutent	VEGF, PDGFR, cKit, FLT3	Renal cell carcinoma, GIST	Myelosuppression, increased serum lipase, fatigue, nausea and vomiting, diarrhea
Proteosome Inhibitors				
Bortezomib	Velcade	26S Proteosome	Multiple myeloma	Myelosuppression, peripheral neuropathy, fatigue/malaise
Monoclonal Antibodies				
Rituximab	Rituxan	CD20	Lymphomas	Infusion related (chills, fever, flushing, nausea, fatigue, pruritus, angioedema)
Trastuzumab	Herceptin	HER-2/Neu (ErbB-2)	Breast cancer	Infusion related (chills, fever, rigors, headaches, nausea and vomiting, diarrhea, cough/shortness of breath, rash), cardiotoxicity (cardiomyopathy and CHF)
Gemtuzumab ozogamicin	Mylotarg	CD33	Acute myelogenous leukemia	Severe myelosuppression, infusion related (chills, fever, changes in blood pressure, shortness of breath), hepatotoxicity
Ibritumomab	Zevalin	CD20	Lymphomas	Myelosuppression
Tositumomab	Bexxar	CD20	Lymphomas	Myelosuppression
Alemtuzumab	Campath	CD52	Chronic lymphocytic leukemia	Infusion related (chills, fever, nausea and vomiting)
Bevacizumab	Avastin	VEGF	Colorectal cancer	GI bleeding, GI perforations, delayed wound healing, hypertension, reversible posterior leukoencephalopathy syndrome, thromboembolism, mucocutaneous hemorrhage
Cetuximab	Erbitux	EGFR	Colorectal cancer, head and neck cancer	Infusion related (chills, fever, anaphylaxis), acneiform rash, interstitial lung disease, hypomagnesemia
Panitumumab	Vectibix	EGFR	Colorectal cancer	Pulmonary fibrosis, hypomagnesemia, rash, paronychia
Histone Deacetylase Inhibitors				
Vorinostat (SAHA)	Zolinza	Histone deacetylase	Cutaneous T-cell lymphoma	Diarrhea, fatigue, nausea, anorexia, pulmonary embolism, thrombocytopenia

ALL, Acute lymphocytic leukemia; *CHF,* congestive heart failure; *CML,* chronic myeloid leukemia; *EGFR,* epidermal growth factor receptor; *GI,* gastrointestinal; *GIST,* gastrointestinal stromal tumor; *PDGFR,* platelet-derived growth factor receptor; *Ph^+,* Philadelphia chromosome–positive; *VEGF,* vascular endothelial growth factor.

include myelosuppression, peripheral edema, nausea, gastrointestinal pain, bone pain, and rash.[21] Imatinib has also been approved for second-line treatment of gastrointestinal stromal tumors because it inhibits cKit, Abl protein, and PDGF, all of which are overexpressed in gastrointestinal stromal tumor cells.

Dasatinib

Dasatinib is an oral dual Bcr-Abl/Src kinase inhibitor. It has also shown activity against Src family kinases (SFKs), c-Kit, PDGF, and others. It is the first drug to be approved to treat chronic myeloid leukemia and Ph^+ acute lymphocytic leukemia patients who are imatinib-resistant or imatinib-intolerant. A series of trials named the START trials illustrated a durable hematologic and cytogenic response to dasatinib in this patient population. Dasatinib has been shown to be effective against all imatinib-resistant Bcr-Abl mutations except T315I. The side effects of dasatinib include grade III and IV neutropenia and thrombocytopenia (that are generally reversible and easily

managed), nausea and vomiting, and fluid retention. Pleural effusions are common, more so in patients with advanced disease, and may be managed by dose reductions, diuretics, or steroids.[56]

Nilotinib

Nilotinib is an analogue of imatinib that is approved for management of chronic or acute phase chronic myeloid leukemia patients who are intolerant or resistant to imatinib. In vitro testing shows that nilotinib is effective against all imatinib-resistant mutations except T315I, but it has lower activity against P-loop mutations. The toxicities of nilotinib include myelosuppression and biochemical abnormalities, such as increased serum lipase and hyperglycemia. Nilotinib has also been shown to prolong the QTc interval with other cardiotoxicities such as pericardial effusions and atrial fibrillation having been reported in a few patients.[56]

Lapatinib

Lapatinib is a dual inhibitor of ErbB-1 (HER-1) and ErbB-2 (HER-2), two receptors in the EGFR family that are common in breast cancer. It is approved for treatment of advanced or metastatic breast cancer with ErbB-2 (HER-2) overexpression in combination with capecitabine. It has been studied in treatment refractory and therapy-naïve patients and as monotherapy or in combination with other chemotherapy and has been beneficial in all populations. Lapatinib is also able to pass through the blood-brain barrier and is a possible treatment for patients with brain metastases. Side effects of lapatinib include nausea, fatigue, itching, diarrhea, acne, and dry skin. There is little to no cardiotoxicity from lapatinib.[53]

Sorafenib

Sorafenib is a small molecule TK inhibitor that is active against renal cell carcinoma and liver carcinoma. Sorafenib inhibits VEGF receptor, PDGF receptor, FLT3, and the RAS family of receptors including RAF-1 and BRAF. Sorafenib studies in renal cell carcinoma show a low partial response rate of about 10%, but high rates of disease stabilization and an increase in progression-free survival. Patients who are taking sorafenib may experience side effects such as diarrhea, hand-foot syndrome, hypertension, hypophosphatemia, fatigue, and neutropenia.[33,46]

Sunitinib

Sunitinib is an oral multitargeted inhibitor that targets VEGF receptor, PDGF receptor, FLT3, and cKit. Sunitinib has been approved for advanced renal cell carcinoma. Studies show it is capable of disease stabilization and an increased rate of progression-free survival compared with placebo or the use of interferon-α. Renal cell carcinoma is very difficult to treat, and sunitinib has shown a modest response rate of around 30%. Another indication for sunitinib is to treat gastrointestinal stromal tumors in patients who fail imatinib treatment or are intolerant of imatinib. Common side effects of sunitinib include neutropenia, thrombocytopenia, elevated lipase, fatigue, nausea, vomiting, and diarrhea.[33,46]

Other sites for TK inhibition are being identified as targets for anticancer therapy. Tipifarnib, an agent currently in clinical trials, is a farnesyltransferase inhibitor that targets RAS, an oncogene implicated in many cancers. Several more drugs are undergoing clinical trials and development.

Proteasome Inhibitors

Proteasomes are ubiquitous and essential intracellular protein complexes that contain protease active sites that degrade many proteins responsible for regulating the cell cycle, apoptosis, transcription, cell adhesion, angiogenesis, and antigen presentation. Bortezomib is the only approved proteasome inhibitor and is indicated for first-line treatment of multiple myeloma and second-line treatment of mantle cell lymphoma. Bortezomib's inhibition of the 26S proteasome prevents the degradation of intracellular proteins, leading to activation of signaling cascades, cell cycle arrest, and apoptosis. Major side effects reported include fatigue, malaise, peripheral neuropathy, and bone marrow suppression.

Monoclonal Antibodies

Malignant cells often have unique antigens expressed on their surfaces known as tumor-associated antigens. MAbs are single immunoglobulin antibodies or fragments specific to a targeted surface antigen. These antibodies are produced in vitro in large quantities by an immortalized plasma cell clone. Some of these antibodies have been made in human form by DNA recombinant technology to reduce the formation of human antimouse antibodies against MAbs. Interactions between human antimouse antibodies and MAbs may reduce the effectiveness of MAbs and may initiate an allergic reaction. Another desirable outcome of using a human sequence, such as the Fc portion, may provide sites of interactions for the human immune system to initiate complement and other immune-mediated lysis of the targeted cells. The binding of these MAbs to the targeted surface antigen may lead to complement-mediated lysis, antibody-dependent cellular cytotoxicity, or signal transduction–mediated apoptosis. Cytotoxins and radioisotopes may also be attached to these MAbs, providing additional mechanisms of action by which these antibodies can target and kill malignant cells. Many MAbs are in clinical trials, and some have been approved more recently by the FDA.[28]

Rituximab

Rituximab is a chimeric MAb consisting of a human and mouse portion, and its target is an antigen CD-20 present on mature B cells. The CD-20 antigen makes an excellent target for a therapeutic approach because this hydrophobic phosphoprotein is present on mature B cells, but not on stem cells, plasma cells, or pre-B cells.[27] This antigen also participates in cell cycle initiation and differentiation. Rituximab was approved by the FDA in 1997, and it was the first MAb on the market with an indication for treatment of cancer. This MAb is used to treat low-grade and follicular lymphomas expressing CD-20 antigen. In clinical trials, rituximab was effective as a single agent and in combination with standard chemotherapy; overall response rates were 48% and 100%, respectively.[27]

The rationale for use of this MAb in combination with chemotherapy is its unique mechanism of action and its adverse effects profile. On binding of rituximab to the CD-20 antigen, the cascade of complement-dependent cell lysis is initiated, and the antibody-dependent cellular cytotoxicity occurs. In addition, rituximab has the ability to sensitize resistant human lymphoma cells. Rituximab is often combined with chemotherapy to treat lymphocytic lymphomas that express the CD-20 antigen. In contrast to chemotherapy-induced adverse effects (e.g., bone marrow suppression, mucositis), the most common adverse effects seen with rituximab are infusion related and include chills, fever, flushing, nausea, fatigue, pruritus, and angioedema. The severity of these infusion-related adverse effects subsides significantly with subsequent infusions.[27]

Trastuzumab

Trastuzumab is a human MAb against human EGFR-2 that is overexpressed in 25% to 30% of patients with breast cancer.[61] The overexpression of this receptor has been associated with more aggressive tumors, lower response rates to standard chemotherapy regimens, and ultimately decreased survival. The mechanism of action of this MAb consists of at least three major effects: alteration of the signaling potential between the

receptor and the nucleus, stimulation of the immune system components that attack and kill the tumor cells, and augmentation of the cytotoxic activity of antineoplastic drugs. Trastuzumab is given intravenously in weekly intervals for prolonged periods. Infusion-related chills, fever, and rigidity can occur frequently with trastuzumab, especially during the first dose. Other common adverse effects include headache, nausea, diarrhea, vomiting, cough, shortness of breath, and rash.[61]

Gemtuzumab ozogamicin

Gemtuzumab ozogamicin is a conjugate of a MAb against CD-33 antigen and a potent antineoplastic agent, calicheamicin. This novel agent has been approved more recently by the FDA for the management of acute myeloid leukemia in elderly patients who are unlikely to tolerate standard induction regimens. The CD-33 antigen is a glycoprotein present on most acute myeloid leukemia cells; however, it is not present on normal stem cells that are necessary for bone marrow recovery. The discovery of a MAb against this leukemic antigen made possible the use of a highly cytotoxic antibiotic, calicheamicin. Calicheamicin is a small molecule that contains two domains, an enediyne portion and a carbohydrate tail, allowing it to bind to the minor groove of the DNA. This binding results in DNA double-stranded breaks.

This potent group of agents has been studied in vitro and in animal trials since the 1970s, but could not be used in clinical practice because of severe, nonselective toxicity. The role of the MAb is to deliver this potent antineoplastic drug to the leukemic cell, which, on binding the drug, subsequently engulfs the molecule. When inside the cell, calicheamicin finds its way into the nucleus and binds to the DNA. This activity is illustrated in Figure 42-15. Most patients have infusion-related adverse effects such as chills, fevers, changes in blood pressure, and shortness of breath. Additional adverse effects that occur days after this drug is administered include hepatotoxicity and severe bone marrow toxicity that can last for 4 to 6 weeks. The incidence of severe mucositis is approximately 4% in clinical trials to date.[34]

Ibritumomab and tositumomab

Two radioimmunoconjugates are available for the treatment of lymphoid malignancies. Tositumomab and ibritumomab are anti-CD-20 murine MAbs that target the same antigen as rituximab. The radionucleotide iodine 131, conjugated to tositumomab, and yttrium 90, conjugated to ibritumomab, provide an additional mechanism of cytotoxicity. The radiation source also allows for greater crossfire effect, radiating nearby malignant lymphoma cells that may not express the CD-20 antigen. It can also bring irradiation to large tumor clusters in which the blood circulation is unable to deliver the MAbs to most of the cells. Both MAbs have been used in refractory indolent non-Hodgkin's lymphoma with good overall response rates.

The toxicity profiles of these radioimmunoconjugates are similar, with the most common toxicity being hematologic (i.e., thrombocytopenia, neutropenia). The onset of myelosuppression is delayed, with a nadir in bone marrow function at 30 to 40 days. The advantages of the ibritumomab–yttrium 90 are the shorter half-life of yttrium 90, allowing easier use in the outpatient setting and greater radiation penetration for the treatment of bulky lymphomas over rituximab alone.[55] The radioisotope iodine 131 associated with tositumomab requires more radiation safety precautions because it emits β and γ radiation.

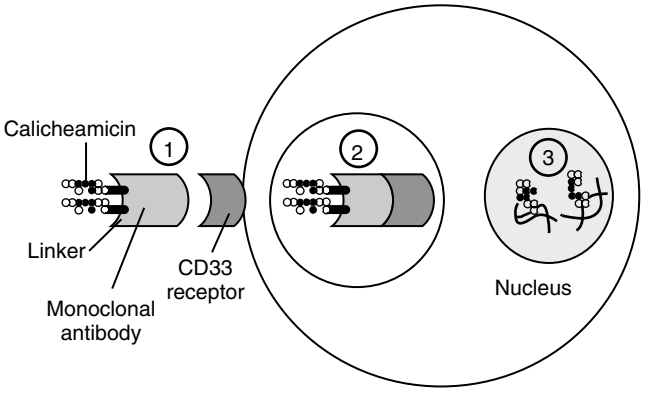

FIGURE **42-15** Gemtuzumab ozogamicin conjugate and its mechanism of action. The three major steps are *(1)* CD33 receptor binding and receptor complex internalization; *(2)* calicheamicin transport to the nucleus; and *(3)* calicheamicin binding to DNA, which causes DNA strand breaks.

Alemtuzumab

Alemtuzumab is a human MAb that targets the CD-52 antigen found on B and T lymphocytes, inducing complement fixation, cell-mediated cytotoxicity, and apoptosis. The CD-52 antigen is not present in progenitor cells. Infectious complications are the most significant side effect associated with this infusional therapy; the most common side effects are fever, chills, nausea, and vomiting. Alemtuzumab may provide a third-line therapy for chronic lymphocytic leukemia for patients who have been treated with alkylating agents and have not responded to fludarabine therapy.[19]

Bevacizumab

Bevacizumab is a recombinant human MAb against VEGF, which is required for blood vessel formation and is produced by many malignant cells. Inhibition of VEGF decreases angiogenesis and increases the permeability of the tumor to chemotherapies. The addition of this MAb to chemotherapy in the treatment of metastatic colorectal cancer has increased the overall response rate and prolonged the median survival by 5 months, improving it from 15.6 months without bevacizumab to 20.3 months in combination with a fluorouracil-based regimen. In addition to its use in colorectal cancer, bevacizumab is being studied for use in combination with chemotherapy for renal cell carcinoma, ovarian cancer, NSCLC, and breast cancer.

The FDA approved bevacizumab for use with chemotherapy for NSCLC and Her-2-negative metastatic breast cancer. The combination of bevacizumab and paclitaxel has prolonged progression-free survival, but not overall survival.[45] Bevacizumab should be avoided in patients with squamous cell lung cancer because of an increased bleeding risk from the lung. Bevacizumab should not be used within 28 days of a major surgery because of concerns over wound healing. Other adverse effects include gastrointestinal bleeding and perforation, hypertension requiring medical treatment, nephrotic syndrome, heart failure, reversible posterior leukoencephalopathy syndrome, thromboembolism and mucocutaneous hemorrhage.

Cetuximab

Cetuximab is a chimeric MAb directed against EGFR, which is overexpressed in various malignant tumors such as NSCLC, head and neck cancer, and colorectal cancer. Cetuximab was first approved for use in metastatic colorectal cancer therapy with irinotecan. It has been approved more recently for use in combination with radiation therapy for locally or regionally advanced squamous cell carcinoma of the head and neck. Compared with radiation alone, the combination of cetuximab and radiation can nearly double the median survival of patients with certain types of head and neck cancers.[4] The binding of cetuximab to the EGFR blocks phosphorylation

and activation of receptor-associated kinases, resulting in inhibition of cell growth and induction of apoptosis. The EGFR is expressed in many normal epithelial tissues, including the skin and hair follicle; this accounts for the common adverse effect of an acne-like rash associated with cetuximab. Other adverse reactions include interstitial lung disease, hypomagnesemia, and infusion-related reactions.

Panitumumab

Panitumumab is a human MAb produced in transgenic mice that targets the EGFR. It is approved for the treatment of colorectal cancer that has progressed after treatment with chemotherapy agents such as fluorouracil, oxaliplatin, and irinotecan. The theoretic advantage of this MAb over cetuximab is a lower incidence of infusion reactions, so no premedications are required. Its toxicity profile includes pulmonary fibrosis, hypomagnesemia, paronychia, and similar to many other EGFR inhibitors, dermatologic toxicities.

Histone Deacetylase Inhibitors

Histone acetylation and deacetylation is important in regulating gene expression by making the genes more available or less available for transcription. Histone deacetylase (HDAC) enzymes collapse the DNA around the histones and reduce gene transcription. Deregulation of histone acetylation has been shown to play a part in the development of several hematologic and solid tumor cancers by leading to oncogenes that stop apoptosis or inhibit other cellular pathways. HDAC inhibitors are used to stop transcription inhibition by oncogenes and to reactivate apoptosis, cellular differentiation, and tumor suppressor genes. They also stop cell cycle transition at G_1 and G_2-M phases, break down chromatin, and may inhibit angiogenesis. There are several HDAC inhibitors in clinical trials. Vorinostat (SAHA) has shown activity in several cancers, and has been approved to treat progressive or treatment-refractory cutaneous T-cell lymphoma.[23] In a phase IIB trial, vorinostat was shown to have a 29.7% overall response rate, with 29.5% response in patients with stage IIB or greater cutaneous T-cell lymphoma. Time to progression was 4.9 months overall and greater than 9.8 months for stage IIB or greater patients. Adverse effects include diarrhea, fatigue, nausea, anorexia, pulmonary embolism, and thrombocytopenia.[50]

COMBINATION THERAPY

The previously discussed drugs are rarely used as single entities for the treatment of a specific tumor. Choriocarcinoma is one of only a few malignancies that can be cured with a single agent (doxorubicin). Resistance of tumor cells to chemotherapy may explain poor initial responses and relapses during treatment. A hypothesis for tumor resistance has been proposed by Goldie and Coldman.[25] Resistant tumors exhibit either inherent resistance or acquired resistance. The possible mechanisms of acquired resistance include defects in the resistant cells, transport, and activation of the chemotherapeutic prodrug to the active species. Also involved may be an alteration of the DNA repair, gene amplification, altered nucleotide pool, increased salvage pathways, and development of pleiotropic drug resistance or multidrug resistance. Research is ongoing to understand better and overcome tumor resistance.

The current chemotherapeutic approach to prevent resistance is similar to the approach described for combination chemotherapy: (1) use agents with different cell cycle specificity, mechanisms of action, toxicities, and potential combinations for synergy, and (2) administer the drugs in intermittent courses and at maximal tolerated doses to maximize cell kill, allow for host recovery, and avoid prolonged drug-free intervals. The dose intensity of a regimen is a well-recognized variable for response and cure in sensitive tumors. The use of alternating non–cross-resistant regimens may improve outcome further, as seen with the ABVD regimen (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine), alternating monthly with the traditional MOPP regimen (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone) for the treatment of advanced Hodgkin's disease. This regimen was made more dose-intensive by combining the two regimens into a monthly cycle MOPP/ABV hybrid program.[11] The ultimate dose-intensive regimens include high-dose chemotherapy, with or without irradiation, requiring bone marrow transplantation or peripheral stem cell reinfusion to rescue the host from total marrow aplasia. Antineoplastic agents are also more successful when used in combination with radiation therapy and surgery for the treatment of tumors such as head and neck carcinomas. Combination regimens containing cisplatin and fluorouracil are being used simultaneously with radiotherapy to render the tissue radiosensitive and as a postoperative adjunct to destroy micrometastases that may have been missed during local surgery.

Targeted therapy approaches are being incorporated into combinations with more traditional chemotherapy agents, as they add a different mechanism of killing tumor cells. Combinations such as rituximab plus CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], prednisone) for non-Hodgkin's lymphoma have been shown to be more effective than chemotherapy alone and have become standard of care. Other combinations, especially with TK inhibitors and chemotherapy, have not shown any added benefit. More studies are needed to establish the place of targeted therapy and chemotherapy combinations in cancer treatment. Many of these newer targeting agents are oral agents and provide an opportunity for the long-term management of malignancies.

Potential Drug Interactions and Relative Contraindications

Most antineoplastic drugs have a narrow therapeutic index. Although drug interactions may enhance or diminish the antitumor effects and result in improvement or treatment failure, drug interactions may also increase or decrease the side-effect profile of the antineoplastic drug. Caution must be used when adding other therapeutic agents in patients undergoing active anticancer therapy. Interactions may occur between antineoplastic drugs and drugs that have no antineoplastic effects. One example is the relative contraindication for the use of NSAIDs such as ibuprofen, aspirin, and others in patients who may be thrombocytopenic from myelosuppressive antineoplastic agents. NSAIDs may affect platelet function and increase gastrointestinal irritation, increasing the bleeding risk in patients with a low platelet count. Other drug-drug interactions may occur from changes in absorption, clearance, or excretion of the antineoplastic drugs; from changes in protein binding; or through the induction or inhibition of isoenzymes of the CYP450 system that metabolize the particular antineoplastic substrate or its metabolites.

Not all the metabolic pathways and interactions for antineoplastic agents have been identified. Many antineoplastic agents are substrates for metabolism by the CYP3A4, CYP2B6, and CYP2D6 isoenzymes. Concurrent use of an antineoplastic agent and the inhibitors of these and other hepatic isoenzymes may potentially cause delayed elimination of an antineoplastic agent and enhance its activity or toxicity. Examples of inhibitors of the CYP3A4 isoenzyme are the commonly used antifungal drugs, fluconazole and ketoconazole, which may possibly increase blood levels of cyclophosphamide, a substrate of a CYP3A4 isoenzyme. This antineoplastic agent is also metabolized by the CYP2B6 isoenzyme, so the metabo-

lism of cyclophosphamide is only partially affected by the inhibitory effects of these antifungal agents. The antibiotic erythromycin can increase the toxicities of vincristine, possibly through inhibition of vincristine metabolism by CYP3A4. Although many analgesics are substrates for metabolism by CYP isoenzymes, no clinically significant drug interactions from CYP isoenzyme effects on these analgesics and antineoplastic drugs have been reported.

Many antineoplastic drugs are excreted by the kidney. Nephrotoxic drugs may increase the toxicity of these agents by delaying drug elimination. Methotrexate is an antifolate antimetabolite with a wide spectrum of activity. It is a weak acid and is eliminated by tubular secretion in the kidney. The renal clearance may be decreased by drugs that inhibit the tubular secretion of methotrexate and compete for secretion or by reduced renal blood flow resulting from inhibited prostaglandin synthesis. Drugs that decrease methotrexate elimination include salicylates, some NSAIDs, probenecid, sulfonamides, and the penicillins. The toxic effects associated with delayed elimination of methotrexate include pancytopenia and mucositis. The risk of this interaction is lower with low-dose methotrexate used for arthritis. During methotrexate therapy, acetaminophen or celecoxib, a cyclooxygenase-2 inhibitor, should be considered as alternatives to salicylates or other NSAIDs for use as non-narcotic analgesic agents.

Some interactions result from pharmacodynamic mechanisms. Procarbazine is a weak monoamine oxidase inhibitor. Caution should be taken in the administration of indirect-acting sympathomimetics while the patient is taking procarbazine to prevent potentially dangerous hypertensive episodes. Direct-acting sympathomimetics such as epinephrine, isoproterenol, and norepinephrine do not seem to interact to the same degree. While receiving procarbazine, the ingestion of ethanol may result in a disulfiram-like reaction: flushing, headaches, nausea, and hypotension.

Other drugs with harmful interactions include warfarin and antineoplastic agents such as 5-fluorouracil, capecitabine, and ifosfamide; close monitoring of the prothrombin time is necessary to prevent life-threatening bleeding. Many interactions have been reported, and consideration should be given to interactions that can result in clinically significant reactions. Not all drug-drug interactions require avoidance of such therapeutic agents. In some cases, dosages may be titrated and patients monitored to minimize the risk.

IMPLICATIONS FOR DENTISTRY

Currently available antitumor drugs cannot distinguish between malignant cells and dividing normal cells and are potentially damaging to both. The mouth, by virtue of the rapid cellular turnover of the oral mucosa, the daily exposure of oral tissues to minor trauma, and the presence of an extensive and potentially infective microflora, is at special risk of developing drug-induced toxicity. Adverse reactions include stomatitis, hemorrhage, acute and chronic infection, and rapid progression of caries and periodontal bone loss. In addition, the pain associated with these conditions can impair nutrition. These issues and their management are discussed in detail in Chapter 50.

CHAPTER 43

Aliphatic Alcohols

FRANK J. DOWD

The aliphatic alcohols of therapeutic value are ethyl alcohol (ethanol) and isopropyl alcohol. Methanol and ethylene glycol, the latter a dihydroxy alcohol, are mainly of toxicologic interest. Propylene glycol, another dihydroxy alcohol, is useful as a food additive and in drug compounding. Isopentanol is one of the longer chain alcohols found in small concentrations in alcoholic beverages. The principal medical use of ethyl and isopropyl alcohol is topical disinfection, as discussed in Chapter 46. Although ethanol has limited clinical application, as the most common intoxicant in Western civilization it is of immense importance because of its potential for abuse and dependence and because it is a major contributing factor to individual and social ills in the United States and other nations.

The alcohols discussed in this chapter are hydroxyl derivatives of aliphatic hydrocarbons (Table 43-1). They are clear, colorless, flammable liquids that are completely miscible with water and most organic solvents. Aliphatic monohydroxy alcohols form a homologous series and, with increasing numbers of carbon atoms, display increasing potency as nonselective central nervous system (CNS) depressants. Dihydroxy alcohols (glycols) have similar CNS properties, whereas trihydroxy derivatives lack depressant effects.

ETHANOL

Ethanol can be obtained as anhydrous alcohol (100% ethanol), as neutral spirits (95% ethanol), and as denatured alcohol. Denatured alcohol, intended primarily for industrial use, is ethanol with a substance added to render it unfit for consumption, such as methanol, benzene, diethyl ether, or kerosene.

The social costs of ethanol abuse are staggering. Ethanol abuse–related costs, including health care costs, criminal damage costs, and workplace costs, are estimated to be several hundreds of billions of U.S. dollars worldwide.[3] Approximately 50% of all fatal traffic accidents are related to the use of ethanol. Drinking aggravates criminal behavior. Ethanol is involved in approximately one third of suicides and rapes, half of assaults, and one half to two thirds of homicides.

Mechanism of Action

It has long been believed that the effects of ethanol on the CNS are mediated by an increase in membrane fluidity, leading to disorder of the membrane lipids and resulting in abnormal activity of ion channels and other proteins. Although there is evidence to support this mechanism, the focus more recently has been on the effect of ethanol on excitatory and inhibitory amino acids in the brain. Ethanol potentiates the effect of γ-aminobutyric acid (GABA) at $GABA_A$ receptors. Its mechanism in this respect is similar to that of other sedatives, such as benzodiazepines, which also enhance the effect of GABA at $GABA_A$ receptors and increase Cl^- conductance. In addition, ethanol exerts an inhibitory effect on the CNS by reducing glutamate activation of excitatory ion channels. More specifically, ethanol inhibits the response of the N-methyl-D-aspartate (NMDA) receptor to glutamate.

Long-term ethanol abuse may cause a change in the subunit structure of the NMDA receptor, leading to an excitatory toxic effect when ethanol is withdrawn acutely. It may also be possible to attribute other side effects, such as chronic CNS effects, to actions on the NMDA receptor. Consistent with this notion is the observation that certain NMDA receptor antagonists can reduce the intake of ethanol in an animal model given long-term treatment. This observation has led to the search for NMDA receptor antagonists as potential therapeutic agents in treating alcohol dependence.

Biochemical mechanisms involved in the CNS effects of ethanol also seem to involve, among others, dopaminergic, adrenergic, serotoninergic, and opioid pathways. Reward mechanisms are enhanced by dopaminergic stimulation and by opioid peptides. Naltrexone, an opioid receptor antagonist, inhibits the desire for alcohol intake, as do dopamine receptor antagonists. Agonists at these respective receptors have the opposite effect. Ethanol can deplete the neurotransmitter 5-hydroxytryptamine, which is consistent with aggressive behavior in an alcohol abuser. Although ethanol has a wide range of effects on neurotransmitters and receptors in the CNS, the exact contributions of these systems to the pharmacologic features of ethanol are unknown at this time. The mechanisms by which these receptors and neurotransmitters are affected are not well described.

Several actions of ethanol seem to be attributable to the drug itself. In many instances, ethanol's effects may result from its primary oxidative metabolite, acetaldehyde.

Pharmacologic Effects

Central nervous system

There is a common but mistaken notion that ethanol is a CNS stimulant. To the contrary, ethanol is a sedative-hypnotic that depresses the CNS in a dose-dependent fashion. Much of the apparent stimulation resulting from ethanol use results from disinhibition of CNS function because of selective depression of inhibitory pathways at lower concentrations of ethanol. Although mental processes, memory, and concentration are reduced, the individual may feel euphoric, confident, and socially uninhibited. Higher doses (intoxication) lead to overall depression of the CNS. As with other CNS depressants, the major acute toxicity of ethanol is respiratory depression from inhibition of the medullary respiratory center.

TABLE **43-1**

Aliphatic Alcohols

	SYNONYMS	CHEMICAL FORMULA
Methyl alcohol	Methanol, carbinol, wood alcohol, wood spirit	CH_3OH
Ethyl alcohol	Ethanol, grain alcohol	CH_3CH_2OH
Isopropyl alcohol	Isopropanol, 2-propanol, secondary propyl alcohol	H_3C \ CHOH / H_3C

TABLE **43-2**

Correlates of Blood Alcohol Concentration (BAC)

BAC (mg/dL)	CLINICAL STATE*
50	Dizzy
80	Drunk (legally)
150	Drunk and disorderly
300	Dazed and dejected
400	Dead drunk
500	Dead

*Classification modified from Gaddum JH: *Pharmacology*, ed 5, New York, 1968, Oxford University Press.

The concentration of ethanol in alcoholic beverages is often listed as the "proof." The actual concentration of ethanol, in percent by volume, is half the proof number: 80 proof equals 40% ethanol by volume. Because of the variability of absorption of different alcoholic beverages, the effects of ethanol are most commonly correlated with the blood alcohol concentration (BAC), as illustrated in Table 43-2. The effects of ethanol are dose-related and progress through the typical sequence of anxiolysis, sedation, hypnosis, anesthesia, and death. Ethanol is a soporific, increasing the time spent in sleep and decreasing the time it takes to get to sleep. With low doses of alcohol, an electroencephalogram displays a reduced frequency and increased amplitude of α waves, and with high doses, the electroencephalogram displays an enhanced δ activity similar to a pattern of deep sleep. At a BAC of approximately 150 mg/dL, there is a reduction in the length, although not in the number, of episodes of rapid eye movement sleep throughout the night, together with reduced movement during sleep. Sleep patterns are disturbed with repeated ingestion, however, so that sleep comes in short segments, and the wake time is actually increased.

At a BAC less than 50 mg/dL, binocular fusion is impaired, and blurred vision occurs. Handwriting deteriorates, fine motor coordination is reduced, and complex sensorimotor tasks begin to show impairment. The Romberg "standing steadiness" test reveals marked unsteadiness and increased body sway at a BAC of 30 mg/dL. At a BAC of 50 to 100 mg/dL, a drinker displays reductions in anxiety, critical judgment, and self-criticism, with enhanced sociability and self-esteem in group situations. Disinhibition, with talkativeness and a feeling of elation, occurs at the same time that mild sedation is produced, along with relaxation, drowsiness, and reduced alertness. Speech, movement, and simple reaction times are slowed. Fear is reduced, and impulsive risk-taking behavior becomes evident. Many performance tasks are unaltered at a BAC of 50 mg/dL, but most are impaired at 100 mg/dL. Sexual motivation may be enhanced at a lower BAC through a reduction in anxiety and muscular tension, and maximum penile diameter, in response to visual stimulation, is increased at a BAC of 25 mg/dL but is reduced at concentrations greater than 50 mg/dL.

At a BAC of 100 to 200 mg/dL, nausea, vomiting, and loss of self-control are common in an inexperienced drinker, whereas an experienced drinker speaks and moves with exaggerated care. Subjective time passes more slowly. Speech becomes slurred, and ataxia with staggering gait occurs. A unique positional alcohol nystagmus is produced in which, with the head tilted to the side, the eyes drift slowly upward and then jerk rapidly downward. Ethanol produces deficits in short-term and long-term memory, and amnesia ("blackouts") may occur. Ethanol increases assertive or aggressive behavior and may precipitate a rage-release reaction, especially if the initial mood of the drinker is unpleasant. Significant analgesia is also produced.

In the range of 300 mg/dL of ethanol, intoxication is severe and is accompanied by a loss of consciousness. There may be mydriasis, sweating, hypotension, and hypothermia. At a BAC of 400 to 500 mg/dL, medullary paralysis, cardiovascular depression, and death are likely to occur.

The legal blood limit for drivers in the United States is 80 mg/dL (0.08%). Drivers younger than 21 years are restricted to a BAC of less than 20 mg/dL—the "zero tolerance policy." Sobriety tests are used to give an indication of BAC.[13] Certain conditions such as sleepiness may make individuals susceptible to the effects of small amounts of ethanol or to the effects of previous exposure to alcohol even when the BAC is undetectable.

Cardiovascular system

Acute alcohol administration results in an elevated catecholamine concentration in blood and urine. Adrenal monoamine release is accompanied by compensatory increases in the activity of medullary tyrosine hydroxylase, dopamine β-hydroxylase, and phenylethanolamine-N-methyltransferase. Vascular smooth muscle exhibits hyperreactivity to norepinephrine at low ethanol concentrations and hyporeactivity at high concentrations. The latter effect may be caused by ethanol-induced facilitation of neuronal monoamine uptake.

The direct actions of ethanol on vasomotor tone, coupled with its complex adrenergic effects and centrally mediated influences, produce variable cardiovascular responses. In general, coronary blood flow is slightly enhanced, but there is no concomitant increase in myocardial oxygen uptake. Myocardial contractility is depressed by ethanol. Direct vasoconstriction has been observed in cerebral and renal vascular beds in vitro, but in vivo the effect of ethanol, occurring only at large doses, is an increase in blood flow to the brain and kidneys. Mesenteric blood flow also seems to be increased.

A consistent cardiovascular effect of alcohol ingestion is cutaneous vasodilation. The increased blood flow to the skin provides a feeling of warmth. In cold environments, heat loss may be greatly accentuated, and alcohol generally should be avoided in treating hypothermic individuals. At low ambient temperatures, individuals under the influence of ethanol have a high risk of hypothermia.

The ethanol metabolite acetaldehyde causes catecholamine release and produces tachycardia, increased cardiac output, and increased arterial blood pressure, effects that are abolished by adrenoceptor blockade. The concentrations of acetaldehyde normally resulting from low amounts of ingested ethanol have little acute effect on the cardiovascular system, however. Long-term effects of ethanol differ from its short-term effects. When ingested in excess on a long-term basis,

ethanol increases the risk of hypertension and adverse cardiac effects. Long-term ethanol abuse can cause a cardiomyopathy characterized by a decreased ventricular ejection fraction and heart failure. Fibrosis of the myocardium may also occur.

Liver

A number of effects of ethanol on the liver have been documented. Acute ingestion of intoxicating amounts of ethanol leads to a reduced liver-metabolizing activity. This effect is reversed when the ethanol is eliminated. In a long-term alcoholic, induction of liver microsomal enzymes is common; if the individual is not intoxicated, drug metabolism may be enhanced. If cirrhosis of the liver occurs, overall metabolism is reduced because of impaired hepatic blood flow and destruction of liver tissue. The use of ethanol has several implications for drug metabolism.

Ethanol can also influence nutritional status. Ethanol inhibits the activation of vitamins A and D and causes depletion of pyridoxine. Trace metals, such as zinc and selenium, are also depleted. Cirrhosis of the liver leads to further reduction in nutritional status. Nutritional deficiencies are also common because ethanol can marginally meet an alcoholic's caloric needs without supplying other nutritional requirements. Other long-term effects are discussed later.

Kidney

Ethanol has a diuretic effect resulting from inhibition of antidiuretic hormone secretion by the posterior pituitary. Urinary Na^+, K^+, and Cl^- concentrations are reduced, whereas Mg^{++} and norepinephrine are increased.

Sexual function

Ethanol interferes with sexual function in men and women. It can cause temporary impotence even though overall aggressiveness may be enhanced. Long-term alcoholism may lead to more lasting impotence and sterility. Testosterone production may be depressed, and testosterone metabolism may be enhanced, the latter as a result of induction of liver microsomal enzymes. Feminization in men is a possible outcome.

Blood lipids

A potential salutary effect of moderate consumption of ethanol relates to cholesterol status. Intake on the order of one to two drinks a day increases the ratio of high-density to low-density lipoproteins in the plasma, an effect inversely correlated with the incidence of coronary heart disease and myocardial infarction. Other effects, such as reduced platelet aggregation, may also provide a cardioprotective effect. In one study, men who were homozygous for the "slow" form of one of the isozymes of alcohol dehydrogenase, ADH3, had an especially enhanced increase in high-density lipoprotein and decreased risk of myocardial infarction.[10]

Alcohol consumption is associated with an increase in serum triglyceride levels. This association may pose a cardiovascular risk, and if the triglyceride levels are high enough, a risk of pancreatitis exists. The overriding issue for the individual and society as a whole is controlling ethanol intake to avoid its many adverse effects.

Other effects

Small oral doses of ethanol temporarily enhance salivary and gastric acid secretion—the increased salivation probably by a conditioned reflex. Large doses of alcohol reduce salivation. Ethanol is a gastric irritant, producing inflammation of the stomach wall in concentrations greater than 15%. Ingestion of solutions of more than 20% ethanol results in increased gastric mucus secretion and in petechial hemorrhage and ulceration. Ethanol retards intestinal absorption of glucose, amino acids, folic acid, thiamine, and vitamin B_{12}. Adrenal gland activation results in increased blood concentrations of corticosteroids, epinephrine, and glucose.

The effects of ethanol on the peripheral vasculature, CNS, antidiuretic hormone secretion, and sexual function are summarized in the following exchange between Macduff and the porter in Shakespeare's *Macbeth*:

> *Macduff: What three things does drink especially provoke?*
> *Porter: Marry, Sir, nose-painting, sleep, and urine. Lechery, sir, it provokes and unprovokes: it provokes the desire but not the performance.*[15]

Absorption, Fate, and Excretion

Ethanol is rapidly absorbed from the stomach and small intestine. After oral ingestion, the rate of absorption largely depends on the gastric emptying time because 75% of a dose is rapidly and completely taken up from the small intestine. Patients with gastrectomy often note enhanced effects of ethanol. The rate of gastric absorption is reduced by the presence of food. Concentrations of ethanol greater than 20% retard absorption by inducing gastric mucosal irritation and pylorospasm.

Approximately 60% of inspired ethanol vapor is absorbed through the lungs, and intoxication can be achieved by this route. Percutaneous absorption can also occur and has led to death when infants were wrapped in ethanol-soaked cloth to treat hyperthermia.

After intravenous ethanol administration, the BAC exhibits an abrupt curvilinear decline, lasting 10 to 30 minutes, caused by distribution throughout total body water. This distributional phase is not noted in serial drinking situations, in which distributional equilibrium occurs in concert with gastrointestinal absorption.

After oral intake, the arterial BAC exceeds the venous BAC because of rapid tissue uptake of alcohol from capillary blood. Maximum electroencephalogram changes occur approximately 25 minutes before the maximum venous BAC is achieved. The BAC after ingestion of a fixed amount of alcohol is a function of sex, age, and adiposity of the drinker; the nature of the beverage; and the time over which it is ingested. In Table 43-3, which shows the influence of alcoholic beverage, age, and sex on BAC, the BAC has been calculated on the basis of reported age-corrected and sex-corrected values for total body water and blood water content.

TABLE **43-3**

Equivalents of Alcoholic Beverages

FORM OF ALCOHOL	CLASSIFICATION OF DRINKER		POTENTIAL RESULTING BAC (mg/dL)*
	SEX	AGE (yr)	
Regular beer (12 oz, 3.5% ethanol)	Male	17-34	22.7
		57-86	25.5
	Female	20-31	27.7
		60-82	30.7
Distilled spirits (1 oz, 40% ethanol)†	Male	17-34	17.1
		57-86	19.3
	Female	20-31	21
		60-82	23.2

*Calculated on the basis of a lean body mass of 153.4 lb (70 kg).
†American proof number is twice the percentage of ethanol by volume.
BAC, Blood alcohol concentration.

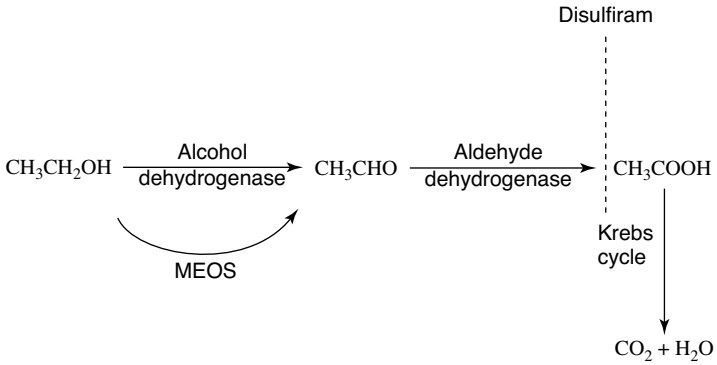

FIGURE **43-1** Metabolism of ethanol and its blockade by disulfiram. Disulfiram inhibits the mitochondrial and cytoplasmic forms of aldehyde dehydrogenase. *MEOS,* Microsomal enzyme oxidizing system.

The tissue alcohol concentration is proportional to lean body weight and tissue water content. Considering the BAC as unity, the relative concentration of ethanol at equilibrium is 1.35 in urine, 1.17 in brain, 1.16 in blood plasma, 1.12 in saliva, 0.05 in alveolar air, and 0.02 in fat.

Under normal circumstances, more than 95% of ingested ethanol is metabolized. High doses of ethanol are associated with lower metabolism (approaching 90%). Metabolism occurs mostly by a three-phase hepatic oxidation (Figure 43-1). Ethanol is initially converted to acetaldehyde by alcohol dehydrogenase, which requires nicotinamide adenine dinucleotide (NAD) as the hydrogen acceptor:

$$CH_3CH_2OH + NAD^+ \leftrightarrow CH_3CHO + NADH + H^+$$

The binding of substrate and coenzyme to alcohol dehydrogenase involves sites on the enzyme containing zinc and sulfhydryl groups. Human alcohol dehydrogenase also oxidizes methanol, isopropyl alcohol, and ethylene glycol. This dehydrogenase reaction is the rate-limiting step in the metabolism of alcohol except in individuals who have a deficiency in the subsequent enzyme.

The second phase, conversion of acetaldehyde to acetate, occurs in liver and other tissues and is catalyzed by aldehyde dehydrogenase, which has a much greater affinity for acetaldehyde than does alcohol dehydrogenase:

$$CH_3CHO + NAD^+ \leftrightarrow CH_3COOH + NADH + H^+$$

In the third step, acetate, as acetyl coenzyme A, is oxidized further through the Krebs cycle to carbon dioxide and water.

The reductive environment resulting from ethanol oxidation upsets hepatic chemistry and results in reduced gluconeogenesis and enhanced triglyceride and lactate formation. Heavy bouts of drinking can cause hypoglycemia, lactic acidosis, and hyperuricemia (because acetate and lactate stimulate the synthesis of uric acid and inhibit its renal excretion), which can precipitate gout, hyperlipidemia, and fatty liver.

An alternative oxidative pathway for alcohol involving the microsomal enzyme oxidation system (MEOS) becomes an important factor in alcohol elimination at high BACs, during which it may account for 10% to 20% of ethanol metabolism.[11] This pathway also yields acetaldehyde. The MEOS pathway is inducible and may account for the higher metabolic inactivation of ethanol seen in individuals who abuse ethanol over the long-term.

Ethanol elimination seems to follow zero-order kinetics (it is pseudolinear regarding time) down to a certain BAC, where it assumes a curvilinear, first-order decline. The reported point at which this change occurs varies according to the study. Such elimination kinetics are best described by modified Michaelis-Menten models because the rate of pseudolinear elimination is dose-dependent, ranging from 16 to 25 mg/dL/hr as the peak BAC increases from 50 to 185 mg/dL. After low -moderate doses of ethanol, the rate of ethanol metabolism is approximately 80 mg/kg/hr, or roughly 5.6 g or 0.2 oz (of 100% ethanol) per hour for a 70-kg adult. Approximately 2% to 10% of absorbed alcohol is excreted unchanged, largely through the lungs and kidneys. Minor amounts are detectable in saliva, tears, sweat, and feces. Because ethanol is metabolized to acetate, it can provide calories (a maximum of approximately 1200 kcal/day). It provides no other essential nutrients, however, such as vitamins, amino acids, or fatty acids.

Drug Interactions

Ethanol produces additive effects with all CNS depressants and increases the hypotensive effects of most vasodilators. Long-acting drugs such as diazepam may cause increased depression with ingested alcohol for 24 hours after the drug was given. The benzodiazepine-ethanol combination seems to pose a particular risk. At high BACs, ethanol may inhibit the metabolism of, and potentiate the effects of, benzodiazepines and some other CNS depressants. Short-term alcohol ingestion may also result in exaggerated clinical responses to oral anticoagulants and hypoglycemic agents.

The use of ethanol influences the in vivo absorption of certain drugs. Short-term ethanol ingestion increases, although long-term alcoholism reduces, the oral absorption rate of diazepam. Ethanol also inhibits the absorption and enhances the breakdown of penicillins in the stomach for 3 hours after ethanol intake. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) promote gastric bleeding when combined with ethanol and can cause gastric hemorrhage in alcoholics who have alcoholic gastritis.

In a long-term alcoholic without liver damage, induction of MEOS activity occurs. Increased enzyme activity appears after approximately 3 weeks of heavy drinking and lasts 4 to 9 weeks after the cessation of drinking. A significant reduction in plasma half-life of, and clinical response to, many drugs occurs (e.g., intravenous anesthetics, barbiturates, antianxiety drugs). In long-term alcoholics, the development of hepatic damage offsets the effects of enzyme induction, and drug sensitivity may return to normal. Eventually, cirrhosis leads to significantly reduced drug metabolism. The induction of liver microsomal enzymes with long-term ethanol ingestion is the basis for the enhanced toxicity of acetaminophen in long-term alcohol abusers. Induction of the cytochrome enzymes, CYP2E1 and CYP3A4, favors the production of reactive and hepatotoxic metabolites of acetaminophen (see Chapter 21).[17] Under certain circumstances, acute ingestion of ethanol can protect against acetaminophen toxicity because at higher blood alcohol levels the metabolism of acetaminophen to toxic metabolites is inhibited despite a concurrent long-term inductive effect of ethanol.

Drugs that inhibit aldehyde dehydrogenase can lead to unpleasant and potentially life-threatening symptoms after ethanol ingestion. These inhibitors include disulfiram (Antabuse), which is given to prevent the use of ethanol by abusers; metronidazole; certain cephalosporins; and oral hypoglycemics. Acutely, acetaldehyde can cause flushing, headache, nausea and vomiting, hypotension, blurred vision, and mental confusion. Because acetaldehyde concentrations vary directly with ethanol intake, high doses of ethanol alone may lead to these symptoms. If aldehyde dehydrogenase is inhibited by drugs such as disulfiram, even low and moderate amounts of ethanol can lead to adverse reactions because of acetaldehyde accumulation. Individuals with a genetic deficiency in aldehyde dehydrogenase, which is common in certain races, also experience the accumulation of acetaldehyde and have alcohol intolerance.

General Therapeutic Uses

Topically applied 70% ethanol is used as a rubefacient, anhidrotic, and antiseptic and as a means to cool the skin in cases of fever. Ethanol is a solvent for the irritating principle of poison ivy, and its early use on affected skin can markedly reduce resulting dermatitis.

Absolute ethanol has been injected to destroy nerves or ganglia in treating intractable pain arising from conditions such as trigeminal neuralgia and inoperable cancer. Other treatment modalities are usually more desirable, however. Ethanol is also used to treat poisoning by methanol, isopropyl alcohol, and ethylene glycol.

Therapeutic Uses and Implications for Dentistry

Uses of ethanol in dentistry as an antiseptic and disinfectant are discussed in Chapter 46. The dentist can expect to encounter alcoholic patients in everyday practice. Alcoholics usually exhibit signs of deficient oral hygiene, such as coated tongue and heavy plaque and calculus deposits. They have twice the rate of tooth loss of the general population, commonly lack mandibular and maxillary first molars, and frequently have severe chronic periodontitis. Chronic asymptomatic enlargement of the parotid, and sometimes submandibular, glands may be observed. The dentist should be aware of the increased incidence of oral leukoplakia in alcoholics and be familiar with its appearance, particularly the erosive form, because 6% of such individuals develop carcinoma, especially of the tongue, within 9 years of diagnosis of the lesion. Postoperative healing time is prolonged in alcoholics; this may be related to a marked increase in collagenase activity, which has been observed in the liver of alcoholics. The potential interactions of ethanol with acetaminophen and NSAIDs should be kept in mind. Large therapeutic doses of acetaminophen should be avoided in moderate to heavy drinkers. Concurrent intake of NSAIDs and ethanol should be avoided.

Alcohol Dependence

Abuse characteristics

Alcoholism is similar to dependence on CNS depressants except that ethanol produces unique direct neurologic, hepatic, and muscular toxicity. Because ethanol can provide a major source of dietary calories, it also promotes malnutrition in chronic drinkers. Ethanol dependence is characterized by marked psychic and physical dependence, moderate tolerance, and a wide range of pathologic sequelae.

Emotional dependence on alcohol is severe. An alcoholic develops a compulsion to obtain and use the drug to the extent that all other activities become secondary, and deterioration of personal and social concerns ensues. Personal, social, and medical problems appear early in life, and life expectancy is decreased. Alcoholism has a partial genetic basis, with a degree of heritability approximately that of diabetes mellitus.

Tolerance develops to ethanol after long-term abuse, but the degree of tolerance, as with other sedative-hypnotics, is much less than that which occurs with opioids. Tolerance to ethanol is partly a result of behavioral adaptation to the effects of ethanol. Adaptive changes by receptor mechanisms and membrane fluidity may also play a role. Induction of MEOS increases the rate of ethanol metabolism. The acute lethal dose of ethanol is not greatly increased, however, over that for nonalcoholics. Cross-tolerance with other sedative-hypnotics also occurs.

Alcohol abstinence syndrome

The severity of acute alcohol abstinence syndrome correlates with the amount and duration of preabstinent ethanol intake. The mildest form is the tremulousness and nausea experienced "the morning after," which is readily reversed by "taking a hair of the dog" (i.e., a small amount of ethanol). The most severe abstinence syndrome is delirium tremens. Severe withdrawal symptoms appear 6 to 8 hours after drinking ceases, peak at 48 to 96 hours, and generally resolve in approximately 2 weeks.

Moderate abstinence results in anorexia, nausea, epigastric upset, tremulousness, sweating, apprehension, and insomnia. In more severe abstinence, additional symptoms of diarrhea, vomiting, nightmares, and agitation occur, together with autonomic signs of tachycardia, hyperpnea, and fever. Delirium tremens, if it occurs, is manifested by all the preceding symptoms together with possible psychosis, seizures, and hyperthermia. Psychotic manifestations include muttering; delirium; paranoia; delusions; and auditory, visual, and tactile hallucinations of a threatening nature. The individual usually displays agitation, confusion, disorientation, and panic. The hallucinatory symptoms appear to be at least partially the result of excessive rebound rapid eye movement sleep that, having been suppressed during the drinking phase, spills over into the waking state during withdrawal. Neuromuscular hyperexcitability is manifested by gross tremors and grand mal convulsions (with a marked sensitivity to stroboscopically induced seizures), both of which correlate with a rapid urinary excretion of Mg^{++} and a resultant hypomagnesemia during withdrawal. Abstinence may also lead to hyperthermia and circulatory collapse.

Pathologic sequelae of alcoholism

Chronic alcoholism is associated with numerous severe physical complications, primarily of the nervous and gastrointestinal systems and of skeletal and cardiac muscle (Table 43-4). Alcohol damage to the liver, in which extensive oxidative ethanol metabolism occurs, results from direct acetaldehyde and ethanol toxicity and the reductive environment brought on by ethanol metabolism. Ethanol metabolism by alcohol dehydrogenase and MEOS activity leads to acetaldehyde production. Acetaldehyde has several short-term and long-term adverse effects. The short-term effects have been previously reviewed. Over the long-term, acetaldehyde is responsible for nutritional depletion in the liver and depletion of glutathione. It enhances lipid peroxidation and membrane damage. Triglyceride accumulation is also favored by the reductive environment from excess NADH production resulting from ethanol oxidation. The incidence of liver cancer is higher in alcoholics.[16]

Ethanol has also been shown to change the flora in the gastrointestinal tract, favoring the growth of certain gram-negative bacteria. This growth leads to the production of more bacterial endotoxins (lipopolysaccharides).[5,12] Damage to the gastrointestinal tract leads to greater absorption of toxins. Endotoxins stimulate liver Kupffer cells, which produce

TABLE **43-4**

Pathologic Sequelae of Alcoholism

SYSTEM OF ORIGIN	SYNDROME	CAUSES	SIGNS AND SYMPTOMS
Nervous system	Wernicke's syndrome	Ethanol toxicity, malnutrition	Confusion, amnesia, confabulation, peripheral neuropathy, diplopia, nystagmus, tremor, ataxia
	Korsakoff's psychosis	Ethanol toxicity, malnutrition	Disorientation, amnesia, confabulation, peripheral neuritis
	Cerebral atrophy	Ethanol toxicity, malnutrition	Irreversible degeneration of frontal lobe cortical cells with premature senility, dementia, personality disintegration
	Cerebellar atrophy	Ethanol toxicity, malnutrition	Irreversible ataxia
	Peripheral neuropathy	Thiamine deficiency	Diminished tendon reflexes, sensory loss in feet or legs, muscle atrophy
Gastrointestinal tract	Esophagitis and gastritis	Secretory and inflammatory effects of ethanol	Heartburn, vomiting, gastric ulceration, hematemesis
	Peptic ulcers	Secretory and inflammatory effects of ethanol	Epigastric pain, anorexia, vomiting
	Pancreatitis	Secretory effect of ethanol, obstruction of pancreatic duct	Weight loss, abdominal pain, blood loss, shock
Liver	Steatosis or fatty liver	Direct toxicity of acetaldehyde and ethanol, reductive environment	Enlarged liver
	Alcoholic hepatitis	Direct toxicity of acetaldehyde and ethanol, reductive environment	Anorexia, vomiting, weakness, jaundice, ascites, enlarged spleen and liver
	Laënnec's cirrhosis	Direct toxicity of acetaldehyde and ethanol, reductive environment	Jaundice, portal hypertension, mental deterioration, renal failure, coma
Skeletal muscle	Alcoholic myopathy	Ethanol toxicity	Cramping, weakness, edema, atrophy of muscle
Cardiac muscle	Alcoholic heart muscle disease	Direct toxicity of ethanol and acetaldehyde	Weakness, shortness of breath, congestive heart failure, pulmonary congestion
Fetus	Fetal alcohol syndrome	Ethanol toxicity	Microcephaly; reduced IQ; facial, cardiac, and genital defects

inflammatory mediators and oxygen radicals that cause apoptotic changes in hepatic parenchymal cells (Figure 43-2). Damage by this mechanism may account partly for short-term and long-term changes. Free radical production in parenchymal cells may also occur, which could contribute to overall liver damage. Polymorphonuclear leukocytes are stimulated to release damaging mediators.

In addition, induction of cytochrome enzymes, especially CYP2E1, and changes to mitochondria lead to generation of reactive oxygen species, which damage hepatocytes (see Figure 43-2). Apoptosis of hepatocytes may also be favored by the ability of ethanol to inhibit insulin-like growth factor receptor signaling. Alcoholic liver damage is heralded by the appearance of steatosis, or fatty liver, which is a benign and reversible syndrome seen almost universally among heavy drinkers. Hepatomegaly, associated with this early phase of liver disease, is caused by lipid accumulation and water retention, resulting in "ballooning" of hepatocytes. The fatty liver phase of liver damage can progress to generalized hepatic inflammation and "florid" alcoholic hepatitis, a condition that has a 10% to 30% fatality rate. In 10% to 15% of heavy drinkers, fatty liver progresses to Laënnec's cirrhosis. The toxic effects on the liver of long-term ethanol abuse are summarized in Figure 43-2.

Ethanol-induced damage in organs lacking significant ethanol oxidative capacity may result from enzyme-catalyzed esterification of fatty acids with ethanol.[2] Transient accumulation of such fatty acid ethyl esters, or their fatty acid metabolites, seems to inhibit oxidative phosphorylation and may alter plasma membranes, leading to damage in organs such as the heart, pancreas, and brain.[2,4]

Cardiovascular complications of alcoholism include cardiac disease, hypertension, and atrial arrhythmias, the first accounting for one third of deaths among heavy drinkers. Alcoholic heart muscle disease results from long-term intake of ethanol.[18] This disease is characterized by cardiomegaly (heart weight doubles in 28% of heavy drinkers), biventricular congestive failure (with pulmonary and peripheral edema), breathlessness, and sometimes arrhythmias. Treatment is the same as for other types of congestive heart failure, coupled with permanent abstinence from ethanol. Alcoholic hypertension is exhibited, especially in white men, as a reversible dose-dependent increase in systolic and diastolic blood pressures and can be associated with only moderately heavy ethanol consumption. The "holiday heart syndrome" refers to severe atrial arrhythmias precipitated by bouts of periodic heavy drinking.[18]

The inflammatory effects of alcohol on the gastrointestinal tract lead to esophagitis and chronic gastritis frequently associated with intense episodes of vomiting, which may lead to gastric laceration and hematemesis. There is a high correlation between heavy drinking and cancer of the mouth and throat. Peptic ulcers and pancreatitis are common among alcoholics.

Effects of alcohol on skeletal muscle may produce acute alcoholic myopathy characterized by muscle cramps, weakness, and swelling, which resolve after a few weeks of alcohol abstinence. In severe cases, extensive muscle degeneration results in myoglobinemia, hyperkalemia, and renal failure. A chronic form of alcoholic myopathy ultimately produces marked muscular atrophy, usually of the pelvic girdle and thighs.

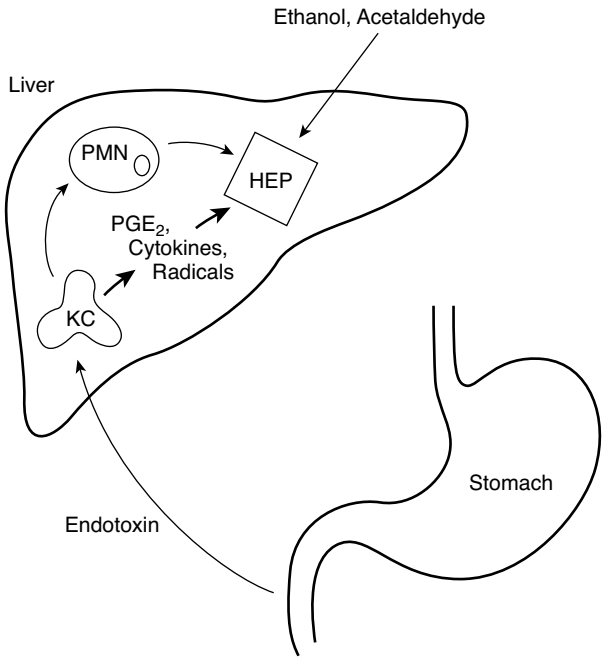

FIGURE **43-2** Mechanism of liver damage from ethanol. Use of ethanol leads to an increase in certain intestinal gram-negative organisms, resulting in an increase in endotoxins. These stimulate Kupffer cells *(KC)* in the liver to produce mediators, including prostaglandin E_2 *(PGE_2)*, cytokines, and free radicals, which damage hepatocytes *(HEP)*. Effects on KC lead to stimulation of polymorphonuclear leukocytes *(PMN)*, which also release mediators that damage liver cells.[5] Ethanol and acetaldehyde induce cytochrome P450 enzymes (CYP), especially CYP2E1, and damage mitochondria resulting in production of reactive oxygen species that damage hepatic hepatocytes.[12] Ethanol or acetaldehyde may also act directly on hepatocytes to alter lipid metabolism, damage cell macromolecules, or block the effect of insulin-like growth factor. (Modified from Thurman RG: Mechanisms of hepatic toxicity, II: alcoholic liver injury involves activation of Kupffer cells by endotoxin, *Am J Physiol* 275:G605-G611, 1998.)

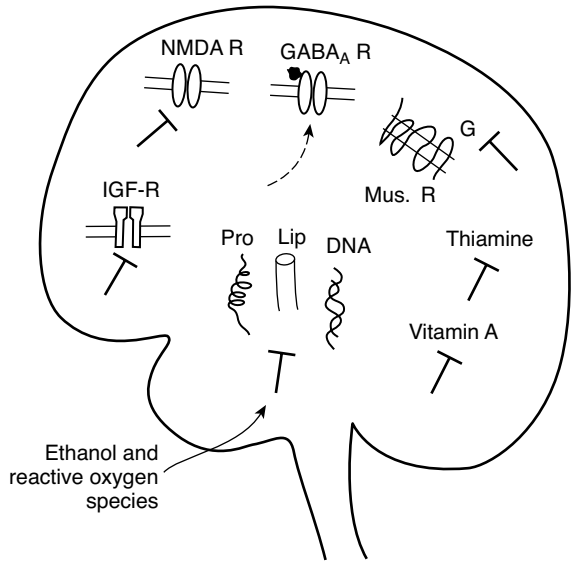

FIGURE **43-3** Mechanisms by which ethanol may damage the brain. Ethanol inhibits N-methyl-D-aspartate *(NMDA)* receptor *(R)* function initially, followed by supersensitivity of the receptor; stimulates $GABA_A$ receptor function *(arrow)*; inhibits muscarinic receptor function *(Mus. R)*; inhibits insulin-like growth factor receptor function *(IGF-R)*; depletes thiamine; and alters the metabolism of vitamin A. In addition, cell toxicity may result from ethanol itself or from reactive oxidative species that alter membrane lipids, proteins, and DNA. *Lip,* Lipid; *Pro,* protein.

Fetal alcohol syndrome is a cluster of physical and mental defects occurring in children of women who consume ethanol during pregnancy.[6] In more than 90% of cases of fetal alcohol syndrome, there is growth deficiency, microcephaly, and short palpebral fissures. Also common are midfacial hypoplasia, mental retardation, and deficiencies in coordination and fine motor skills. The mental and motor deficiencies may be causally related to the developmental abnormalities of cortical neurons, as observed in rats prenatally exposed to ethanol.[14] The degree of dysmorphogenesis correlates with mental deficiency, with IQs ranging from 55 to 82. Neither the dysmorphic nor the intellectual aspects of fetal alcohol syndrome improve with age. Pregnant patients should be advised to avoid alcoholic beverages and to be aware of the alcoholic content of food and drugs.

Central and peripheral nerve degeneration occur, resulting in a wide range of neurologic disorders involving psychological and personality changes and peripheral neuritis, sensory loss, and muscle atrophy. Changes in the nervous system are related partially to malnutrition, and most respond to thiamine administration, indicating a thiamine deficiency.[9]

Ethanol changes plasma membranes and their component lipids and alters protein and DNA synthesis. Mechanisms accounting for these changes may be at the receptor or signal transduction level, or both, and may be one result of producing reactive oxygen species. Ethanol has also been shown to inhibit the proliferation and growth of glial and neuronal cells resulting from muscarinic receptor stimulation. Muscarinic receptors have been proposed to play a crucial role in synaptogenesis in the developing brain.[7] Ethanol may disrupt this process by inhibiting signaling at the G protein level. Changes in vitamin A metabolism and the previously mentioned inhibition of the insulin-like growth factor receptor are also potential mechanisms of fetal damage. It has also been reported that ethanol can cause an apoptotic pattern in the developing rat brain that is consistent with its ability to block NMDA receptors and to stimulate $GABA_A$ receptors. Toxic effects of ethanol on the brain are summarized in Figure 43-3.

Women are more susceptible to the toxic effects of ethanol than men. The smaller average size of women is part of the reason blood alcohol levels are higher than in men for comparable alcohol intakes. Women also have higher levels of alcohol dehydrogenase and produce higher levels of tissue and plasma acetaldehyde. In addition, estrogens enhance the toxic effect of ethanol on the liver. Tissue hypoxia, fibrosis, extent of fat distribution, and level of endotoxin all are elevated in women compared with men, and estrogen seems to be a major factor.

Treatment of alcoholism

The treatment of alcoholism involves the detoxification of an acutely inebriated individual, medication to prevent severe symptoms of abstinence, and long-term rehabilitation. The rate of detoxification is determined largely by the rate at which the liver disposes of the ethanol, but the nature of the withdrawal period also depends on the degree of dependence, the environment, and the nutritional status of the patient. The symptoms associated with abstinence are usually treated with

a benzodiazepine (e.g., diazepam, oxazepam). Supplemental dietary thiamine and other vitamins may be given. In addition, three other drugs are approved for treating alcohol dependence: naltrexone, disulfiram, and acamprosate. All modalities of drug treatment for alcoholics are more clinically effective when accompanied by behavioral therapy.

Naltrexone is a long-acting opioid receptor antagonist. Although it is available orally, for treating alcohol dependence the approved form is a once-a-month extended-release intramuscular injection. Naltrexone reduces the rewarding effects of alcohol by interfering with the activation of dopaminergic reward pathways in the brain. The most common adverse effect of naltrexone is nausea. Liver damage can result from abnormally high doses. The pharmacology of naltrexone is discussed further in Chapter 20.

Disulfiram is used in avoidance therapy for alcoholics because alcohol intake with disulfiram leads to very unpleasant reactions in patients. Disulfiram is rapidly converted to metabolites such as diethyldithiocarbamate and diethylthiomethylcarbamate. These and possibly other metabolites probably account for the action of the drug (see Figure 43-1). Disulfiram inhibits aldehyde dehydrogenase through the formation of a covalent disulfide bond between an enzymic thiol group and an active drug metabolite. The enzyme is inhibited irreversibly. Disulfiram also inhibits other enzymes, notably dopamine β-hydroxylase and oxidases of MEOS.

Oral doses of disulfiram have an onset of action of approximately 12 hours, and the effects are evident for 2 weeks after treatment is stopped. The protracted duration of action is based on the irreversible nature of the binding of disulfiram metabolites. Only with the synthesis of new enzyme does the metabolism of ethanol return to normal. Disulfiram itself commonly produces drowsiness, and in large daily doses it may cause paresthesias and muscle weakness. The drug may exaggerate schizophrenia or depression, possibly through alteration of central monoamine concentrations caused by the inhibition of dopamine β-hydroxylase.

If ethanol is ingested during disulfiram treatment, symptoms of acetaldehyde poisoning develop. Drinking 1.2 oz of 80 proof liquor causes flushing, tachycardia, palpitation, and tachypnea, all lasting approximately 30 minutes. Ingestion of more than 1.6 oz of 80 proof liquor produces intense palpitation, dyspnea, nausea, vomiting, and headache lasting up to 90 minutes. Unconsciousness, hypotensive shock, and sudden myocardial infarction may occur. For this reason, disulfiram must be used only under strict medical supervision.

Disulfiram inhibits oxidative biotransformation, but not glucuronide conjugation of benzodiazepines (see Chapter 13). Hypotensive episodes may occur during general anesthesia as a result of dopamine β-hydroxylase inhibition and depletion of neuronal norepinephrine. Even large therapeutic doses fail to alter the cardiovascular response to pressor amines of either the direct-acting or indirect-acting variety. Paraldehyde, because of its metabolic conversion to acetaldehyde, produces toxic reactions in patients taking disulfiram.

Acamprosate (calcium acetylhomotaurine) is a GABA analogue that is used to reduce relapse in alcoholics. The drug can reduce nerve excitotoxicity caused by alcohol; this is likely due to its ability to block group 5 metabotropic glutamate receptors (mGluR5).[8] This activity seems to promote abstinence and reduce alcohol withdrawal symptoms. Acamprosate can be used in combination with naltrexone or disulfiram. Diarrhea is the most common adverse effect, although other gastrointestinal symptoms may occur. There is evidence from animal studies that acamprosate is a teratogen. Rarely, the drug may be associated with renal failure or suicidal ideation.[1]

METHANOL

Methanol is widely used as an industrial solvent, as a denaturing agent for ethanol, and in "canned heat." Poisoning occurs when substances containing methanol are used as beverages in place of alcohol or when industrial workers are exposed to atmospheres containing methanol vapor. The metabolism of methanol involves the same enzyme systems as that of ethanol. Its elimination follows zero-order kinetics, but at a much slower rate than ethanol. This slow metabolism accounts for the delay in symptoms of methanol poisoning, which are caused by its oxidized metabolites formaldehyde and formic acid.

Symptoms of methanol poisoning include early mild inebriation followed in 6 to 30 hours by dizziness, headache, vertigo, and occasional nausea and vomiting. As acidosis is produced by the accumulation of formic acid, extreme abdominal pain develops, respirations increase in depth and frequency, and the patient lapses into coma. Visual symptoms are characteristic of methanol intoxication. Blurred vision, with spots or gray mist, photophobia, and eye tenderness, commonly occurs. The pupils are dilated, and the light reflex becomes sluggish. Permanent blindness is not uncommon even if the victim completely recovers. Visual damage develops because of the high rate of retinal oxidation of methanol, leading to formaldehyde and formic acid accumulation with edema and permanent damage to ganglion cells.

Death follows the ingestion of 2 to 8 oz of methanol and is associated with blood concentrations of 74 to 110 mg/dL of methanol and 9 to 68 mg/dL of formic acid. The urinary methanol concentration is approximately twice that in blood and is diagnostic of methanol poisoning. The direct cause of death is cessation of respiration. Breathing becomes shallow and slow, tonic seizures develop, and the victim dies with a marked terminal inspiratory gasp.

The treatment of choice is hemodialysis, which provides rapid recovery without residual effects. Peritoneal dialysis, although also indicated, is less efficient. Acidosis is treated with intravenous infusions of sodium bicarbonate solution. Because ethanol is the preferred substrate for alcohol dehydrogenase, the administration of ethanol can be used to inhibit the formation of toxic methanol metabolites. For this purpose, ethanol should be administered intravenously or given orally to maintain a BAC of 100 mg/dL.

ISOPENTANOL

Isopentanol is also present in alcoholic beverages, albeit typically at concentrations less than 0.5%. At least some effects of ethanol are shared by isopentanol, including induction of liver microsomal enzymes and enhancement of acetaminophen toxicity. The combination of isopentanol and ethanol may constitute a synergistic combination for some responses.

ISOPROPYL ALCOHOL

Isopropyl alcohol is used as an antiseptic and disinfectant in dentistry. In a concentration of 70%, it is used as rubbing alcohol, and it is present in many hand lotions. Isopropyl alcohol is oxidized in vivo to acetone, which is largely excreted in expired air at 10 times the rate of ethanol.

Toxicity arises if isopropyl alcohol is ingested. Symptoms are similar to the symptoms of ethanol intoxication but are marked by nausea, vomiting, abdominal pain, hematemesis, and melena. Severe renal dysfunction for 2 to 3 weeks is seen in survivors. Extensive hemorrhagic inflammation and edema of the bronchopulmonary tree are observed in fatal cases.

Hemodialysis is the treatment of choice in isopropyl alcohol poisoning. Ethanol seems to increase, rather than reduce, the toxic effects of isopropyl alcohol.

ETHYLENE GLYCOL

Ethylene glycol is used as an antifreeze and is highly toxic if ingested. Ethylene glycol is a CNS depressant. It is metabolized by alcohol dehydrogenase to glycoaldehyde and then by aldehyde dehydrogenase to glycolic acid. Glycolic acid is converted to oxalic acid. Metabolites seem to be largely responsible for the acute renal toxicity seen with ethylene glycol. This finding may be particularly true for oxalic acid, which forms crystals in the renal tubules.

Toxicity caused by ethylene glycol is treated by correcting the metabolic acidosis with sodium bicarbonate. Ethanol is also used to prevent the conversion of ethylene glycol to its metabolites by competing for alcohol dehydrogenase. To treat ethylene glycol toxicity, 4-methylpyrazole, a potent inhibitor of alcohol dehydrogenase, is used.

PROPYLENE GLYCOL

Propylene glycol is used as a replacement for ethylene glycol. It is an effective antifreeze and is much less toxic than ethylene glycol. Propylene glycol is also used as a solvent for drugs and in food. Although it can depress the CNS, little effect is seen at concentrations normally encountered.

DRUGS USED FOR DETOXIFICATION FROM ALCOHOL AND FOR TREATMENT OF ALCOHOL DEPENDENCE

Nonproprietary (generic) name	*Proprietary (trade) name*
Benzodiazepines	
Diazepam	Valium
Oxazepam	Serax
Opioid antagonist	
Naltrexone	Vivitrol
Alcohol dehydrogenase inhibitor	
Disulfiram	Antabuse
Glutamate (mGluR5) receptor antagonist	
Acamprosate	Campral

CHAPTER 44

*Anticaries Agents**

SARAT THIKKURISSY

Dental caries is a pathologic process of microbial etiology that results in localized destruction of tooth tissues. From an anatomic and microbiologic perspective, there are several different types: pit and fissure caries, smooth surface caries, root caries, and deep dentinal caries. The process of tooth destruction involves dissolution of the mineral phase, consisting primarily of hydroxyapatite crystals, by organic acids produced by bacterial fermentation. To appreciate the activities of anticaries agents, it is imperative to understand that the initiation and progression of caries is based on the principle of remineralization versus demineralization as part of a dynamic continuum. The resulting balance between these two directly controls the effusion and diffusion of minerals into and out of the enamel lattice. Figure 44-1 outlines protective and pathologic factors for dental caries.[25] The biologic basis of dental caries involves three principal factors: the host, particularly the saliva and teeth; the microflora; and their substrate, the diet. In addition, a fourth factor, time, must be considered in any discussion of the causes of caries. These factors can be portrayed as four overlapping circles (Figure 44-2).

For caries to occur, conditions within each of these factors must be favorable. Caries requires a susceptible host, a cariogenic oral flora, and a suitable substrate, all of which must be present together for a sufficient length of time. Modern-day caries prevention is based on attempts to modify these three core features. Examples include therapies used with the intent to (1) increase the resistance of the host (fluoride therapy, occlusal sealants, immunization), (2) reduce the number of cariogenic microorganisms in contact with the tooth (plaque control and antiplaque agents), (3) modify the substrate by selecting noncariogenic foods, and (4) reduce the time that the microflora is provided with substrate by limiting the frequency of intake of fermentable substrate. Consideration of all four factors is beyond the scope of this chapter. Dietary factors, caries immunization, and occlusal sealants are discussed in detail in textbooks on nutrition and cariology. Concerning host factors, an adequate quantitative and qualitative flow of saliva are well-recognized protective mechanisms. Problems of xerostomia, particularly as a side effect of various drugs, are discussed elsewhere in this book. This chapter addresses fluorides as the anticaries agents for increasing host resistance to decay and as antibacterial agents.

Fluorine is a member of the halogen family. It is the most electronegative of all the elements, which makes it extremely reactive. Fluorine combines with almost every element. It is also reactive with organic radicals. It is rarely found in the free state in nature but is widely distributed as fluorides* in the earth's crust, ranking seventeenth in abundance (0.06% to 0.09%). It usually occurs in minerals such as fluorspar (CaF_2), cryolite (Na_3AlF_6), or fluorosilicates (Na_2SiF_6) and in rocks in the form of mica, hornblende, and pegmatite. In biologic mineralized tissues, such as bones and teeth, it occurs as an impure apatite crystal, not as fluorapatite ($Ca_{10}[PO_4]_6F_2$). The lattice of biologic apatite crystals contains many impurities, either in the lattice itself or adsorbed on the surface.[81] Carbonate ions (2% to 5%) substitute for some phosphate ions; some Ca^{++} is substituted by other ions, such as Na^+, K^+, Mg^{++}, and Zn^{++}; and some hydroxyl ions are substituted by fluoride. The approximate representation of the formula of this apatite is $Ca_{10-x}(Na)_x(PO_4)_{6-y}(CO_3)_z(OH)_{2-u}(F)_u$. Although only some of the hydroxyls of the apatite lattice are substituted by fluoride (i.e., u is much smaller than 2), this change profoundly alters the resistance of enamel to demineralization.

In this discussion, fluoride therapy for the prevention of dental caries is considered under two main headings: systemic fluoride and topical fluoride. Although such a division is convenient for didactic purposes and serves to distinguish between the very low dosages used systemically and the higher concentrations of fluoride used topically, it has become increasingly evident that such a separation is not absolute and that fluorides, while being ingested for their systemic effect, also have a topical benefit even at low concentrations on teeth that are already erupted. This topical effect can be direct, while the fluoride-containing water, tablets, or drops are being ingested, or indirect, from the slight elevation in salivary fluoride concentration after ingestion. Conversely, topical fluoride agents may be swallowed, particularly by young children, and exert a systemic effect on teeth that are still undergoing mineralization.

Previous theories held that systemically acquired fluoride (pre-eruptive) was of prime importance in caries prevention and that it was unnecessary to continue the use of fluoridated water after the enamel had calcified.[52] Subsequent findings clearly showed a benefit, however, of posteruptive or topical fluoride exposure; in children in some communities that stopped fluoridating the water or in children who moved away from fluoridated communities, caries rates increased. More recently, some investigators have argued that posteruptive or topical fluoride effects are of sole importance in caries prevention and that systemic benefits are minimal.[24,47] Careful analyses of caries epidemiology in teeth according to their eruption time, as related to the onset of water fluoridation, have revealed, however, significant pre-eruptive and posteruptive

*The author recognizes Dr. Ernest Newbrun for his past contributions to this chapter.

*In this chapter, the term *fluoride* is used to indicate the element as the free anion or as linked to other elements in molecular form.

FIGURE **44-1** Schematic diagram representing the balance between pathologic factors and protective factors in the dental caries process. (From Featherstone JD: The continuum of dental caries—evidence for a dynamic disease process, *J Dent Res* 83[Spec No. C]:C39-C42, 2004.)

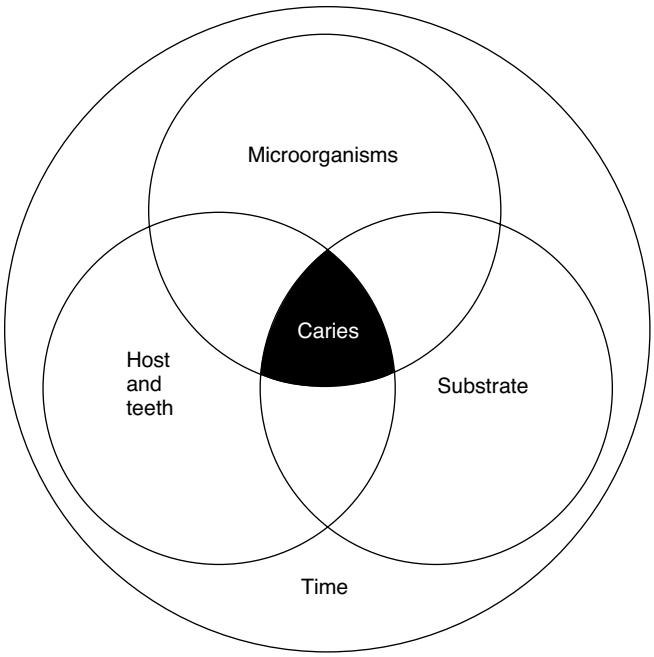

FIGURE **44-2** Etiology of dental caries. The three inner circles represent the factors involved in the carious process; all three must be acting concurrently for caries to occur. The fourth all-inclusive *circle* represents time, which affects each of the individual factors.

beneficial effects.[30,77] Approximately two thirds of the greatest reductions in pit and fissure caries came from pre-eruptive fluoride, whereas in smooth surfaces the decrease was only 25%. In approximal surfaces, half the reduction was from pre-eruptive fluoride, and half was from posteruptive fluoride.[31] Maximal caries-preventive effects of fluoridated water were achieved by optimal pre-eruptive and posteruptive exposure of all surfaces types.[77]

SYSTEMIC FLUORIDE

Fluoridation of Communal Water Supplies

Classic epidemiologic surveys of the prevalence of dental caries, carried out by Dean and others during the late 1930s and early 1940s, showed an inverse relationship between caries prevalence and fluoride concentration in drinking water. Initially, these surveys were limited to school-age children residing in different cities with naturally high or low fluoride concentrations in the public water supplies (Figure 44-3). Subsequently, it was shown that adults and children who have continually consumed fluoridated water lose fewer teeth and have lower incidences of decayed, missing, and filled teeth. Of increasing importance regarding geriatric dentistry is the finding that lifelong residence in communities with naturally occurring fluorides is associated with a significant reduction in the prevalence of root caries or root fillings in the population.[6,79]

Dental fluorosis (discussed later) has been directly related to the concentration of fluoride in the drinking water. An optimal level of fluoride in the water supply provides significant protection against caries yet entails minimal risk of fluorosis. The optimal concentration depends on the annual average maximum daily air temperature in the community (temperature influences the amount of water ingested). In temperate climates, where the annual average maximal daily air temperature is 14.7° C to 17.7° C (58.4° F to 63.8° F), the optimal level of fluoride is 1 ppm. Carefully controlled independent studies conducted during the 1940s-1960s have shown that if fluoride is added to the domestic water supply to bring it up to optimal levels (controlled water fluoridation), decay could be reduced by 50% to 60% (Figure 44-4). These clinical trials were conducted in the United States and Canada, which were the first countries to initiate such programs, and in diverse populations in Australia, Hong Kong, Ireland, Germany, The Netherlands, New Zealand, and the United Kingdom. More recently, because of the widespread daily use of topical fluoride and the ingestion of fluoride-containing foods and beverages made in fluoridated communities, the difference in caries prevalence between fluoridated and nonfluoridated communities has been observed to be 15% to 40% depending on the age group and area examined.[59]

In some regions of the United States, a high proportion of the population is living in optimally fluoridated communities, so that the minority of the population where the water fluoride is suboptimal may be getting significant amounts of fluoride from food and beverage products processed in the optimally fluoridated areas, yielding a "diffusion" or "halo" effect on caries reduction. Failure to account for the diffusion effect may result in underestimation of the total benefit of water fluoridation, especially in high-diffusion exposure regions.[29] Studies in Canada have documented the processing of beverages, especially soft drinks, in fluoridated communities and their distribution in nonfluoridated areas.[14] The halo effect does not uniformly apply throughout the United States, however.

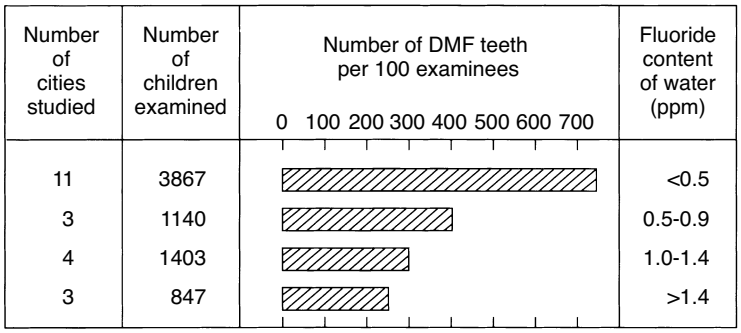

FIGURE **44-3** Data from 21 U.S. cities grouped according to fluoride content of the drinking water. An inverse relationship between caries prevalence and fluoride content of the water is illustrated. *DMF,* Decayed, missing, and filled teeth. (From Newbrun E, editor: *Fluorides and dental caries,* ed 3, Springfield, IL, 1986, Charles C Thomas.)

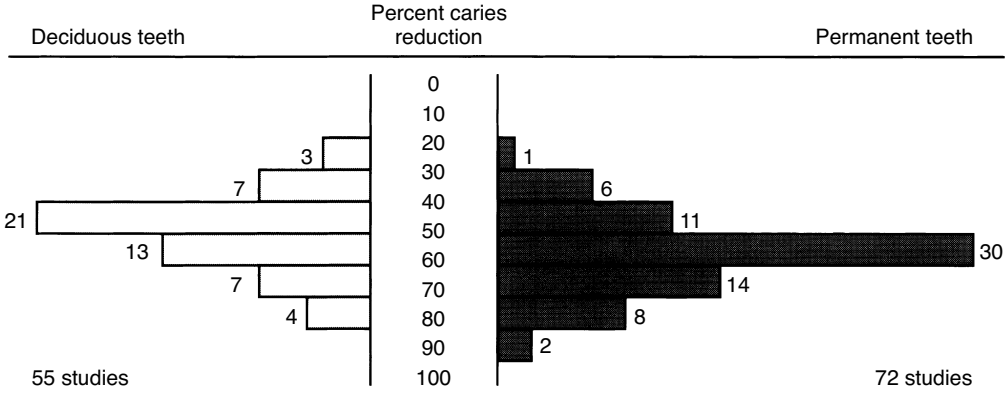

FIGURE **44-4** Caries reductions (percentage) observed in 55 studies on the effectiveness of controlled fluoridation in 20 countries. Fifty-five studies gave results for the deciduous dentition, and 72 studies gave results for the permanent dentition. (From Murray JJ, Rugg-Gunn AJ: *Fluorides in caries prevention,* ed 2, Bristol, 1982, John Wright & Sons.)

Marked regional differences exist; in a 2006 Centers for Disease Control and Prevention (CDC) report on populations receiving optimally fluoridated public drinking water, it was noted that 54% of the population in Utah received optimally fluoridated public drinking water, a 148% increase from a similar 2002 report, whereas regionally close Nevada reported 72% of its population receiving optimally fluoridated public drinking water, an increase of 4%.[10] The state-by-state fluctuations are presented in Table 44-1. In the United States, approximately 184 million individuals (69% of the population) were provided with optimally fluoridated drinking water.[10] These totals were also higher than those reported in 2002 (162 million, 66%).[3] Worldwide, more than 300 million individuals are now consuming water that either is adjusted to or naturally contains an optimal concentration of fluoride.

Opponents of water fluoridation have questioned its safety, yet careful comparisons of communities with optimal versus suboptimal concentrations of fluoride in water supplies have found no significant difference in the frequency of birth defects or in mortality statistics (including deaths from heart disease, cancer, and stroke). Optimal fluoridation of drinking water does not pose a detectable cancer risk to humans, as evidenced by extensive human epidemiologic data.[86] Thorough medical examinations of children in fluoridated and nonfluoridated communities were undertaken in some of the initial studies of controlled water fluoridation; no significant differences in health or in growth and development were found. One study was quite detailed and included tonsillectomy rates; height and weight; onset of menstruation; bone density by x-ray examination of hands and knees; skeletal maturation; blood hemoglobin titer; erythrocyte and leukocyte count; urinalysis; and skin moisture, texture, color, and eruptions.[74] The conclusion of this long-term pediatric study was that the reduction in caries was accompanied by no indication of any adverse effect from the use of fluoridated water.

Some concern has been raised about a possible relationship between fluoride in the water supply and frequency of hip fractures. Of several studies, two showed a protective relationship, four found no relationship, and three reported an increased relative risk. These conflicting findings are caused by the multifactorial pathogenesis of osteoporotic fractures (cigarette smoking, having a small thin frame, history of previous fracture, excessive alcohol intake, estrogen deficiency, physical inactivity) and may prove impossible to resolve by current epidemiologic-ecologic methods.[43] The collective results of all these studies on hip fracture rates have yielded relatively small or no associations or have had weak statistical power and do not provide a basis for altering public health policy regarding water fluoridation.[27] An expert committee of the World Health Organization concluded, "With respect to hip fracture and bone health, there is no scientific evidence for altering current public health policy on the use of fluorides for caries prevention."[23] Finally, a meta-analysis of articles on fluoridation and bone fracture published between 1966 and 1997 found that the relative risk was 1.02. It concluded that water fluoridation has little protective or deleterious effect on fracture risk.[40]

Another area that has garnered much speculation and public attention has been the theorized relationship between fluoride exposure and osteosarcoma. Bassin and colleagues[7] suggested a potential positive correlation between fluoridated drinking water and osteosarcoma in males. This study had several notable weaknesses, which included being largely interview-based and subject to recall bias, associating fluori-

dated community drinking water with actual consumed fluoride, and lack of biologic analysis of fluoride concentrations in bone. Bassin and colleagues[7] are quick to emphasize that further studies that directly evaluate fluoride uptake and address confounding variables are required before any preliminary conclusions can be made.[4] More detailed discussion of some of the claimed health risks of water fluoridation can be found elsewhere.[34,60]

Opponents have focused more recently on the use of fluorosilicic acid and its Na^+ salt, which together account for 91% of the fluoridating agents used by American water works.[84] They have asserted that the fluorosilicate ion (SiF_6^-) promotes

the solubilization of lead from the distribution system, increasing the lead concentration in the tap. In addition, they believe that residual fluorosilicate is responsible for reducing gastric pH and converting particulate lead to bioavailable lead ion, increasing its uptake in the bloodstream.[50,51] Supposedly such higher blood lead concentrations account for aggressive and violent behavior. Although the kinetics of the dissociation and hydrolysis of fluorosilicate are poorly understood, all the rate data suggest that equilibrium should have been achieved by the time water reaches the consumer's tap, if not by the time it leaves the water plant.[84,85] There is no proof that the ingestion of lead or its bioavailability is increased.

Communal water fluoridation continues to be the cornerstone of an ideal caries prevention program. Its efficacy in reducing caries prevalence has been amply shown. Its safety has also been well established. The cost benefits are impressive, but even more important are the value of teeth saved from extraction and the avoidance of pain and discomfort from carious lesions and of time lost from school or work.

Fluoridation of School Water Supplies

Because central water supplies are unavailable to large segments of the world's population, other methods of caries prevention have been sought. Research has shown that adjusting the fluoride content of a school's water supply produces a reduction in dental caries with no objectionable dental fluorosis. Children spend 20% to 25% of their total waking hours in school annually, and this figure may be increased if after-school programs are considered. To compensate for this part-time exposure to fluoride, the currently recommended concentration for school water fluoridation is 4.5 times the optimal value recommended for community water fluoridation in the same geographic area. One disadvantage of school fluoridation is that children are 5 to 6 years old before they begin attending school and drinking the water. Maximal caries prevention accrues when fluoridated water is consumed from birth. Continued protection is not provided when the children leave school. Operating and maintaining small fluoridation systems (i.e., systems serving <500 people) creates practical and logistic difficulties.

Fluoride Supplements

Communal water fluoridation is the best method for providing systemic fluoride because the benefits accrue automatically without any conscious effort required. Where water fluoridation is not feasible because of individual wells (approximately 20% of the U.S. population), or where political opposition, apathy, or lack of funds prevent its implementation (approximately 30% of the U.S. population), supplements offer an alternative source of systemic fluoride. Fluoride tablets, drops, and lozenges have been proved unequivocally to be effective cariostatic agents, provided that such supplements are taken on a daily basis continuously from birth to approximately 16 years of age. The cariostatic effects of fluoride supplements have ranged from less than 10% to more than 80%, generally depending on how soon after birth supplementation starts and on the degree of compliance.[19] The highest caries reductions have been reported in private pediatric practices in which there is a high degree of motivation on the part of the professionals who prescribe the supplements, the parents who give the supplements to their young children, and the children themselves as they get older and become responsible for taking the supplements. When distribution of fluoride supplements has been attempted on a large scale, such as by community health centers, well-baby clinics, and county health departments, long-term compliance has been poor. An estimated 16% of U.S. children younger than 2 years used fluoride supplements in 1986,[61] but compliance tends to decrease in older children. There has been some debate on the efficacy of fluoride supplementation, and a 2008 systematic review commissioned by the American Dental Association (ADA) concluded that "during the first 3 years of life, however, there is only limited evidence regarding the effectiveness of fluoride supplements in preventing caries."[39]

TABLE **44-2**

American Dental Association Dosage Schedule (mg/day) for Fluoride Supplements*

	FLUORIDE CONCENTRATION (ppm) IN PRIMARY DRINKING WATER		
AGE (yr)	**<0.3**	**0.3-0.6**	**>0.6**
0-0.5	0	0	0
0.5-3	0.25	0	0
3-6	0.5	0.25	0
6-≥16	1	0.5	0

*Council on Dental Therapeutics, 1994.

Professional fluoride supplementation should ideally be based on a caries-risk assessment.[1] The correct dosage in prescribing fluoride supplements depends on two factors: the age of the child and the existing fluoride concentration in the water supply (Table 44-2). The latter information can be obtained from the local water supply authority (except in the case of private well water). Failure to determine the fluoride concentration in the communal water source can result in a fluoride overdosage and consequent dental fluorosis. For young infants, drops are more convenient than tablets because they can be directly dispensed into the child's mouth with a medicine dropper or added to foods (e.g., cereals) or beverages (e.g., milk, formula, or juices). For older children whose primary teeth have erupted, fluoride tablets or lozenges are indicated, which provide systemic benefits when swallowed and topical benefits as they are chewed and swished around the teeth. Fluoride tablets or lozenges are available in 0.25-mg, 0.5-mg, and 1-mg strengths. No more than 120 mg of fluoride (264 mg of sodium fluoride) should be dispensed in any one container, which should be provided with a child-proof top and labeled: "Caution—store out of reach of children." A sample prescription of a fluoride supplement for a 2-year-old residing in a community with 0.1 ppm of fluoride in the water supply is shown in Figure 55-5.

Because fluoride supplements are taken as a single bolus that causes a rapid elevation in blood fluoride concentrations, most studies have identified them as a major risk factor for dental fluorosis.[73] Current fluoride prescription practices have undergone close scrutiny, and it is generally agreed that a reduction in dosage is indicated in the age period from birth to 6 years because this is the period when the permanent anterior teeth are vulnerable to dental fluorosis (the "window of vulnerability"). A reduced dosage schedule of fluoride supplements has been accepted by the ADA, American Academy of Pediatric Dentistry, and American Academy of Pediatrics, as shown in Table 44-2.[2] In the 6-month to 3-year age cohort, it is recommended that fluoride drops be prepared in a more dilute form, such as containing 0.25 mg of fluoride in 0.25 mL (instead of in a single drop), to minimize overdispensing errors at home. In Canada, a more drastic reduction in dosage—with no supplements until age 3 years; 0.25 mg at ages 3, 4, and 5 years; and 1 mg from age 6 years—has been recommended.[13]

Insufficient data exist to establish the efficacy of prenatal supplements given to pregnant mothers in reducing caries in offspring. The U.S. Food and Drug Administration (FDA)

does not permit any fluoride preparation to be labeled, represented, or advertised for prenatal use. Only a small portion of the enamel of some of the primary teeth (mostly of the incisors) has entered the stage of secondary mineralization (maturation stage) at birth and almost no permanent teeth except the tips of the first molars (which are at the formative stage).[17] It is more important to ensure that adequate fluoride supplements are taken regularly after birth. The concentration of total fluoride in human milk is approximately 0.05 ppm and in cow's milk, approximately 0.1 ppm. Both types of milk are negligible sources of fluoride. Although an infant gets very little fluoride from a mother's milk, in most cases there is no need to supplement breastfed children who reside in optimally fluoridated communities. Because the average duration of nursing in the United States is only 4 months, the amount of fluoride obtained from optimally fluoridated water supplies used in preparing formula and baby food suffices. If an infant resides in a suboptimally fluoridated community, the dosage schedule shown in Table 44-2 should be followed.

Vitamins neither interfere with nor potentiate the caries-preventive effects of fluoride supplements, but they do increase the cost to the patient. If the child needs vitamins, a fluoride-vitamin combination may be more convenient, but children are unlikely to require vitamins from birth to teens. Some fluoride-vitamin preparations contain 60% total sugar as a sweetener to mask the taste of some of the B vitamins. Such products are contraindicated for caries prevention.

TOPICAL FLUORIDE

Not all fluoride agents and treatments are equal. Different fluoride compounds, different vehicles, and vastly different concentrations of fluoride, ranging nearly 100-fold, have been used with different frequencies and durations of application (Table 44-3). All these variables can influence the clinical outcome regarding caries prevention and management. The efficacy of topical fluoride in caries prevention depends on the concentration of fluoride used, the frequency with which it is applied and probably the duration of application, and, to some extent, the specific fluoride compound used.[48,57,58]

Regarding the concentration of fluoride used, most fluoride dentifrice studies have shown a dose-response effect,[57,70] and the trend in clinical effectiveness of professionally applied topical fluoride agents is similar (Table 44-4).[32,37,88] Regarding the frequency of topical fluoride application, in studies of the same commercial stannous fluoride dentifrice, the efficacy of unsupervised use once per day or *ad libitum* was an approximate 21% caries reduction,[38,41] whereas the efficacy of supervised use three times per day was an approximate 45% caries reduction (Table 44-5).[9,64]

No controlled clinical trials have been reported in which the same concentration of a topical fluoride agent has been tested for varying durations of application. In vitro testing of sodium fluoride and acidulated phosphate fluoride (APF) solutions has shown that fluoride uptake is time-related, and in the case of APF solutions the most rapid uptake occurs during the first 4 minutes.[42] It is unknown, however, whether a more rapid fluoride uptake means greater caries reduction.

Professional Topical Application of Fluorides

Solutions, gels, and foams

Semiannual topical application of concentrated fluoride (2% sodium fluoride, 8% stannous fluoride, or APF containing 1.23% fluoride) by a dentist or dental hygienist provides an average 26% reduction of decay of permanent teeth of children living in nonfluoridated areas.[69] Neutral sodium fluoride solutions (2%) were first tested in the early 1940s and were shown to reduce caries. Teeth were first cleaned with pumice paste, and the solution was applied to the teeth for 3 minutes. The application, but not the pumicing, was repeated at weekly intervals for a total of four applications at ages 3, 7, 11, and 13 years.[44] This sequence of application was used more widely in public health programs than in private practice. In 1958, 8% stannous fluoride was also shown to be an anticaries agent.[55] The procedure again involved coronal polishing, and the stannous fluoride was applied for 4 minutes semiannually. Aqueous stannous fluoride solutions have the disadvantages of undergoing rapid hydrolysis and oxidation; because of this instability, they must be freshly prepared for each treatment. Stannous fluoride has a low pH (approximately 2.7) and has a disagreeable acidic and metallic taste. Many investigators have also reported that teeth stain (from light brown to black) at carious lesions, hypocalcified areas, and around the margins of restorations after stannous fluoride application.[54] This discoloration is caused by the conversion of tin phosphates, which form on the enamel, to tin sulfides, which have the characteristic dark brown or black color.

In the United States, the most popular form of office fluoride therapy is the application of APF in the form of a solution, gel, or foam. APF agents should have a pH of approximately 3.0 and contain 1.23% fluoride and 0.1 mol/L of orthophosphoric acid. The low pH of this agent favors

TABLE 44-3

Range of Therapeutic Fluoride Concentrations in Topical Agents Used to Prevent Caries

METHOD/VEHICLE	FLUORIDE CONCENTRATION (ppm)
Mouth rinse, daily	230
Dentifrices, children	250-500
Mouth rinse, weekly	920
Dentifrices, adult	1000-1500
Self-applied gels or rinses, prescription	5000
Professionally applied sodium fluoride solutions	9200
Professionally applied APF solutions, gels, foams	12,300
Professionally applied stannous fluoride solutions	19,500
Professionally applied varnishes	22,600

DMF, Decayed, missing, and filled teeth.

more rapid fluoride uptake by enamel, and the presence of the orthophosphate prevents enamel dissolution by the common ion effect. Application of one of these solutions or gels is preceded by a coronal polishing, and the agent should be applied for 4 minutes, usually in a disposable tray applicator. The procedure should be repeated semiannually. The need for coronal polishing preceding application of APF gels has been called into question, and clinical trials indicate that the efficacy of the gels is similar regardless of whether coronal polishing is performed.[71] Some commercial products have been promoted on the basis of claims that they need to be applied for only 1 minute instead of 4 minutes. Some studies have suggested that prolonged application of APF gels can affect the surface morphology and properties of composite resins.[46] These claims have not been supported by clinical trials showing caries reductions; until they are, a 4-minute application of the agent should be the designated method.

Because these agents used in the dental office contain relatively high concentrations of fluoride, the operator should observe certain precautions to prevent inadvertent ingestion of them by the patient, who should be in an upright position in the chair.[31] If fluoride supplementation (in the dental office or at home) is used on younger children, there is typically a reduced likelihood of adequate expectoration. A child's ability to spit should be assessed before use of fluorides.[62,87] If solutions are used, the teeth should be carefully isolated with cotton rolls or gauze swabs, and solution sufficient only to wet the surfaces of the teeth and keep them wet should be applied. If gels in trays are to be used, only a minimal amount of gel should be dispensed in the tray, sufficient to cover the teeth, but not to exude from the tray. A saliva ejector, or better still high-vacuum suction, should be used during the 4-minute application of the agent. On removal of the tray, any excess gel should be wiped away from the teeth and gingiva with gauze, and the patient should be instructed to expectorate thoroughly. The recommended procedures to reduce fluoride ingestion from professional gel tray applications are summarized in Box 44-1.

BOX **44-1**

Recommended Procedures to Reduce Fluoride Ingestion from Professional Gel Tray Applications

Place patient in an upright position.
Warn patient not to swallow the gel.
Use small amounts (≤2.5 mL per tray).
Use custom-fitted or stock trays with absorptive liners.
Use suction.
Remove excess gel from teeth and gingiva with gauze.
Have patient expectorate thoroughly after treatment.

Varnishes

The previously discussed agents (sodium fluoride, stannous fluoride, and APF) are all aqueous preparations, but other research has involved nonaqueous solutions that are applied as varnishes with longer retention time on the tooth surface. In 1964, Schmidt[76] tested the practicality of a 2% sodium fluoride lacquer in an alcoholic solution of natural resins. After clinical trials of this fluoride varnish showed its efficacy as an anticaries agent,[33] it was marketed in Germany as a 5% sodium fluoride preparation under the brand name of Duraphat. This product is now widely used for office topical applications throughout Europe, the Middle East, Australia, New Zealand, and Asia; it is currently used in more than 40 different countries throughout the world.

In the mid-1970s, a difluorosilane agent containing 0.7% fluoride in a polyurethane varnish was introduced for caries prevention in Europe as Fluor Protector. This agent boasts a high fluoride uptake by enamel.[68] It is available in the United States as a cavity varnish to seal and prevent the permeation of fluids and metal ions.

In 1994, a 5% sodium fluoride varnish under the name of Duraflor obtained FDA approval for its use in the United States as a cavity liner. Subsequently, the Duraphat formulation of 5% sodium fluoride varnish received FDA approval as a dentin-desensitizing agent and as a cavity liner "medical device." A practitioner can use fluoride varnish for caries prevention as an off-label use on the basis of professional judgment.[89] Extensive literature exists on the clinical efficacy of Duraphat varnish as a safe and effective anticaries agent for use in children.[8,66] One advantage of fluoride varnishes is that they adhere to tooth surfaces, permitting prolonged fluoride exposure and uptake. In a meta-analysis of the efficacy of fluoride varnishes[32] using rigid criteria for inclusion of data, a mean caries reduction of 38% for fluoride varnishes was obtained (see Table 44-4).

Self-Applied Topical Fluoride in the Home

One of the most effective means of caries reduction involves the daily (on school days) self-application of 1.1% sodium fluoride gel (about 40% of the concentration of fluoride used for professional office applications) in custom-fitted trays for 5 minutes daily. The custom-fitted maxillary and mandibular trays ("toplicators") are fashioned by vacuum-drawing, heat-treated sheets of polyvinyl over plaster models of the teeth. This procedure, first shown in supervised school programs, reduced decay by approximately 75% after 2 years in nonfluoridated communities[22] and by approximately 30% in fluoridated communities.[21] This form of self-therapy is best suited only for high-risk caries patients who are sufficiently motivated to conform with the daily regimen. It is not intended for very young children, but is appropriate for school-aged children and has been found to be effective for adults with xerostomia after radiation therapy to the head and neck region.[18]

The advantage of this technique is that fluoride preparations are held in intimate contact with the teeth daily for 5 minutes. Saliva is excluded from the field of application so that it cannot dilute the effective concentration of the active agent in the gel. Intermittent biting pressure on the plastic trays tends to pump the fluoride into pits, fissures, and interproximal spaces. Because the trays are custom-made, a minimal amount of gel (usually 0.5 mL) is required in each tray. The main disadvantage is the high cost of fabricating individual trays for each patient, which renders it impractical for school-based programs.

Self-application by brushing with a fluoride gel (0.4% stannous fluoride) has been used as an alternative to the custom-fitted tray method and has been actively promoted by several commercial manufacturers of these products. Although published clinical data have not been provided to support the efficacy of these agents, many of the stannous fluoride gels have been accepted by the Council on Scientific Affairs of the ADA, presumably based on the findings with stannous fluoride dentifrices. The gels vary considerably in the amount of available tin ion.[82] The original formulation, developed at the Veterans Administration Hospitals, had an unpleasant taste, so many high-risk caries patients either refused to use the gel or used it only sporadically. Commercial products have been formulated with more acceptable flavors to encourage better compliance. Because the fluoride uptake is time-dependent, applying a gel containing 1000 ppm of fluoride for approximately 1 minute by brushing does not provide as much fluoride uptake as from a gel in a custom-fitted tray containing 5000 ppm applied for 5 minutes. No direct comparisons are available to determine the clinical efficacy of these two techniques for caries prevention.

Fluoride Mouth Rinses

In the mid-1960s, Scandinavian researchers showed that a biweekly rinse for 1 minute with a solution of 0.2% sodium fluoride (920 ppm of fluoride) was more effective in reducing decay than an annual treatment with 10% stannous fluoride professionally applied, equally effective as four professional treatments with 2% sodium fluoride applied every 3 years, and approximately as effective as the daily use of the fluoride dentifrices then available.[83] It was also shown that daily rinsing for 1 minute with an even more dilute solution containing 0.05% sodium fluoride (230 ppm of fluoride) gave even greater caries protection. Fluoride mouth rinsing results in approximately 30% less decay.[72]

The original Scandinavian findings have since been reproduced in many different countries around the world, and now a weekly fluoride rinse has become widely adopted in many school-based preventive dentistry programs. The popularity is based on the fact that it is safe, effective, relatively inexpensive, and easy to learn; requires little time (approximately 5 minutes of class time weekly); and can be supervised by nondental personnel. Compliance may vary and is generally better in elementary schools than in junior and senior high schools. Compliance depends on successfully motivating and interesting classroom teachers and the school administrators in the preventive dentistry program.

Fluoride mouth rinses were prescription items when originally introduced, and the 0.2% sodium fluoride rinse still requires a prescription. In 1983, the FDA approved the sale of 0.05% sodium fluoride mouth rinses, 0.1% stannous fluoride mouth rinses, and 0.4% stannous fluoride gels as over-the-counter products. In the case of the 0.05% sodium fluoride rinse, 10 mL of the solution (the recommended dosage) contains only 2.3 mg of fluoride. The products are packaged with childproof caps, and their labels state that use is restricted to individuals 6 years and older. The rinse should be vigorously swished around the mouth for 1 minute and then expectorated. The dentist needs to advise the patient, or parent, of these instructions to ensure that the agent is present for enough time to ensure efficacy and to avoid unnecessary ingestion of the rinse.

Fluoride Dentifrices

In the 1940s, the first clinical evaluations of dentifrices containing fluoride were undertaken with products in which fluoride was simply incorporated into existing dentifrice formulations. Because the abrasive systems used in these early dentifrices contained Ca^{++} salts that interfered with the availability of fluoride, these products were ineffective or less than fully effective in reducing decay. The first report of a clinical decrease in the incidence of caries with a fluoride-containing dentifrice compared with the similar use of a nonfluoride dentifrice involved a dentifrice system containing stannous fluoride (0.4%) with an abrasive, calcium pyrophosphate, that had been heat-treated to increase its compatibility with fluoride.[56] In 1960, this dentifrice was given provisional acceptance, and in 1964 full acceptance, by the ADA's Council on Dental Therapeutics. This acceptance stimulated other manufacturers to develop and test various fluoride formulations and abrasive systems. Currently, the sale of these products exceeds $1 billion annually in the United States, and approximately 98% of all toothpastes sold contain some form of fluoride. With few exceptions, fluoride toothpastes dominate dentifrice markets in most Western industrialized countries. The original stannous fluoride formulation has been superseded by more compatible and effective formulations.

Sodium monofluorophosphate (MFP) (Figure 44-5) was first tested as a therapeutic agent in dentifrices in the early 1960s. Numerous clinical trials of dentifrices containing 0.76% or 0.8% MFP have since been conducted by different groups in various countries. In almost all these trials, some degree of effectiveness (i.e., approximately 25% caries reduction) has been shown after 1 to 3 years of use.[16] In the United States, MFP of 0.76%, or 1000 ppm of fluoride, is the most commonly used therapeutic ingredient in commercial toothpastes. A dose-response effect has been shown; dentifrices with less MFP are less effective,[45,53] and dentifrices with more MFP (1500 ppm, 2000 ppm, and 2500 ppm of fluoride) are more effective.[11,15,26,35,48,80]

Sodium fluoride was the first fluoride to be tested in a toothpaste and was originally found ineffective because of incompatibility with the earlier abrasive systems used. Later, when tested with acrylic particles or hydrated silica as the abrasive, sodium fluoride–containing dentifrices were found to provide significant cariostatic benefits. A dose-response

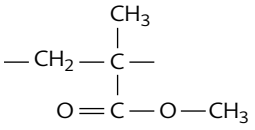
TABLE **44-6**

Clinically Effective Fluoride Abrasive Systems in Dentifrices

FLUORIDE COMPOUND	ABRASIVE SYSTEM	FORMULA
Stannous fluoride (SnF_2)	Calcium pyrophosphate	$Ca_2P_2O_7$
	Insoluble sodium metaphosphate	$(NaPO_3)_x$
	Silica	SiO_2
Sodium fluoride (NaF)	Calcium pyrophosphate	$Ca_2P_2O_7$
	Insoluble sodium metaphosphate	$(Na_2PO_3)_x$
	Polymethyl methacrylate	*
	Silica	SiO_2
Sodium monofluorophosphate (Na_2PO_3F)	Calcium carbonate	$CaCO_3$
	Aluminum oxide	Al_2O_3
	Insoluble sodium metaphosphate	$(Na_2PO_3)_x$
	Silica	SiO_2
	Dibasic calcium phosphate	$CaHPO_4$
	Calcium pyrophosphate	$Ca_2P_2O_7$
Amine fluoride	Insoluble sodium metaphosphate	$(Na_2PO_3)_x$

x, ≥2.
*Composed of repeating units of methylmethacrylate:



relationship has been reported with sodium fluoride toothpaste tested at 0 ppm, 250 ppm, 500 ppm, and 1000 ppm of fluoride.[67] A sodium fluoride formulation (1100 ppm of fluoride) with silica abrasive has been found to be more effective than the earlier stannous fluoride–calcium pyrophosphate dentifrice, undoubtedly because of the greater availability of fluoride in this newer system.[75,92] Several commercial products now use sodium fluoride as the active therapeutic ingredient. The original stannous fluoride formulation has been superseded by more compatible and effective formulations. Clinically effective fluoride toothpastes with compatible abrasive systems are summarized in Table 44-6.

In Europe, an amine fluoride dentifrice containing two compounds—diethanol aminopropyl-N-ethanol octadecylamine-dihydrofluoride and cetylamine hydrofluoride (see Figure 44-5) at a concentration providing 1250 ppm of fluoride—has been used for many years. Both substances have a long aliphatic chain, containing 16 or 18 carbon atoms, which is responsible for the dentifrice's property of lowering surface tension. This dentifrice has also been shown to be effective in reducing dental decay.[75]

The widespread use, most commonly twice a day, of fluoride-containing dentifrices has had a profound effect in reducing caries in many developed countries and accounts for some of the secular decline in caries observed in communities lacking optimal fluoride concentrations in the water supply. The degree of effectiveness may vary with different dentifrice formulations.

As a response to concerns about fluorosis, low-concentration (250 ppm, 400 ppm, and 500 ppm fluoride) toothpastes are available in Austria, Belgium, Czechoslovakia, Finland, France, Germany, Israel, Luxembourg, The Netherlands, New Zealand, Portugal, Sweden, Switzerland, and the United Kingdom. Dose-response efficacy data indicate, however, that a dentifrice with a lower fluoride concentration provides less caries protection. From the growing literature on dentifrice retention and ingestion, it has been estimated that for children younger than 6 years, the average retention was 27% of the amount placed on the brush.[70] Because most children brush twice daily, this could contribute 0.3 to 0.6 mg to total fluoride intake, depending on how much toothpaste (0.5 to 1 g) is used habitually. Although several of the early studies that looked at the dentifrice-fluorosis relationship have not found an association, they have generally been small and lacked sufficient statistical power to show such an association if there were one.[63] Several more recent studies have attributed much of the increase in fluorosis prevalence to early use of fluoride dentifrice, especially before 2 years of age.[36,49,63,65,91] To avoid unintentional ingestion of fluoride from dentifrices, the following guidelines are provided:

1. Parents should brush preschool children's teeth until they can do it properly by themselves.
2. Parents should apply the dentifrice to the toothbrush of preschool children until they can do it properly by themselves.
3. Parents of preschool children should supervise their tooth brushing activity, and dentifrices should be stored out of the reach of toddlers.
4. Preschool children should use a child-size toothbrush.
5. Only a smear (younger children) or pea-sized (older children) amount of dentifrice should be applied to the toothbrush bristles.
6. Children should be taught to spit out thoroughly after tooth brushing.

Of increasing interest in recent years is the question as to the bioavailability of fluoride from dentifrice after brushing and the effect of rinsing habits. Studies have shown reduced fluoride concentrations in saliva of adults and children who rinsed with water immediately after brushing, with some studies citing near zero levels of fluoride absorption after multiple water rinses.[5,78,93]

FLUORIDE TOXICOLOGY

Acute Toxicity

Paracelsus said that "all substances are poison; there is none which is not a poison. The right dose differentiates a poison and a remedy." Fluoride is no exception to this historic observation. When ingested in amounts of 1 to 3 mg/day, as would be the case in optimally fluoridated communities, fluoride is perfectly safe. A dose of 5 to 10 g of sodium fluoride (approximately 2.5 to 5 g of fluoride) is fatal for an adult, however, and lesser amounts are lethal to children. Incidents of acute fluoride poisoning have been recorded, including industrial accidents, fumigant inhalation, ingestion of household insecticides containing fluoride, and suicide attempts.

Patients with severe fluoride poisoning characteristically exhibit nausea, vomiting, and diarrhea; progressive hypotension, pronounced hypocalcemia and hypomagnesemia, and acidosis; and cardiac irregularities, including ventricular tachycardia and sometimes fibrillation and asystole. Successful treatment is based on early initiation of the following procedures:

1. Steps to prevent further systemic absorption of fluoride (e.g., administration of emetics to induce vomiting, gastric lavage with fluids containing Ca^{++})
2. Cardiopulmonary monitoring and preparation for endotracheal intubation and direct-current cardioversion
3. Prompt and frequent blood analyses, especially for plasma Ca^{++}, Mg^{++}, K^+, and pH

4. Intravenous infusion of salt solutions as needed to correct acid-base imbalances and restore plasma electrolytes to the normal range
5. Alkaline diuresis to enhance fluoride excretion
6. Appropriate treatment of severe cardiac arrhythmias

A few dentally related fluoride fatalities have been recorded. One case followed office topical therapy in which inappropriate agents and procedures were used, and adequate treatment was not provided for management of the overdose.[12] The other two cases resulted from ingesting fluoride tablets from containers that were not equipped with a child-proof cap.[20,90] There have been numerous reported and unreported occasions, however, when patients have had transitory nausea from unintentional swallowing of concentrated fluoride topical agents used in the dental office. When recommended procedures are followed, as listed in Box 44-1, the topical application of fluoride agents in the office or the self-application of fluoride agents in the home does not pose a risk of acute toxicity.

Chronic Toxicity

At one time chronic fluoride inhalation was an industrial hazard of cryolite workers handling crushed sodium aluminum fluoride in aluminum refineries. It resulted in crippling skeletal changes with calcification of ligaments, kyphosis, and limitation of motility in the spinal column and thorax. Modern regulations of industrial hygiene require air scrubbers to remove fluoride particles. Crippling skeletal fluorosis is not a public health problem in the United States, as evidenced by the reports of only five cases in 30 years. Of greater concern is fluorosis of the dentition.

Dental fluorosis is a hypomineralization of enamel produced by chronic ingestion of excessive amounts of fluoride during tooth development. Fluorosis may range in severity from a few white flecks to extensive brown staining and pitting. Pits are secondarily produced defects of posteruptive origin rather than true hypoplasias. The hypomineralization is mostly in the outer third of enamel. The secretory stage of enamel development is a crucial time for fluorosis to occur. Ameloblasts are more sensitive to fluoride than are other cells. The mineralization phase is also affected. In excess, fluoride interferes with the normal postsecretory, pre-eruptive development of enamel. Chronically high concentrations of fluoride interfere with deposition of mineral, degradation of matrix proteins (amelogenin and enamelin), and withdrawal of water during enamel maturation.

The prevalence and severity of fluorosis depend on the amount or concentration of fluoride, the duration of exposure, the state of tooth development (i.e., age when exposed), and individual variations in susceptibility (e.g., body weight). In the oral health survey of U.S. schoolchildren sponsored by the National Institute of Dental Research in 1987, 52% were found to have questionable, very mild, or mild fluorosis—forms that are not a serious cosmetic problem. Only 1.3% had moderate or severe fluorosis involving pitting or brown staining. Approximately 2% of U.S. schoolchildren may have perceived esthetic problems that could be attributed to currently recommended levels of fluoride in the drinking water.[28] If the natural water supply contains in excess of 2 ppm of fluoride, the prevalence of fluorosis can be reduced by changing the source of the water supply or by defluoridation with activated alumina or bone char for adsorption.

Some fluorosis can also be prevented by stopping the use of fluoride supplements in communities that already provide optimal levels in the water supply. Because supplements require a prescription, dentists, physicians (particularly pediatricians), and pharmacists need to be better educated on when supplementation is indicated and when it is not. Finally, some fluorosis can be prevented by decreasing the unintentional ingestion of fluoride from dentifrices by young children. Children younger than 6 years need to be instructed to use only a pea-size portion of paste, to spit out thoroughly after brushing, and to avoid swallowing the paste. Dentifrice manufacturers have a responsibility to provide better and more conspicuous labeling in this regard. These data support the concept that use of fluoride supplements during the first years of life, especially in the first year of life, has been associated with an increased risk of fluorosis.[39]

CHAPTER 45

*Antiplaque and Antigingivitis Agents**

ANGELO J. MARIOTTI

The periodontium, which is responsible for the retention of teeth in the maxilla and mandible, consists of four different tissue types. Cementum and alveolar bone are the hard tissues to which the fibrous periodontal ligament anchors the tooth into the skeleton, and the gingiva is the covering tissue of the periodontium (Figure 45-1). The gingiva is a unique body tissue because it allows the penetration of calcified tissue (i.e., teeth) into an intact mucosa, while protecting the underlying periodontal tissues. The buildup of infectious organisms on these structures give rise to some of the most common diseases in humans.

The accumulation of microorganisms on the tooth surface along the gingival margin can alter the structure and function of the gingiva, inducing an oral inflammatory reaction; clinically, this is known as *gingivitis*.[64] During adolescence, the occurrence of gingivitis is almost universal, and in adulthood, it affects approximately 50% of the population.[2] Because of the frequent appearance of gingivitis, this disease remains a principal concern for the dentist, as it can be converted to other, more destructive forms of periodontal disease.[64] The prevention or cure of gingivitis is of particular interest to dentists.

Dental caries is another common oral disease the prevalence of which varies in regard to the tooth surface and age of the individual.[25] Although caries is a worldwide problem associated with dental plaque and refined carbohydrates, some individuals, particularly individuals in lower educational, lower socioeconomic, and older age groups, are at greater risk.[25]

The most common method of eliminating gingivitis or preventing dental caries is by the mechanical removal of the microorganisms found in dental plaque via tooth brushing and flossing. Effective mechanical removal of plaque is a tedious, time-consuming process, however, which is affected by an individual's gingival architecture, tooth position, dexterity, and motivation. Consequently, incomplete removal of dental plaque by mechanical means allows for the induction and continued progression of gingivitis and dental caries. Pharmacologic agents that prevent or reduce plaque can aid the dentist by effectively preventing or eliminating these diseases. The development of safe, effective, topically applied antiinfective agents would help in the maintenance of healthy hard and soft tissues. This chapter examines the relationship of the unique pharmacokinetic characteristics of common antiplaque and antigingivitis agents and drugs available in mouth rinses and dentifrices to manage dental plaque.

RATIONALE FOR BIOFILM DRUG THERAPY

Many different types of materials accumulate on teeth. The most ubiquitous and important deposit is dental plaque or dental biofilm. Dental biofilm consists primarily of microorganisms in an organized matrix of organic and inorganic components.[85] Bacteria account for at least 70% of the mass of the biofilm; 1 mm^3 of dental biofilm contains more than 100 million bacteria consisting of more than 400 different species.[41,69] The organic matrix of biofilm consists of polysaccharide, protein, and lipid components, whereas the inorganic matrix is primarily composed of calcium and phosphorus ions.[85]

The dental biofilm found above the gingival margin of the tooth is called *supragingival*, and the dental biofilm found below the gingival margin (i.e., in the gingival sulcus or pocket) is called *subgingival*. Dental biofilm has been considered to be a common denominator in caries and periodontal diseases. This concept is a gross oversimplification, however, because there are different types of bacteria, some of which may be cariogenic, some of which may be periodontopathic (with subsets leading to different forms of periodontal diseases), and some of which may be relatively innocuous and cause only low-grade dental disease.

Gingivitis is due principally to the accumulation and retention of dental biofilm coronal to the gingival margin.[45,62] The accumulation of supragingival biofilm is also a prime influence in the development of the subgingival biofilm.[16] As undisturbed biofilm matures, it changes in composition and becomes more complex. A bacterial succession occurs whereby microorganisms associated with gingival health (i.e., gram-positive rods and cocci) are replaced by microorganisms associated with gingivitis (i.e., gram-negative cocci and rods) and spiral-shaped organisms and spirochetes. As a consequence of the change in microflora, inflammation-induced changes in the gingiva cause an increase in epithelial cell turnover and connective tissue degradation, resulting in anatomic changes that tend to deepen the gingival sulcus causing a gingival pocket to form.[37] This change in gingival architecture and the subgingival environment provides a new and better protected niche for bacteria to grow. Here, they are continually bathed by exudate from the gingival crevice and end products from the supragingival biofilm. Control of supragingival biofilm also has a profound influence on the developing composition of periodontitis-associated subgingival biofilm.[37]

Dental caries is a chronic disease that is characterized by the progressive decalcification of tooth structure. The biofilm contains bacterial species (e.g., *Streptococcus mutans*) that convert refined carbohydrates to lactic acid and other acids.[103] These acids can dissolve tooth mineral, resulting in a subsurface lesion initially and a cavity if the process continues over time. The unimpeded progress of dental caries can penetrate the enamel or cementum and progress through the dentin to the dental pulp. When the dental pulp is affected, a pulpitis develops resulting in tooth pain (i.e., toothache).

Some current commercially available therapeutic measures for control of biofilms include agents that act directly

*The author recognizes Dr. Ernest Newbrun for his past contributions to this chapter.

on the microflora and agents that interfere with bacterial attachment or the mechanical removal of the biofilm or both. Discussion of mechanical techniques is beyond the scope of this chapter, but excellent comprehensive reviews on mechanical plaque control can be found elsewhere in the dental literature.[15,29]

PHARMACOKINETICS OF THE ORAL CAVITY

The therapeutic outcome of topically applied agents used to control oral infections depends on the characteristics of drugs that take advantage of the unique physiologic and anatomic circumstances found in the oral cavity. This section is a broad overview of important oral pharmacokinetic principles.

Absorption

The vascularity of the oral cavity, combined with a thin epithelial lining in some areas, allows for the absorption of drugs at a rapid rate.[43,94] Nonionized drugs, such as nitroglycerin, take advantage of these tissue characteristics and diffuse rapidly across the oral mucosa into the bloodstream. In contrast to most drugs, for which the principal objective is to introduce the agent into the bloodstream rapidly, the goal of oral topical agents is to be retained in the oral cavity for as long as possible.[35] Rapid oral absorption can lead to toxic effects elsewhere in the body and a significant reduction of the free drug in the oral cavity. In most instances, the drugs used to restrain plaque levels are highly ionized and are generally unable to penetrate the oral mucosa.

Distribution

When an agent is topically applied in the oral cavity, the free drug can act at the primary site (i.e., bacteria in the plaque), or it can be partitioned to compartments where the drug binds nonspecifically. These drug reservoirs include the enamel, dentin, and cementum of the tooth; the oral mucosa; the organic and inorganic components of plaque; and salivary proteins.[20]

The fraction of the administered dose that is nonspecifically bound to oral reservoirs depends on the concentration, amount of time, and chemical nature of the agent used. A 1-minute rinse with 0.2% chlorhexidine results in approximately 30% of the total amount dispensed being retained after 1 hour, whereas a 3-minute rinse with 0.1% sodium fluoride results in less than 1% of the administered dose being found in the oral cavity after 1 hour.[31] The ability of oral agents to bind nonspecifically and reversibly to oral reservoirs is an important quality for a sustained release of drugs to occur.

Metabolism

In the oral cavity, drug metabolism occurs in mucosal epithelial cells, microorganisms, and enzymes found in the saliva and in renal and hepatic tissue after the drug is swallowed. Although biotransformation of agents in the oral cavity is potentially an important aspect of reducing effective drug concentrations, quantitatively it accounts only for a small percentage of drug inactivation.

Clearance from the Oral Cavity

Salivary flow is crucial in the removal of many agents from the oral cavity. Human saliva has a diurnal flow that varies from 500 to 1500 mL of secretion in the daytime to less than 10 mL of secretion at night.[5] The rate of clearance of a drug from the oral cavity is of profound importance in determining the duration of time a drug is in contact with the tooth surface.[20]

Substantivity

The time that a drug is in contact with a particular substrate in the oral cavity is defined as *substantivity*.[104] Drugs that have a prolonged duration of contact are considered to have high

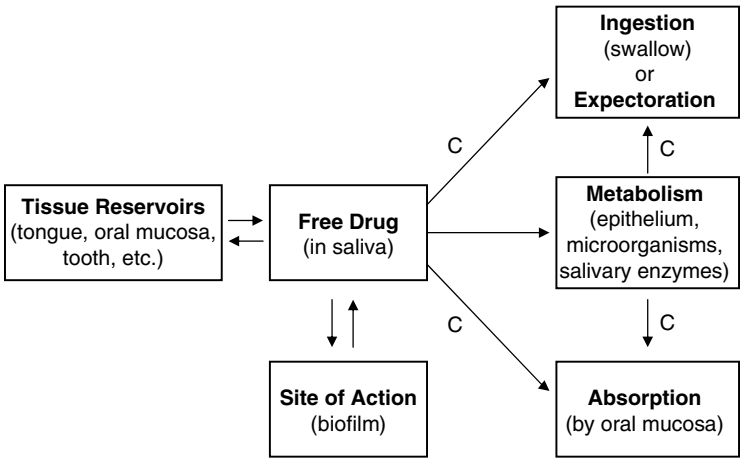

FIGURE **45-2** Pharmacokinetic factors that affect substantivity of agents. *C,* Clearance from the oral cavity.

substantivity.[105] In the oral cavity, substantivity depends on two important pharmacokinetic features: (1) the degree of reversible, nonspecific binding to oral reservoirs and (2) the rate of clearance by salivary flow (Figure 45-2).

Oral reservoirs are an important source for the continued release of drugs. The oral compartments that accumulate a drug must be able to bind reversibly large portions of the administered dose and release therapeutic concentrations of free drug to the site of action over long periods. Effective agents with high substantivity ideally would not bind irreversibly or with high affinity to oral reservoirs.[20,31]

Salivary flow also significantly affects the substantivity of topically applied liquid agents. The clearance of an agent from the oral cavity is directly proportional to the rate of salivary flow. During periods of high salivary flow, there would need to be a greater release of drug from oral reservoirs to maintain therapeutic concentrations.[20,31] Strategies that use natural or drug-induced periods of low salivary flow can increase the substantivity of an oral agent.

IDEAL PROPERTIES OF ANTIPLAQUE AGENTS

The pursuit of an ideal agent to reduce dental biofilms has been an ongoing search in dentistry for centuries.[107] In 1890, Willoughby D. Miller, an American dental surgeon, stated in his now-famous book, *The Micro-Organisms of the Human Mouth*, that "we ought to be able by means of properly chosen antiseptic material . . . to prevent as well as arrest microbial-induced diseases in the oral cavity."[67] Since that time, numerous antiplaque mouth rinses have been introduced to the public, many with dubious claims, and only more recently have dentists been able to prescribe therapeutically effective agents. Considering that the average time a person spends mechanically removing plaque from teeth is approximately 37 seconds,[106] having a "chemical" toothbrush would be a great benefit to improve oral health.

The principal properties of an ideal antiplaque agent include efficacy, stability, low clearance, safety, and taste (Box 45-1). An antiplaque agent must be able to suppress meaningfully or eliminate specific pathogens with no untoward local or systemic side effects. It should not allow the overgrowth of opportunistic organisms or encourage the development of resistant organisms. When used, it should be slowly released over time in the oral cavity with continued antimicrobial effect. The agent should be stable at room temperature and have a color and taste that is pleasing to the consumer. Last but not least, it should be relatively inexpensive to purchase. No such perfect antiplaque agent exists today.

BOX **45-1**

Properties of an Ideal Antiplaque Agent

Safety (nontoxic, nonallergenic, nonirritating)
Efficacy (statistically and clinically meaningful reduction of plaque and gingivitis)
Specificity (affects only the pathogenic flora)
Substantivity (binds to and releases slowly from the tooth surface)
No induced drug resistance
Acceptable taste
Low cost

The myriad claims regarding antiplaque efficiency of drugs has led the American Dental Association (ADA) Council on Scientific Affairs[19] to develop guidelines for testing the long-term efficacy of chemotherapeutic products for control of supragingival dental plaque and gingivitis. The requirements of these guidelines are summarized in Box 45-2 and have been adopted, in some cases with modifications, by the U.S. Food and Drug Administration (FDA), the Canadian Dental Association, and the British Dental Association. To be considered acceptable, a product should be tested in at least two, independently conducted, 6-month clinical trials in populations that represent individuals for whom the product is intended.

The Council on Scientific Affairs has set a mean estimated proportionate reduction in gingival inflammation across two studies of no less than 20% for establishing definite improvement (i.e., clinical significance) of mean gingivitis scores when measured against a masked placebo agent. This last requirement is important because participants in studies that use a placebo agent often show improvement simply because they are in a dental study; have had their teeth, plaque, and gingiva examined; and subsequently are more dentally aware. The Council also recommends that, in addition to measuring plaque quantitatively by any of the traditional indexes, investigators should obtain microbiologic samples from several supragingival sites and should characterize the oral flora in a control group and in the test group. In evaluating the efficacy of a chemotherapeutic agent on gingivitis, the Council recommends that subjective scoring of gingiva, based on tissue color or estimated degree of swelling, and objective measures, such as extent of gingival bleeding on probing or the amount of crevicular fluid flow, should be made.

ANTIPLAQUE AND ANTIGINGIVITIS AGENTS

Bis-biguanides

The bis-biguanides, chlorhexidine and alexidine, are cationic agents with fungicidal activity and bactericidal action against gram-positive and gram-negative organisms. Chlorhexidine is a chlorophenyl biguanide (Figure 45-3) that has been used as the acetate and, more commonly, the gluconate salt (which is more soluble) in mouth rinses, gels, and dentifrices for control of plaque and gingivitis. It binds to anionic groups on the bacterial surface, probably the phosphate groups of teichoic acid in gram-positive bacteria and the phosphate groups of lipopolysaccharides in gram-negative bacteria. When the bis-biguanide binds to the organism, the cell's membrane becomes permeable, allowing the cytoplasmic contents to leak. At higher concentrations, chlorhexidine causes precipitation of cytoplasmic proteins. By virtue of their cationic properties, the bis-biguanides also bind electrostatically to hydroxyapatite of teeth, to acquired pellicle, to plaque, and to buccal mucosa.

In one of the earliest studies on the dental applications of chlorhexidine, Schroeder[91] showed a 73% reduction of supragingival calculus plaques formed on carrier foils in short-term (3-day) tests. Subsequently, Löe and Rindom Schiøtt[61] showed that chlorhexidine was the most effective antiplaque and antigingivitis agent that had been tested until that time. In short-term trials with an experimental gingivitis model, a twice-daily rinse with 0.2% chlorhexidine gluconate completely prevented accumulation of plaque and the onset of gingivitis. These observations have been confirmed in numerous trials in humans and animals. Chlorhexidine mouth rinse in this experimental model prevented the development of white-spot lesions associated with incipient caries.[63]

The efficacy of chlorhexidine mouth rinse as an antiplaque/antigingivitis agent is dose-dependent in the range of 0.03% to 0.2%.[6,55] The volume and frequency of use and the concentration are important in determining the clinical response.[57] Although no significant difference in response was found between a 0.2% and a 0.12% chlorhexidine mouth rinse when administered in a 15-mL dose twice daily (delivering a total of 60 mg and 36 mg of the agent),[92] a significant difference in response was found between a 0.2% and a 0.1% chlorhexidine mouth rinse when administered in a 10-mL dose twice daily (providing 40 mg and 20 mg of the agent).[6] Additional factors, such as bioavailability of the formulation, may also affect the dose response.

Long-term use (6 months) of chlorhexidine mouth rinses has shown plaque reduction and significant prevention of gingivitis in children[57] and adults.[38] In a short-term study (21 days), 0.12% chlorhexidine mouth rinse used twice daily was clearly effective in reducing plaque (62% to 99%) compared with placebo, whereas rinsing with a phenolic compound containing essential oils, or sanguinarine with zinc chloride, resulted in no significant reduction in plaque.[95] The chlorhexidine rinse was superior to the other agents in its ability to maintain optimal gingival health during the entire 3 weeks the mouth rinses were used. Similarly, a 0.2% chlorhexidine rinse was approximately twice as effective as a sanguinarine rinse in a 19-day nonbrushing study in which plaque and gingivitis scores were assessed.[70] Fluoride (100 ppm), when combined with chlorhexidine (0.12%), does not interfere with the antiplaque/antigingivitis activity of a mouthwash.[49] The ADA Council on Scientific Affairs has accepted a mouth rinse containing 0.12% chlorhexidine gluconate as a safe and effective adjunct to brushing and flossing and regular professional care in helping prevent and reduce supragingival plaque and gingivitis.[18]

Chlorhexidine rinses occasionally produce some undesirable side effects, the most conspicuous being the development of yellow-brown stains on the teeth, anterior restorations, and the dorsum of the tongue. Although the stain is extrinsic, it cannot be removed by brushing with a normal toothpaste; mechanical polishing is necessary for its removal. Chlorhexidine also tends to promote supragingival calculus formation. A few individuals have had mucosal desquamation and soreness. Solutions containing bis-biguanides have a disagreeable, bitter taste that requires masking by compatible flavoring agents to be palatable. Some patients have a persistent aftertaste or disturbed taste sensation.

BOX **45-2**

Guidelines for Evaluating Chemotherapeutic Products for the Control of Supragingival Plaque and Gingivitis

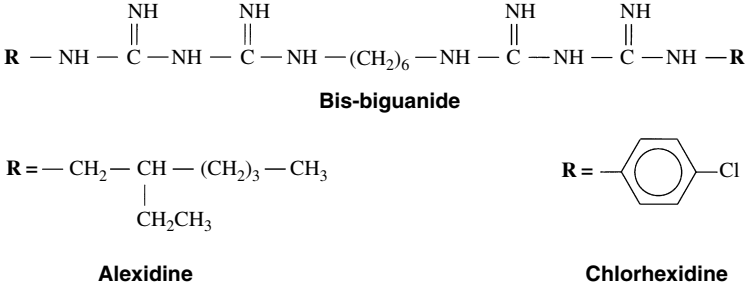

FIGURE **45-3** Structural formulas of bis-biguanides.

Extensive safety testing of the short-term and long-term effects of these compounds shows extremely low levels of toxicity locally and systemically. The low toxicity is a result of the poor absorption of chlorhexidine by the oral cavity and gastrointestinal tract, resulting in a limited amount entering the bloodstream. When chlorhexidine directly contacts mammalian connective tissue cells, there is usually a harmful effect. In cell culture, chlorhexidine can adversely affect gingival fibroblast attachment to root surfaces.[14] Protein production in human gingival fibroblasts was reduced at chlorhexidine concentrations that would not normally affect cell proliferation.[65] Such findings corroborate earlier studies showing delayed wound healing in standardized mucosal wounds after rinsing with a 0.5% chlorhexidine solution.[8] No teratogenic or reproductive changes have been found.

Bis-biguanides are effective as antiplaque and antigingivitis agents. They should not be used prophylactically, but as therapeutic agents for patients with active disease. This use requires proper diagnosis and supervised care until the disease is controlled. In the United States, these agents are for prescription use only. Chlorhexidine mouth rinses can serve as an important adjunct to regular oral hygiene for short-term application, particularly in the healing phase after periodontal surgery, oral surgery, and insertion of immediate dentures and for the treatment of acute necrotizing ulcerative gingivitis.[55] Chlorhexidine rinses can also be used for intermittent short-term application three to four times a year to prevent repeated denture stomatitis, limit plaque and gingivitis in patients with dental implants, and suppress the salivary titers of *S. mutans* in patients with high caries activity. Finally, long-term use of such a mouth rinse on a daily, weekly, or biweekly basis may benefit special patients with agranulocytosis, leukemia, hemophilia, thrombocytopenia, kidney disease, bone marrow transplantation, or acquired immunodeficiency syndrome (AIDS); patients being treated with cytotoxic or immunosuppressive drugs or radiation therapy; and patients who are physically handicapped or mentally retarded (Box 45-3).

Investigators have tested more intensive, professionally applied antimicrobial treatment with varnishes containing high concentrations of chlorhexidine compounds: 5%, 10%, 20%, and 40%.[54,82-84,86-89] The goals were to suppress *S. mutans* for an extended period, to prevent the increase of *S. mutans* normally accompanying placement of fixed orthodontic appliances, and possibly to eliminate them from the mouth. In these studies, *S. mutans* was successfully suppressed and in some cases eliminated for up to 22 months. There was no long-term effect on *Actinomyces* species or *Streptococcus sanguis,* however. A 40% chlorhexidine varnish, applied to exposed root surfaces of patients who had had periodontal surgery, was as effective as a fluoride varnish in preventing root caries.[87]

Bis-biguanides are useful adjuncts in the treatment of periodontal disease or rampant caries. They are not a panacea or magic bullet; in the absence of conventional therapeutic and preventive measures, bis-biguanides alone have been unable to cure periodontal disease or prevent caries.

Nonionic Bisphenols

Triclosan is a broad-spectrum antimicrobial compound whose chemical name is 2,4,4′-trichloro-2′-hydroxydiphenyl ether (Figure 45-4).[90] Originally, triclosan was used extensively in soaps, antiperspirants, and cosmetic toiletries as a germicide.[90] Currently, triclosan has been incorporated into toothpaste and mouth rinse because of its wide spectrum of antimicrobial effects, anti-inflammatory actions, and only modest toxicity.[66]

Triclosan is active against a broad range of oral gram-positive and gram-negative bacteria.[90] The antibacterial actions of triclosan were originally thought to affect cell membrane integrity by binding to membrane targets and interfering with transport mechanisms.[90] More recent work has shown that the effects of triclosan in bacteria occur by inhibiting the enzyme enoyl-acyl carrier protein reductase, which results in a reduction of type II bacterial fatty acid synthesis and lipid synthesis.[59,66,97]

Although triclosan has broad antimicrobial activity, the compound is rapidly released from oral tissues resulting in poor antiplaque properties as assessed in clinical studies of plaque formation. Improvement of triclosan substantivity was accomplished by incorporation of triclosan in a polyvinylmethyl ether maleic acid (PVM/MA) copolymer.[74] With the combination of PVM/MA copolymer and triclosan, the substantivity of triclosan has been increased up to 12 hours in the oral cavity.[28] Triclosan plus PVM/MA copolymer is available in the United States as a toothpaste. The commercially available dentifrice contains 0.3% triclosan with 2% PVM/MA copolymer. This product was tested in numerous short-term clinical studies and in controlled clinical trials.[21] In a review of 16 clinical trials, a meta-analysis showed a 49% reduction

BOX **45-3**

Clinical Indications for Chlorhexidine

Rights were not granted to include this box in electronic media.
Please refer to the printed publication.

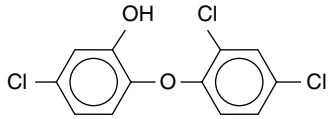

FIGURE **45-4** Structural formula of triclosan.

in plaque and a 49% reduction in gingival inflammation.[21] The same toothpaste composition also exhibited significant anticalculus properties with reported reductions in calculus formation of 55%.[74] Finally, of considerable interest is the observation that triclosan inhibits gingival inflammation by a mechanism independent of its antiplaque activity. An explanation of this surprising effect stems from research that shows triclosan can reduce prostaglandin E_2 production by cells stimulated with cytokines or by direct suppression of microsomal prostaglandin E synthase-1 expression in gingival fibroblasts.[28]

Extensive safety testing of the short-term and long-term effects of triclosan has shown extremely low levels of toxicity locally and systemically.[28] Nonetheless, triclosan infrequently gives rise to some undesirable side effects. There are concerns that triclosan, similar to many other disinfectants, has the potential to induce bacterial resistance, but the data to support this contention have been controversial.[13] Although triclosan has a low allergenic potential, contact dermatitis has been reported in the literature.[13] In addition to bacterial resistance and allergenic potential, there are environmental concerns about triclosan. It has been suggested that triclosan may combine with chlorine from tap water to produce chloroform gas, a potential human carcinogen. It has been reported, however, that the chloroform gas produced from triclosan and tap water was less than the amount present in regular chlorinated water.[13]

Phenolic Compounds

Phenol and its derivatives, thymol, chlorothymol, and hexylresorcinol, although used in many mouth rinses, have several limitations, including objectionable taste, poor water solubility, rapid discoloration, and toxicologic and allergenic properties. Phenolic compounds used in clinical trials have shown mixed results as antiplaque agents, with some studies reporting no reduction compared with placebo and others claiming reduced plaque and gingivitis scores.[6,27] In several studies of long-term, twice-daily use of a rinse containing thymol and essential oils (menthol, eucalyptol, methyl salicylate), in combination with normal oral hygiene, plaque and gingivitis were reduced below levels seen with a placebo rinse.[22,26,80] In one long-term study of this agent, the observed reductions in plaque and gingivitis scores were not impressive, however.[34]

The modest effect of these essential oils on supragingival biofilms may be a result of their poor substantivity and a modest effect on inhibiting bacterial enzymes. No adverse reactions have been reported. Antiseptic mouth rinses containing a combination of these essential oils (thymol, 0.064%; menthol, 0.042%; eucalyptol, 0.092%; methyl salicylate, 0.06%; plus alcohol, 26.9%) have received the ADA Council on Scientific Affairs Seal of Acceptance as a safe and effective adjunct to brushing and flossing and regular professional care in helping to reduce supragingival plaque and gingivitis.[17]

Quaternary Ammonium Compounds

Surface-active compounds characteristically have hydrophobic and hydrophilic groups in their molecule. They are classified as anionic (e.g., detergents such as sodium lauryl sulfate), cationic (e.g., quaternary ammonium compounds), and nonionic (e.g., polysorbate). In general, they exert their bactericidal effect by inactivating membrane-associated enzymes or by physically disorganizing the membrane itself.

Quaternary ammonium compounds are represented by cetylpyridinium chloride (Figure 45-5). Quaternary ammonium compounds are capable of reducing surface tension and adsorbing to negatively charged surfaces. They have greater activity against gram-positive bacteria than against gram-negative bacteria and are inactivated by the presence of organic matter; by low pH; and by anionic compounds, soaps, and metallic ions. Several over-the-counter mouth rinses contain cetylpyridinium chloride, benzethonium chloride, or domiphen bromide at concentrations of 0.025% to 0.075%. Studies of these agents have reported modest plaque reductions compared with placebo rinses.[11,60] Occasional side effects of quaternary ammonium compounds include oral ulceration and discomfort and a mild burning sensation of the tongue. Quaternary ammonium compounds have a lingering bitter, unpleasant taste. Judicious flavoring can overcome this limitation. As a group, the quaternary ammonium compounds are moderately effective antiplaque agents.

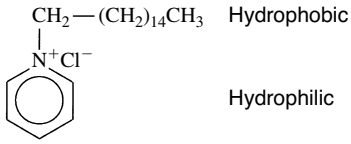

FIGURE **45-5** Structural formula of cetylpyridinium chloride showing the hydrophobic and hydrophilic substituents characteristic of quaternary ammonium disinfectants.

Fluorides

Fluorides are widely used in caries prevention, for which they have been highly effective. For caries prevention, systemic application via drinking water (1 mg/L), tablets (0.25 to 1 mg), or drops (0.125 to 0.5 mg) or topical application by mouthwashes (200 to 1000 mg/L), gels for home use (900 mg/kg) and professional use (9000 to 19,000 mg/kg), and dentifrices (1000 mg/kg) are available. In contrast to the efficacy of fluorides in preventing carious lesions, these agents have relatively poor antibacterial properties. The weak therapeutic benefit of fluorides on gingivitis is due to a modest inhibition of glycolysis in plaque bacteria. At sufficiently high concentrations, fluorides can act as antibacterial agents, however, by their ability to inhibit many enzymatic reactions involved in glycolysis and in glucose transport into cells. The antimicrobial activity varies with the particular organism and type of compound and with the fluoride concentration, pH, and length of exposure. Sodium fluoride, monofluorophosphate, and stannous fluoride are the compounds used in topical agents.

A few well-controlled clinical studies suggested a potential plaque-inhibiting effect for dentifrices containing stannous fluoride. These results were most likely due to the stannous ion rather than to fluoride, however. It has been proposed that the positive charge of the stannous ion may interfere with bacterial membrane function, bacterial adhesion, and glucose uptake, inhibiting the formation of plaque. When the antimicrobial potencies of sodium fluoride and stannous fluoride were compared directly in vitro, stannous fluoride was the more effective agent, suggesting an additive effect of the stannous ion. Several short-term in vivo studies[10,73,101] have shown that rinsing with stannous fluoride or using a toothpaste with stannous fluoride diminishes the formation of plaque. A meta-analysis of several clinical studies evaluating the effects of stannous fluoride in toothpaste showed a modest reduction of dental plaque[75] with a statistically significant decrease in gingival inflammation when stannous fluoride was compared with sodium fluoride controls.[39,75]

In addition to being a component of toothpaste, stannous fluoride has been added to mouth rinses. Daily rinsing with stannous fluoride (0.3%) for 1 minute resulted in less plaque, measured by tooth surface area and plaque thickness, than daily rinsing with sodium fluoride (0.2%).[9] When all oral hygiene was stopped (no brushing) and only rinsing was permitted, subjects using a stannous fluoride solution formed significantly less plaque than subjects using a placebo rinse.

Several studies have also shown that rinsing with stannous fluoride solutions or application of stannous fluoride gels improved gingival health; the benefits were not as great as with chlorhexidine,[45] and other studies have not found the improvement to be statistically significant.[56,58,73,111] In a long-term (18 months) clinical trial, no differences were observed in gingivitis, bleeding, or mean proportions of microbial forms in the stannous fluoride (0.4%) or sodium fluoride (0.22%) groups compared with the placebo group. Daily rinsing with stannous fluoride resulted in more exogenous staining of the teeth than sodium fluoride or placebo rinses.[111]

When used as topical agents, fluorides can exert antibacterial effects. Their efficacy in clinical trials in reducing plaque and gingivitis remains unproved. The lack of statistically significant effects may result from too brief an application. Commercially available 0.4% stannous fluoride gels vary considerably (from 21% to 102% of what is theoretically claimed) in the availability of the stannous ion.[102] Clinical studies to test the benefits of stannous fluoride as an adjunct to plaque control and reduction of gingivitis should ensure that the agent contains the maximal available stannous and fluoride ions, that it is applied for an adequate period, and that there is good patient compliance with the regimen.

Oxygenating Agents

Agents such as peroxides and perborates release molecular oxygen. Periodontal pathogenic bacteria can be killed by peroxides in vitro.[68] Hydrogen peroxide has been used in aqueous form, in gels, in dentifrices, and in a paste with sodium bicarbonate[51] for treatment of periodontal disease. Some studies have reported that the salt and peroxide regimen is effective in changing clinical measures of periodontal disease when combined with professional care,[79,112] but it is generally no more effective than conventional oral hygiene. Mouth rinses with hydrogen peroxide have been reported to reduce plaque formation and gingivitis and to arrest ulcerative gingivitis. In one long-term study (18 months) of orthodontic patients with fixed appliances, a once-daily rinse with 1.5% hydrogen peroxide and 0.05% sodium fluoride as an adjuvant to normal oral hygiene prevented the increase in gingival indices and bleeding tendency scores seen in the control group that used 0.05% sodium fluoride only.[12] In a short-term study (7 days) with no tooth brushing, 1.5% hydrogen peroxide, used as a mouth rinse or in an oral irrigator, was of no therapeutic value in the prevention or the treatment of experimental gingivitis.[50]

Antiplaque and antigingivitis claims have been made for some commercial products, but because of their rapid breakdown in the presence of organic material and bacterial catalase, their effects are at best transient. The oxygenating cleansers approved by the FDA for over-the-counter use include (1) hydrogen peroxide, 3%, applied full strength or diluted to half-strength for use as an oral rinse; (2) carbamide peroxide, 10% to 11%, applied directly or swished as a rinse; and (3) sodium perborate monohydrate, 1 to 2 g in 30 mL of warm water, as an oral rinse. These products should not be swallowed. Occasionally, patients have oral ulceration after frequent use (three times per day) of 3% hydrogen peroxide mouth rinse.[78]

Morpholino Compounds

Delmopinol is a morpholino-ethanol compound (2-[3-(4-propylheptyl)morpholin-4-yl]ethanol) that acts as a cationic surfactant and prevents the attachment and the adherence of plaque bacteria to the tooth surface (Figure 45-6). The hydrochloride salt is marketed in the United States as a 0.2% oral rinse, and this is the first mouth rinse that the FDA has approved as a device.[47]

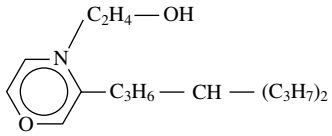

FIGURE **45-6** Structural formula of delmopinol.

In two long-term supervised studies (6 months), delmopinol (0.2%), when used as a 60-second rinse twice a day (as a supplement to normal mechanical oral hygiene), reduced plaque, gingivitis, and bleeding sites compared with a placebo rinse, but caused significantly greater staining of the teeth and transient anesthesia of the oral mucosa.[44,56] In both studies, chlorhexidine was more effective than delmopinol in limiting plaque formation and gingivitis, but was considered less tolerable by the patients because of the tooth discoloration. A later review of a pooled analysis of eight clinical studies, in which patients rinsed with 0.2% delmopinol with and without supervision, found a 20% reduction in plaque and an 8% reduction in gingival inflammation (i.e., bleeding on probing) when delmopinol was compared with placebo controls.[1] Local side effects reported from the pooled studies included modest staining of tooth and tongue, transient anesthesia of the tongue, disruption of taste, and infrequent mucosal soreness and erosion.[1] Oral rinses of 0.2% delmopinol are well tolerated and effective in preventing the accumulation of dental plaque.

Table 45-1 summarizes information on antiplaque agents. Some proprietary sources of antimicrobial agents are listed in Table 45-2.

Photodisinfection

Photodynamic disinfection is a nonantibiotic therapy for the treatment of a broad spectrum of bacterial, fungal, and viral infections. In the oral cavity, a photosensitive compound can be used to destroy microorganisms within the periodontal pocket without the use of antibiotics or antiseptics. In a simple, two-step process, methylene blue is added to the subgingival biofilm where it selectively binds to periodontal pathogens. The second step is the excitation of methylene blue (Figure 45-7) with a nonthermal diode laser at a wavelength of 670 nm. The energy gained by methylene blue allows it to react lethally with the microorganism via a redox reaction or the formation of highly reactive oxygen species. This form of photodynamic action has been shown to inactivate bacterial virulence factors and disrupt selectively the bacterial membranes of a wide range of periodontal pathogens.[52,110] Preliminary clinical studies have shown that photodisinfection in combination with scaling and root planing can lead to statistically significant improvements in periodontal probing depths, clinical attachment levels, and inflammation compared with scaling and root planing alone at 12 weeks after therapy.[4]

Systemic Antibiotics

Although some human studies have shown plaque reductions after administration of penicillin and erythromycin, enterally and intravenously administered antibiotics are not indicated for control of oral biofilms. The principal reasons for not typically using systemic antibiotics for the control of supragingival or subgingival biofilms is that local infections can be addressed directly by the individual or dentist, and antibiotic administration would require daily application with increased risk of potentially serious drug side effects and the emergence of drug-resistant microorganisms.

TABLE **45-1**

Comparison of Antiplaque Agents

ACTIVE AGENT	CONCENTRATION (%)	PHARMACOLOGIC ACTIONS	HOW DISPENSED	EFFECT ON PLAQUE*	EFFECT ON GINGIVITIS*
Chlorhexidine	0.12	Disrupts cell membranes; precipitates intracellular proteins	Prescription	↑↑↑	↑↑↑
Delmopinol hydrochloride	0.2	Prevents attachment and adherence of bacteria to tooth surface	Prescription	↑↑	↑
Stannous fluoride	0.454	Suppresses select bacterial enzymes and alters bacterial aggregation	Over-the-counter	↔	↑↑
Thymol†	0.064	Suppresses bacterial enzymes	Over-the-counter	↑	↑
Triclosan	0.3	Inhibits enoyl-acyl carrier protein reductase; reduces type II bacterial fatty acid synthesis and lipid synthesis	Over-the-counter	↑↑	↑↑

*Effect: ↑↑↑ = significant; ↑↑ = moderate; ↑ = modest; ↔ = none.
†Antiseptic rinses also contain eucalyptol, methyl salicylate, and menthol.

TABLE **45-2**

Antimicrobial Agents Used in Proprietary Mouth Rinses, Toothpastes, and Oral Products

TYPE	AGENT	PROPRIETARY (TRADE) NAMES
Phenolic compounds	Phenol	Chloraseptic, Phenaseptic, Cepastat
	Thymol	Listerine, generic antiseptic products
Nonionic bisphenols	Triclosan	Colgate Total
Oxygenating agents	Sodium peroxyborate	Amosan
	Carbamide peroxide	Gly-Oxide
	Hydrogen peroxide	Peroxyl, Orajel Perioseptic Rinse
Quaternary ammonium compounds	Cetylpyridinium chloride	Cepacol, Anitbacterial Mouthwash Gold, Scope, Viadent Advanced Care
	Domiphen bromide	Scope
Fluoride	Stannous fluoride	Proctor & Gamble Crest Pro Health
Morpholino compounds	Delmopinol hydrochloride	Decapinol
Bis-biguanides	Chlorhexidine	Peridex, PerioGard, generic chlorhexidine products

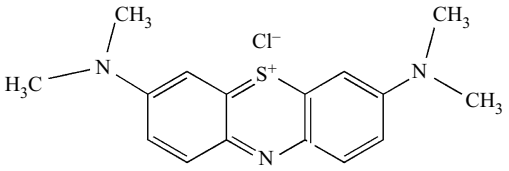

FIGURE **45-7** Structural formula of methylene blue.

Local Drug Delivery of Anti-infective Agents

Controlled drug delivery in the mouth allows sustained local availability of high concentrations of chemotherapeutic agents, such as tetracyclines (minocycline, doxycycline), chlorhexidine, or metronidazole. Intraperiodontal pocket devices permit the release of agents into the crevicular fluid at bactericidal concentrations, while avoiding wasteful and potentially toxic systemic administration. Local delivery devices, originally consisting of drug-filled cellulose hollow fibers containing tetracycline, were pioneered by Goodson and colleagues in the late 1970s.[32] In the past 35 years, improved products have been developed and marketed (Table 45-3), such as Actisite (nonresorbable monolithic fiber of ethylene-vinyl acetate impregnated with tetracycline), PerioChip (bioabsorbable wafer of cross-linked gelatin containing 2.5 mg of chlorhexidine), Arestin (bioresorbable polymer microspheres containing 1 mg of minocycline), Atridox (bioabsorbable polymer gel containing 42.5 mg of doxycycline hyclate), and Elysol (glycerol mono-oleate and sesame oil containing 25% metronidazole).

The FDA has approved Actisite, PerioChip, and Arestin as adjuncts to scaling and root planing. Atridox has FDA approval as a stand-alone therapy for the reduction of probing depths, bleeding on probing, and gain of clinical attachment. Although Actisite was the first of the controlled-release antimicrobial products to be made commercially available in 1994, it is no longer marketed. Because it was nonresorbable, it needed to be removed at the end of therapy. It was also time-consuming and tedious to insert into pockets and had a tendency to dislodge. Elysol is not available in the United States; it is marketed in Asia and Europe.

The pharmacokinetics of release of all these products indicates antimicrobial concentrations at levels in excess of the minimum inhibitory concentrations for periodontal pathogens.[33,77] A meta-analysis of relative effects on probing depth reduction from studies comparing scaling and root planing plus local sustained-release agents with scaling and root planing alone have shown statistically significant probing depth reductions with adjunctive use of minocycline gel and microencapsulated minocycline, whereas gains in clinical attachment levels were observed only with chlorhexidine chip and doxycycline gel.[42] Their efficacy in clinical studies is similar, with an average greater reduction of 0.5 mm or less in probing pocket depth compared with scaling and root planing alone.[23,48,72,98,109]

TABLE **45-3**

Controlled Local Drug Delivery Products

PRODUCT	RESERVOIR ACTIVE INGREDIENT	AMOUNT	DESCRIPTION	FDA APPROVED	DURATION
Actisite	Tetracycline	0.55 mg/cm of filament, 12.7 mg/dose	Nonresorbable ethyl-vinyl acetate monofilament	Yes, but no longer available in U.S.	>240 hr
Arestin	Minocycline	1 mg/dose	Biodegradable polyglycolide-lactide polymer microspheres	Yes	>14 days
Atridox	Doxycycline	42.5 mg/dose	Biodegradable polymer	Yes	>7 days
Elysol	Metronidazole	25%	Bioresorbable glyceryl mono-oleate + sesame oil gel	No, sold only in Europe, Asia	<12 hr
PerioChip	Chlorhexidine	2.5 mg/dose	Bioabsorbable cross-linked gelatin wafer	Yes	>200 hr

FDA, U.S. Food and Drug Administration.

Some authors consider the clinical benefits of most slow-release devices, even when showing statistical significance, as not impressive and do not recommend their routine use.[77] Local delivery systems have potential limitations and benefits. If used as a monotherapy (e.g., Atridox),[30] problems can include failure to remove calculus. The benefits include the ease of application, selectivity in targeting a few diseased sites that were unresponsive to conventional therapy, and possible enhanced treatment results at specific locations.[3] Limited data also suggest that local delivery of anti-infectives may be beneficial in preventing recurrent attachment loss in the absence of maintenance therapy. Because of the limited efficacy of these agents in clinical studies of periodontal parameters, ultimately the choice may hinge on an agent's handling characteristics.

LIMITATIONS OF TOPICAL ANTIMICROBIAL THERAPY

After reviewing specific chemotherapeutic agents, several problems common to their general use need to be considered. Effective therapy requires that an adequate amount of the drug remain at the plaque site long enough for the drug to exert a therapeutic effect. This principle has been largely ignored by many who have tried to prevent or treat bacterial infections of tooth surfaces with antimicrobial agents. Most compounds have been tested as topical agents in vehicles such as mouth rinses, dentifrices, chewing gums, and gels, all requiring repeated application.[104] Investigators have usually performed these studies without knowing the concentration of the drug necessary to inhibit the growth of the odontopathic plaque microorganisms. Such highly empiric modes of administration may not accurately reflect a given drug's therapeutic potential. As might be expected, the results have been variable.

In most cases, in vitro tests have been conducted on planktonic plaque organisms (freely floating in a tube of culture medium) to determine the minimum inhibitory and bactericidal concentrations of an active agent used in topically applied products.[71] Although these measurements provide important information about the antimicrobial spectrum and potency of a formulation, by themselves they are not predictive of clinical effectiveness.[7] This is because plaque microbiota exist not just as planktonic organisms in saliva, but as a biofilm of densely packed bacteria, often in an extracellular matrix. Biofilm experiments indicate that the necessary minimum inhibitory concentrations of antimicrobial agents are at least 50 times higher than for bacteria growing under planktonic conditions.[77] Laboratory tests with biofilm models have been developed that may be more predictive of clinical effectiveness.[93] Such tests still do not include potential interactions, however, between salivary components or other oral hygiene products and the active ingredient. Such interactions can be tested only by a clinical trial.

A relationship between dental plaque accumulation and gingivitis has been well established by the gingivitis that develops when volunteers cease all oral hygiene.[62] In general, when such subjects resume cleaning their teeth, the gingivitis resolves. In studies in which various mouth rinses or dentifrices are used as the vehicle to deliver chemotherapeutic agents, a reduction in plaque scores is not always accompanied by a parallel decrease in the gingival index, however.[100] No convincing evidence supports a linear relationship between the quantity of plaque and the extent of oral disease.[53] There are three explanations for this apparent paradox.

First, plaque scoring does not consider the specific periodontal pathogenic components of that plaque. Second, the indices that have been used for measuring oral hygiene are based on plaque surface area score[36,76] or on plaque thickness[96] and depend on the amount of plaque on the buccal or lingual surfaces. They do not emphasize fissure or interproximal plaque, although a modification of the Navy plaque index has attempted to give more emphasis to interproximal areas.[81] Similarly, the plaque thickness index[96] can be adapted to score interproximal areas. Third, current plaque indices do not consider subgingival extension, only supragingival sites. Most of these standard methods for measuring the efficacy of chemotherapeutic antiplaque agents ignore the sites that are most likely to be involved in periodontal diseases and caries.

Another important problem in the topical use of chemotherapeutic antiplaque agents is their continuous dilution and elimination by saliva. Even if the minimum inhibitory concentration of a drug were initially used, rapid clearance from the oral cavity may prevent maintenance of an effective concentration. The failure or limited success of many agents in preventing caries or periodontal diseases can be attributed to their transitory presence in the mouth. It is not that they cannot kill plaque microflora or hydrolyze plaque matrices; many of them do so in the test tube. It is primarily a problem of effective delivery. To overcome this limitation, agents with substantivity have been sought. Investigators have explored the use of controlled-release devices for delivering chemotherapeutic drugs into the periodontal pocket, overcoming the problem of salivary dilution. The agent either is embedded in a polymer matrix that permits gradual local release for days or weeks after insertion or is incorporated into a biodegradable

matrix. Extensive animal and clinical trials are necessary to determine which drugs and concentrations would be most effective.

Not all mouth rinses used to control plaque and gingivitis can be used by all individuals. More specifically, alcohol, which is important in placing ingredients into solution, can have disadvantages for the patient to use. Most mouth rinses contain alcohol at a concentration of 5% to 27%, to dissolve active (e.g., chlorhexidine, essential oils) and many inactive (e.g., flavoring agents) ingredients to prevent their separation or precipitation. When alcohol is present, it can be potentially toxic to young children[46,99] or possibly tempt alcoholics who accidentally swallow the mouth rinse.[24] Alcohol-containing mouth rinses can affect many types of dental materials (e.g., composite resins, glass ionomer cements) used in the oral cavity.[40,108]

FUTURE DIRECTIONS

Today, prevention of periodontal disease and dental caries is achieved most effectively and principally through mechanical plaque control; however, a dentition free of supragingival and subgingival biofilm is extremely difficult to accomplish and to maintain. On an annual basis, Americans spend more than three quarters of a billion dollars on oral rinsing agents, although few effective, plaque-inhibiting oral rinses are available at this time, and many are associated with side effects that prohibit long-term use.

The goal of future product development is not so much an improvement in the antiplaque performance of the existing, effective compounds, but rather a lessening of their side effects and a development of better delivery systems. Products that combine various known compounds with well-established plaque-inhibiting properties are currently under investigation. In the future, chemoprevention of supragingival biofilm will depend on products that are effective, substantive, and safe.

CHAPTER 46

Antiseptics and Disinfectants

JOHN A. MOLINARI

The historical importance for routine infection control procedures was underscored by epidemiologic investigations and other scientific evidence in the 1970s and 1980s. It was estimated at that time that an office treating 20 patients a day would encounter one active carrier of hepatitis B virus (HBV) every 7 days.[9] This early finding, coupled with the fact that most microbial infections, including those caused by HBV, hepatitis C virus (HCV), and human immunodeficiency virus (HIV), can be infectious before distinct signs and symptoms appear, makes the likelihood of unknowingly treating an infectious patient a certainty. Failure to treat every patient as potentially infectious—that is, with *standard precautions*, previously termed *universal precautions*—places the health care worker and all patients at needlessly increased risk of infection.[5,7]

The overall goals of infection control programs are as follows: (1) to reduce the numbers of pathogenic microorganisms to levels where patients' normal defense mechanisms can prevent infection, (2) to break the cycle of infection and eliminate cross-contamination, (3) to treat every patient and instrument as capable of transmitting infectious disease, and (4) to protect patients and health care workers from infection and its consequences.[7,15] The proper use of barrier techniques (gloves, mask, gown, eye protection, rubber dam), proper sterilization, disinfection, and antisepsis protocols accomplishes these goals.

It is important at the beginning of this chapter to understand the differences between the terms *sterilization*, *disinfection*, and *antisepsis*.[8,28] *Sterilization* is the ultimate goal of any infection control protocol because it is the killing of all forms of microorganisms. To eradicate resistant viruses and bacterial endospores effectively requires the application of high heat or chemicals or both for a sufficient time. The most widely used means of attaining this objective in a dental office are dry heat, steam, and chemical vapor sterilization units. In medicine and industry, sterilization includes ethylene oxide and formaldehyde gases, ultraviolet and gamma radiation, and filtration. *Disinfection* is the application of chemicals to destroy most pathogenic organisms on inanimate surfaces. Although some chemicals used for disinfection are capable of achieving sterilization given sufficient time of exposure, their use to effect sterilization is discouraged because of the number of conditions that can lead to failure in this application. *Antisepsis* is the use of chemicals to destroy or inhibit pathogenic organisms on skin or living tissue. The difference between disinfection and antisepsis may seem small, but it leads to a wide divergence in the products used and the regulation of the products. Disinfectants fall under the regulatory authority of the U.S. Environmental Protection Agency and are subject to that agency's rules for demonstration of effectiveness and use in the workplace. Antiseptics, because they are intended for application on living tissue, fall under the regulations of the U.S. Food and Drug Administration (FDA) regarding effectiveness and clinical use.

Numerous treatment area surfaces can become contaminated with saliva, blood, and other potentially infectious substances during provision of care. The routine use of chemical disinfectants and disposable supplies has become historically more appropriate in certain instances because it is neither possible nor necessary to sterilize all contaminated items or surfaces. This trend is especially applicable in dentistry, where many instruments and environmental surfaces become contaminated with saliva and blood during routine procedures.[8,9] Organisms contained in these fluids include staphylococci, streptococci, *Mycobacterium tuberculosis*, cytomegalovirus, herpes simplex virus (HSV), HBV, HCV, HIV, and a number of upper respiratory tract viruses such as influenza and rhinoviruses. Environmental surfaces in particular do not lend themselves to sterilization and must be cleaned and disinfected or covered with disposable barriers.[5,7,11]

Before selecting an environmental surface disinfectant, products under consideration should be compared with criteria for an ideal disinfectant. These criteria are as follows: The disinfectant should have the widest possible antimicrobial spectrum, including the ability to kill the vegetative form of all pathogenic organisms. The chemical agent should be able to remain active in the presence of organic matter (i.e., blood, saliva, sputum). It should be inexpensive, odorless, effective at room temperature, noncorrosive, nonstaining, nontoxic to humans, and require a short time of exposure. Given the numerous similarities in chemical composition and metabolism between humans and microorganisms, this ideal is unlikely to be achieved. In practice, however, proper use of available chemical disinfectants reduces the numbers of viable pathogenic organisms on surfaces to levels that allow a healthy person's natural defenses to prevent infection.

The ideal antiseptic would have properties similar to those of an ideal disinfectant. Selective toxicity to microorganisms but not to human cells is of primary importance for antiseptics. The degree of selectivity of the antiseptic agents can vary depending on the tissues with which they come in contact. An antiseptic intended for handwashing can be less selective than one used in an oral rinse because the highly keratinized epithelium of the skin affords a greater degree of protection from the antiseptic than does the oral epithelium.

Various antiseptics and disinfectants can be classified according to mechanism of action: agents that denature proteins, agents that cause osmotic disruption of the cell, and agents that interfere with specific metabolic processes. Agents that cause protein denaturation or osmotic disruption tend to kill the organisms and are described as bactericidal, virucidal,

TABLE **46-1**

Antimicrobial Activity of Different Classes of Disinfectants and Antiseptics

CLASS OR AGENT	GRAM-POSITIVE BACTERIA	GRAM-NEGATIVE BACTERIA	BACTERIAL SPORES	TUBERCLE BACILLI	VIRUSES		FUNGI
					HBV	HIV	
Halogens	+	+	±	±	+	+	+
Aldehydes	+	+	+	+	+	+	+
Phenols	+	+	–	+	–	+	+
Alcohols	+	+	–	+	±	+	±
Chlorhexidine	+	+	–	–	–	+	±
Surface-active agents							
Anionic	+	–	–	–	–		–
Cationic	+	±	–	–	–		+
Oxidizing agents	+	+	+	+	+	+	+
Heavy metals	+	±	–	–	±		+

HBV, Hepatitis B virus; *HIV,* human immunodeficiency virus.

TABLE **46-2**

Characteristics of Common Chemical Disinfectants

AGENT	ACTIVITY	LIABILITIES
Chlorine dioxide	Rapid disinfection activity; can be used for sterilization with 6 hr of exposure	Corrosive; activity greatly reduced in the presence of protein and organic debris; requires good ventilation
Glutaraldehyde	As 2%-3.2% immersion preparation, broad-spectrum antimicrobial activity; sporicidal after 10 hr of contact; long use life	Very irritating to skin and mucous membranes; allergenic with repeated exposures
Hypochlorite	Rapidly acting, broad-spectrum bactericidal, sporicidal, virucidal disinfectant	Irritating to skin; corrosive; can degrade some plastics
Iodophors	Rapidly acting, broad-spectrum bactericidal disinfectant; residual antimicrobial activity remains on surface after drying	Corrosive to some metals; may discolor some surfaces; inactivated by hard water
Phenols	Broad-spectrum antimicrobial activity; effective in presence of detergents	Can degrade plastics; irritating to skin and eyes; inactivated by hard water and organic debris

or fungicidal in nature. Interference with specific metabolic processes usually affects cell growth and reproduction without killing the cell, causing a bacteriostatic/virustatic/fungistatic effect.

Table 46-1 lists representative classes of compounds used as disinfectants or antiseptics with their effectiveness against various representative organisms. The aldehyde and certain halogen-based and oxidizing compounds have the broadest range of effectiveness. These agents also tend to be the most toxic to human tissue. Consequently, their use has been primarily limited to disinfection. The other chemical classes are less effective antimicrobial agents, but also tend to be less harmful to human tissue and find use as disinfectants and antiseptics. Some distinguishing features of the chemical groups are listed in Table 46-2, and their major clinical uses are noted in Table 46-3.

HALOGENS AND HALOGEN-RELEASING COMPOUNDS

Halogens and halogen-releasing compounds include some of the most effective antimicrobial compounds used for disinfection and antisepsis. Their primary mode of action seems to depend on the free halogen reacting covalently with key

TABLE **46-3**

Miscellaneous Uses of Disinfectants and Antiseptics

AGENT	FORMULATION (WEIGHT/VOLUME)	USE
Alcohol	70%	Solvent and adjuvant for other agents; prevention of bedsores
Parachlorophenol	Variable	Root canal debridement
Phenol	0.5%-1.4%	Relief of sore throat
Eugenol	Variable	Relief of pulpal pain
Guaiacol	Variable	Relief of pulpal pain
Sodium hypochlorite	5% solution	Root canal debridement
Iodine solution	8%-9% iodine	Plaque-disclosing solution
Povidone-iodine	Solution with 1% available iodine	Plaque-disclosing solution
Formaldehyde	4% (10% formalin)	Fixative for tissue biopsy specimen
Hydrogen peroxide	3% 30%	Wound cleaning Tooth bleaching

microbial enzyme systems.[10] Despite many years of research and use, the exact mechanism is unknown, although reactions with sulfhydryls and disulfides within proteins seem to be the most likely sites of action. Chlorine and iodine have historically been the most useful and effective halogens.

Chlorines

The salts (Na^+, Ca^{++}, and Li^+) of hypochlorite, in the form of chloride lime, have been used since the mid-1800s as a source of chlorine for disinfection and as an antiseptic. Because of the irritating nature of sodium hypochlorite formulations, they are currently used primarily as disinfectants. This halogen primarily functions as an antimicrobial in the form of hypochlorous acid, into which it is rapidly converted in water. Elemental chlorine is a potent germicide and kills most bacteria in 15 to 30 seconds at concentrations of 0.10 to 0.25 ppm.[10] The presence of a base in commercial preparations of sodium hypochlorite helps to stabilize the hypochlorite, which first must be converted to hypochlorous acid before it can release the chlorine. Useful dilutions for surface disinfection range from 1:10 to 1:100 in water, with exposure times of 10 to 30 minutes.[5] Sodium hypochlorite surface disinfectants have an efficacious, broad antimicrobial spectrum dating back to the 1970s, when a 1:10 dilution of bleach in water was shown to be effective against HBV in hospitals. Disadvantages of bleach solutions include a strong tendency to corrode metals, an odor that some people find offensive, and the need for diluted disinfectant solutions to be prepared fresh daily. Current commercially available diluted hypochlorite disinfectants are more stable and remain active longer than earlier formulations. In addition, even though they are destroyed during disinfection, tubercle bacilli seem to be more resistant to hypochlorite compared with other common pathogens.[25]

Iodine and Iodophors

Iodine compounds have a long infection-control history as antiseptics and disinfectants. Iodine is relatively nontoxic and noncorrosive; it is not inhibited by the presence of organic compounds, and it possesses a broad spectrum of activity. Iodine makes a nearly ideal antimicrobial agent. Originally used as elemental iodine (with potassium iodide or sodium iodide added for increased solubility) in aqueous solutions or in tinctures (alcohol solutions), iodine has the disadvantages of discoloring skin and other material, having an odor, and being painful on open wounds.

The development of iodophors—iodine or triiodide complexed with natural polymers such as polyvinyl pyrrolidone or polyether glycols—led to the application of iodine-containing preparations as antiseptics and surface disinfectants. One of the reasons for this application is their additional capability as surfactants, allowing them to be used as excellent cleaning agents. Iodophors have little or no odor, increase the solubility of iodine, are less allergenic than tinctures of iodine, reduce discoloration of surfaces, and provide a reservoir for sustained halogen release. Compared with aqueous solutions with the same total iodine concentration, the concentration of free molecular iodine (the active antimicrobial agent) is lower in iodophor preparations. This liability is offset by the release of iodine from the polymer complex as the free iodine, which reacts with microorganisms. When used with a spray-wipe-spray technique, iodophor disinfectants are efficient cleaning agents and effective surface disinfectants.[8,28]

Iodophors are also widely accepted as antiseptics for hand hygiene. The combination of iodine with water-soluble carrier molecules offers unique advantages for routine hand and surgical washing by prolonging the release of halogen to epithelial tissues and reducing skin irritation resulting from frequent wash procedures. Active iodine that is released from the surfactant also increases tissue permeability and has a residual antimicrobial effect.

The combination of sodium chloride with sodium bromide has been introduced within the last few years and has proved to be an effective, broad-spectrum, tuberculocidal surface disinfectant. The active ingredients are prepared separately in tablet form (one containing sodium chloride and the other containing sodium bromide). When the tablets are dissolved in water, the resultant solution provides an appropriate broad-spectrum antimicrobial effect and is compatible with most dental equipment surfaces.

ALDEHYDES

Glutaraldehyde (1,5-pentanedial) was first proposed as an antimicrobial in the early 1960s, and achieved wide use in dentistry and medicine as an immersion disinfectant.[29] The antimicrobial action seems to be the result of the cross-linking of microbial proteins. Glutaraldehydes are not significantly affected by the presence of organic material.[16] In health care facilities, caution must be used with glutaraldehyde because repeated exposure of skin and mucous membranes can cause sensitization, irritation, and damage. At least 10 cases of occupational asthma have been reported from the use of glutaraldehydes, which underscores the importance of using them only in well-ventilated areas and never using glutaraldehyde as a surface disinfectant.[11]

Marketed primarily as alkaline 3.2% aqueous solutions, glutaraldehydes can retain activity against tubercle bacilli, spores, viruses, and fungi when stored for 30 days after activation. Activation occurs by alkalization of the glutaraldehyde solution. Alkalization also can reduce the stability of the solution, however. The reuse life of a glutaraldehyde solution (i.e., the length of time the solution remains effective when challenged by dirty instruments, dilution, and evaporation) may be considerably shorter than 30 days.[23]

The use of glutaraldehyde in dentistry as a "cold sterilant" has declined considerably in recent years. The most recent *CDC Guidelines for Infection Control in Health-Care Settings—2003* discouraged processing heat-sensitive semicritical items using chemical sterilization.[7] At best, its use should be limited to the few instruments and small items that should be sterilized but cannot withstand the high heat required by sterilization methods available in a dental office. Such use requires initial cleaning of the item to remove contaminating bioburden, prolonged (i.e., 6 to 10 hours) immersion in the solution, and a terminal thorough rinse with sterile water to remove all glutaraldehyde from the sterilized material.

PHENOLS AND RELATED COMPOUNDS

Lister introduced a simple phenol (i.e., carbolic acid) as an all-purpose surgical disinfectant and antiseptic into hospitals in the mid-1850s, but its irritating and toxic nature led to its replacement by numerous substituted phenolic compounds. These substitutions have increased the antimicrobial effect of phenol without significantly increasing its human toxicity. Later generations of phenolic compounds also have been shown to be effective as handwash antiseptics and disinfectants in health care settings.

A few historically important phenolics exhibited a local anesthetic effect, making them useful antiseptics particularly when pain is associated with infection. In general, the phenols have the advantage of retaining their antimicrobial effectiveness in the presence of organic material, which makes them useful when the complete removal of tissue and debris is impossible or impractical. Cresol, the active ingredient in

coal-tar disinfectants, is a mixture of the three isomers of methylphenol. It has 3 to 10 times the antimicrobial activity of phenol but approximately the same human toxicity. Mixtures of cresol with detergents formed by the saponification of various vegetable oils have been used as surface disinfectants since the early 1900s.[14] The original proprietary formulation of Lysol was a 50% mixture of cresol in saponified vegetable oil.

Eugenol (2-methoxy-4-allylphenol) and guaiacol (*o*-methoxyphenol) have weak antimicrobial activity, but are useful for their rapid analgesic properties. Eugenol remains a common component in many sedative pastes used in dentistry and is the active phenolic component in oil of cloves. Prolonged contact of eugenol with tissue, as when sealed in a root canal preparation, can lead to severe tissue damage without pain, however, because of the agent's analgesic properties.[4] The use of eugenol in dentistry has dramatically declined in recent years because of its potential for allergic sensitization with repeated exposure.

Bisphenols include numerous phenolics, which have primary usage as handwash antiseptics. These include hexachlorophene, chlorhexidine gluconate, and parachlorometaxylenol. This class of agents, especially hexachlorophene (2,2′-methylene-bis[3,4,6-trichlorophenol]), proved to be effective antimicrobials a few decades ago when used with detergents. Hexachlorophene was shown to accumulate on the skin with repeated use, reaching a maximal level in 3 to 4 days, at which time the resident bacterial count on the skin was reduced by 95% to 99%. It was shown to be most effective against gram-positive organisms, which constitute the most common components of the bacterial skin flora and remain major potential pathogens for cross-infection. The substantivity and effectiveness of hexachlorophene made it a widely used component in surgical soaps. Over-the-counter soaps containing greater than 0.1% hexachlorophene were banned by the FDA in the late 1970s, however, after clinical reports were published concerning their accumulation in scalp tissues of infants, cutaneous absorption, and neurotoxicity.[17]

Chlorhexidine gluconate (CHG) antiseptics (see Chapter 45) are among the most used and effective phenolic derivatives for hand hygiene. CHG is a cationic bis-biguanide whose antimicrobial activity derives from its attachment onto microbial cytoplasmic membranes, with resultant disruption of membrane function. Subsequent precipitation of intracellular contents ultimately leads to cell death.[6] Many different CHG handwash preparations are available. Although aqueous or detergent antiseptics containing 0.5% to 0.75% CHG show a greater antimicrobial effect than plain soap (i.e., anionic detergent), most health professional facilities that use CHG-containing products use more effective 2% to 4% CHG products.[20,21]

As shown in Table 46-1, the antimicrobial spectrum of CHG is maximal against gram-positive bacteria, with less activity against gram-negative bacteria and fungi. Only minimal activity, at best, is observed against *M. tuberculosis*. CHG's antiviral effectiveness in vitro is significantly better against enveloped viruses, such as HSV, HIV, and influenza, compared with nonenveloped viruses (i.e., rotaviruses, adenoviruses, and enteroviruses). Despite this finding, chlorhexidine has been shown to be an effective virucidal agent, with demonstrated in vitro activity against HSV, cytomegaloviruses, influenza viruses, parainfluenza viruses, and HBV within a 30-second exposure. Although CHG hand antiseptics exert their antimicrobial effects more slowly than alcohol-based formulations, CHG has a major functional advantage because it remains effective in the presence of blood. CHG and alcohol antiseptics have also been included in the same hand hygiene preparations, and shown to be effective, because of the observation that 0.5% to 1% CHG added to alcohol sanitizers can dramatically increase the residual activity of products containing only alcohol. Of major importance for this class of chemical is the fact that CHG hand antiseptics exhibit remarkable persistence by accumulating in epithelial tissues during the course of multiple handwashes throughout the day. This property is termed *substantivity* and is the result of the active chemical form accumulating in the epithelium, leaving a residual antimicrobial effect after each wash procedure.

In Europe, 0.2% solutions of chlorhexidine have been used as oral rinses since the 1970s.[13] The effectiveness of chlorhexidine in oral rinses results primarily from its substantivity. The cationic nature of chlorhexidine allows it to bind to hard and soft tissues within the oral cavity; it is released over time to provide a continuing bacteriostatic effect. Used twice daily, these solutions have been shown to be effective in reducing plaque formation and gingivitis.[1,3,22] The major side effects are staining of the teeth, an increase in calculus formation, and alteration in taste perception.

Parachlorometaxylenol (PCMX), also termed *chloroxylenol*, is a halogen-substituted phenolic compound that has found widespread use as an effective handwash antiseptic. Its antimicrobial activity against susceptible bacteria occurs from disruption of the microbial cell wall and enzyme inactivation. PCMX is more active than chlorhexidine as a broad-spectrum antiseptic because it is most effective against gram-positive bacteria, is less active against gram-negative organisms, and exerts some antifungal effects. Of special importance in health care settings is the ability of PCMX to kill *Pseudomonas* species. Because of its ability to penetrate epithelial surfaces, PCMX has been shown to be an effective alternative to chlorhexidine gluconate in many handwash preparations, with little reported allergic sensitization potential.[21]

Triclosan (2,4,4′-trichloro-2′-hydroxydiphenyl ether) has been used in antimicrobial soaps and investigated in numerous mouth rinses and dentifrices as an antiplaque agent.[19,22] This bacteriostatic antimicrobial has been added to soaps and other consumer products (i.e., toothpastes) in concentrations ranging from 0.2% to 2%. The chemical exerts its antimicrobial action at multiple sites on and in bacterial cells. It actions include affecting cytoplasmic membrane functions and synthesis of RNA, fatty acids, and proteins by binding with the carrier protein reductase. Triclosan is bacteriostatic and fungistatic, with a reasonably broad-spectrum range of antimicrobial activity with substantivity. A relatively low toxic effect on *Pseudomonas aeruginosa* strains diminishes some of its clinical usefulness, but its epithelial substantivity has allowed inclusion of triclosan in many medicated hand soaps, antiperspirants, and dentifrices. Although this chemical is included in numerous commercial formulations, triclosan is less effective than CHG, iodophors, or alcohol-based antiseptics at reducing bacterial counts on hands after a 1-minute handwash. The antimicrobial efficacy may also be affected by pH changes, and the presence of surfactants and emollients on epithelial tissues. In addition to its antimicrobial activity, triclosan seems to have a direct anti-inflammatory effect. This effect may result from the inhibition of a portion of the histamine cascade.[18]

As mentioned at the beginning of this section, carbolic acid was the first antimicrobial to have widespread use in hospitals as an antiseptic and a disinfectant. In addition to the later generations of phenolics discussed earlier, numerous phenolic compounds have found widespread use as environmental surface disinfectants.[14] The introduction and subsequent widespread use of phenolic surface disinfectants that are synthetic mixtures of two or three phenolic compounds have led to the commercial availability of numerous similar products. The phenols are chosen to act synergistically, yield-

ing a product that is a more effective disinfectant than a comparable concentration of its individual components. In addition, many synthetic mixtures are diluted with water before use, which enhances their cleaning effectiveness relative to alcohol-phenol–based products.[24] One common example is the combination of o-phenylphenol and o-benzyl-p-chlorophenol. These cidal antimicrobials act as cytoplasmic poisons by penetrating and disrupting cell walls, which triggers denaturation of intracellular microbial cell proteins. These phenolics are able to penetrate target microbial cells more intensely than many other antimicrobial chemicals, which can cause localized tissue damage if they accumulate onto intact skin. Because of this potential toxicity issue, most phenolic derivatives are primarily used as disinfectants, with the exception of bisphenols.[14]

ALCOHOLS

Alcohols (see Chapter 43), especially ethanol and isopropanol, have been used for many years as antimicrobials and as carriers for other water-insoluble antimicrobials such as iodine and phenols. Only a brief discussion is included here; the reader is directed to Chapter 43 for a more detailed description of alcohols as antimicrobials. Their low cost, rapid evaporation, and lack of residue make them useful for disinfecting inanimate objects. Their ability to denature and precipitate proteins greatly decreases their antimicrobial effectiveness in the presence of bioburden (blood and saliva), however, and they have a detrimental effect on dental equipment surfaces, such as leather-like chair coverings and plastic items. Precipitated proteins can coat microorganisms, protecting them from direct exposure to the destructive alcohols. The ineffectiveness of alcohols against many bacterial spores, viruses, and fungi further reduces their usefulness as disinfectants for surfaces or instruments.

The use of alcohols as topical antiseptics in addition to disinfection has also been documented for more than 100 years. The use of isopropanol, ethanol, or *n*-propanol in combination with other antimicrobials, such as chlorhexidine gluconate, iodine, or quaternary ammonium compounds, can effectively reduce bacterial concentration on hands.[2,21] Their rapid, broad-spectrum antimicrobial activity against gram-positive and gram-negative bacteria, tubercle bacilli, and a wide array of viruses is augmented by the fact that regrowth of bacteria on washed hands occurs slowly. In recent years, an increasing number of studies have investigated the clinical use of waterless, alcohol-based hand sanitizers in gel or rub delivery systems. These products were developed partly to overcome the longer times required for soap and water handwashing procedures and an observed lack of handwashing compliance by health care workers in clinical facilities. Investigations of these formulations in medical settings have shown them to be effective alternatives to washing unsoiled hands with soap and water or antimicrobial soap and water, along with improving health care professional compliance.[12,26,27]

SURFACE-ACTIVE AGENTS

Surface-active agents are compounds that produce a detergent effect because of their ability to interact noncovalently with membrane proteins and lipids. Anionic agents such as common soaps and dodecylsulfate phosphate detergents seem to be effective primarily because of their cleaning and emulsifying ability. Agents that possess specific antimicrobial activity are almost exclusively effective against gram-positive bacteria only.

Cationic agents, as exemplified by the quaternary ammonium compounds, were used for many years as cold sterilization solutions. Referring to them as sterilizing solutions was a grave misnomer because they are totally ineffective against bacterial spores, tubercle bacilli, many gram-negative bacteria, fungi, and viruses. Bioburden, hard water, and time reduce the effectiveness of these solutions against even gram-positive bacteria.[8,11] As a result of these limitations, the Council on Dental Therapeutics of the American Dental Association (ADA) eliminated these compounds in 1978 as disinfectants from the ADA's Accepted Product List. Despite these antimicrobial drawbacks, various surface disinfectant solutions and impregnated cloth wipes containing later generation quaternary ammoniums are marketed. These preparations are good cleaning agents and are often formulated with other antimicrobial agents that serve as the primary broad-spectrum disinfectants. Cetylpyridinium chloride, benzethonium chloride, and similar cationic agents are also used in mouth rinses (see Chapter 45) and sore throat remedies.

OXIDIZING COMPOUNDS

Hydrogen peroxide is the most common of numerous oxidizing compounds that have been used primarily as antiseptics in health care. Hydroxyl radicals released during decomposition of the parent molecule are believed to be responsible for the primary microbicidal effect. Concentrations potentially useful for antisepsis (e.g., 3%) are active against vegetative bacteria; higher concentrations (≥6%) are sporicidal. These agents are also referred to as oxygenating compounds because they release molecular oxygen. For many years, hydrogen peroxide has been marketed only as an antiseptic, although in addition to its antimicrobial activity, it serves as an effective debridement agent for treating soft tissue wounds and infections. Hydrogen peroxide yields high concentrations of antimicrobial hydroxyl radicals in tissues and target microorganisms, with adverse effects on bacterial membrane lipids, DNA, and other cell components. More recently, hydrogen peroxide environmental surface disinfectants have become available, with tuberculocidal activity.

In combination with sodium bicarbonate, hydrogen peroxide was advocated for use against the anaerobic bacteria prevalent in periodontal disease. The basis for this use was the assumption that the oxygen released by the peroxide would be toxic to the anaerobic bacteria. This was not true; the ubiquitous presence of peroxidase enzymes in the periodontal tissues and fluids quickly destroys any peroxide, resulting in little, if any, toxicity to the microorganisms present.

HEAVY METALS

Heavy metals, particularly mercury and silver compounds, have a long history as antimicrobial agents. Organic mercurials are still used in some countries as fumigants, but they have been replaced by more effective and less toxic compounds in dentistry and medicine. Silver nitrate was commonly used in dentistry to treat oral ulcers, but is no longer used because it delays healing and alters cellular morphology. In medicine, silver nitrate eye drops remain useful in the prophylaxis of gonococcal infection in newborns.

Tin, the stannous ion, is an effective antimicrobial. As a disinfectant, it is complexed with organic anions, forming triorganotins. The primary applications of these compounds are in industry and agriculture. In dentistry, stannous fluoride has become popular again as a fluoride source in dentifrices, particularly in dentifrices marketed for their effect on gingival health. The ability of tin to inhibit bacterial growth and

plaque formation supported its initial use in dentifrices and as a topical fluorine salt. Subsequently, problems with stability, taste, and staining led to its replacement for a time by sodium fluoride and monofluorophosphate as a source of fluoride in these products.

USES IN DENTISTRY

Many commercially available antiseptics and disinfectants continue to play important roles in accomplishing infection control goals. The dental team can do much to reduce the presence of pathogenic organisms and greatly enhance the potential for an uneventful recovery from dental procedures. Effective infection control protocols include thorough handwashing techniques with appropriate antiseptics, combined with appropriate barrier techniques (gloves, masks, eye protection, rubber dam), disposable covers for surfaces, disinfection of nonsterilizable surfaces and equipment, and heat sterilization of all compatible equipment. Disinfectants are an important tool in achieving effective infection control.

The range of antiseptics for home use in control of oral microorganisms, plaque reduction, and prevention of gingivitis has mushroomed in recent years. New prerinses, dentifrices, and mouth rinses appear every day using new antiseptic compounds and reformulations of old ones. These agents and their uses are considered in Chapter 45.

REPRESENTATIVE ANTISEPTICS AND DISINFECTANTS

Nonproprietary (generic) name	*Proprietary (trade) name*
Halogens and halogen-releasing compounds	
Chlorine-based	
Chlorine dioxide	Dent-A-Gene
Hypochlorite solution	Dispatch
Iodine-based	
Iodine solution	—
Iodine tincture	—
Iodoform gauze	Nu Gauze
Oxychlorosene	Clorpactin WCS-90
Povidone-iodine	Betadine, ACU-dyne
Miscellaneous iodophors	Biocide, Surfacide, Wescodyne
Aldehydes	
Formaldehyde	Formalyde-10
Glutaraldehyde	Banicide, Cidex 7, Cidex Plus, Multicide Plus, Omnicide, ProCide D, Sterall, Vital Defense-D
Phenols	
Combined phenols in 57% ethanol	Coe Spray II
Eugenol	—
Formocresol	Buckley's Formo Cresol
Hexachlorophene	pHisoHex, Septisol
Parachlorometaxylenol	Medical Lotion Soap
Phenol	Vicks Chloraseptic
o-phenylphenol and o-benzyl-p-chlorophenol	Birex SE, Multicide, Omni II, Vital Defense
Phenylphenol in 67%-79% ethanol or isopropanol	Lysol IC spray, MSD Surface Disinfectant
Triclosan	Septi-Soft, Septisol NPD, Stridex Face Wash
Alcohols	
Ethanol	Alcare, Alco-Gel
Isopropyl alcohol	Stat-One Isopropyl Rubbing Alcohol
Alcohols and quaternary ammonium compounds	
Aseptic wipes	Metriwipes, Discide Ultra Wipes, Sani-Cloths
Biguanides	
Chlorhexidine	Dyna-Hex, Hibistat, Hibiclens, Peridex, PerioGard
Surface-active agents (cationic)	
Benzalkonium chloride	Mycocide, Zephiran
Benzethonium chloride	Critic-Aid, Puri-Clens
Cetyldimethylethyl ammonium bromide	(Cetylcide-G)
Cetylpyridinium chloride	Cepacol
Cetyltrimethyl ammonium bromide	Cetrimide B.P., Cetavlon
Methylbenzethonium chloride	In Orasept
Oxidizing compounds	
Hydrogen peroxide	Stat-One Hydrogen Peroxide
Carbamide peroxide (urea peroxide)	Cankaid, Gly-Oxide, Proxigel
Heavy metals	
Organic mercurials	
Merbromin	Mercurochrome
Nitromersol	Metaphen
Thimerosal	—
Silver compounds	—
Silver nitrate	—
Silver protein	Argyrol S.S. 10%

CHAPTER 47

*Analgesic Use for Effective Pain Control**

PAUL J. DESJARDINS AND ELLIOT V. HERSH

Fear of pain is a significant reason why many people avoid seeking dental care. No matter how successful or how effectively performed, most dental surgical procedures produce tissue trauma and release potent mediators of inflammation and pain. In the past, postoperative pain was thought to be inevitable and harmless. We now know that unrelieved pain after surgery or trauma has negative physical and psychological consequences. Acute pain is often associated with a reactive anxiety and an increase in sympathetic nervous system activity, resulting in tachycardia, hypertension, diaphoresis, mydriasis, and pallor. A patient with severe tooth or jaw pain may avoid eating or drinking and may become malnourished and dehydrated. Severe chest, abdominal, or back pain may lead to shallow breathing and cough suppression in an attempt to "splint" the injured site, followed by retained pulmonary secretions and pneumonia.[19,37] Unrelieved pain may also delay the return of normal gastric and bowel function in a postoperative patient.[41] If managed aggressively, pain is preventable or controllable in most cases.

Undertreatment of pain is a significant medical problem. Numerous clinical surveys have shown that postoperative pain is often inadequately treated because of undermedication, leaving patients to suffer needlessly.[14,31] Recognition of the widespread inadequacy of pain management and the detrimental effects of untreated pain has led to corrective efforts in numerous health care disciplines involved with pain management. These efforts culminated in 1992, when the Agency for Health Care Policy and Research, a division of the U.S. Public Health Service, published its *Clinical Practice Guideline* for *Acute Pain Management: Operative or Medical Procedures and Trauma*.[2] This guideline represents the efforts of a multidisciplinary panel of expert clinicians and researchers. It provides an excellent framework for the care of patients with acute pain and includes a section on pain control specifically for dental surgery.

PAIN CLASSIFICATION

Successful treatment of painful conditions with analgesics requires a basic understanding of the relevant pathophysiology. Painful conditions can be divided into two basic categories—nociceptive pain and neuropathic pain—based on the condition's underlying pathophysiologic features. Nociceptive pain is a result of mechanical, thermal, or chemical activation of nociceptive afferent receptors and can be classified as either somatic or visceral in origin. Somatic nociception involves pathologic conditions of the skin, muscles, fascia, and bones and is well localized. Examples include the pain associated with traumatic injuries and pain after the completion of oral surgery procedures. In both conditions, inflammatory mediators sensitize or activate nociceptive receptors, resulting in transduction of the noxious stimulus into electrical and biochemical signals between neurons. The electrical signals are conducted to the brain for interpretation. Visceral nociceptive pain is poorly localized, may be referred to superficial somatic regions, and involves pathologic conditions in deep, visceral tissues. An example is angina resulting from myocardial ischemia, which can be referred to the jaw, neck, or arm.

Neuropathic pain is thought to be a result of aberrant somatosensory activity either in the peripheral nervous system or the central nervous system (CNS) (see Chapter 23). It is frequently characterized by paroxysmal shooting or electrical shock–like pains, often on a background of burning or constricting sensation. Examples of neuropathic pain encountered in the orofacial region include trigeminal neuralgia, burning mouth syndrome, and postherpetic neuralgia. Orofacial pain of neuropathic origin generally requires more sophisticated diagnostic testing and management; this sort of care is frequently available at specialized clinical practices.

Pain may also be characterized as acute or chronic based on its temporal and other characteristics. Acute pain frequently has a known cause, has identifiable tissue damage, responds to conventional analgesic therapy such as nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids, usually subsides as healing occurs, and has a predictable end point. Acute pain is associated with anxiety and the physiologic "flight or fight" responses of increased pulse, blood pressure, and respiratory rate. In contrast, chronic pain is of greater than 3 to 6 months' duration, and patients with chronic pain do not usually manifest the physiologic arousal seen with acute pain because the body has adapted to the pain state. These patients may exhibit, however, reactive depression and decreased function. Often, despite numerous diagnostic tests, the area where the pain seems to emanate appears normal or adequately healed, if there was an initial injury. The psychological aspects of the chronic pain syndrome can become so entwined with the patient's presentation of pain that these aspects must now also be adequately addressed to increase the likelihood of a successful treatment outcome.

PAIN ASSESSMENT

Successful assessment and control of pain depend partly on establishing effective communication between the dentist and the patient. Patients should be informed that pain relief is an

*The authors recognize Dr. Warren Vallerand for his past contributions to this chapter.

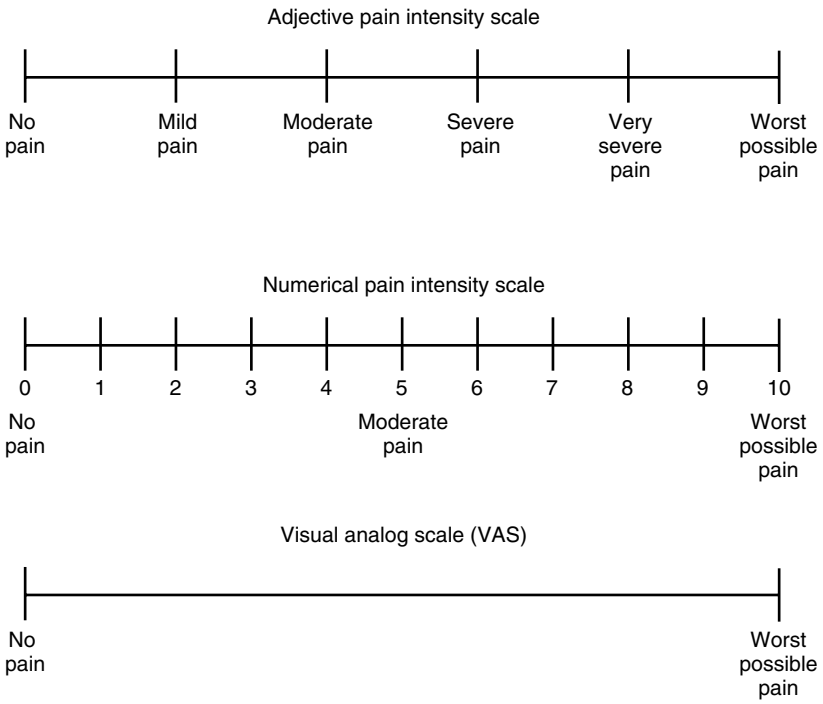

FIGURE **47-1** Pain intensity scales. A 10-cm baseline is recommended for the visual analog scale and for the other scales if used for graphic rating (i.e., linear measurement of patient responses).

important part of their health care. Because pain is a subjective phenomenon, the care provider must accept that the patient's self-report is the most accurate and reliable indicator of the existence and intensity of pain and any resultant distress.[2] This orientation is reflected in a commonly cited definition of pain: Pain is whatever the person experiencing it says it is and exists whenever he or she says it does.[27] Self-report measurement tools such as adjective or numerical rating scales or visual analogue scales can assist the patient in quantifying and characterizing the pain (Figure 47-1).

These tools are reliable, valid, and easy for the patient and the dentist or assistant to use. They may be administered by showing a diagram to the patient and asking the patient to indicate the appropriate rating. Some tools may also be used by simply asking the patient for a verbal response (e.g., "On a scale of 0 to 10, with 0 as no pain and 10 as the worst pain possible, how would you rate your pain?"). Patients who may have difficulty communicating require particular attention. This group includes patients who are cognitively impaired; psychologically or severely emotionally disturbed patients; young children; very old patients; and patients whose language, level of education, or cultural background differs significantly from that of the health care team.

Assessment of the patient's pain is a crucial part of the initial evaluation to estimate analgesic requirements. To determine the adequacy of the chosen analgesic regimen, the clinician must also assess pain intensity and pain relief at the peak of the analgesic effect and at regular intervals after the initiation of analgesic treatment.[9]

MISCONCEPTIONS REGARDING PAIN AND ANALGESICS

A significant barrier to the effective use of analgesics in managing pain involves several misconceptions regarding pain and analgesia held by patients and health care providers.

- *Misconception 1*: *Patients who are in pain always have observable signs*. Although many patients in acute pain exhibit evidence of anxiety, distress, or decreased function, many do not. Such overt pain behaviors also may not be seen at all in patients attempting to adapt to, and cope with, persistent pain. Expecting patients to display these pain behaviors and making the decision to dispense analgesics contingent on the display of these behaviors only serve to reinforce pain behaviors that may interfere with recovery. To treat the pain effectively, the clinician first must believe the patient's complaint of pain irrespective of the patient's physical presentation.
- *Misconception 2*: *Obvious pathology, test results, and the type of surgery determine the existence and the intensity of pain*. Although the ability to identify a pathologic process underlying a patient's pain complaint is a key element in planning and initiating definitive treatment, failure to identify the source of a patient's pain does not mean that it does not exist. Patients with chronic neuropathic pain frequently present such diagnostic challenges. As medical and diagnostic technology progresses, clinicians are better able to understand the mechanisms underlying disease processes that might have gone undiagnosed, or misdiagnosed, in the past. Failure to identify an organic source for a patient's pain does not mean that the pain does not exist.
- *Misconception 3*: *Patients should wait as long as possible before taking a pain medication because this period of abstinence teaches them to have a better tolerance for pain*. Pain that is untreated often escalates in severity and disability. Without treatment, sensory input from injured tissue reaches spinal cord neurons and causes subsequent responses to be enhanced. Pain receptors in the periphery also become more sensitive after injury. Studies have shown long-lasting changes in cells within the spinal cord pain pathways after brief painful stimuli.[7] These physiologic studies confirm long-standing clinical impressions that established pain is more difficult to suppress.[2,7,15] Aggressive pain prevention and control that occurs before, during, and after a painful event such as dental surgery can yield short-term and long-term benefits. Patients should be encouraged to use analgesics before pain becomes severe and difficult to control.

CHOICE OF ANALGESIC REGIMEN

Pharmacologic control of pain can be directed at any of three nociceptive processes: (1) initiation of impulses, (2) propagation of the impulses, and (3) perception of painful stimuli. NSAIDs are thought to act primarily at the site of initiation of nociceptive impulses. Although separating their anti-inflammatory effects from their analgesic effects is difficult, nonopioid drugs, such as salicylates, other NSAIDs, and cyclooxygenase (COX)-2 inhibitors, work predominantly in the periphery by preventing the synthesis and release of inflammatory mediators that sensitize nociceptive receptors to other algesic mediators, such as bradykinin, and to physical forces. More recent studies suggest that NSAIDs may also have central effects.[6,24] Acetaminophen has been shown to have analgesic and antipyretic properties, but it lacks significant anti-inflammatory effects. Acetaminophen seems to exert its effects in the CNS and in the periphery.[1,28,39]

Local anesthetics can be administered topically or parenterally to block the propagation of nerve impulses originating from nociceptive stimuli at a peripheral site so that they do not reach the spinal cord or brain. Administration of long-acting local anesthetics can have significant value in delaying the onset of pain after oral surgery procedures and decreasing the overall level of discomfort in the immediate recovery period. The systemic use of local anesthetics also has some use in the management of chronic pain.

Opioids decrease the perception of pain in the CNS. Opioid analgesics act in the CNS at receptors in the spinal cord, rostroventral medulla, and periaqueductal gray matter. These anatomic loci are considered important to the perception of pain (see Chapter 20). Laboratory studies have also identified and characterized opioid receptors in peripheral tissue. This finding has led to clinical studies that have identified opioids as contributors to antinociceptive responses in the peripheral nervous system.[22,29] Likewise, there has been a search for drugs that reduce the incidence of opioid peripheral side effects, most notably constipation, in patients taking these drugs for various types of pain.[4]

Analgesic Selection

Before initiating treatment with analgesics, the practitioner must choose a specific drug or drugs, each with its own route of administration, dose, and frequency. Given the myriad analgesics available, how does one select the most effective agent? It is important to analyze each situation and individualize the analgesic regimen to fit each patient's current condition best.

The cause of the pain, the pain severity, and the medical history of the patient are the most important pieces of information in choosing an analgesic regimen. Equally important, and often overlooked, is the patient's recent and past history of painful conditions and how they were treated. A patient who has had episodes of pain treated with analgesics in the past may be acutely aware of which analgesics are likely to be most effective in a new situation and which are not, so asking the patient which analgesic has worked best in the past and which he or she would prefer is appropriate. Some practitioners may be uncomfortable with this approach because they believe that it amounts to the patient dictating treatment and may arouse suspicion regarding drug-seeking behavior. The patient, however, should be considered the authority on his or her pain.[2] Unless the requested drug is inappropriate, the patient's judgment and preference should be taken into account. This strategy increases the likelihood of compliance with the prescribed regimen.

In considering the choice of analgesic, it is reasonable to estimate the degree of pain that might be anticipated after a certain procedure based on the clinical and personal experience of the practitioner and to base the choice of analgesic on that estimate. The empiric nature of this approach must always be kept in mind. Inadequate pain relief may indicate the need for an increase in dose, more frequent administration, or a different drug. A common misconception is that a given stimulus will produce the same amount of pain in different patients. No data support this assumption. Pain threshold and tolerance and analgesic requirements vary widely among patients.

Local anesthetics

In addition to providing the pain control required to carry out most operative dentistry or dentoalveolar surgery, local anesthetics may also decrease pain after treatment. The perioperative administration of a long-acting anesthetic agent (e.g., bupivacaine) as an addition to or substitute for an agent with shorter duration (e.g., lidocaine) can delay the onset of postprocedural pain after dental surgery. Even in the presence of general anesthesia, the administration of local anesthetic agents during oral surgery procedures significantly reduces the quantity of postoperative pain medications consumed.[15] Because of the potential for self-inflicted injury and a lack of relevant clinical data, long-acting agents are not recommended for use in children younger than 12 years. In the case of acute pulpitis pain, topical benzocaine 20% applied to the open tooth cavity and surrounding soft tissue seems to provide rapid and temporary pain relief.[18]

Nonopioid analgesics

The category of nonopioid analgesics is composed of various drugs (e.g., NSAIDs, COX-2 inhibitors, acetaminophen) that have a similar mechanism of action and share clinically important analgesic, anti-inflammatory, and antipyretic properties. These agents differ from opioid analgesics in the following ways: (1) there is a ceiling effect to the analgesia; (2) they do not produce tolerance or physical dependence; (3) they are antipyretic, which in the dental postsurgical setting is a disadvantage because this property can mask a sign of infection; and (4) they possess anti-inflammatory and analgesic properties except for acetaminophen, which has minimal anti-inflammatory activity. Pharmacologic management of mild-moderate dental and orofacial pain should begin, unless there is a contraindication, with a nonopioid analgesic drug. As a general rule, any analgesic regimen should include a nonopioid drug, even if pain is severe enough to require the addition of an opioid. Most controlled clinical trials in postoperative dental pain directly comparing full doses of aspirin, acetaminophen, ibuprofen, and other NSAIDs with oral doses of single-entity opioids such as codeine, 60 mg, or oxycodone, 5 mg, have shown the superiority of nonopioids in analgesic efficacy.

Nonopioids of the conventional NSAID or highly selective COX-2 class are most effective in treating postprocedural pain when given before the procedure or immediately after a short procedure, preventing the synthesis of prostaglandins that quickly follow the surgical insult. The delayed use of NSAIDs postoperatively inhibits the subsequent prostaglandin synthesis and provides analgesia, but it does not interfere with the effects of the prostaglandins already produced. Preoperative administration of NSAIDs or COX-2 inhibitors delays the onset of postoperative dental pain and lessens its severity and subsequent analgesic requirements (Figure 47-2).[10,11,13,21] A recommended strategy that takes advantage of these properties would be to administer a full therapeutic dose of an NSAID preoperatively and after the surgical procedure simply to dose "around-the-clock" for the first day or two, in an effort to prevent breakthrough pain.

NSAIDs all share a qualitatively similar side-effect profile. With the exception of true allergic reactions; bronchoconstriction in asthmatics (see Chapter 21); and prior gastroin-

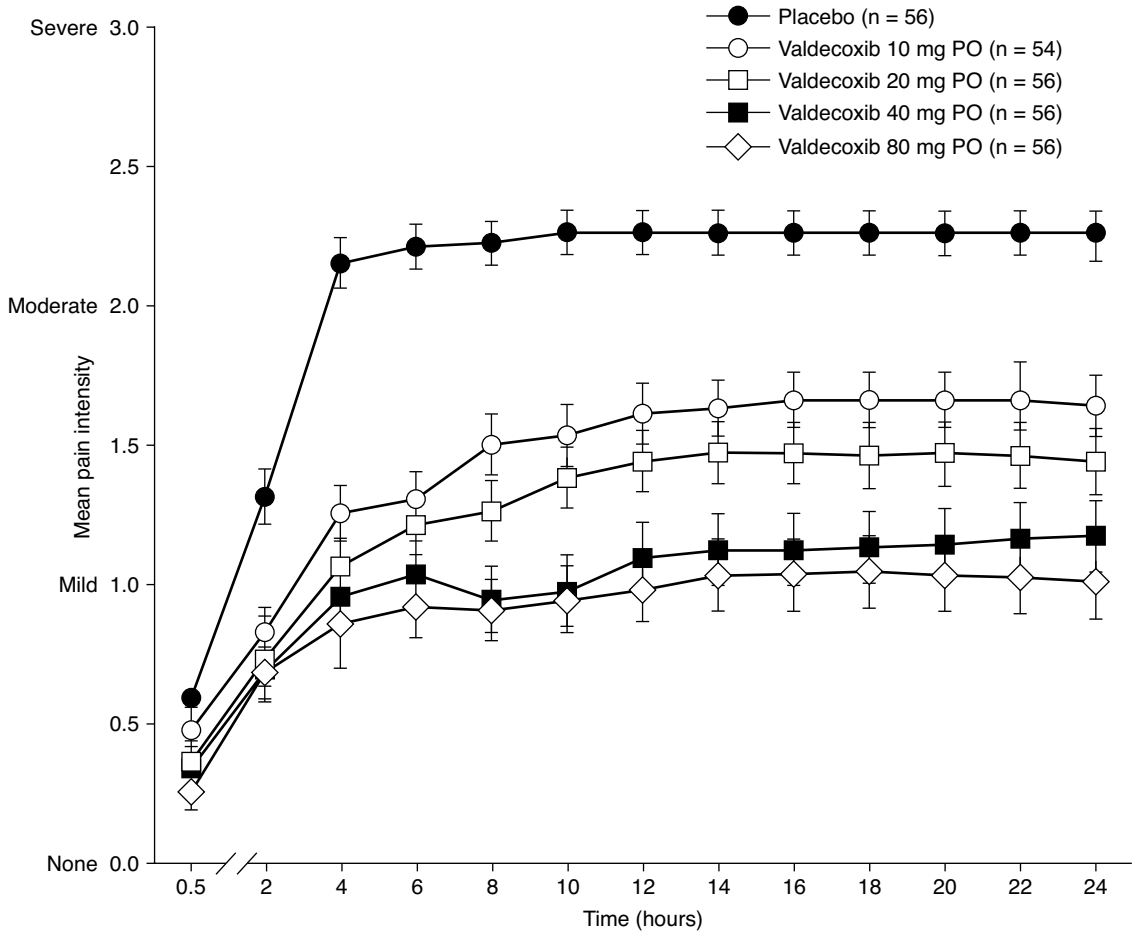

FIGURE **47-2** Effect of single preoperative doses of the cyclooxygenase-2 inhibitor valdecoxib on mean pain intensity after dental impaction surgery. Brackets indicate the standard error. (From Desjardins PJ, Shu VS, Recker DP, et al: A single preoperative oral dose of valdecoxib, a new cyclooxygenase-2 specific inhibitor relieves post-oral surgery or bunionectomy pain, *Anesthesiology* 97:565-573, 2002.)

testinal perforations, ulcerations, or serious bleeding reactions, however, a patient's inability to tolerate one specific NSAID or COX-2 does not mean the patient would be intolerant of all other NSAIDs. Also, patients may vary in their relative analgesic response to various NSAIDs. If a patient did not respond previously to a particular drug at the maximal therapeutic dose, an alternative NSAID can be considered. When treating chronic temporomandibular joint disease and other chronic orofacial pains, if a benefit is not apparent within 3 to 4 weeks, a change to an alternative drug class, such as a tricyclic antidepressant or an anticonvulsant (gabapentin), should be considered to avoid additional NSAID side effects in the absence of a therapeutic response.[16]

The oral route of administration is preferred for nonopioids. Some patients, such as young children or patients with intermaxillary fixation after maxillofacial surgery or trauma, are unable to swallow tablets or capsules. For these patients, liquid formulations of acetaminophen or ibuprofen should be considered. For the rare dental patient who is unable to take any medications by mouth, parenteral (ketorolac) or rectal (acetaminophen, aspirin) dosage forms are available.

As discussed in Chapter 21, only one highly selective COX-2 inhibitor, celecoxib, remains on the market in the United States. Its use in acute pain should be considered only in patients who are at increased risk for serious gastrointestinal events, such as patients with a previous history of gastrointestinal ulcers. Although a more appropriate role for celecoxib would be the management of more chronic orofacial pain, in which the duration of NSAID therapy may be measured in weeks or months, increasing the likelihood of untoward gastrointestinal events, the one published clinical trial of celecoxib, 100 mg twice a day, in temporomandibular joint disease patients could not show a therapeutic advantage of this drug over placebo after 6 weeks of therapy. The nonselective NSAID naproxen at a dose of 500 mg twice a day was superior to placebo and celecoxib in several measures of analgesic efficacy and function.[38]

Opioid analgesics

Opioid analgesics are added to nonopioids to manage pain that is moderate to severe or that does not respond to nonopioids alone. Opioids differ from nonopioids in that there is no ceiling effect on their analgesic response. The only dosing limitation is based on side effects. Although injectable opioids and oral opioid combinations are effective for management of moderate-severe acute pain, they are frequently underused and prescribed at subtherapeutic doses as a result of misconceptions and fears regarding their use. Fear of possible respiratory depression and habituation causes some practitioners to underprescribe and underdose opioids. At therapeutic doses employed in peripheral-narcotic combination drugs (see Table 21-7), clinically significant or even measurable respiratory depression does not occur. Even with increasing doses, this adverse event rarely occurs when appropriate starting doses are used and then titrated to effect based on the patient's analgesic response and side effects. Patients vary greatly in

their analgesic dose requirements and responses to opioid analgesics. Relative potency estimates provide a rational basis for selecting the appropriate dose to initiate analgesic therapy or when switching from one opioid to another or from one route of administration to another.

Physical dependence and tolerance can occur in virtually all patients taking opioid analgesics for a prolonged period. In most instances in which opioids or opioid combinations are used in dentistry, the duration of therapy is so short (generally ≤7 days) that these clinical phenomena are not seen. Tolerance is managed with careful upward titration of the dose until adequate pain relief is reobtained. The effects of physical dependence are easily avoided by the gradual tapering of opioids on discontinuation of therapy as opposed to abrupt withdrawal, which is likely to cause withdrawal symptoms. Addiction is a phenomenon that rarely occurs in patients taking opioid analgesics for pain (see Chapter 51).[40] Most patients taking pain medication stop taking the medication when the pain stops.

Early reports on the incidence of medical patients with addiction problems were fraught with methodologic flaws and significantly overestimated the risk.[26,35] More recent studies provide a more accurate estimate. In 1980, the Boston Collaborative Drug Surveillance Project identified only four cases of addiction among 11,882 hospitalized patients with no history of substance abuse who received at least one dose of an opioid.[34] A national survey of burn units found no cases of addiction in almost 10,000 patients treated for burn pain.[32] Another study surveying patients attending a headache clinic revealed that only 3 of 2369 patients had a management problem with analgesics used to treat intermittent headaches.[30]

Dentists must remain vigilant, however, for drug-seeking patients, who often request a specific opioid (often oxycodone) at a specific dose that is at the higher end of the therapeutic range for pain that is not readily evident or should not be that severe. In addition, dentists who overprescribe opioids are subject to punitive actions by their state dental boards and the U.S. Drug Enforcement Administration.

Opioid analgesics include pure agonists, such as codeine and oxycodone, and agonist/antagonists, such as pentazocine and butorphanol. As a general rule, agonist/antagonists should not be used as first-line therapy. There is no convincing evidence that these drugs offer any advantage over pure opioid agonists. Agonist/antagonists become less effective at high doses because they have a ceiling effect (see Chapter 20), frequently cause dysphoria, and may cause confusion and hallucinations. In addition, they may cause withdrawal symptoms when given to patients physically dependent on opioid agonists. Occasionally, agonist/antagonists may be useful in treating individuals unable to tolerate other opioids.[3]

In 1990, the World Health Organization proposed a stepwise approach for the management of cancer pain.[9] This approach (Figure 47-3) has subsequently been recommended for the treatment of noncancer pain as well. The first step, representing treatment of mild pain, is to administer a nonopioid drug. In many dental surgical procedures, NSAIDs alone can achieve excellent pain control.[8,12] Nonopioid therapy should be considered the cornerstone for management of acute dental pain. Pain that does not respond adequately to nonopioid agents should be treated with the combination of a nonopioid and an opioid such as codeine, hydrocodone, or oxycodone. Even when insufficient alone to control pain, NSAIDs can reduce the dose of opioid required to achieve relief.[20,25] A few recent studies suggest that combining a full therapeutic dose of an NSAID with a full therapeutic dose of acetaminophen may produce pain relief equivalent to an NSAID/opioid combination without the typical opioid-mediated side effects.[5] A limitation to the studies is that the typically strong analgesic action of the NSAID was not observed because of the dose, formulation, or study design used.

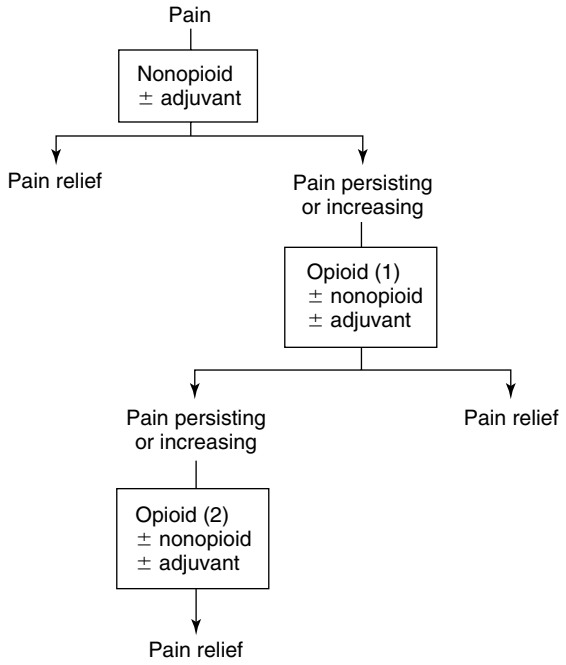

FIGURE **47-3** Stepwise process in choosing analgesic medication. Opioid *(1)* indicates a standard oral opioid in a conventional dose; opioid *(2)* indicates increasing doses or a change in opioid to increase the analgesic effect. (Based on recommendations of the World Health Organization, as described in Deglin JH, Vallerand AH: *Davis's drug guide for nurses*, ed 5, Philadelphia, 1997, Davis.)

More severe pain, or pain that persists, should be treated with a combination of a nonopioid and a more potent opioid, such as morphine or hydromorphone. Adjuvant agents, such as certain anticonvulsants or tricyclic antidepressants, may be added when indicated. Several adjuvant agents, including the anticonvulsant gabapentin and several tricyclic antidepressants, have proved effective in the treatment of temporomandibular joint and neuropathic orofacial pain when NSAIDs and opioids have failed.[23,33,36] Chapter 23 contains a more thorough discussion of medications employed in chronic orofacial pain.

Because most dental care is provided to ambulatory dental outpatients, oral administration of opioid analgesics is preferred whenever possible. It is convenient and inexpensive. Even severe postsurgical pain can be treated effectively with orally administered opioids in the proper doses. For a patient who is unable to swallow a tablet or capsule, numerous liquid formulations of opioids are available (e.g., codeine, hydrocodone, oxycodone). Peak drug effects (including side effects) occur 1.5 to 2 hours after the oral administration of most opioids (except for sustained-release tablets). Patients may take a second opioid dose safely 2 hours after the first dose if the pain persists and side effects are mild at that time.[3,9]

For patients unable to take medications by mouth, intravenous, intramuscular, or rectal routes of administration can be considered. Use of the intravenous or intramuscular route to deliver analgesics is almost exclusively limited to inpatient hospital settings. Of the two routes, intravenous administration is preferred. Intravenous bolus administration provides the most rapid and predictable onset of effect. Time to peak effect varies with drug lipid solubility, ranging from 1 to 5 minutes for fentanyl to 20 minutes or longer for morphine.

Although commonly used, intramuscular injections can themselves cause pain and trauma and may deter patients from requesting pain medication. Also, absorption from intramuscular sites can be erratic and variable. Several opioids are available in rectal suppository form (e.g., hydromorphone, morphine). Sustained-release opioids (e.g., controlled-release morphine and oxycodone) seem to have little role in the management of acute dental pain.

As mentioned previously, opioids almost always should be administered with nonopioids for maximal pain relief in cases of dental pain. Many opioids are marketed in combination with a nonopioid, and it is the latter component that limits the dose. The upper dose limit for acetaminophen is 4000 mg/day. For combinations containing 325 mg of acetaminophen, the maximum number of tablets per day is 12. For combinations containing 500 mg of acetaminophen, the maximum number of tablets per day is eight. In children who weigh less than 45 kg, the limit is 90 mg/kg of acetaminophen.

One controversial area of change in pain therapeutics is in the use of potent opioids in patients with severe or unremitting chronic pain from either malignant or nonmalignant disease. Pain specialists have advocated the use of potent opioids in such patients when all other reasonable therapeutic approaches have failed. Special considerations and management approaches, including documenting failed approaches, closely monitoring refill records, and having patients sign contracts with the health care provider, are thought to be essential to avoid future medical and legal challenges to the patient and provider.

Principles of Analgesic Use

Analgesics should be administered initially on a regular time schedule. If the patient is likely to have pain requiring analgesics for 48 hours after dental surgery, analgesics might be ordered on a fixed time schedule (e.g., every 4 hours) while awake, not as needed, for the first 36 hours. This schedule provides more stable plasma concentrations of the agent with less breakthrough pain. If only as-needed medications are used, several hours and higher doses may be required to relieve pain, leading to a cycle of undermedication and pain alternating with periods of overmedication and unnecessary adverse effects. Later in the postoperative course, as the patient's analgesic dose requirement diminishes, dosing may be switched to an as-needed basis.

Children should also be given adequate doses of analgesics. Children may not communicate their pain effectively and are frequently undermedicated for pain. The clinical effects and pharmacokinetics of opioids in children older than 6 months are approximately the same as in adults. Starting doses of opioids and nonopioids may be calculated according to weight. Aspirin should be avoided in children because of its well known association with Reye's syndrome.

Dentists should be familiar with several opioid and nonopioid analgesics. Different patients vary greatly in their response to, and ability to tolerate, different agents. For this reason, it is important to be familiar with the recommended dose, side-effect profile, and time course of several agents in each category. Because of the potential for adverse drug interactions between commonly prescribed analgesic drugs and other drugs a patient may be taking (see Chapter 21), an up-to-date medical history is also crucial.[17]

Patients should be followed closely, particularly when beginning or changing analgesic regimens. Analgesics are more beneficial if the clinician monitors pain relief and adverse effects frequently and adjusts the regimen as needed to optimize therapy. This monitoring is particularly important when using an agent or combination with which the physician has little or no experience or when changing from one analgesic to another.

Although pain is a common occurrence in patients seeking or undergoing dental care, it is generally manageable and often avoidable. Tools required to keep pain at a minimum include accurate assessment, methodical preventive regimens, and aggressive treatment. Rational clinical practice guidelines[2] and equianalgesic charts allow practitioners to determine the appropriate analgesic regimen and dose for each patient.

CHAPTER 48

Management of Fear and Anxiety

DANIEL A. HAAS

Fear and anxiety of dental procedures are common emotions. The severity ranges widely, with mild apprehension being reported by 75% of the population,[59] and severe anxiety, leading to avoidance of dental treatment, being reported by 4% to 21%.[11,21,49] As shown in Table 48-1, the prevalence of fear and anxiety is not restricted to one culture but shows consistency internationally.[11] Dental anxiety has not diminished but has remained stable over the past 50 years despite advances in the delivery of dentistry.[61] It has also been shown that this fear begins in childhood and can persist throughout life, leading to avoidance of dental care and contributing to diminished oral health.[23] Although mild fear may have only a minor effect on oral health, detrimental consequences for overall health can result if true phobia causes patients to avoid treatment despite significant symptoms.[8,49]

Approximately 40% of the population do not receive routine dental care, with apprehension being cited as the most common reason.[4] These patients often require special nonpharmacologic or pharmacologic approaches to allow dental procedures to be done. Pharmacologic approaches involve drugs that produce effects ranging from minimal sedation to general anesthesia.

Dentistry has historically been at the forefront in the development of anesthetic techniques to manage fear and anxiety. As described in Chapter 17, two dentists, Horace Wells and William Morton, were largely responsible for the clinical introduction of general anesthesia. The first description of nitrous oxide (N_2O) as a sedative, as opposed to a general anesthetic, appeared in a textbook on anesthesia for dentistry published in 1908.[17] The modern form of N_2O and oxygen sedation evolved in the 1940s and 1950s, and this practice has become a standard component of the predoctoral dental curriculum.[3] Intravenous anesthesia with hexobarbital was pioneered by the English dentist S.L. Drummond-Jackson in the 1930s. Shortly after World War II, Harold Krogh and Adrian Hubbell developed the use of thiopental for oral surgery. Intravenous conscious sedation (now termed *moderate sedation*) was introduced by Niels Jorgensen in 1945.

Behavioral or psychological techniques to manage anxiety in dental patients are unquestionably important, but their detailed description lies beyond the scope of this textbook. This chapter summarizes the pharmacologic approaches to the management of fear and anxiety in dental patients, with emphasis on the administration of minimal-moderate sedation. Complete understanding of this subject requires comprehension of the pharmacologic features of the specific drugs, which are described in other chapters.

GENERAL PRINCIPLES

Indications for Use

The primary indication for pharmacologic methods of patient management is the presence of anxiety, fear, or phobia sufficient to prevent the delivery of needed dental care. *Anxiety* may be defined as a stress response to an ill-defined or anticipated situation[46] and may consist of patterns of autonomic arousal with thoughts of fear and feelings of threat.[54] Dental anxiety may be related to specific dental procedures or may be precipitated by a mere visit to the dentist's office. Although anxiety of dentistry usually originates from past experiences as a child,[40] it may develop in adulthood and not be associated with any previous adverse event.[66]

Fear is defined as an emotional response to a perceived immediate threat.[24,57] Fear of dentistry may evolve from many sources, including past traumatic experiences, concerns about physical loss and disfigurement, observation of anxiety or fear in others, and exposure to frightening anecdotes by friends or the mass media.[59] Specifically, fears of the anesthetic "shot" and dental "drill" are the most common.[36,47] A *phobia* is a persistent and irrational fear that results in a compulsion to avoid a specific object, activity, or situation.

A strong relationship exists between anxiety and pain. Expectation of pain contributes significantly to dental anxiety, and anxiety can reduce pain tolerance[59] to the extent that normally innocuous stimuli, such as touch, may be interpreted as pain. Many cases of failed mandibular block are a result of patient anxiety.[67] Anxiety can also contribute to adverse reactions in the dental chair; these are commonly misdiagnosed as either allergic or toxic reactions to the local anesthetic or vasoconstrictor. Comprehensive pain control requires an ability to manage fear and anxiety.

Other potential indications for the use of pharmacologic methods for patient management include cognitive impairment, such as in mentally challenged patients or patients with Alzheimer's dementia. These patients may be unable to cooperate sufficiently to permit treatment or perhaps even an adequate intraoral examination. Another indication is the presence of motor dysfunction, such as in patients with cerebral palsy or Parkinson's disease, whose tremor or uncoordinated movements may be exacerbated by the anxiety of being in the dental office. Pharmacologic management may also be required for a pediatric patient who may not understand the treatment and is reacting normally for a young child. Traumatic or extensive dental procedures are additional potential indications when coupled with anxiety, the need to immobilize the patient, or inability to render the patient pain-free with local anesthesia. Finally, some patients cannot physiologically tolerate the stress that even a minimal amount of anxiety

TABLE **48-1**

International Prevalence of Dental Fear and Anxiety

COUNTRY	PREVALENCE OF HIGH DENTAL FEAR AND ANXIETY
Australia	13.7%
Canada	4.4-16.4%
Denmark	4.2%
Iceland	4.8%
Japan	20.9%
Netherlands	3.9-10.8%
New Zealand	12.5-21.1%
Singapore	7.8-20.8%
Sweden	3.9-6.7%
United States	10-19%

American Society of Anesthesiologists Physical Status Classification System

CLASS	DESCRIPTION
I	Normal, healthy patient
II	Patient with mild systemic disease
III	Patient with severe systemic disease that limits activity, but is not incapacitating
IV	Patient with incapacitating systemic disease that is a constant threat to life
V	Moribund patient not expected to survive 24 hr with or without operation
E	Emergency operation of any type; E is appended to the patient's physical status

may induce; patients with ischemic heart disease, labile hypertension, or stress-induced asthma are included in this group. Any of the modalities defined subsequently—minimal sedation, moderate sedation, deep sedation, or general anesthesia—may be used to treat these patients.

Identification of Fearful or Anxious Patients

To address the needs of fearful or anxious patients, the dentist must first be able to recognize or diagnose anxiety and fear. Discussion of how to identify these patients accurately is beyond the scope of this chapter but can be found in other excellent sources.[24,48] The degree of anxiety should be determined as part of an appropriate history and patient evaluation. Observation of the patient and questions addressing possible anxiety caused by dentistry may aid in diagnosis. Patient interviews can identify specific concerns, such as fear of the injection of local anesthetic, the sound of the handpiece, or certain surgical procedures. Standardized measures of anxiety, such as the Corah scale,[13] may be useful in quantifying the severity of anxiety.

Treatment Planning

After identifying an anxious, fearful, or phobic patient, thought should be given to the optimal method of managing the patient. Initially, nonpharmacologic methods of anxiety reduction should be considered.[41,54,57] Appropriate chairside manner is often all that is required; this includes use of basic behavioral modification, positive suggestion, and reassurance. This approach is valuable not only when used alone, but also when used with more specific therapies for anxiety reduction. Specific psychological interventions that may be helpful include desensitization and hypnosis. Although these techniques would not overcome poor chairside manner, they can effectively aid the dentist in achieving patient comfort.

Despite effective chairside manner, many patients still wish to receive sedation or anesthesia. It has been reported that more than 50% of Americans classified as having high fear or anxiety preferred sedation for their dental care.[21] The same study showed that three times as many subjects reported a preference for parenteral sedation or general anesthesia when undergoing dental treatment than were actually receiving these modalities.[21] This same pattern was seen in a subsequent Canadian study in which patients were asked if they would prefer to have sedation or general anesthesia for each of five procedures.[11] There were large differences in this preference compared with actual prevalence for each procedure—specifically, 3.8-fold difference for cleaning, 2.8-fold difference for restorative dentistry, 9.6-fold difference for endodontics, 15.9-fold difference for periodontal surgery, and 2.2-fold difference for extraction. The low preference/prevalence ratio for extractions suggests that dental patients have better access to sedation/anesthesia services for extractions than for other procedures. Extrapolation of these results suggests that nearly 25 million American adults are definitely interested in sedation or general anesthesia for dentistry regardless of the cost.

An absolute requirement basic to the success of patient management is effective local anesthesia. One cannot avoid this necessity in most invasive dental procedures unless complete general anesthesia is being administered. Even then, there may be benefits to the so-called preemptive use of local anesthetic.[34,45,68] The dentist should not be misled into thinking that poor local anesthetic technique can be overcome by administering a sedative. Only when the anesthetic failure is strictly caused by anxiety[67] would sedation be fully effective.

The approach to anxiety control should be individualized. It is as faulty to assume that every patient requires general anesthesia for the removal of impacted teeth as it is to assume that no patient requires anxiety control for a simple dental procedure or examination.

The ability to use a particular pharmacologic approach depends on the level of training of the dentist and the applicable laws and regulations.[3] Education for minimal sedation, such as given through inhalation and oral administration, is within the realm of the predoctoral dental curriculum. More advanced forms, such as moderate sedation, given either orally or parenterally, usually require training at a postdoctoral or continuing education level, although some dental schools have shown that it can be part of a predoctoral program. The most advanced modalities—deep sedation and general anesthesia—require the most formal training. Education for advanced modalities entails a specific postgraduate program devoted to anesthesia (i.e., an accredited residency in dental anesthesiology or an accredited oral and maxillofacial surgery residency, which must include advanced training in anesthesia as part of its curriculum).

Patient Selection

Before choosing pharmacologic adjuncts for patient management, the dentist should carefully review the patient's medical history. In this context, the American Society of Anesthesiologists (ASA) Physical Status Classification System can be helpful (Box 48-1). This assessment tool can be used to estimate the patient's overall ability to tolerate the stress of a

planned procedure. It can also help determine the need for further patient evaluation and the degree of monitoring required for the procedure.

ASA I and II patients are usually suitable candidates for sedation or general anesthesia in the outpatient setting. Although outpatient general anesthesia is often inappropriate for ASA III patients, these same patients are at increased risk during stressful procedures when fear and anxiety are not adequately controlled. Techniques to control anxiety involving minimal, moderate, or possibly even deep sedation may be particularly valuable to ASA III patients because they reduce the release of endogenous catecholamines.[18,20] ASA IV (and higher) patients are not candidates for sedation or anesthesia in the dental office.

PHARMACOLOGIC APPROACHES

Several pharmacologic approaches can be used to manage fear and anxiety in dental patients. These are commonly referred to collectively as the *spectrum of pain and anxiety control*, which incorporates all major routes of administration and levels of central nervous system (CNS) depression.[43] The route of administration is not synonymous with the level of CNS depression. A spectrum of fear and anxiety control as depicted in Figure 48-1 shows the range of sedation or anesthesia normally sought from the various routes and techniques of administration. In its simplest form, this spectrum is divided into techniques expected to leave the patient awake or to render the patient unconscious. These modalities correspond to sedation and general anesthesia. More recently, definitions of the various levels of sedation have been standardized to include the states of minimal, moderate, and deep sedation.[3] The characteristics of these states and of general anesthesia are defined next and compared in Table 48-2:

Minimal sedation is a minimally depressed level of consciousness, produced by a pharmacologic method, that retains the patient's ability to maintain an airway independently and continuously and to respond normally to tactile stimulation and verbal command. Although cognitive function and coordination may be modestly impaired, ventilatory and cardiovascular functions are unaffected.

Moderate sedation is a drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.

Deep sedation is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimulation. The ability to maintain ventilatory function independently may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.

General anesthesia is a drug-induced loss of consciousness during which patients are unarousable, even by painful stimulation. The ability to maintain ventilatory function independently is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.

Minimal and moderate forms of sedation are not substitutes for appropriate chairside manner and use of behavioral techniques but are used to reinforce positive suggestion and reassurance in a way that allows dental treatment to be performed with minimal physiologic and psychological stress. These techniques should carry a margin of safety wide enough to render unintended loss of consciousness unlikely.[55] Deep sedation or general anesthesia can be induced by many of the same drugs that induce moderate sedation. The resulting state depends on patient susceptibility, age, medical status, and degree of anxiety and the drug or drugs used and doses admin-

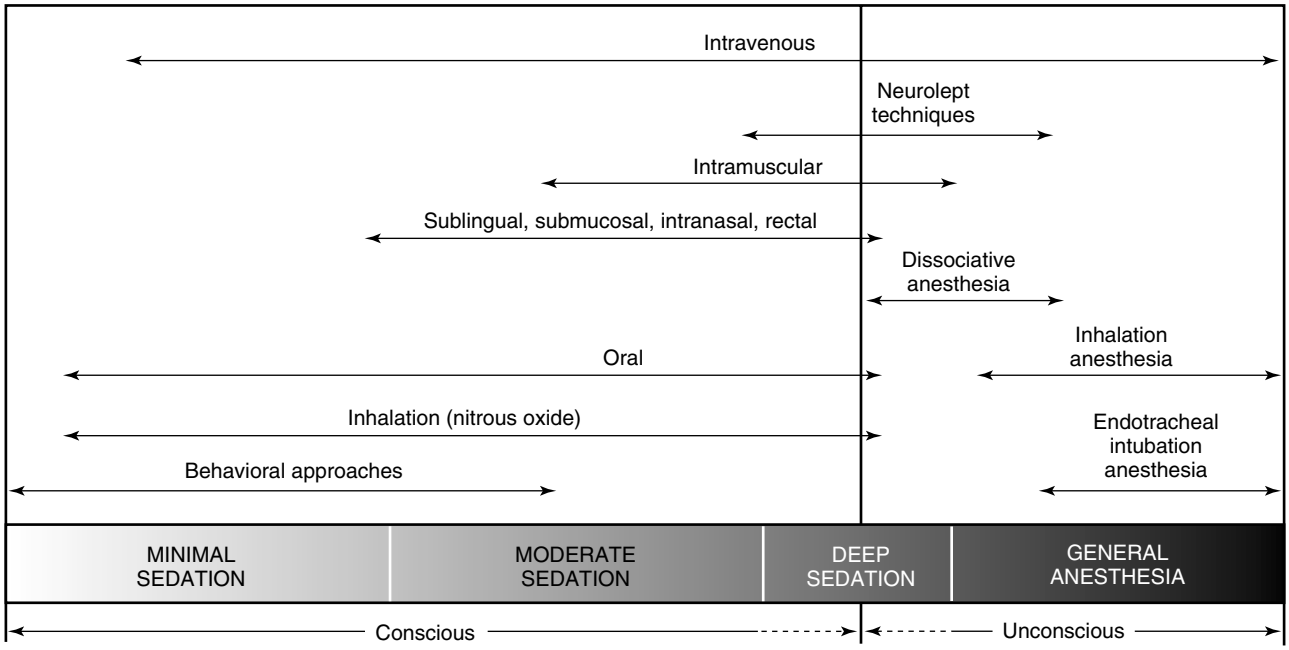

FIGURE **48-1** The spectrum of fear and anxiety control in dentistry. The range of central nervous system depression normally achieved by various techniques is illustrated by arrows. The depth of sedation or anesthesia induced by a given drug primarily depends on the dose administered, route used, and susceptibility of the patient.

TABLE **48-2**

Comparison of Minimal Sedation, Moderate Sedation, Deep Sedation, and General Anesthesia

CHARACTERISTICS	MINIMAL SEDATION	MODERATE SEDATION	DEEP SEDATION	GENERAL ANESTHESIA
Consciousness	Maintained	Maintained	Obtunded	Unconscious
Protective reflexes	Intact	Intact	Depressed	Absent
Unassisted airway maintenance	Present	Present	May be absent	Absent
Response to verbal command	Present	May be obtunded	Absent	Absent
Response to tactile stimulation	Present	Present	Absent	Absent
Response to painful stimulation	Present	Present	Reflex withdrawal	Absent
Vital signs	Stable	Usually stable	Usually stable	May be labile
Anxiety	Decreased	Decreased	Absent	Absent
Monitoring required	Basic	Intermediate	Advanced	Advanced
Efficacy	Mild anxiety	Moderate anxiety or fear	Most patients	All patients
Relative risk	Low	Low to intermediate	Intermediate	High
Recovery time	Rapid	Intermediate	Intermediate	May be prolonged
Postoperative sequelae	Uncommon	Uncommon	Uncommon	More common

istered. Either deep sedation or general anesthesia may be indicated when lighter forms of CNS depression are insufficient to permit treatment.

If a separate trained anesthesia provider is not used to administer deep sedation or general anesthesia, a team approach is indicated. For this approach, at least three individuals must be in the operatory: the dentist (trained in anesthesia), the anesthetic assistant, and the operative assistant. Under the direction of the dentist, the primary functions of the anesthetic assistant are to assess the patient; monitor vital signs; record appropriate information; and, as required or permitted by relevant laws and regulations, establish intravenous access, administer medications, assist in the maintenance of a patent airway, monitor recovery, and assist in any emergency procedures. The primary functions of the operative assistant are to keep the operative field free of blood, mucus, and debris and to assist in the management of the dental procedure.

Reliable morbidity and mortality data for the different forms of sedation or general anesthesia are scarce, but several studies have shown that, overall, the techniques used in dentistry should be considered safe.[22,39,42,51,69] Increased mortality is usually associated with inadequate training or inadequate monitoring of the patient.[15,16,25,33,38] In a review of adverse events related to sedation in pediatric patients, the use of three or more sedating drugs was more strongly associated with adverse outcomes than was the use of only one or two.[15,16] If the goal is minimal or moderate sedation, one must avoid administering excessive doses of a sedative to a patient who remains uncooperative while conscious because it could easily lead to a deepening of sedation in which airway patency and protective reflexes may be lost. Any subsequent lack of oxygenation can rapidly lead to a tragic result. Although the progression from moderate to deep sedation can be accomplished easily, it requires a significantly increased degree of practitioner training, patient monitoring, and physical resources (e.g., anesthetic equipment and supplies) to be performed safely.

MINIMAL AND MODERATE SEDATION

Numerous routes of administration can be used to achieve minimal or moderate sedation: inhalation, oral, intravenous, intramuscular, submucosal, sublingual, rectal, and intranasal. The first three are commonly used and are discussed in detail in this chapter, whereas the latter five are used less frequently and are reviewed only briefly here.

The intramuscular route provides an onset and uptake intermediate between that of oral and intravenous routes. There is a limited ability to titrate with this route, but it can be particularly advantageous for patients who are incapable of cooperating, such as cognitively impaired patients.[6] Its use should be restricted to clinicians with training in at least parenteral moderate sedation.

The submucosal route is analogous to a subcutaneous injection given intraorally and shares many of the same characteristics as the intramuscular route. The submucosal route has no apparent advantage over any of the others, other than the fact that the dentist may be more comfortable giving an injection by this route. The sublingual (or transmucosal) route, restricted to drugs with high lipid solubility and available in suitable formulations, is similar to the oral route except that there is a more rapid absorption by the oral mucosa and no first-pass effect. The difference in recommended dosages can be large when comparing oral versus sublingual absorption depending on the extent of first-pass metabolism in the intestine and liver. The onset of effect after sublingual administration may take several minutes for some drugs and considerably longer for others.

The rectal route is not often used in dentistry, with the exception of pediatric patients. Disadvantages of this route include inability to titrate, inconsistencies in absorption, often poor patient acceptance, and inconvenience.

The intranasal route involves the topical application to the nasal mucosa and is characterized by a potentially rapid absorption and onset of action. It is sometimes used as an alternative to intramuscular injection for uncooperative children. Its benefits are diminished, however, by variable absorption (especially if the patient sneezes), the discomfort of mucosal irritation, and the potential for damage to the nasal mucosa.

As stated earlier, the route of administration is not synonymous with the depth of sedation. Any route has the potential to induce any degree of sedation or anesthesia. Management of an anxious patient can be discussed according to route of administration, however, because the inhalation and oral techniques are most commonly used for minimal and moderate sedation and are normally the first to be considered. The intravenous route is more likely to be selected to induce a greater depth of effect. Table 48-3 compares the routes of administration for sedation. Commonly used drugs, their

TABLE **48-3**

Comparison of Routes of Administration for Sedation

CHARACTERISTIC	INHALATION	ORAL	INTRAVENOUS
Ability to titrate	Excellent	Minimal	Excellent
Technique difficulty	Easy	Very easy	Moderate
Ability to reverse	Excellent	Variable*	Variable*
Onset	Rapid	Slow and variable	Rapid
Duration	Controlled	Prolonged	May be prolonged
Patient acceptance	Good	Very good	Fair
Efficacy	Good	Good	Very good
Need for escort home	No	Yes	Yes

Drugs, Routes, and Doses for Minimal or Moderate Sedation

DRUG	ROUTE OF ADMINISTRATION	APPROXIMATE DOSE*
Nitrous oxide	Inhalation	20-50%
Diazepam	Oral, IV	0.05-0.3
Midazolam	Oral, IV	0.03-0.1 (IV), 0.3-1 (oral)
Alprazolam	Oral	0.002-0.007
Lorazepam	Oral	0.015-0.06
Triazolam	Oral	0.002-0.007
Hydroxyzine	Oral	0.5-1
Promethazine	Oral	0.5-1
Chloral hydrate	Oral	40-50
Fentanyl	IV	0.0006-0.0015
Meperidine	IV	0.5-1
Morphine	IV	0.05-0.1
Nalbuphine	IV	0.05-0.1
Propofol†	IV infusion	0.025-0.1/min

*In mg/kg unless otherwise marked.
†The use of propofol is generally restricted in the United States to dentists with formal advanced training in general anesthesia.

routes of administration, and doses for minimal and moderate sedation are summarized in Table 48-4.

Inhalation Sedation

Inhalation sedation refers to the administration of N_2O and oxygen (N_2O-O_2) (pharmacologic features are described in Chapters 17 and 18). N_2O-O_2 inhalation is a technique of choice for dental procedures that require minimal-moderate sedation. The analgesia produced by N_2O-O_2 ameliorates the incidental discomforts associated with dental treatment. As with other modalities of sedation, however, N_2O-O_2 is not a substitute for effective local anesthesia.

Inhalation sedation units must meet stringent safety standards, including color coding of compressed gas cylinders, a pin-indexed or diameter-indexed safety system to prevent incorrect connection of gas cylinders, minimum O_2 flow, and an O_2 fail-safe valve to shut off the N_2O if O_2 delivery is interrupted. All mechanical devices can fail, however, and careful technique and continuous observation of the patient are more effective in preventing accidents than simple reliance on mechanical safeguards.[64] The reader is referred elsewhere for a thorough discussion of the safety and design features of inhalation equipment.[12,43]

Advantages

The advantages (and disadvantages) of the inhalation route are summarized in Table 48-3. Because of its relative insolubility in blood, N_2O has a rapid onset of action, with clinical effects becoming apparent within a few minutes. This property of N_2O allows for titration to effect. In this context, *titration* is defined as the incremental administration of small amounts of a drug until a desired clinical effect is observed. The ability to titrate a drug enables the dentist to control its ultimate effect and eliminates the need to guess the correct dose for a particular patient. This characteristic is a major reason why N_2O-O_2 has long been considered a near-ideal technique for minimal or moderate sedation. In the event that a patient inadvertently receives too much drug, the effect can be rapidly decreased by reducing the concentration administered. The inhalation route is the only one in which the actions of a drug can be quickly adjusted in either direction.

Another major advantage of N_2O-O_2 inhalation is that recovery is rapid. Normally, there is no residual effect on the patient's psychomotor skills and ability to operate a motor vehicle soon after termination of N_2O-O_2 inhalation.[31,37] When it is not combined with any other sedative agent, N_2O-O_2 is the only sedation technique in which a patient may be discharged home alone; all other sedation techniques require that the patient be discharged in the care of a responsible adult.

Disadvantages

N_2O-O_2 sedation for typical dental procedures has comparatively few disadvantages. There are a few patients for whom this method would be ineffective. Most patients have the desired clinical effect between 20% and 50% N_2O. Another disadvantage is the requirement for patient cooperation. Success with this technique requires the patient to breathe through the nose and to leave a nasal hood in place throughout the procedure. Claustrophobic patients and apprehensive children may be unable to tolerate the nasal hood.

Acute or chronic nasal obstruction precludes the use of N_2O-O_2 because the patient is unable to inhale the administered gases. Patients who are mouth breathers for other reasons are also unsuitable candidates. Because of a risk of expansion and rupture of enclosed gas spaces, contraindications include recent vitreoretinal surgery with intraocular gas infusion, pulmonary bullae, pneumothorax, intestinal obstruction, or an obstructed middle ear. Pregnancy may be considered a relative contraindication because of the usual preference to avoid the administration of any drug during pregnancy. Nevertheless, if drug-induced sedation is to be carried out for a pregnant patient, N_2O-O_2 is preferred over most other sedatives and may be the technique of choice for a short procedure

(e.g., <1 hour). Two minor disadvantages are the cost and space needed for the N_2O-O_2 equipment.

The potential risks stemming from the ability of N_2O to disrupt vitamin B_{12}–dependent biochemical pathways are discussed in Chapters 17 and 18. It is currently unknown to what extent these concerns apply to the use of inhalation sedation for typical dental procedures. Patients with known mutations causing abnormalities in folate-cycle enzymes may be at risk when administered N_2O.[60] A postulated link between autism and genetically based disturbances in the folate metabolic pathway may be exacerbated by prolonged administration of N_2O.[30] A final disadvantage is the occupational health hazards from trace anesthetic gases, as discussed in Chapters 17 and 18.

For two groups of patients, it is not the N_2O that is the concern, but the high inspired O_2. First, patients with severe chronic obstructive pulmonary disease may have chronically elevated carbon dioxide tensions and depend on the hypoxic drive to stimulate breathing. When elevated O_2 concentrations occur, as during N_2O-O_2 administration, the stimulus for involuntary breathing may be removed, leading to respiratory depression and a worsening of respiratory acidosis. Second, patients who have had bleomycin chemotherapy within the past year may be predisposed to pulmonary fibrosis after exposure to high O_2 concentrations.[5]

Clinical application

Administration begins with 100% O_2 at an appropriate flow rate, approximately 6 L/min for most adults. With the reservoir bag filled and O_2 flowing, the mask is placed on the patient. The operator initially adjusts the O_2 flow to meet the patient's minute respiratory volume and then administers a 20% concentration of N_2O to the patient (keeping total gas flow unchanged) and waits 1 to 2 minutes to judge clinical effectiveness. As necessary, the operator increases the N_2O concentration in 5% to 10% increments until the patient exhibits the desired clinical signs and symptoms. In a few patients, doses of 20% or less may be sufficient.

The dentist should advise the patient of the symptoms that may be experienced and that the goal is to feel comfortable. Symptoms occurring during inhalation sedation may include lightheadedness; tingling of the fingers, toes, or lips; warmth; and euphoria. The clinician should not be dogmatic in describing potential symptoms because failure to experience one or more of them may be misinterpreted by the patient as a failure of the technique. When the patient reports being comfortable, the dentist stops increasing the N_2O percentage and begins treatment. Oversedation may be indicated by excessive drowsiness, loss of response to verbal command, inappropriate movement, hearing abnormalities, visual disturbances, sweating, or nausea. Patients should be monitored by clinical assessment of level of consciousness, adequacy of respiration, heart rate, and blood pressure.

Recovery is accomplished by terminating N_2O flow and administering 100% O_2 at the previously established flow rate for approximately 5 minutes (to allow for scavenging of exhaled N_2O) or longer if clinical signs and symptoms warrant. Recovery should be evaluated by visual observation, patient report, and, if necessary, assessment of the postoperative vital signs relative to baseline values.

Oral Sedation

The oral route is the second most frequently used route to accomplish minimal or moderate sedation in dentistry. It has numerous advantages and disadvantages (see Table 48-3).

Advantages

The oral route is commonly used to achieve minimal or moderate sedation because of the ease of administration. Most adults readily accept oral medication; however, young children, mentally challenged patients, and demented patients may not willingly swallow drugs, particularly in tablet or capsule form. Problems such as overdose, idiosyncratic reactions, allergy, and other adverse events may occur whenever drugs are administered, but such reactions are less likely to arise when drugs are given orally, and if they do develop, they are often less intense. Nevertheless, careful administration of any drug by even this route is required because fatal reactions have resulted from oral sedation.[15,16,32]

Disadvantages

The major disadvantage of oral sedation is the inability to titrate reliably, so the dentist cannot adjust for individual patient response. After a drug is taken orally, it is often impractical to provide an additional dose because of the delay in absorption and onset of action. There can also be a delay in drug equilibration between the plasma and effect site concentrations, which can lead to overdose if additional doses are administered on the basis of patient anxiety.[23,29] A predetermined dose is best administered while recognizing, on one hand, the risk of an excessive dose leading to prolonged action or inadvertent deep sedation and, on the other hand, the risk of an insufficient dose, in which case the patient would be inadequately sedated to allow dental treatment.

A further disadvantage of oral sedation is the potential for a prolonged duration of action. The patient can remain under the influence of the drug postoperatively and should not leave the dental office unescorted. Specific contraindications to oral sedation depend on the drug used.

Clinical application

The oral route may be used the night before the dental procedure if the patient needs a hypnotic to ensure adequate sleep. Preoperative anxiety reduction before the patient is transported to the dental office may be a second indication for oral premedication. Dosages for these two indications should be kept low enough to minimize the likelihood of oversedation because the dentist is not present to deal with any potential adverse event. The third indication is the most common one: the administration of an oral drug for minimal or moderate sedation during the dental procedure. Ideally, a dose used to induce sedation should be administered to the patient in the dental office, taking into account the time required for drug absorption. Although great variability exists, initial clinical effects are often evident approximately 30 minutes after ingestion, with peak effects occurring at about 1 hour. Patients should be monitored by clinical assessment of level of consciousness, adequacy of respiration, heart rate, and blood pressure as necessary. At the end of the case, patients should be discharged to the care of a responsible adult only when they are oriented and ambulatory, have stable vital signs, and show signs of increasing alertness. The patient should be instructed not to drive a vehicle, operate hazardous machinery, or consume alcohol for the remainder of the day.

Determinants of dose. The suggested doses for sedation recommended in this chapter apply to a typical 70-kg, healthy adult. Some factors modify these recommendations. The first consideration is the patient's weight. Determining a dose based on body surface area is theoretically more accurate, but using body weight has the advantage of simplicity. Extremes of age are another consideration. The dosage regimens for pediatric patients may often be determined by body weight or surface area calculations. Specific doses for certain drugs may differ in young children, however, for reasons other than body size.[14] Geriatric patients may react much more profoundly to CNS depressants with respect to depth and duration of action. As a general recommendation, one should

consider an initial dose for an elderly patient of half that usually administered for a typical adult of the same body size.

Medical history and concurrent medication may influence the dose to be used. In particular, drugs affecting the CNS must be assessed, not only regarding interactive potential leading to excessive CNS depression and subsequent respiratory and cardiovascular depression, but also regarding the possibility of cross-tolerance and decreased effect of the planned medications. History of the patient's response to mood-altering drugs such as alcohol may indicate an altered dose requirement.

Patients with chemical dependencies require special consideration. Patients who take large amounts of alcohol, opioids, or other mood-altering drugs may require an increased dose of sedative because of tolerance. A patient who is recovering from chemical dependency should ideally have an oral sedative administered only after thorough consultation with the patient and the health professional treating the dependency.

Finally, increased anxiety often correlates with increased dose requirement. Larger doses (although still within the acceptable range) are generally indicated for patients with an increased need for pharmacologic sedation.

Specific drugs

Numerous drugs are available for oral sedation. The following is a summary of the drugs commonly used in dentistry.

Benzodiazepines. Benzodiazepines are typically the drugs of choice for oral sedation. As described in Chapter 13, benzodiazepines have a wide margin of safety compared with other antianxiety and sedative drugs. They are well absorbed, and most have a rapid onset of action. Relative contraindications to the use of benzodiazepines include myasthenia gravis, obstructive sleep apnea, and acute angle-closure glaucoma.

Diazepam is the prototypic benzodiazepine and has a long history of use in dentistry. It is efficacious, but it has active metabolites and may have a prolonged duration of action. It may be administered orally for minimal or moderate sedation in adults in doses ranging from 2 to 30 mg. For children, doses of 0.3 to 0.6 mg/kg have been suggested.[50,63] It is available in tablets (2 mg, 5 mg, and 10 mg) and as a syrup (5 mg/5 mL and 25 mg/5 mL).

Triazolam is an effective anxiolytic and amnestic agent; it has a rapid onset of action and a short elimination half-life. This short duration of action is ideally suited to dentistry, allowing for rapid recovery, which is important for outpatient procedures.[9] Triazolam has been shown to be as effective as intravenous diazepam for moderate sedation.[35] Significant adverse reactions of triazolam (e.g., behavioral abnormalities), widely publicized in the lay press, are associated with repeated use of high doses, particularly in elderly patients.[26,56] A significant interaction can occur with drugs that inhibit the biotransformation pathway of triazolam. Specifically, CYP3A4, which metabolizes triazolam, can be inhibited by numerous drugs, including erythromycin, clarithromycin, azole antifungals (ketoconazole, fluconazole, itraconazole), cimetidine, fluvoxamine, and several antiviral drugs including ritonavir. Concurrent administration of these drugs inhibits triazolam's intestinal and hepatic breakdown, leading to increased and prolonged plasma concentrations; grapefruit juice has the same effect.[28] These drugs may potentiate the magnitude and duration of triazolam's sedative effect.

Overall, triazolam's pharmacologic advantages make it a drug of choice for oral sedation in dentistry. The adult dose range is 0.125 to 0.5 mg, and it is available in 0.125-mg or 0.25-mg tablets. A more recent trend in dentistry is to use triazolam in multiple doses to increase or extend the sedative effect. Increased patient monitoring (including continuous pulse oximetry and repeated checks for patient verbal responsiveness) and avoiding spacing doses too close to each other are important considerations to ensuring patient safety.

Lorazepam is an effective premedicant. Although it can elicit satisfactory sedation for dental procedures, it has the potential drawbacks of profound anterograde amnesia and an unusually long duration of action. Peak effects may occur 1 to 6 hours after administration, making appropriate scheduling difficult. It may be considered for longer dental appointments, (e.g., >3 hours). Doses typically of 2 mg (range 0.5 to 4 mg) are suggested for adults; it is available as 0.5-mg, 1-mg, or 2-mg tablets. Lorazepam is not recommended in pediatric patients.

Midazolam, widely used parenterally, is also available as an oral formulation for use in pediatric patients. It is not normally used orally in adults in the United States or Canada. It has a rapid onset and short duration of action. Similar to triazolam, oral midazolam is contraindicated in patients taking erythromycin or other strong CYP3A4 inhibitors because the resulting interaction can lead to increased plasma concentrations of midazolam with subsequent increased and prolonged sedation.[28] Midazolam's high first-pass effect leads to large differences in the parenteral and oral dosing recommendations. For oral midazolam, the usual dose is 0.5 to 0.6 mg/kg, but doses of 1 mg/kg (to a maximum of 20 mg) have been approved.[27]

Alprazolam may be given for longer procedures as an alternative to lorazepam. Alprazolam (but not lorazepam) is subject to the same CYP3A4 interactions as triazolam. The usual adult dose is 0.25 to 0.5 mg. Other benzodiazepines, such as flurazepam, oxazepam, temazepam, and nitrazepam, may also be considered for use in minimal or moderate sedation.

Zolpidem and zaleplon. Zolpidem and zaleplon are sedative-hypnotics related pharmacologically to benzodiazepines because they interact with a subtype of benzodiazepine receptors (see Chapter 13). They are similar to triazolam (also classified as a sedative-hypnotic) in providing anxiolysis, sedation, and a rapid onset of action, with peak effects occurring in 20 minutes. Prolonged sedation is not a problem because of their short metabolic half-lives and conversion to inactive derivatives. Possible disadvantages are their relative lack of anticonvulsant and muscle relaxant properties. Some question remains regarding whether zolpidem and zaleplon produce specific anxiolytic effects common to the benzodiazepines. The average adult dose is 10 mg; zolpidem and zaleplon are available in 5-mg and 10-mg tablets (zolpidem) and capsules (zaleplon). Zolpidem is characterized as a category B drug with regard to pregnancy and may be considered an oral sedative of choice for pregnant women. These drugs are contraindicated in patients with liver disease.

Alcohols. Chloral hydrate has been widely administered for moderate sedation in pediatric dentistry.[16] The drawbacks to this agent are outlined in Chapter 18. It is usually administered in the form of a syrup, with the recommended dose of 40 to 50 mg/kg when administered alone, not to exceed 1000 mg. Although commonly considered to be safe,[2] chloral hydrate has a narrower safety margin than benzodiazepines. It also is a mucosal irritant, may precipitate cardiac arrhythmias, and can produce prolonged recoveries. As with other sedative-hypnotics intended for pediatric sedation, chloral hydrate should not be administered at home. It is usually available at a concentration of 500 mg/5 mL.

Antihistamines. Promethazine is a phenothiazine derivative with antihistaminic properties that is used for minimal-moderate sedation, particularly in pediatric patients. In addition to causing sedation, it is also noted for having

anticholinergic and antiemetic effects. Promethazine may also have modest antidopaminergic properties that can lead to dyskinesia in sensitive individuals. The recommended dose for oral sedation is 25 to 50 mg in adults and 0.5 to 1 mg/kg in children if administered alone. Promethazine has been used in combination with opioids, in which case doses should be reduced. It is available in tablet form (12.5 mg, 25 mg, and 50 mg) and as a syrup in a concentration of 6.25 or 25 mg/5 mL.

Hydroxyzine, the only antihistamine approved specifically as an antianxiety drug, is similar to promethazine in that it is an antihistamine and induces sedation and has anticholinergic and antiemetic effects. Recommended doses range from 50 to 100 mg for adults, if given alone, and 0.65 to 1 mg/kg for children. If it is combined with either chloral hydrate or an opioid, doses should be reduced. It is available in tablet (10 mg, 25 mg, and 50 mg), capsule (25 mg, 50 mg, and 100 mg), and liquid (10 mg/5 mL syrup and 25 mg/5 mL suspension) formulations.

Ketamine. Ketamine is discussed in more detail later because it is primarily used intramuscularly or intravenously to induce dissociative anesthesia, an anesthetic state considered deeper than moderate sedation. It is best used by clinicians trained in deep sedation and general anesthesia. It has been used orally in doses approximating 6 mg/kg as a premedicant (see Chapter 18).[1,62]

Opioids. As described in Chapter 18, opioids are important in sedation and anesthesia but are much more effective intravenously than orally because of their high first-pass metabolism.

Intravenous Sedation

The intravenous route is the most effective method to achieve any level of sedation.[7] The advantages and disadvantages of this route of administration are summarized in Table 48-3.

Advantages

The intravenous route makes possible the rapid attainment of blood concentrations at which drugs are clinically effective. Intravenous injection leads to a very short latent period, which ranges from 30 seconds—the time it may take to go from the intravenous site to the site of action in the brain—to a few minutes (or longer for drugs of low lipid solubility). The ability to titrate drugs and minimize the likelihood of overdosage and to enhance drug action rapidly are other advantages. In clinical practice, the operator requires 2 to 15 minutes to titrate a drug to a desired clinical end point. One more advantage is that a patent intravenous line provides the ideal route for drug administration in the event of an emergency.

Disadvantages

Patients must be cooperative to permit venipuncture. Many children actively resist, and intravenous sedation for children is often undesirable or impossible. Another disadvantage of this route is that the rapid onset of action and the accentuated drug effects likely to be observed tend to magnify problems associated with drug overdose or side effects. As stated earlier, administering intravenous sedation requires advanced training, in part because adverse effects may occur more readily and with more severe consequences.

Clinical applications

For intravenous sedation, monitoring should include, at a minimum, oxyhemoglobin saturation, heart rate, blood pressure, and adequacy of respiration.

Benzodiazepines. As with the oral route, benzodiazepines are the ideal drugs to induce intravenous sedation. Diazepam is lipid-soluble and water-insoluble and is formulated in propylene glycol. This vehicle is often irritating on intravenous administration and may lead to thrombophlebitis.[58] Irritation may be minimized by slow administration into large-caliber veins or by use of a formulation of diazepam dissolved in an injectable emulsion (not currently available in the United States). Diazepam is prepared as a 5-mg/mL solution. The drug must be titrated slowly, with sedative and anxiolytic effects usually beginning at doses of 2 to 10 mg, although great interpatient variability is possible. Appropriate moderate sedation often corresponds with ptosis. By this route, diazepam has a rapid onset of 30 to 60 seconds, with peak effects occurring after approximately 3 minutes. The duration of sedation is dose-dependent, but averages approximately 45 to 60 minutes for sedative doses. Overall, diazepam is an effective agent for intravenous sedation, but it has the disadvantages of slow elimination, active metabolites, and the potential for thrombophlebitis.

Midazolam injection is water-soluble and, when administered intravenously, does not cause venous irritation. Midazolam is rapidly eliminated and is converted to essentially inactive metabolites. After intravenous administration, it has a rapid onset of 30 to 60 seconds, with peak effects reported to occur after 3 to 5 minutes, which may be slightly slower than with diazepam. The distributional half-life is very short, 6 to 15 minutes, leading to a short duration of action of approximately 45 minutes. The duration of action is dose-dependent. It has been suggested that midazolam is approximately three times as potent as diazepam. Moderate sedation is achieved by doses approximating 0.07 mg/kg, titrated slowly in 1-mg increments. Midazolam is provided in strengths of 1 mg/mL and 5 mg/mL. A 1-mg/mL solution is recommended for moderate sedation to facilitate accurate titration.

Barbiturates. As discussed in Chapter 18, barbiturates have continued application in general anesthetic induction, but they are inferior to benzodiazepines for minimal-moderate sedation. Pentobarbital, which has been used parenterally as part of the Jorgensen technique, may be administered in divided doses usually up to 100 mg. When administered intravenously, it has a clinical action lasting 2 to 3 hours. It may be useful for long dental procedures.

Opioids. The pharmacologic characteristics of opioids are discussed in Chapter 20. These drugs are not used alone for sedation, but are commonly given to supplement benzodiazepines or other sedatives either to facilitate moderate sedation or, with increasing doses, to induce deep sedation or general anesthesia. They are useful for painful procedures such as those common in dentistry and oral surgery. Opioids typically provide the advantages of profound analgesia and sedation with minimal cardiovascular effects. The duration of action varies with the drug. Administration of an opioid should be timed so that the peak effect coincides with the most painful part of the procedure.

In general, ASA III patients, such as patients with significant cardiovascular disease, and elderly patients require lower doses of opioids than younger ASA I or II patients. Specific concerns with intravenous opioids include respiratory depression and chest wall rigidity. The latter syndrome is characterized by an increase in muscle tone leading to severe truncal stiffness. It seems to be more prevalent with high doses, with bolus administration of rapidly acting opioids, in elderly patients, and when N_2O is coadministered. Chest wall rigidity is treated with either naloxone or a neuromuscular blocker.

Opioids and related drugs commonly used for sedation include fentanyl, meperidine, morphine, pentazocine, nalbuphine, and butorphanol. Fentanyl is particularly suited for procedures of short duration. The dose for sedation is on the

order of 1 μg/kg. At this dose, it can be expected to have a duration of action of 30 to 60 minutes. Advantages of fentanyl over other opioids include cardiovascular stability, a relatively short duration of action, and lack of histamine release. Fentanyl is more likely to produce chest wall rigidity.[65] Remifentanil is related to fentanyl and is given by intravenous infusion. Its advantages are its rapid onset and its very short duration of action.

Meperidine is administered for sedation in doses of 0.5 to 1 mg/kg, usually not exceeding 100 mg. At these doses, meperidine can be expected to have a duration of action of 1 to 2 hours. In addition to its expected effects of analgesia and sedation, meperidine is noted for its antisialagogue effect and potential to induce tachycardia. It is contraindicated in patients taking monoamine oxidase inhibitors or amphetamines and should be used cautiously, or not at all, in patients with asthma because of the potential for histamine release. A more recent concern is its potential to interact with other drugs—serotonin-selective reuptake inhibitors and various other antidepressants—that can increase the activity of endogenous 5-hydroxytryptamine (serotonin).

Morphine, the first opioid to be isolated in pure form, is still used for intravenous sedation in cases lasting more than 2 hours. Its slow onset of action (peak effect takes 20 minutes or longer) makes titration difficult, so the drug is usually given initially in standard doses, such as 5 mg, with additional increments given only after the drug has had time to become effective and as needed by patient response.

Pentazocine is a mixed agonist-antagonist, which results in a ceiling effect regarding analgesia and respiratory depression. Adverse reactions include a potential for psychotomimetic effects, such as disorientation, confusion, depression, hallucinations, dysphoria, diaphoresis, and dizziness. In doses approximating 0.5 mg/kg, to a maximum of 30 mg, pentazocine can be expected to have a duration of action of 1 to 2 hours. Nalbuphine is also a mixed agonist-antagonist used for sedation. A dose of 0.1 mg/kg, up to a maximum of 10 mg, may be considered. A third agonist-antagonist, butorphanol, has been used for sedation in doses of 0.02 mg/kg, usually to a maximum of 2 mg.

Jorgensen technique. The Jorgensen technique, also known as the Loma Linda technique, has had a long history of safe use. This technique involved the titration of pentobarbital incrementally until the patient was minimally sedated. At this point, a solution containing 25 mg of meperidine and 0.32 mg of scopolamine was administered in a ratio of 1 mL of solution per 20 mg of pentobarbital to a maximum of 5 mL. A final 10% of the baseline barbiturate dose was then given. Although the classic Jorgensen technique is rarely used today, it did prove the practicality and safety of intravenous sedation in restorative dentistry when drugs are carefully titrated and the patient remains responsive to verbal command.

Propofol. Propofol, an intravenous general anesthetic, is described in Chapter 18. In low doses, propofol can be used for moderate sedation or deep sedation.[53] This use requires careful infusion at a rate of 25 to 100 μg/kg/min. Fospropofol, a prodrug that releases propofol on hydrolysis by the enzyme alkaline phosphatase, has been developed specifically for moderate intravenous sedation. Compared with propofol, it has a slower onset and extended duration of action.

Dexmedetomidine. Dexmedetomidine is a centrally acting α_2-adrenoceptor agonist similar in properties to clonidine. Originally indicated for sedation of intubated patients in the intensive care unit, the drug has been approved for moderate sedation. Xerostomia, hypotension, and bradycardia are the most common side effects. An initial evaluation of dexmedetomidine given as a loading dose of 0.1 μg/kg/min for 5 minutes and followed by a continuous infusion of 0.2 μg/kg/hr seemed to be safe and effective for dental patients.[52]

DEEP SEDATION AND GENERAL ANESTHESIA

Many of the drugs described for intravenous moderate sedation can also induce deep sedation or general anesthesia. The characteristics of these deeper levels of CNS depression are summarized in Table 48-1. Drugs used only for general anesthesia, such as volatile anesthetics, are described in Chapter 18. These techniques require more advanced monitoring than does moderate sedation. Techniques used for deep sedation are described next.

Benzodiazepine-Opioid Combinations

The combination of midazolam with fentanyl has been shown to be effective and safe for the induction of moderate sedation.[19,22] These same drug combinations, when administered in higher doses or in more susceptible patients, are also effective in inducing deep sedation. Use of either diazepam or midazolam with an opioid such as fentanyl, meperidine, or morphine can provide effective deep sedation. These drugs are often combined further with N_2O-O_2, propofol, or methohexital.

Neuroleptanalgesia and anesthesia

Neurolepsis, a drug-induced state of indifference to one's surroundings, was commonly used in the past.[10] In its strictest sense, neurolepsis is rarely used today, but it was the forerunner of deep sedation techniques now practiced. Classically, neuroleptanalgesia was induced by using droperidol, a butyrophenone antipsychotic, in combination with an opioid, usually fentanyl. This state is characterized by somnolence without total unconsciousness, psychological indifference, good analgesia, amnesia, and decreased motor activity. When droperidol and fentanyl were combined with N_2O-O_2, the effect was referred to as *neuroleptanesthesia*. Droperidol, which also had wide use as an antiemetic, is used much less commonly today because of governmental concerns regarding its potential to induce serious cardiac dysrhythmias, including QT interval prolongation and torsades de pointes.

Methohexital

The ultrashort-acting barbiturate methohexital is administered for outpatient deep sedation and general anesthesia in dentistry, but its use has diminished since the introduction of propofol.[44] It may be administered alone for procedures of short duration, although it is more commonly administered in combination with other agents, such as benzodiazepines, opioids, and N_2O-O_2.[22] A dose of 1 to 1.5 mg/kg is used for the induction of general anesthesia, whereas increments of 10 mg can be injected for maintenance of deep sedation. The use of methohexital is characterized by a more rapid induction, more rapid recovery, and increased heart rate compared with thiopental. Its disadvantages include the potential for respiratory depression, apnea, hiccough, and coughing. It is contraindicated in patients with certain forms of porphyria, as described in Chapter 13.

Propofol

Propofol (see Chapter 18) is characterized by its short duration of action even after repeated administrations or continuous infusion. The rapid recovery makes it advantageous for ambulatory sedation and general anesthesia in the dental

office. Propofol compares favorably with methohexital for providing sedation and anesthesia for regional blockade, dentistry, and other short procedures. The most frequent adverse effects of propofol include pain on injection and apnea and hypotension in higher doses.

Propofol has been administered by continuous infusion specifically for moderate sedation in dentistry.[53] Because of the increased likelihood of inducing deep sedation or general anesthesia, it is best to monitor the patient with these deeper states in mind. The dose for induction of general anesthesia is 2 to 2.5 mg/kg. If used alone, a titrated infusion of 25 to 100 μg/kg/min should accomplish moderate sedation in healthy adults. Similar doses can produce deep sedation when used after benzodiazepine or opioid injection.

Ketamine

In addition to its use as an oral or intramuscular agent, ketamine can be administered intravenously as an adjunct for deep sedation or general anesthesia. It has been suggested that administering ketamine as a sole agent by low-dose intravenous infusion may provide analgesia, amnesia, and sedation.[7] For use as a general anesthetic agent, ketamine is administered in a dose of 1 to 2 mg/kg intravenously or 5 to 10 mg/kg intramuscularly. For use in sedation or analgesia only, the suggested doses are 200 to 750 μg/kg intravenously, followed by 5 to 20 μg/kg/min as a continuous infusion, or 2 to 4 mg/kg if given intramuscularly.

REVERSAL AGENTS

Specific antagonists are available for opioids and benzodiazepines.

Naloxone

As described in Chapters 18 and 20, naloxone is a reversal agent for the opioid analgesics. The primary indication is in the treatment of opioid-induced respiratory depression, chest wall rigidity, or overly deep sedation. The drug has a peak effect in 5 to 15 minutes, with a duration of action of 45 minutes. Naloxone should be used with caution. Particular concern is warranted regarding patients with cardiac irritability or opioid dependency. Convulsions, alterations in blood pressure, ventricular tachycardia, and ventricular fibrillation have been reported to occur. Therapeutic doses are best administered by titrating slowly in 0.1-mg increments to effect, often to a final dose of 0.4 to 0.8 mg in cases of true opioid overdosage. The duration of action is short, so there is a danger that the antagonistic effect of naloxone will wear off before the agonistic effect of the opioid, resulting in a return of respiratory difficulties. After the administration of naloxone, the patient should be carefully monitored for 1 hour or more, depending on the opioid being antagonized.

Flumazenil

Flumazenil, a specific benzodiazepine receptor antagonist, exerts little effect by itself. When administered to reverse benzodiazepine-induced CNS depression, however, it causes a rapid reversal of unconsciousness, sedation, amnesia, and psychomotor dysfunction. In the presence of a high dose of agonist, flumazenil first reverses the loss of consciousness and respiratory depression, but drowsiness and amnesia may persist. These latter two signs diminish after higher doses of flumazenil. Onset is rapid, with the peak effect occurring in 1 to 3 minutes. The duration of action is dose-dependent, depending on the specific agonist being reversed and how much of it was administered. Incremental doses of 0.1 to 0.2 mg of flumazenil intravenously (up to 3 mg) can be used. Reports indicate that 3 mg may provide 45 to 90 minutes of antagonism.

Flumazenil seems to have few adverse effects other than the important possibility of resedation. The adverse cardiovascular sequelae sometimes seen with naloxone after reversal of opioid overdosage do not occur with flumazenil. Agitation and headache have been reported. Convulsions have occurred in epileptic patients taking benzodiazepines for their condition. Patients taking medications that may cause seizures, such as tricyclic antidepressants, may also be susceptible to convulsions. Flumazenil is indicated whenever rapid reversal of benzodiazepine agonist action is required. As with any reversal agent, the potential for resedation demands that whenever this agent is used to treat an emergency, the patient must be monitored in recovery beyond the potential duration of action of flumazenil.

SUMMARY

Significant progress in the science of dentistry has resulted in important advances in the prevention and treatment of caries and periodontal disease. Many patients fail to benefit from modern dentistry, however, because of fear and anxiety regarding dental treatment. Dentists who are able to use the techniques discussed in this chapter have the capability to carry out dentistry in a compassionate manner for these patients. Patients deserve and expect to be treated as atraumatically as possible, and the administration of judiciously selected drugs can help achieve this goal.

CHAPTER 49

Antibiotic Prophylaxis

THOMAS J. PALLASCH

The discussion in this chapter is as evidence-based as possible in a field where evidence established by observational studies and randomized controlled trials is limited or nonexistent and where "expert" opinion has reigned often with total disregard for whatever evidence was available. Antibiotic prophylaxis has often been and is still used to "prevent" accusations that all was not done for the patient, in the hope of thwarting malpractice litigation. This practice has led to a gross overuse of antibiotics for defensive medicine with ensuing adverse effects and increased microbial resistance for which plaintiff's attorneys have consistently refused to take responsibility. Often the justification for antibiotic prophylaxis to prevent metastatic or surgical infection is based on surrogate markers that do not reflect the true clinical situation. Antibiotic prophylaxis may reduce bacteremias associated with dental treatment, but that is not proof that this also reduces infective endocarditis (IE).[93]

The 2007 American Heart Association (AHA) Guidelines for the Prevention of Infective Endocarditis have assiduously reviewed all the evidence, particularly the alleged association of dental treatment procedures and IE and the efficacy of antibiotic prophylaxis for prevention of IE along with suitable recommendations based on current evidence.[93] Some of that evidence is not repeated in this chapter, and the reader is encouraged to consult the original document.[93] Other excellent and exhaustive studies have explored the basis for antibiotic prophylaxis for nonvalvular cardiovascular devices,[9] prosthetic joints, and other situations associated with controversial antibiotic prophylaxis[46,56] and, finally, the basis for it all—"the focal infection theory."[59]

Concerns have been repeatedly expressed about the risk versus benefit for β-lactams as prophylactic agents and the risk of anaphylactic shock,[58] particularly if antibiotic prophylactic prevention of IE does not work. In addition, data have now appeared showing that surgical prophylaxis in hospitals is associated with increased risk of *Clostridium difficile* infection,[14] and hospital and community use of antibiotics enhances colonization by methicillin-resistant *Staphylococcus aureus*.[85]

PRINCIPLES OF ANTIBIOTIC PROPHYLAXIS

Antibiotic prophylaxis may be indicated if the infection to be prevented is common but not fatal or if it is rare but carries an unacceptably high mortality rate.[6] The principles of antibiotic prophylaxis were established 30 to 40 years ago but have not often been appreciated.[52,60,83,90] These principles are as follows: (1) satisfactory risk and cost/benefit ratios should exist in which the benefit to the patient significantly outweighs medical and financial risks, (2) the antibiotic must be in high concentrations at the target site (blood or tissue) before the onset of the bacteremia or surgery, (3) an antibiotic loading dose (two to four times the maintenance dose) must be used, (4) the antibiotic chosen should be effective against the most likely microorganism to cause the infection, and (5) the antibiotic is continued only as long as microbial contamination of or from the operative site continues.[58,83,90]

The adverse effects of antibiotic prophylaxis include (1) antibiotic allergy and toxicity, (2) superinfections (onset of a new infection while treating another infection), (3) selection of antibiotic-resistant organisms, and (4) induction of resistance gene transfer.[56-58] Contraindications to antibiotic prophylaxis include the following: (1) an at-risk group cannot be sufficiently defined to prevent overuse and abuse of antibiotic prophylaxis, (2) efficacy of prophylaxis is too limited or unreliable, (3) the bacteremia to be prevented is too seldom a cause of infection, and (4) prophylaxis is directed at any and all potential microbial pathogens, rather than the colonization of a single pathogen.[56,58] Antibiotic prophylaxis is primarily intended for two clinical situations: (1) to prevent metastatic bacteremias and (2) to prevent postsurgical infections. The science to support either of these situations is limited or essentially nonexistent.

PREVENTION OF METASTATIC INFECTIONS

With the advent of the 2007 AHA endocarditis prevention guidelines,[93] the guidelines for the prevention of endocarditis of the Working Party of the British Society for Antimicrobial Chemotherapy (BSAC)[24] and the guidelines of the National Institute of Health and Clinical Excellence (NICE) of Britain,[82] the indications for IE prophylaxis have declined to a very few situations or, in the case of the NICE recommendations, to none. Box 49-1 lists these indications according to the AHA. There are none for NICE because this organization could find no evidence for any prophylaxis, including IE. Box 49-2 lists the general conclusions of the AHA, and Box 49-3 lists the cardiovascular and noncardiovascular conditions for which there is no evidence for benefit from antibiotic prophylaxis.

A systematic review of the literature by Lockhart and colleagues[46] concluded that the evidence for antibiotic prophylaxis is essentially only "expert" opinion (author's quotation marks) or case studies with general agreement that such prophylaxis is not useful or effective and in some cases potentially harmful. These clinical situations include native heart valves; prosthetic heart valves and pacemakers; hip, knee, and shoulder prosthetic joints; renal dialysis shunts; vascular grafts; immunosuppression secondary to cancer or cancer

BOX **49-1**

Recommendations of 2007 American Heart Association Endocarditis Prevention Guideline

Dental Procedures for Which Endocarditis Prophylaxis Is Recommended

All dental procedures that involve manipulation of gingival tissue or the periapical region of the teeth or perforation of the oral mucosa*

Cardiac Conditions Associated with the Highest Risk of Adverse Outcomes from Endocarditis for Which Prophylaxis with Dental Procedures Is Reasonable

- Prosthetic cardiac valves or prosthetic material used for cardiac valve repair
- Previous IE
- CHD†
- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or catheter intervention, during the first 6 months after the procedure‡
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplant recipients who develop cardiac valvulopathy

Oral Prophylaxis Regimens Before a Dental Procedure in Situations with High Risk

Single dose 30-60 minutes before procedure

	AGENT	ADULTS	CHILDREN
Oral	Amoxicillin	2 g	50 mg/kg
Allergic to penicillins or ampicillin	Cephalexin§ *or* Clindamycin *or* Azithromycin *or* clarithromycin	2 g 600 mg 500 mg	50 mg/kg 20 mg/kg 15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin *or* ceftriaxone *or* Clindamycin	1 g IM or IV 600 mg IM or IV	50 mg/kg IM or IV 20 mg/kg IM or IV

From Wilson W, Taubert KA, Gewitz M, et al: Prevention of infective endocarditis: guidelines from the American Heart Association. A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia and the Quality Care and Outcomes Research Interdisciplinary Working Group, *Circulation* 116:1736-1754, 2007.

*The following procedures and events do not need prophylaxis: routine anesthetic injections through uninfected tissue, taking dental radiographs, placement of removable prosthodontic or orthodontic appliances, adjustment of orthodontic appliances, placement of orthodontic brackets, shedding of deciduous teeth, and bleeding from trauma to lips or oral mucosa.

†Except for the conditions listed, antibiotic prophylaxis is no longer recommended for any other form of CHD.

‡Prophylaxis is reasonable because endothelialization of prosthetic material occurs within 6 months after the procedure.

§Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

CHD, Congenital heart disease; *IE,* infective endocarditis; *IM,* intramuscular; *IV,* intravenous.

chemotherapy; systemic lupus erythematosus; and insulin-dependent type 1 diabetes.

A review by Baddour and coworkers[9] concluded that there is no evidence to support antibiotic prophylaxis before dental treatment for patients with arterial grafts, cardiac pacemakers and implanted defibrillators, Dacron carotid patches, left ventricular assist devices, and peripheral or coronary artery stents. There is still considerable confusion regarding antibiotic prophylaxis before dental treatment in patients with various orthopedic prosthetic devices. The 1997 and 2003 Advisory Statements of the American Dental Association (ADA) and the American Academy of Orthopaedic Surgeons (AAOS) clearly advise that: "Presently no scientific evidence supports the position that antibiotic prophylaxis to prevent hematogenous infections is required prior to dental treatment in patients with total joint prosthesis."[1,2] The confusion regarding the use of prophylaxis for certain immunocompromised patients and patients less than 2 years after device placement is discussed subsequently.

History of Endocarditis and Antibiotic Prophylaxis

Antibiotic prophylaxis to prevent IE began in 1955 based on some limited animal data, but primarily on the assumption that if antibiotics treat infections, they surely must prevent them. IE prophylaxis arose from the observation that dental treatment was associated with an increase in bacteremia rates, although it was well known at that time that daily living activities also produced bacteremias at roughly the same intensity as dental treatment. This emphasis on possible prevention was understandable considering that in the preantibiotic era, IE in all its forms (acute, subacute, and chronic) was universally fatal, with the only question being how soon the patient would die.

Currently, most studies on antibiotic prophylaxis given before dental treatment have been shown to reduce, but not eliminate, these bacteremias. It is still unknown how many bacteria (inoculum size) are necessary to induce IE. It was also assumed that if the bacteremias were reduced, endocarditis would be prevented. There have never been any data to support this assumption; however, thousands of lawsuits have been filed alleging negligence against dentists with millions of dollars transferred from them and their insurance carriers to the dental patient allegedly developing IE. This hypothesis was expanded to promote antibiotic prophylaxis to prevent orthopedic joint prosthesis infections. Many other alleged metastatic diseases have supported the 100-year-old observation that: "Previously sclerosed endocarditis was in most cases due to mouth organisms."[8]

This theory that metastatic bacteremias were the cause of anatomically distant diseases was embodied in the focal infection theory. At the turn of the 20th century, the focal infection theory proposed that a focus of infection (a confined area that contained bacteria) disseminated these microorganisms and their products in blood to distant body sites where a new infection arose.[59] These foci of infection were primarily located in the mouth, tonsils, and gallbladder and were alleg-

Conclusions of the American Heart Association

Primary Reasons for Revision of Infective Endocarditis Prophylaxis Guidelines

IE is much more likely to result from frequent exposure to random bacteremias associated with daily activities than from bacteremia caused by a dental, GI tract, or GU tract procedure.

Prophylaxis may prevent very few cases of IE, if any, in individuals who undergo a dental, GI tract, or GU tract procedure.

The risk of antibiotic-associated events exceeds the benefit, if any, from prophylactic antibiotic therapy.

Maintenance of optimal oral health and hygiene may reduce the incidence of bacteremia from daily activities and is more important than prophylactic antibiotics for a dental procedure to reduce the risk of IE.

Summary of Major Changes in Updated Document

Bacteremia resulting from daily activities is much more likely to cause IE than bacteremia associated with a dental procedure.

Only a very few cases of IE might be prevented by antibiotic prophylaxis even if prophylaxis is 100% effective.

Antibiotic prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of IE.

Recommendations for IE prophylaxis are limited only to the conditions in Box 49-1.

Antibiotic prophylaxis is no longer recommended for any other form of CHD except for the conditions listed in Box 49-1.

Antibiotic prophylaxis is reasonable for all dental procedures that involve manipulation of gingival tissues or periapical region of the teeth or perforation of oral mucosa only for patients with underlying cardiac conditions associated with the highest adverse outcome from IE (see Box 49-1).

edly responsible for myriad diseases, including arthritis, neuralgias, myalgias, asthma, cancer, pancreatitis, thyroid disease, and "nervous diseases of all kinds."[59] After the loss of millions of teeth, tonsils, and gallbladders, the focal infection theory faded away in the 1930s and 1940s, only to be resurrected today with alleged causation of sarcoidosis, multiple sclerosis, amyotrophic lateral sclerosis, myasthenia gravis, Tourette's syndrome, and other diseases by focal infections. The "oral-systemic connection" is another resurrection of the focal infection theory with as much "evidence" as in the past but with an ever-expanding group of associated diseases, including cardiovascular disease, preterm birth, diabetes mellitus, and Alzheimer's disease.[59]

IE is a bacterial or fungal infection of one or more of the cardiac valves (aortic, mitral, tricuspid, or pulmonary) or the mural endocardium. The primary pathology is the formation of valvular vegetations composed of fibrin and platelets resulting from abnormal jets of blood that damage the valves over time and lead to the vegetations, which become infected by microorganisms in the blood (bacteremias, fungemias). Most IE is caused by staphylococci and streptococci owing to their ability to attach to surfaces using various adhesion molecules.[93]

The rationale for antibiotic prophylaxis to prevent IE with cardiac valvulopathy has been that (1) certain cardiac defects predispose to endocarditis, (2) most microbes causing IE are susceptible to antibiotics, (3) the risk of bacteremias is increased by certain invasive medical and dental procedures, (4) antibiotic prophylaxis reduces the incidence and magnitude of such bacteremias, and (5) antibiotics prevent bacterial attachment to damaged cardiac valves or their multiplication after they become attached.[57,58,93] These suppositions remain valid for the greater risk of IE in individuals with damaged cardiac valves, but it is becoming increasingly obvious that routine bacteremic sensitivity to antibiotics is now unlikely, that it does not follow that reducing bacteremias reduces IE, and that bacteremias associated with daily living are much more likely to produce IE than a few dental appointments in a given year. The lack of evidence for dental treatment being the cause of IE, prosthetic joint infections (PJIs), brain abscesses (BAs), and other potentially bacteremic infections has been challenged since the mid-1970s by numerous individuals,[55] and this has resulted in the new guidelines by the AHA, BSAC, and NICE. Reason and science have finally prevailed after 100 years.

EVIDENCE BASE FOR ANTIBIOTIC PROPHYLAXIS

Data Included in the American Heart Association Guidelines

The 2007 AHA statement on the prevention of IE has been an extensively reviewed document. Twenty-three members of the Writing Group; several content and foreign reviewers; and all members of the AHA Science and Advisory Group encompassing some 70 experts, including cardiologists, infectious disease specialists, and dentists, were involved. The AHA statement has been endorsed by the American College of Cardiology, the Infectious Diseases Society of America, the American Academy of Dermatology, the American Academy of Pediatrics, the International Society of Chemotherapy for Infection and Cancer, the Pediatric Infectious Disease Society, and the American Dental Association.[93] The following discussion summarizes the findings of the AHA and presents relevant data.

An overriding concept that guided the development of the AHA 2007 endocarditis prevention guidelines was that prophylaxis should no longer be based on the lifetime risk of acquiring endocarditis but rather on the highest risk for an adverse outcome from IE. The risk of serious morbidity and higher mortality is much greater in a patient with a prosthetic heart valve than a patient with a bicuspid aortic valve infected with viridans group streptococci (VGS). This greater risk does not mean that antibiotic prophylaxis has a better chance of preventing IE in a patient with a prosthetic valve, only that the pathologic sequelae are greater, and that in the remote chance that prophylaxis would work, it is worth the attempt. This conclusion was based on a thorough review of the literature on IE regarding its etiology, causative factors, pathophysiology, and risk factors for acquisition. Particular emphasis was placed on the role of dental treatment bacteremias in IE causation and the role of antibiotic prophylaxis in its prevention. The document also included a thorough discussion of the various AHA recommendations over the years since 1955 and their progression to the present form.

Essentially, the guidelines state that there is no evidence that antibiotic prophylaxis is effective in preventing IE associated with dental treatment procedures, that the risk of bacteremias from daily living activities is magnitudes greater than that associated with dental treatment, and that such dental treatment procedures are a very small risk for IE. In addition, the guidelines clearly state the following: (1) there is no evidence that the incidence of IE is greater with a higher versus a lower magnitude of bacteremia, (2) the role of the duration of bacteremias is uncertain, (3) a presumed relationship between poor oral hygiene and IE risk is controversial, (4) bleeding from a dental procedure is an unreliable predictor of bacteremia, and (5) no data indicate that a reduction in bacteremia with amoxicillin reduces the risk of or prevents IE. The absolute risk rate for IE from a single dental procedure was between 100,000 and 1 million depending on the type and severity of the cardiac valvular pathology (Box 49-4).[56,59,93]

The absolute risk rate for endocarditis from a dental treatment procedure is essential to the determination of a risk/benefit assessment of antibiotic prophylaxis to prevent IE.[56,59] One would need to premedicate 100,000 to 1 million patients to achieve one successful IE prevention, assuming that antibiotic prophylaxis works and dental treatment bacteremias cause 1% of VGS-induced IE (see Box 49-4).[56] Because the mortality rate from VGS-associated IE is less than 10%, and the rate of anaphylactic death from penicillin is at least 1 per 1 million, it is likely that the risk of death is greater from the prevention than the disease.[57,87]

In 1975, Podgrell and Welsby[64] published an estimate of the odds of IE occurring after a single dental procedure as 1 per 140,000. These data remained unappreciated until the popularization of evidence-based medicine. More specifically, the concept of absolute risk rates for disease incidence and prevalence determination were used to determine how many in a given population actually get the disease or benefit from its treatment. Steckelberg and Wilson[78] published the absolute risk rates for IE in individuals with varying severity of cardiac valvular pathology. Using data from the United States about the annual dental visits per year (1.6), the annual incidence of community IE (11,200 cases), and the percent caused by VGS (25%), it was calculated that (1) the risk for VGS-caused IE in the general population, if all were caused by dental treatment–induced bacteremias, is 1 per 142,000 (very close to the Podgrell-Welsby estimate), and (2) if only 1% were caused by dental treatment, the odds were approximately 1 per 14 million.[56,59]

The risk rate increased substantially depending on the severity of the cardiac pathology using the Steckelberg and Wilson criteria.[78] The odds for patients with (1) previous endocarditis are 1 per 95,000; (2) heart valve prostheses, 1 per 114,000; (3) rheumatic heart disease, 1 per 142,000; (4) congenital heart disease, 1 per 475,000; and (5) mitral valve prolapse with regurgitation, 1.1 per 1 million.[56,59,78] It has likewise been calculated that the risk for PJIs from dental treatment was 1 per 2.5 million, and for BAs the odds ranged from 1 per 1 million to 10 million dental procedures.[58]

Another important consideration is the difference between the incidence of oral bacteremias resulting from dental treatment and oral bacteremias resulting from daily living activities (e.g., brushing, flossing, chewing, mastication, bruxing, and water spray devices). In 1984, Guntheroth[26] estimated the cumulative time for bacteremias from a single dental extraction was 6 to 30 minutes, but 5370 minutes for bacteremias over 1 month of daily living activities. Roberts[70] estimated that tooth brushing twice daily for 1 year gave a 154,000 times greater bacteremic exposure than a single tooth extraction exposure and a cumulative yearly risk 5.6 million times from daily living activities versus a single tooth extraction.

BOX 49-4

Absolute Risk Rate for Various Metastatic Focal Infections From a Single Dental Treatment Procedure

Brain Abscess
1 per 1 million to 1 per 10 million

Prosthetic Joint Infection
1 per 2.5 million

Infective Endocarditis
If all general population VGS-IE cases were caused by dental treatment: 1 per 143,000
If only 1% of VGS-IE cases were caused by dental treatment: 1 per 14 million
If 1% of VGS-IE cases were caused by dental treatment bacteremias
- Risk with previous IE: 1 per 90,000
- Risk with cardiac valve prosthesis: 1 per 114,000
- Risk with rheumatic heart disease: 1 per 142,000
- Risk with congenital heart disease: 1 per 475,000
- Risk with mitral valve prolapse with regurgitation: 1 per 1.1 million

BOX **49-5**

Relative Bacteremia Incidence with Dental Treatment Bacteremias Versus Activities of Daily Living

Dental Treatment Bacteremias	
Tooth extraction	40-80%
Periodontal surgery	36-88%
Simple prophylaxis	0-40%
Buccal anesthetic injection	16%
Intraligamentous injection	97%
Rubber dam/matrix/wedge	9-32%
Nonsurgical endodontic treatment	0-15%
Activities of Daily Living	
Tooth brushing	0-26%
Dental flossing	20-58%
Wooden cleansing devices	20-40%
Water irrigation devices	7-50%
Mastication	17-51%

From Pallasch TJ: Antibiotic prophylaxis: problems in paradise, *Dent Clin North Am* 47:665-679, 2003.

The data in Box 49-5 on the relative incidence of bacteremias comparing dental procedures versus daily living activities have been available for many years.

A determination of the incubation period for IE (from the onset of the bacteremic event to the onset of signs and symptoms) is important for determination of causation. Only one such study has been performed for enterococci and VGS.[77] The median incubation period for 77 cases was 5 days for enterococci and 7 days for VGS, with 84% displaying signs and symptoms within 14 days.[77] The difficulties with this calculation are that the early signs and symptoms of IE are vague and resemble influenza (e.g., fever, chills, night sweats, myalgias, arthralgias) and could be due to a bacteremia occurring days before the dental procedure or some days after.

All of the various IE prevention guidelines stress "good or optimal oral hygiene" as a primary prevention measure, although there are no evidence-based data to support the contention that good oral hygiene reduces the incidence of IE. What constitutes good or optimal oral hygiene has never been defined. It is well established that VGS are antagonistic to periodontopathic microorganisms and that VGS are associated with good oral health.[29,81] Periodontal disease is not a significant factor in IE causation because only about 120 cases of IE have been associated with periodontal pathogens (i.e., mostly with *Aggregatibacter actinomycetemcomitans*).[56] Undocumented opinion prevails regarding the role of oral hygiene in IE prevention.

Another difficulty with antibiotic prophylaxis using β-lactam antibiotics is in regard to their mechanism of action. Many studies claim that penicillins given before a bacteremia-producing procedure reduce the bacterial level commonly within seconds to minutes after initiating the procedure. Other studies indicate no significant effect.[93] Based on the mechanism of action of β-lactams (slow bacterial killing by inhibition of cell wall synthesis), it is difficult to understand how an antibiotic that kills in hours reduces bacteremias in seconds to minutes.[17] It is also known that many oral bacteria, particularly VGS, are resistant to β-lactams, further compromising the efficacy of antibiotic prophylaxis (see Chapter 39).

The claim that a single dose of antibiotic is not a factor in the global epidemic of microbial resistance to antibiotics ignores the millions of other practitioners who may be doing the same thing daily for similar reasons around the globe. This prescribing pattern leads to cumulatively millions of unnecessary antibiotic doses annually. This attitude underlies the concept of health care practitioners who tend to focus on the patient in front of them and forget about the effects of their treatment on others whom they may unintentionally harm.

It has been customary to place the entire blame for IE on the bacteria that attach to the damaged cardiac valve and the health practitioners who initiate the bacteremia. It was always an enigma as to why this belief was held to be true because it has been documented that ongoing bacteremias are a way of life for humans—even to the possibility of millions per year.[70] Yet IE is a very rare disease with an incidence of 11 to 50 per 1 million individuals annually in the United States. One answer often overlooked is the failure of the host defense system of the patient. One of the major defenses against blood-borne bacteria is the blood platelet, which possesses a remarkable ability to kill bacteria in the blood and in or on the cardiac valve vegetation. This antibacterial activity is related to aggregating bacteria to clear them from the blood and the release of microbicidal agents similar to other antimicrobial proteins.[16,40,95] These platelet antimicrobial proteins are synergistic with penicillins but are antagonized by tetracyclines over a wide range of minimum inhibitory concentrations (0.16 to 1.25 μg/mL), as seen with low-dose doxycycline in the treatment of periodontal disease.[94] It may take a combination of bacteremias, vegetations, and a failure in host platelet antimicrobial defenses to precipitate IE.

When considering the economic impact of antibiotics on IE, it has been estimated that all antibiotic prophylaxis regimens are less cost-effective than clarithromycin, which has a price tag of $88,007 per quality-adjusted life-year saved.[85] Other estimates are $20 million to prevent 35 IE cases with erythromycin in mitral valve prolapse, $1 million per life saved with penicillin for mitral valve prolapse prophylaxis, and $96 million to prevent 32 fatal cases of VGS-associated IE or $300,000 for every nonfatal case assuming a 10% fatality rate using the 1997 AHA guidelines.[58]

The risk/benefit ratio for penicillin prophylaxis in the prevention of IE has always been contentious. Two studies in the 1980s indicated that the mortality from penicillin prophylaxis exceeds that of IE. The risk/benefit ratio for penicillin is favorable only in cases when the highest incidence (50 per 1 million population) and the highest mortality rate (40%) coexist.[53] A study by Tzukert and associates[87] found that 1.36 individuals per 1 million population were likely to die from penicillin anaphylaxis, whereas only 0.26 deaths per 1 million could be ascribed to dental treatment–induced IE. A more recent study calculated that penicillin prophylaxis might prevent 9 cases of IE per 10 million population at moderate to high risk for IE, but would cause 181 penicillin-induced anaphylactic deaths (18 per 1 million).[3] According to these studies, penicillin prophylaxis would result in a net loss of life and be unethical. Added to this finding may be the increase in methicillin-resistant *S. aureus* colonization with community and hospital use of antibiotics[85] and the increase in hospital-acquired *C. difficile* with surgical antibiotic prophylaxis.[14]

The diagnosis of IE can be difficult, leading to underdiagnosis with subsequent serious morbidity and mortality and overdiagnosis leading to iatrogenic disease, antibiotic misuse, and malpractice allegations against dentists without merit. Although the incubation period can be useful to rule out causation of IE, a disturbing practice has developed to diagnose IE. On the basis of a self-reported fever, an unconfirmed cardiac murmur, or one or two positive blood cultures, IE has been diagnosed. In 1994, the Endocarditis Service of the Duke University Hospital devised a list of criteria for the diagnosis

BOX **49-6**

Modified Duke Criteria for Diagnosis of Infective Endocarditis

Major Criteria

Blood culture positive for IE

Typical microorganisms consistent with IE from two separate blood cultures: viridans streptococci, *Streptococcus bovis,* HACEK group, *Staphylococcus aureus,* or community-acquired enterococci in the absence of a primary focus, *or*

Microorganisms consistent with IE from persistently positive blood cultures defined as follows: at least two positive blood samples drawn >12 hours apart or all of three or most of greater than or equal to four separate cultures of blood (with the first and last sample drawn at least 1 hour apart)

Evidence of endocardial involvement

Echocardiogram positive for IE defined as follows: oscillating intracardiac mass on valve or supporting structures in the path of regurgitant jets or on implanted material in the absence of an alternative anatomic explanation; *or* abscess; *or* new partial dehiscence of a prosthetic valve—new valvular regurgitation (worsening or changing of preexisting murmur is insufficient)

Minor Criteria

Predisposition: heart condition, intravenous drug use

Fever: temperature >38° C

Vascular phenomena: major arterial emboli, septic pulmonary infarcts mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway's lesions

Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor

Microbiologic evidence: positive blood culture, but does not meet a major criterion as noted above (excludes single blood cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis), or serologic evidence of active infection with organism consistent with IE

Definition of Infective Endocarditis

Definite Infective Endocarditis

Pathologic criteria: microorganisms shown by culture of histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; or vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

Clinical criteria: two major criteria; or one major criterion and three minor criteria; or five minor criteria

Possible Infective Endocarditis

One major criterion and one minor criterion; *or* three minor criteria

Rejected

Firm alternative diagnosis explaining evidence of IE; *or*

Resolution of IE syndrome with antibiotic therapy for ≤4 days; *or*

No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy ≤4 days; *or*

Does not meet criteria for possible IE as listed

From Li JS, Sexton DJ, Mick N, et al: Proposed modifications to the Duke Criteria for the diagnosis of infective endocarditis, *Clin Infect Dis* 30:633-638, 2000.
HACEK, Haemophilus, Actinobacillus, Cardiobacterium, Eikenella, Kingella; IE, infective endocarditis.

of IE based primarily, but not exclusively, on the echocardiogram.[18] This list was later modified with additional criteria and is now known as the Modified Duke Criteria.[37,42]

The Modified Duke Criteria are often used in research studies to establish a strict case definition of IE because the data accumulated would be worthless and misleading if the disease studied was not IE. These criteria are used far less often in the community and hospital diagnosis of IE. Attempts may be made in the future to assess whether the incidence of IE has increased with the virtual elimination of dental antibiotic prophylaxis to prevent IE. Unless the Modified Duke Criteria (Box 49-6) are used in this analysis, the data generated would greatly overestimate the IE incidence. Because IE has not declined since the advent of antibiotic prophylaxis, such data would require scrutiny and skepticism.

The question has arisen regarding whether the 2007 guidelines, listed in Box 49-1, are indicated for patients with heart murmurs. The simple answer is that heart murmurs do not need premedication with antibiotics. According to the study by Lockhart and colleagues,[46] only individuals with cardiac transplants require prophylaxis, but it may be wise to consult with the physician to ascertain if other solid organ transplants may also have developed cardiac valvulopathy. In a retrospective study of 1000 patients using M-mode, two-dimensional, and pulsed continuous color Doppler echocardiograms, it was determined that cardiac valve abnormalities greatly increase with age.[15] According to this study, if the 1997 AHA guidelines were used, 30% of individuals younger than age 30, 50% of individuals older than age 60, and 42% of all individuals would have required antibiotic prophylaxis before dental treatment. If these data are correct, an enormous number of patients "needing" antibiotic prophylaxis according to these guidelines never received it, yet there was no subsequent increase in IE incidence.

In the discussion of antibiotic prophylaxis to prevent metastatic bacteremias, important concepts or data are often overlooked or not fully appreciated. Two studies have published data on bacteremias present before dental treatment. In one study, an 80% incidence of bacteremia (1.5 cfu/mL of blood) was present before dental extraction versus 90% (2.1 cfu/mL of blood) after extraction.[30] In the second study, a pre-extraction bacteremia of 31% (3.6 cfu/mL of blood) was present versus 42.9% incidence (5.9 cfu/mL of blood) after extraction.[47] A reduction in these bacterial counts by prophylaxis is a surrogate marker intended to substitute for the actual clinical end point (IE reduction).[4,7,65] A randomized trial to determine whether prophylactic antibiotics were effective in preventing IE would require 6000 patients and be prohibitively expensive for a disease that is so rare.[93]

A reduction in bacteremias alone does not translate to a reduction in IE because it is unknown just how many bacteria (i.e., inoculum size) are required to initiate IE.[93] Virtually all studies on the reduction of bacteremias by antibiotic prophylaxis have relied on statistical significance to determine clinical significance. Statistical significance is useful to determine whether the result happens by chance, but this sometimes has only a modest bearing on whether the finding would benefit the patient (i.e., clinical significance). Statistical significance must be placed into perspective with clinical significance for any study.[4,65,80]

There are some additional items for the clinician to remember concerning the 2007 AHA guidelines.[93] First, if antibiotic prophylaxis is inadvertently not administered before dental treatment, it may be given 2 hours after the procedure. The addition of a preprocedural antibacterial mouth rinse has not been proven to be beneficial in the prevention of IE. Lastly, if an antibiotic is used for prophylaxis, that same antibiotic should not be used again unless the next appointment has been scheduled 10 days later. If this cannot be done, another approved antibiotic should be considered.

A final question concerns methods to inform physicians who have been prescribing for a patient who has been taking antibiotic prophylaxis before dental treatment for situations that are no longer recommended by the AHA. These guidelines recommend several talking points, which include the greater risk from random bacteremias than bacteremias associated with dental treatment, the limited or nonexistent efficacy of prophylaxis, its associated adverse effects, and the possible benefits of good oral hygiene.[93] Further help in regard to dentist-physician interactions can be found in an article by Brown and associates[13] that addresses the proper format for the dentist-physician consultation.

POTENTIAL BUT UNDOCUMENTED ANTIBIOTIC PROPHYLAXIS SITUATIONS

Antibiotic prophylaxis has sometimes been recommended for the following clinical situations, but without any randomized controlled trials or observational studies to address efficacy. Currently, there are two case-control studies that evaluate the relationship between dental patient treatment and IE.[35,84] There are no case-control studies available for the situations listed in Box 49-3. What evidence exists is presented here.

Orthopedic Joint Prostheses

The 1997 and 2003 Advisory Statements of the ADA and the AAOS state: "Presently no scientific evidence supports the position that antibiotic prophylaxis to prevent hematogenous infections is required prior to dental treatment in patients with total joint prostheses."[1,2] The absolute risk rate for a PJI from a dental treatment procedure has been estimated, in the worst-case scenario, to be 1 per 2.5 million assuming 30 to 40 cases of PJIs per 100,000 person-years (0.03% to 0.04%).[56,59] No documented case of dental treatment bacteremia infecting a joint prosthesis exists. Four genetically identical *Streptococcus sanguis* organisms, from highly septic oral cavities, were isolated from the mouth and the prosthetic joint, but were unrelated to dental treatment.[10] To place PJIs in added perspective, two studies have determined a 9% and 17% bacterial contamination of the prosthetic joint surgical site before placement,[5,21] an 11% microbial contamination of allografts of the femoral head,[89] and a 6.4% to 15% contamination of the surgical blades used in prosthetic joint replacements.[71]

The incubation period for PJIs allegedly caused by dental treatment procedures is difficult to determine but is likely considerably longer than that associated with VGS-associated IE. An incubation period of 5 to 60 months (average 31 months) was determined[50] with the inherent difficulty of determining the precise time of the onset of the bacteremia. Another estimate was 4 to 104 months (average 39 months),[66] and two cases from *Clostridium perfringens* and *Streptococcus pneumoniae* estimated incubation periods of 10 months (*C. perfringens*) and 7 months (*S. pneumoniae*).[48] The advantage of these two cases was that the onset of the bacteremia could be precisely determined.

Depending on the particular version of the ADA/AAOS guidelines, it is advised that the practitioner may or should consider antibiotic prophylaxis for certain immunocompromised patients, such as patients with systemic lupus erythematosus, drug-induced or radiation-induced immunosuppression, hemophilia, human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), insulin-dependent diabetes mellitus, malignancy, malnourishment, and previous PJIs. There are no data to support the contention that the aforementioned patients are at greater risk for PJIs than patients without these disorders.

The ADA/AAOS guidelines have been misinterpreted regarding the 2-year period after prosthetic joint placement, with some advocating mandatory prophylaxis during this period. There is no such admonition in the guidelines. Data from the Mayo Clinic indicate an exponential decline in PJIs over this 2-year period ending in a very low plateau level at about 2 years after placement.[54] If, despite these data, the practitioner wishes to use antibiotic prophylaxis in such patients, the dose is 2 g of amoxicillin, cephalexin, or cephradine or 600 mg of clindamycin 1 hour orally before the dental procedure.[1,2]

A preponderance of evidence supports the premise that antibiotic prophylaxis is not beneficial in preventing hematogenous infections in patients with prosthetic joints. However, in February 2009, the AAOS recommended that antibiotic prophylaxis, prior to any procedure that may cause a bacteremia, is recommended in patients undergoing a joint replacement or with a prosthetic joint.[2] Even though the position was not based on new data or a cogent rationale, the report from the AAOS stated that "given the potential adverse outcomes and cost of treating an infected joint replacement, the AAOS recommends that clinicians consider antibiotic prophylaxis for all total joint replacement patients prior to any invasive procedure that may cause a bacteremia."[2]

Breast and Penile Implants

No scientific evidence supports antibiotic prophylaxis before dental treatment for patients with breast[12,63] or penile implants. The risk of late infections (>7 months after placement) for breast implants is 1 per 10,000.[62] In a survey of urologists, most believed that prophylaxis before dental treatment was inappropriate.[44]

Brain Abscess

After IE and PJIs, the third metastatic infection likely to involve a dentist in negligence litigation comprises BAs, subdural empyemas, and spinal epidural abscesses. Data show that streptococci are the most likely cause of BAs and that most occur in the frontal and temporal lobes supplied by the middle cerebral artery. Microbes can reach the brain by direct contiguous spread (sinuses, middle ear), via head trauma, or via blood (hematogenous). Microbial penetration into the brain past the blood-brain barrier may occur by three mechanisms: (1) transcellularly (e.g., streptococci, *Escherichia coli*, *Neisseria meningitidis, Candida* species), (2) paracellularly (e.g., *Borrelia* species, trypanosomes), and (3) via "Trojan Horses" within infected phagocytes (e.g., *Listeria monocytogenes* and *Mycobacterium tuberculosis*).[34] The oral cavity is not the most likely source of BA because otitis media and sinusitis account for 50% to 60% of BAs in the United States, with 20% having no known source.[58,59]

VGS are found in BAs attributed to other anatomic sources, such as otitis media/mastoiditis (23.3%), sinusitis (15.7%), and hematogenous (10%).[58] It is often unappreciated that VGS are ubiquitous microorganisms found commonly not only in the oral cavity, but also in the gastrointestinal and genitourinary tracts, skin, mucosa, and eye owing to their ability to stick to surfaces and their survivability in various environments.

BAs are very rare and are diagnosed at a rate of 1 per 10,000 hospital admissions with an absolute risk rate for

dental treatment association of 1 per 1 million to 1 per 10 million.[58] The incubation period for BAs is approximately 16 to 18 days with a mean time to hospitalization of 12 days. The mean time from onset of bacteremia to diagnosis and hospitalization is approximately 30 days.[56]

It is occasionally alleged that epidural abscesses and subdural empyemas are caused by oral streptococci from dental treatment procedures. Historically, the incidence of spinal epidural abscesses has been similar to BAs at 0.2 to 1.2 to 3 per 10,000 hospital admissions.[74] The microbial etiology of epidural abscesses includes staphylococci (57% to 93%), streptococci (18%), and gram-negative organisms (13%) as determined in 830 patients.[25] Subdural empyema is usually attributed to sinusitis, meningitis, or trauma or surgery.[53] Possibly 1% of subdural empyema are of oral microbial origin, and the etiology is often polymicrobial, which includes staphylococci, streptococci, and various anaerobes.[38]

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia is an autosomal dominant disorder characterized by abnormal vascular development; nosebleeds and telangiectasia at multiple sites (lips, oral cavity, nose); and a family history of arteriovenous malformations of the lungs, liver, brain, spine, and gastrointestinal tract.[75,86] The prevalence of the disorder is 1 per 5000 to 1 per 8000 individuals,[76] and it predisposes to BAs and ischemic stroke because of bypassing of the blood filtering system of the pulmonary capillaries, blood hypoxia, or infection of a previously sterile embolus.[76]

Two more recent studies have examined the incidence of BAs in patients with hereditary hemorrhagic telangiectasia with regard to microbial etiology.[73,76] One recommended antibiotic prophylaxis before dental treatment without addressing the AHA data on antibiotic prophylaxis or BA data.[76] Sell and coworkers[73] examined 55 cases with 15 caused by various streptococci, which included 9 by peptostreptococci (*Micromonas micros*), 3 by *Fusobacterium* species, 2 by *Actinomyces* species, and 1 by C*apnocytophaga* species. The authors did not recommend antibiotic prophylaxis. Shovlin and colleagues[76] examined 210 cases including 57 experiencing either BA or ischemic stroke between the ages of 9 and 70 years (9.05% over this time period). The time from the alleged onset of dental treatment–induced bacteremia to diagnosis was "weeks." Antibiotic prophylaxis before dental treatment in patients with hereditary hemorrhagic telangiectasia cannot be recommended on an evidence-based approach.

Nonvalvular Cardiovascular Devices

The issue of whether bacteremias from dental treatment are responsible for infections of various nonvalvular cardiovascular devices has been addressed with literature reviews by Baddour and associates[9] and Lockhart and colleagues[46] and subsequent studies.[23] No relationship between VGS bacteremias and infections has been shown in these patients (see Box 49-6).

Hemodialysis

No observational or randomized controlled studies have been done to determine if antibiotic prophylaxis in patients on hemodialysis or with indwelling catheters results in IE. Lockhart and colleagues[46] found no correlation with dental procedures in such patients. In a study of long-term hemodialysis patients from 1983-1997, 20 cases of IE occurred in 1559 patients, with 3 attributed to VGS.[49] In 1445 patients receiving long-term hemodialysis, 63 cases of bacteremia were detected (0.7 per 100 patient-months), with 2 associated with VGS.[28] Virtually all IE cases were caused by staphylococci.[9,46]

Splenectomy

Individuals without spleens have a small but significant lifelong susceptibility to infection, particularly with *S. pneumoniae, Haemophilus influenzae,* and *N. meningitidis*. None of these are typical oral flora. In 5902 cases of post-splenectomy infection, 0.8% were caused by VGS.[31] In 77 more recent cases, none were caused by VGS.[91]

Solid Organ Transplants

Antibiotic prophylaxis for the prevention of IE in patients with solid organs transplants is not generally recommended because no study has determined that such patients are at risk for bacteremic infections,[61] but the AHA recommends prophylaxis for cardiac transplant patients who develop cardiac valvulopathy.[93] The AHA guidelines do not address valvulopathy and prophylaxis in patients with other solid organ transplants. Patients with liver, pancreas, kidney, and other solid organ transplants have a tendency to develop marantic valve lesions (nonbacterial thrombotic endocarditis) similar to that seen in patients with systemic lupus erythematosus.[79] A medical consultation may be called for to determine if marantic lesions are present.

Diabetes Mellitus

No data support the use of antibiotic prophylaxis in diabetic dental patients.[46] Only 2% of surveyed infectious disease specialists would recommend prophylaxis before dental treatment in patients with poorly controlled diabetes.[45]

Immunocompromised Patients

Dental patients with a suppressed granulocyte count of 500 to 1000 have been suggested to be at risk for bacteremia-related infections, but there are no evidence-based studies to support this contention. In patients with bone marrow transplants, the greatest risk for VGS infections is in the early stages and is proportional to the magnitude of the oral mucositis present.[20,88] Severely neutropenic patients should receive only emergency dental care. Dental patients with HIV/AIDS are not at greater risk for IE or its complications.[56,69] Intravenous drug users have an IE rate of 3.8 per 1000 if HIV-negative and 13.8 per 1000 if HIV-positive.[22] The microorganisms involved are virtually all commensals, and greater than 70% of cases involve the tricuspid valve with a 5% mortality rate.[22,41] The question of antibiotic prophylaxis for patients with head and neck radiation to prevent osteoradionecrosis has never been settled. A review by Wahl[92] found no evidence that prophylaxis prevents osteoradionecrosis infections. If antibiotic prophylaxis is used, there is no consensus regarding the drug, dose, timing, or duration.[33]

Collagen and Myeloproliferative Disorders

Many patients with collagen or myeloproliferative disorders are at risk for developing cardiac valvular disorders, which include systemic lupus erythematosus, Marfan syndrome, Ehlers-Danlos syndrome, Hurler's syndrome, pseudoxanthoma elasticum, polycythemia vera, and essential thrombocytopenia.[67,68] The valvular damage is usually of the Libman-Sacks type (e.g., marantic, nonbacterial thrombotic vegetations), which then may become infected. Libman-Sacks/marantic endocarditis may also be seen in patients with cancer, burns, septicemia, disseminated intravascular coagulation, rheumatoid arthritis, and primary antiphospholipid syndrome.

DENTAL SURGICAL PROPHYLAXIS

More recent systematic reviews and meta-analyses strongly suggest that antibiotic prophylaxis after dental treatment is

ineffective in preventing infection or other postoperative complications.[68,72] Such an approach violates the principles of antibiotic prophylaxis established more than 40 years ago, which require an antibiotic be in the target site (blood or tissues) before the bacteremia or surgery for it to be successful.[60,83,90]

More recent studies are now beginning antibiotic prophylaxis 1 hour before the surgery and terminating the antibiotic at the end of the surgery because the risk of postoperative infection greatly increases if the prophylaxis is continued more than 1 to 2 days after the surgery.[60] Most of these studies done to date have shown no benefit,[11,27,32,43,72] with one meta-analysis indicating the number needed to treat (NNT) to prevent one alveolar osteitis or infection was 13 to 25 patients.[68] In a meta-analysis of local antibiotics or antiseptics to prevent localized osteitis, the antibiotic judged best was tetracycline with NNT of 3 to 8 to prevent 1 localized osteitis, and the antiseptic was chlorhexidine with NNT of 4 to 36 to prevent 1 localized osteitis.[27]

All these meta-analyses suggest that these studies on antibiotic prophylaxis for the prevention of oral surgical infections primarily in third molar extractions were poorly performed with none meeting the strict criteria of the Cochrane Research Group.[39,68,72] In general, these studies had limited value because of (1) small sample sizes with limited power, (2) lack of comparison groups, (3) no monitoring of patient compliance with the antibiotic protocol, and (4) poor monitoring of the interventions.

It is also difficult to support dental surgical antibiotic prophylaxis based on biologic plausibility and the increasing incidence and prevalence of microbial resistance to antibiotics. All postoperative infections in dentistry are polymicrobial, and one of the tenets of antibiotic prophylaxis is to direct it toward the most likely microorganism to cause the infection.[60,90] Antibiotic prophylaxis has been documented to be effective only for the prevention of surgical infections in clean-clean and some clean-contaminated surgeries. With an estimated 700 potential pathogens in the oral cavity, it hardly qualifies as a "clean" operating area. In addition, oral microorganisms show a 20% to 40% resistance rate to common antibiotics, and orofacial infections are rarely life-threatening. More recent data on the increased colonization rates with methicillin-resistant *S. aureus* on antibiotic exposure[85] and the increase in *C. difficile* infections associated with hospital antibiotic prophylaxis[14] must now be added to the risk/benefit calculation for dental surgical antibiotic prophylaxis.

FUTURE OF ANTIBIOTIC PROPHYLAXIS

There is an old adage that new scientific theories go through three phases on the road to acceptance: (1) the theory is not true; (2) the theory is true but unimportant; and (3) the theory is true and it is important, but we knew it all along.[19] Relying on current evidence-based science, it is now established that bacteremias from dental treatment are rarely, if ever, a cause of IE, PJIs, and myriad other systemic disorders. The future use of antibiotic prophylaxis should be restricted to the AHA guidelines for IE prevention and surgical prophylaxis in the hospital environment.

In the future, evaluations of IE associated with dental treatment cannot rely solely on hospital discharge records because of potential errors (e.g., 28% to 45% of death certificates incorrectly identify the cause of death) in discharge records.[36,51] To ascertain the true number of IEs associated with any procedure, the strict case definition of the Modified Duke Criteria must be used.

CHAPTER 50

Oral Complications of Cancer Therapy

RAJESH V. LALLA, MICHAEL T. BRENNAN, AND MARK M. SCHUBERT

The management of cancer has become increasingly complex with the use of more aggressive chemotherapy and radiation protocols, plus the expanded application of combination protocols. Such protocols include several modalities of treatment including surgery, chemotherapy, radiation therapy, and newer immune-mediated treatments. The result is the opportunity for increased disease control and cure. Protocols that use high-dose regimens of chemotherapy, or chemotherapy combined with radiation therapy followed by hematopoietic cell transplantation (HCT), are also increasingly being used to treat many cancers.

These various advances in cancer therapy are lifesaving, but often have significant morbidity and complications. Considerable attention is now being paid to the medical significance of complications of cancer therapy and the effects these complications have on quality of life. Studies have shown that the oral complications of cancer therapy can significantly interfere with the course of cancer therapy, adversely affect general quality of life, and increase the cost of care.[78] In addition, a number of chronic orofacial complications can significantly affect long-term quality of life and oral function after cancer therapy. Successful prevention and treatment of the oral complications of cancer therapy can reduce pain, suffering, and disability while decreasing the risk of complications that may interfere with ongoing cancer therapy or result in lifelong functional compromise.

The oral complications of chemotherapy and radiation therapy are similar in many respects, but some complications are unique to the specific treatment modality. Both treatment approaches cause oral mucositis, taste dysfunction, and salivary gland dysfunction. A significant difference exists between the two modalities relative to whether the toxicity is transient (i.e., during chemotherapy) or progressive and permanent (as is often the case with radiation therapy). Because cancer chemotherapy is predominantly administered systemically, systemic toxicities can increase the risk of oral complications (e.g., myelosuppression resulting in oral infection and bleeding). In contrast, the effects of radiation are primarily limited to the irradiated tissues.

ORAL COMPLICATIONS OF CHEMOTHERAPY

In general, the therapeutic effects and toxicities of cancer chemotherapy arise from damage to rapidly dividing cancer and normal cells. Only a few anticancer agents can specifically target cancer cells. Consequently, most cancer chemotherapeutic agents inadvertently damage normal tissues of the body. Because the growth fraction for cancer is usually much higher than most normal tissue compartments, there is a quantitative difference in damage to the cancer cells compared with normal cells. Although systemic toxic effects of cancer chemotherapy usually result from damage to rapidly dividing cells, some toxicities result from damage that is not specifically related to cell division (Box 50-1).

Oral complications of cancer therapy may result directly from the cytotoxic effects (direct toxic effects) of the drugs on oral tissues (including salivary glands) or result from therapy involving distant tissues (indirect toxic effects). The clinical presentation of complications generally represents the results of complex interactions among multiple factors. These oral complications are listed in Box 50-2.

A number of factors affect the clinical expression of oral toxic effects of chemotherapy, the most prominent being which chemotherapeutic agent is administered along with its dose and schedule. The high turnover rate of oral mucosal tissues puts them at risk for the cytotoxic effects of many antineoplastic agents. Direct mucosal damage may be accentuated by many factors, including (1) salivary gland dysfunction, which compromises the barrier and lubricating functions provided by saliva; (2) mucosal trauma or irritation (e.g., from normal oral function, medications, and mouth breathing); and (3) infections caused by indigenous oral flora (especially opportunistic oral pathogens), acquired pathogens, and the reactivation of latent herpesviruses that cause local and systemic complications in patients who become immunosuppressed.[62]

Direct Oral Toxic Effects

Oral mucositis

The terms *oral mucositis* and *stomatitis* were often used interchangeably in the past, but they do not reflect identical processes. *Stomatitis* is a more general term and is applied to any inflammatory condition of the oral tissues, regardless of cause, including infections and autoimmune disorders. The term *oral mucositis* is increasingly being applied to inflammation and breakdown of the oral mucosa resulting from damage caused by chemotherapeutic agents or radiation therapy.[64] *Oral mucositis* is the preferred term to represent the direct mucosal toxicity of cancer therapies on oral mucosal tissues.

Epidemiology. Oral mucositis is a significant problem in patients receiving chemotherapy for solid tumors. In one study, 303 of 599 (51%) patients receiving chemotherapy for solid tumors or lymphoma developed oral or gastrointestinal (GI) mucositis, or both.[17] Oral mucositis developed in 22% of 1236 cycles of chemotherapy, GI mucositis developed in 7% of cycles, and oral and GI mucositis developed in 8% of cycles. Among patients who receive high-dose chemotherapy before HCT, an even higher percentage (approximately 75% to 80%) developed clinically significant oral mucositis.[83]

BOX 50-1

Systemic Toxicity of Cancer Chemotherapy

DIRECT TOXICITIES	OTHER TOXICITIES
Bone marrow	Heart
Neutropenia	Liver
Thrombocytopenia	Lung
Anemia	CNS
Gastrointestinal mucosa	Kidney

BOX 50-2

Oral Complications of Cancer Chemotherapy

DIRECT TOXICITIES	INDIRECT TOXICITIES
Oral mucositis	Myelosuppression
Salivary gland dysfunction	Neutropenia, immunosuppression
Neurotoxicity	Anemia
Trigeminal nerve neuropathies	Thrombocytopenia
Taste dysfunction	Infection
Dentinal hypersensitivity	Viral (HSV, VZV, CMV, EBV, other)
Temporomandibular dysfunction	Fungal (*Candida, Aspergillus,* other)
Myofascial pain	Bacterial
Temporomandibular joint dysfunction	Gastrointestinal mucositis
Dental and skeletal growth and development (pediatric patients)	Nutritional disturbances
Abnormalities in dentition	Nausea and vomiting
Changes in jaw development	Acidic damage to oral tissues
Osteonecrosis related to bisphosphonate therapy	Heightened gag reflexes

Morbidity. Oral mucositis can be very painful and can significantly affect nutritional intake, mouth care, and quality of life.[16,42] For patients receiving high-dose chemotherapy before HCT, oral mucositis has been reported to be the most debilitating complication of transplantation.[4,80] In patients immunosuppressed because of chemotherapy, increased severity of oral mucositis was found to be significantly associated with an increased number of days requiring total parenteral nutrition and parenteral narcotic therapy, increased number of days with fever, incidence of significant infection, increased time in the hospital, and increased total inpatient charges.[83] A reduction in the next dose of chemotherapy was twice as common after cycles with mucositis than after cycles without mucositis.[17] Mucositis is not only a concern for pain and suffering, but can also cause dose-limiting toxicity of cancer chemotherapy with direct effects on patient survival.

FIGURE **50-1** Oral mucositis ulcer involving the right lateral and ventral tongue.

Pathogenesis and clinical presentation. The mucosal surfaces throughout the oral cavity have different cellular turnover rates, which can vary from 4 to 5 days for nonkeratinized buccal and labial mucosa to 14 days for the orthokeratinized hard palate. The more rapid the cell division rate of the progenitor epithelial cells, the higher the susceptibility to damage from chemotherapy and radiation therapy. The mechanisms involved are more complex, however, than simply direct damage to oral epithelial cells from chemotherapy or radiation therapy. The currently accepted model for the pathogenesis of mucositis postulates five stages associated with tissue damage and healing. Initiation of direct tissue injury is thought to be mediated by production of reactive oxygen species resulting in cell death. This stage is followed by activation of second messengers that upregulate the production of proinflammatory cytokines in mucosal epithelium and submucosal tissues and lead to widespread tissue injury. Through feedback mechanisms, these cytokines can amplify the cascade of tissue injury further, leading to ulceration and secondary infection. The final stage is characterized by the stimulation of epithelial proliferation and differentiation, leading to mucosal healing.[77]

Histologically, the mucosal damage is characterized by mucosal atrophy, inflammatory cell infiltrates, collagen degradation, and edema.[49] Clinically, these changes are initially evident as mucosal redness. As the damage increases to basal epithelial cells, ulceration can manifest as isolated lesions. The process progresses to confluent ulcers, often covered by a white pseudomembranous fibrin exudate (Figure 50-1).

Because of the complex cascade of events that occur, lesions may arise 1 to 2 weeks after stomatotoxic chemotherapy. Lesions are usually limited to nonkeratinized areas such as the buccal and labial mucosa, lateral tongue, and soft palate. Keratinized tissues, such as the attached gingiva, dorsal tongue, and hard palate, are less commonly affected. Mucositis typically heals 2 to 4 weeks after the last dose of stomatotoxic therapy has been delivered.[43] Oral infections caused by organisms acquired during hospitalization and the reactivation of latent viruses (e.g., herpes simplex virus [HSV], cytomegalovirus [CMV], varicella-zoster virus [VZV]) can also influence the clinical presentation of mucositis and may prolong the duration of ulcerative lesions.

The presence of oral dryness resulting from direct toxic effects of chemotherapeutic agents on the salivary glands concomitant nonchemotherapeutic agents with xerostomic side

TABLE **50-1**

Agents Studied for Oral Mucositis

CLASS OF AGENT	AGENT	STATUS OR MASCC/ISOO* GUIDELINE REGARDING MANAGEMENT OF ORAL MUCOSITIS
Cryotherapy	Ice chips placed in the mouth starting 5 min before administration of chemotherapy and replenished as needed for 30-60 min, depending on half-life of agent	Recommended during administration of bolus chemotherapy with 5-fluorouracil, edatrexate, and melphalan[55]
Growth factor	IV keratinocyte growth factor-1 (Kepivance, Amgen)	Recommended in patients with hematologic malignancies receiving high-dose chemotherapy and total body irradiation before autologous stem cell transplantation; FDA-approved in this population[79,85]
	IV fibroblast growth factor-20 (Velafermin, CuraGen)	Development for chemotherapy-induced mucositis recently halted because of negative results from clinical trials[45]
Anti-inflammatory agents	Benzydamine hydrochloride mouth rinse	Recommended for patients receiving moderate-dose RT, based on previous evidence,[24,44] but not FDA-approved; phase III trial halted because of negative results of interim analysis
Antioxidants	IV amifostine (Ethyol, MedImmune)	No guideline; insufficient evidence of benefit for radiation-induced oral mucositis[6,9]
	Topical N-acetyl cysteine (RK-0202, RxKinetix)	Currently in clinical trials for radiation-induced oral mucositis[68]
Promoters of healing	Topical glutamine (Saforis, MGI Pharma)	Currently in clinical trials for chemotherapy-induced oral mucositis[63]
Antimicrobial agents	Antimicrobial lozenges	Not recommended for prevention of radiation-induced oral mucositis[3]
	Systemic acyclovir and analogues	Not recommended for prevention of chemotherapy-induced oral mucositis[3]
	Chlorhexidine mouth rinse	Not recommended for prevention of radiation-induced oral mucositis or for treatment of chemotherapy-induced oral mucositis[3]
Topical coating agents	Topical sucralfate	Not recommended for prevention of radiation-induced oral mucositis[3]
Laser therapy	Laser	Suggested when necessary technology/training is available in patients receiving high-dose chemotherapy or chemoradiotherapy before hematopoietic cell transplant[5,55,71]

FDA, Food and Drug Administration; *RT,* Radiation therapy.

effects, or dehydration leads to decreased hydration and lubrication of the mucosa. This oral dryness may exacerbate mucositis lesions by traumatizing existing lesions or cause sufficient trauma that may initiate a new oral lesion.

Management. Management of mucositis currently is focused on palliation of pain and efforts to reduce the influence of secondary factors on mucositis. Based on an extensive systematic review of the literature, the Mucositis Study Group of the Multinational Association for Supportive Care in Cancer and the International Society of Oral Oncology (MASCC/ISOO) has developed clinical practice guidelines for the management of mucositis.[37] These guidelines are discussed subsequently and addressed in Table 50-1.

Pain control. Pain control is provided through various strategies, including topical anesthetics, mucosal coating agents, and systemic pain medications. Focal application of topical anesthetic agents is preferred over widespread oral administration for many reasons. Generalized oral mucosal anesthesia carries the risk of accidental mucosal trauma. Generalized rinsing with anesthetics also may reduce or eliminate the gag reflex, which may increase the risk of aspiration pneumonia. Systemic absorption or swallowing of anesthetics from ulcerated mucosa can result in systemic toxicity, depending on the agent and the dose that is swallowed. However, when mucositis becomes extensive, intentional generalized topical applications of anesthetics are often used to reduce pain.

A common approach to managing oral mucositis is to use a combination solution that includes many different agents, such as topical anesthetics, coating agents, and antifungal drugs. When using these rinses, the clinician faces numerous considerations, as follows:

1. Are all the agents necessary? Topical antifungals have not been shown to be effective for prophylaxis, especially in immunosuppressed patients. Is a topical coating agent necessary, or would a simple topical anesthetic suffice? Are the agents collectively compatible?
2. Are all the agents and their nonactive ingredients well tolerated? Diphenhydramine elixir contains alcohol, coloring, and flavoring agents, all of which can irritate damaged mucosa.
3. Have the medications been compounded in the correct proportions, and is the patient using an adequate volume for appropriate dosing? Does compounding reduce the concentration of each agent to a suboptimal level?
4. What is the cost/benefit ratio for the rinse, and are the added pharmacy costs for compounding a combination rinse offset by significantly improved effectiveness and convenience compared with single agents? Because the primary goal of these rinses is to provide pain relief, this can be an important consideration.

When topical pain control strategies become inadequate for controlling pain, systemic analgesics are necessary. Opioids are usually the drugs of choice. Various delivery systems such as time-release oral tablets, dermal patches, and suppositories can also be used to provide adequate pain relief.

The combination of long-term indwelling venous catheters and computerized drug administration pumps to provide patient-controlled analgesia has significantly increased the ability to control severe mucositis pain while reducing the dose and side effects of opioid analgesics. The MASCC/ISOO guidelines recommend patient-controlled analgesia with morphine for patients undergoing HCT.[3]

Maintenance of oral hygiene. Multiple studies have shown that good oral hygiene plays an important role in the management of oral mucositis.[8,10,47] The MASCC/ISOO guidelines recommend use of a standardized oral care protocol including brushing with a soft toothbrush, flossing, and use of nonmedicated rinses (e.g., saline or sodium bicarbonate rinses). Patients and caregivers should be educated regarding the importance of effective oral hygiene.[53]

Therapeutic interventions. Various agents have been studied to prevent oral mucositis or to reduce its severity, including cryotherapy, growth factors, anti-inflammatory agents, antibacterial agents, promoters of healing, and mucosal coating agents. Table 50-1 lists selected agents studied more recently for oral mucositis. The MASCC/ISOO recommendations are also provided for agents where a guideline exists.

Salivary gland dysfunction

Saliva has an important role in maintaining oral health. Although the effects of ionizing radiation on salivary gland tissue have been well documented, the corresponding effects of cancer chemotherapy have not. Overall, the studies on effects of various chemotherapeutic agents on salivary gland function have produced inconsistent results, with trials showing varied effects on flow rate, sialochemistry, and dry mouth complaints.[34,41,60] No histopathologic investigations of major salivary glands have been reported, but a postmortem study showed minor salivary gland damage after the administration of various chemotherapeutic agents, with changes evident in the first 3 weeks after chemotherapy administration followed by gradual healing with minimal or no sequelae several weeks to months after therapy. Clinical observations support the contention that alterations in salivary function associated with cancer chemotherapy are generally reversible, in contrast to the alterations seen after salivary gland exposure to radiation therapy.

Patients with salivary gland dysfunction should be assessed to determine whether they are receiving other drugs that can alter salivary function (e.g., anticholinergics, antiemetic drugs, or tricyclic antidepressants). Oral dryness can also be exacerbated by mouth breathing, oxygen administration, or dehydration.

Attempts to manage salivary gland dysfunction can have beneficial effects on the quality of oral health of cancer patients. Frequent rinsing with normal saline can help keep mucosal surfaces moist, clear debris, and stimulate salivary gland function for short periods. Saliva replacements (mouth-wetting agents) may provide temporary symptomatic relief. Other strategies to stimulate salivary glands include the use of "taste stimulation" with sugar-free gum or candies and regimens that use cholinergic drugs. Bethanechol, cevimeline, and pilocarpine, which directly stimulate salivary glands, have been reported to be useful for treating xerostomia when functional salivary gland tissue remains.[46] Increasing the ingestion of moist foods (e.g., flavored gelatins), sauces, and gravies can ameliorate the discomfort of eating. Dry or cracked lips should be kept lubricated with agents such as lanolin-based creams and nonperfumed, nonmedicated skin moisturizing agents. The use of antibiotic-containing topical agents on the lips may be indicated to prevent secondary infection, especially in immunosuppressed patients.

Neurotoxicity

Direct neurotoxicity from cancer chemotherapy has been noted with certain chemotherapeutic drugs (most commonly the microtubular agents vincristine and vinblastine, and taxol). This neurotoxicity may result in severe, deep-seated, throbbing mandibular or maxillary pain that can mimic dental pathology (i.e., toothache). Neurotoxicity is generally considered a dose-limiting complication for these drugs, and prompt diagnosis is important.[52] Appropriate dental/periodontal examinations (including tooth vitality testing as necessary) must be performed to rule out pulpal or periodontal sources of pain. Opioid-containing analgesics may be useful in controlling pain, and the use of neurologically active medications may be considered. The neurotoxicity may be transient and generally subsides shortly after dose reduction or cessation of chemotherapy.

Tooth thermal hypersensitivity is occasionally reported by patients after chemotherapy. Symptoms usually resolve spontaneously within a few weeks to months after the discontinuation of chemotherapy. Topical brush-on fluorides, desensitizing toothpastes, and dentin varnishes can be helpful in reducing or eliminating symptoms.

Taste dysfunction is a neurosensory problem that can be associated with cancer chemotherapy.[12,22] Taste receptors are neuroepithelium-derived cells, with a turnover rate of approximately 10 days. They generally regenerate if not irreversibly damaged. In addition, the damage to olfactory receptor cells must be considered when a patient has taste dysfunction. Aberrations in taste perception can vary from hypergeusia to hypogeusia to dysgeusia. Some patients simultaneously report several different symptoms—hypergeusia with some tastes and dysgeusia with others. Patients receiving cancer chemotherapy occasionally report a bad taste that results from the diffusion of drug into the oral cavity, known as "venous taste phenomenon."

Temporomandibular joint and myofascial pain disorders may manifest as facial pain, headache, temporomandibular joint dysfunction, and occasionally ear or throat pain. The myofascial-based complaints generally result from clenching or bruxing in response to stress, sleep dysfunction, or occasionally central nervous system (CNS) toxicity from certain medications. The short-term use of muscle relaxants or anxiolytic agents plus physical therapy (i.e., moist heat applications, massage, and gentle stretching) often resolves these problems. Occlusal splints can be used while sleeping to help patients with more persistent clenching/bruxing tendencies and who present with pain on awakening.

Alterations in dental and skeletal growth and development

As the number of long-term survivors of childhood cancer has increased, the risk for damage to developing dental and skeletal structures from cancer therapies has become apparent. Chemotherapy-related damage to developing teeth includes hypoplastic dentin and enamel, shortened and conical roots, taurodontic-like teeth, microdontia, incomplete enamel formation, and complete agenesis of teeth.[15,33,50,67] Eruption patterns may be altered, and changes in alveolar, mandibular, and maxillary bone growth and development can have orthodontic and cosmetic implications. The addition of radiation to treatment protocols (e.g., cranial irradiation for leukemia or total body irradiation for HCT) significantly increases the risk for damage to developing teeth.

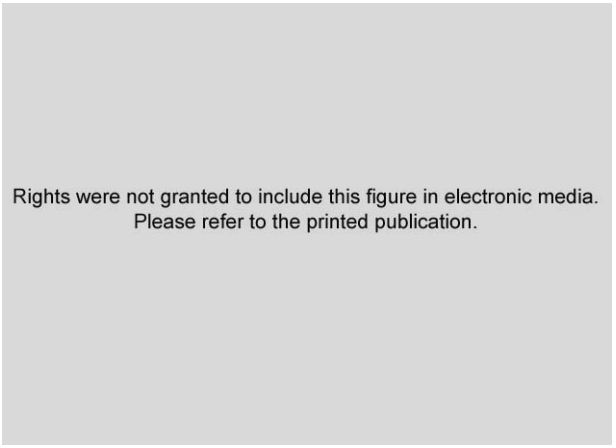

FIGURE **50-2** Osteonecrosis of the jaw related to bisphosphonate therapy. (Courtesy Dr. Cesar Migliorati. From Migliorati CA, Siegel MA, Elting LS: Bisphosphonate-associated osteonecrosis: a long-term complication of bisphosphonate treatment, *Lancet Oncol* 7(6):508-514, 2006.)

Osteonecrosis of the jaws related to bisphosphonate therapy

In recent years, osteonecrosis of the jaws (ONJ) has emerged as a new oral complication in patients receiving bisphosphonate therapy. Although this complication has also been reported in patients receiving oral bisphosphonates for osteoporosis, cancer patients receiving intravenous bisphosphonates are at significantly higher risk.[56] The complication manifests as exposed bone in the mandible or maxilla, often accompanied by infection, pain, and swelling (Figure 50-2). The risk for bisphosphonate-associated ONJ seems to be related to a combination of (1) the antiresorptive potency of the bisphosphonate administered, (2) the amount of the drug deposited in bone, and (3) the occurrence of situations requiring bone to heal or remodel. Most cases have been reported after dental extractions or dental surgeries, but bisphosphonate-associated ONJ can also occur spontaneously.

Studies have shown that the risk for osteonecrosis increases with duration of bisphosphonate therapy and varies by the bisphosphonate agent used. One study reported that of 105 patients receiving intravenous zoledronic acid, risk for osteonecrosis was 1% after 12 months of use, 7% at 24 months, and 21% after 24 months. In the same study, of 127 patients receiving either intravenous pamidronate alone or intravenous pamidronate before or after intravenous zoledronic acid, risk for osteonecrosis was 0% up to 24 months, 2% at 36 months, and 7% at 48 months.[2] Another study found that the frequency of ONJ in bone malignancy cases, treated with mainly intravenous zoledronate or pamidronate, was 1 in 87 to 114 (0.88% to 1.15%). If extractions were done, the calculated frequency of ONJ was 1 in 11 to 15 (6.67% to 9.1%). In this study, the frequency of ONJ in osteoporotic patients, mainly receiving weekly oral alendronate, was 1 in 2260 to 8470 (0.01% to 0.04%). If extractions were done, the calculated frequency was 1 in 296 to 1130 (0.09% to 0.34%). The median time from initiation of therapy to the onset of ONJ was 12 months for zoledronate, 24 months for pamidronate, and 24 months for alendronate.[51]

Effective treatment protocols have not yet been identified for ONJ. It is generally believed that stopping bisphosphonate administration may not promote healing because it is estimated that bisphosphonates may remain in bone for up to 10 years. Prevention is crucial. Patients should receive a dental evaluation before receiving intravenous bisphosphonates. Any dental disease requiring surgery or extractions should ideally be completed and allowed to initially heal before the start of bisphosphonate therapy.[54]

Indirect Oral Toxic Effects

Although direct toxic effects are generally the most visible oral complications of cancer chemotherapy, indirect oral effects can potentially be of more concern. The most important indirect toxicities are oral infections associated with myelosuppression and immunosuppression associated with damage to myelogenous stem cells and cellular elements of the immune system. Preexisting oral and dental infections can spread, with the oral cavity serving as the point of entry for organisms into deeper tissues and the systemic circulation.[32,40] Other indirect toxic effects to the oral cavity are thrombocytopenia, anemia, and GI toxicity (i.e., nausea, vomiting, and alteration in absorption of nutrients).

Oral mucosal infections

The risk for infection increases as the degree and duration of immunosuppression increase. In addition, as immunosuppression worsens, the classic signs and symptoms of oral infection (e.g., redness, swelling, pain) may be reduced because of the same diminished immune responses. Patients who receive cancer therapy can have chronic low-grade oral infections (periodontal disease and endodontic infections) that can become serious infections when the patients become immunocompromised, yet these infections may also go undetected longer because of a lack of cellular response by the immune system. Because of the myelotoxic effects of many cancer therapies, as the neutrophil and platelet numbers decrease, many cancer patients are instructed to stop tooth brushing and flossing when blood counts decrease below certain thresholds. Stopping oral hygiene may unfortunately increase the risk of oral infection.

Fungal infections. Superficial colonization by *Candida* species, especially *Candida albicans,* is a common finding in cancer patients receiving chemotherapy. As the degree and duration of immunosuppression increase in patients receiving myelosuppressive/immunosuppressive therapy, there is a distinct increase in the risk for invasive oral fungal infections such as aspergillosis and mucormycosis and numerous other invasive fungal organisms. Yeast and fungal organisms generally have low infectivity, but with changes in the local or systemic immunity, they can pose a significant infectious risk.

Factors affecting oral colonization and infection risk include alterations in competing oral bacterial flora (most commonly associated with the use of systemic antimicrobials), decreased salivary gland flow rates, and immunosuppression. The latter is especially related to neutropenia. Alteration in host oral bacterial flora in cancer patients with myelosuppression supports increased candidal colonization. With the development of new strategies to prevent and treat fungal infections, however, the fungal organisms associated with oral infections are changing. The widespread use of fluconazole prophylaxis has been associated with increasing numbers of *Candida glabrata* (*Torulopsis glabrata*) and *Candida krusei* infections that may have decreased sensitivity to fluconazole and other antifungal agents.[84]

Oral candidal infections can have various clinical presentations—pseudomembranous, erythematous, atrophic, hyperplastic, and invasive. The most common form is pseudomembranous candidiasis, in which mild to heavy surface colonization occurs with raised, white, debris-like masses of organisms. With hyphal invasion of the upper cellular layers of the mucosal epithelium, the mucosal surface can become atrophic, often with little or no evidence of pseudomembra-

nous masses. Atrophic or erythematous candidiasis is particularly common on the dorsal tongue, where the only clinical evidence of infection may be a patchy loss of filiform papillae. Candidal infections of the lip commissures usually manifest with cracking, pain, and varying degrees of erythema. With deeper mucosal invasion, a hyperplastic or ulcerative lesion can be noted. Invasive candidiasis is usually characterized by discrete, firm, almost leathery, white-yellow lesions with marginal erythema. These lesions are primarily noted in patients who are significantly immunocompromised and are at high risk of systemic dissemination. Although oral candidal infections are classically reported to be associated with symptoms of "metallic taste" and "increased sensitivity to spices," this is not frequently noted in infections associated with cancer therapy.

The diagnosis of *Candida* infection often requires correlation of the clinical presentation of lesions with laboratory tests. Clinical lesions are often nonspecific, and because *Candida* can be a normal inhabitant, reliance only on fungal cultures may lead to false-positive results. Using direct microscopic examination (with Gram stain or potassium hydroxide to identify pseudobranching hyphae) followed by culture to determine the species of the fungus can be helpful. Increasing numbers of *Candida* organisms on culture (1+ to 4+) generally correlate with increasing significance of infection. Because different species of *Candida* can have different sensitivities to different antifungals, speciation becomes particularly important in cases in which the patient has not responded to therapy or when there is frequent recurrence of oral candidiasis. For hyperplastic and invasive candidiasis, cultures from surface swabs and scrapings can produce false-negative results, and biopsy with culture from tissue samples along with specific stains for *Candida* may be required to establish a definitive diagnosis.

More recent Cochrane reviews addressed the efficacy of various antifungal drugs in prevention and treatment of oral candidiasis in cancer patients.[11,87] Nystatin, although commonly used, was found to be ineffective, possibly because it is not absorbed in the GI tract. Drugs partially absorbed from the GI tract, such as topical clotrimazole or miconazole, were found to be effective and can be useful for superficial oral infection. Persistent or locally invasive infection (including atrophic and erythematous candidiasis), especially when a risk exists for systemic spread, should be treated with appropriate systemic agents. Systemic azoles (e.g., fluconazole, itraconazole, ketoconazole) that are fully absorbed in the GI tract are very effective against the organisms and generally considered the most effective way to prevent or reduce fungal colonization and subsequent infection. These drugs are secreted in saliva; salivary concentrations of fluconazole are directly proportional to plasma concentrations.[38] It has been suggested that systemic antifungals may be less effective for oral candidiasis in patients with decreased salivary production because of reduced oral delivery of the drug through saliva. In one study, salivary concentrations of fluconazole were not found to correlate to response to therapy,[27] however; this area requires further research.

The treatment of disseminated candidal infections remains difficult and can be complicated by the presence of azole-resistant organisms. Amphotericin B and the newer agent caspofungin are the systemic antifungals of choice for severe deep mycoses, especially in immunocompromised patients. Organisms that can cause serious oral infections in immunocompromised cancer patients include *Aspergillus, Mucor,* and *Rhizopus*. These infections often have a nonspecific appearance and can be confused with other oral toxic effects. Diagnosis depends on laboratory tests, and systemic therapy must be instituted immediately because these infections can spread systemically and lead to fatal outcomes.

Viral infections. Herpes group viruses can cause significant oral disease in patients receiving cancer chemotherapy.[70,72,73] HSV, VZV, CMV, and Epstein-Barr virus (EBV) are recognized causes of oral lesions in cancer patients. Most infections with HSV, VZV, and EBV represent reactivation of latent virus, whereas CMV infections can result from either reactivation of latent virus or newly acquired virus. Other viruses causing oral lesions in cancer chemotherapy and HCT patients are adenovirus, coxsackieviruses, and human herpesvirus. The diagnosis of viral lesions in the mouth can be made through direct immunofluorescent examination of scrapings from lesions, through viral culture, and sometimes through examination of biopsy material with immunohistologic stains specific for each virus.

Herpes Simplex Virus. The clinical presentation of oropharyngeal HSV infections can vary from localized herpes labialis to widespread oropharyngeal ulcerations. When they are superimposed on chemotherapy-induced mucositis, HSV lesions can be difficult to recognize clinically. A sudden and dramatic onset or worsening of ulcerative mucositis in patients who are HSV antibody–positive or who have possibly been exposed to HSV often warrants testing to determine the possibility of oral HSV infection.

Acyclovir and valacyclovir prophylaxis for HSV is effective[28] and is routinely used in most transplant centers for HSV-seropositive patients undergoing HCT. Oral dosing may be switched to parenteral administration if the patient is unable to tolerate oral drugs because of nausea or oral or esophageal ulcerative mucositis, or if GI absorption is inadequate. Many cases of HSV infection initially suspected to be caused by acyclovir resistance may be related to inadequate dosing or decreased GI absorption of oral acyclovir. Acyclovir-resistant HSV is, however, a growing concern. Early diagnosis of HSV infection is important, and infections are usually successfully managed with systemic acyclovir. Topical antiviral therapy is not encouraged in this setting.

Varicella-Zoster Virus. The most frequent presentation of VZV infection in patients receiving cancer therapies is herpes zoster lesions that are characterized by vesicular eruptions that follow dermatomal distributions. In immunocompromised patients, severe VZV infections can involve multiple dermatomes, and a significant risk exists for dissemination that can result in a serious, life-threatening disease. In susceptible patients, primary VZV infection can manifest with the typical vesicular skin lesions of chickenpox; however, in immunosuppressed patients, primary VZV infection represents a potentially fatal infection. Direct immunofluorescent examination of swab material and viral cultures are used to diagnose VZV infections. Acyclovir and famciclovir are currently the drugs of choice to treat these infections.[75]

Cytomegalovirus. CMV can cause oral lesions in immunosuppressed patients. CMV lesions have a nonspecific appearance with a tendency for irregular ulcerations covered with a pseudomembranous fibrin exudate.[48,72] Surface swabs for direct immunofluorescence have only a fair reliability for diagnosing CMV, possibly because the virus seems to infect primarily endothelial cells and fibroblasts (i.e., deep to the surface) and yields low numbers of free virus. Cultures may improve the detection of CMV, but the most reliable technique to diagnose this disease seems to be biopsy with immunohistochemical stains specific for CMV. Ganciclovir is the drug of choice.

Epstein-Barr Virus. EBV-related hairy leukoplakia lesions have been described in immunosuppressed patients without human immunodeficiency virus infection, including bone

marrow transplant patients.[7] These lesions have no apparent clinical significance. EBV-related lymphomas and immunoblastic sarcomas can manifest, however, with oral lesions and head and neck lymphadenopathy with a potentially fatal outcome. T-cell–depleted grafts for HCT patients have been associated with an increased risk for EBV lymphomas. These lymphomas are generally responsive to radiation therapy.

Bacterial infections. The different environmental niches of the oral cavity—mucosal surfaces, periodontal sulci, and tooth surfaces—harbor a wide array of organisms. In immunosuppressed patients, the potential for acquisition of nonoral bacteria must also be considered. As with fungal and viral infections, the risk for bacterial infection increases as the severity and duration of immunosuppression increase. Neutropenia is the primary risk factor predisposing to bacterial infection, with risk increasing significantly when the neutrophil count decreases to less than 500/mm^3. Antibiotic prophylaxis is indicated in these situations.[14] As infectious disease protocols and antibiotics have evolved, the pressures on the oral microflora have been constantly altered. Over the years, oral flora in cancer patients have shown a shift from a risk for overgrowth by primarily gram-negative enteric bacilli (e.g., *Pseudomonas*, *Escherichia coli*, *Serratia*, and *Klebsiella*) to the re-emergence of a risk for infection primarily from gram-positive organisms, especially streptococcal and staphylococcal species. Mucositis and mechanical disruption in the oral mucosa can create a point of entry for oral bacteria, and oral colonization or secondary infection of the oral tissues can increase the severity and course of oral mucositis.[77]

Chlorhexidine oral rinses can promote a decreased rate of colonization by bacteria in and around teeth and reduce gingival infections. Although topical chlorhexidine (0.12% to 0.2%) is effective in reducing gram-positive bacterial colonization and associated periodontal infections, studies using chlorhexidine to diminish the severity and duration of mucositis have produced inconsistent results, with some studies showing benefit and others showing no benefit.[3]

Poorly fitting removable prosthetic appliances can abrade oral mucosa and increase the risk of microbial invasion into deeper tissues. The dentist should adjust dentures before the start of chemotherapy and instruct patients to change soaking solutions daily. Patients undergoing chemotherapy who are at risk for mucositis are encouraged to reduce or eliminate denture use during chemotherapy to decrease the risk of mucosal trauma and irritation that may exacerbate oral mucositis. Denture-soaking cups that do not use an antiseptic solution can readily become colonized with various pathogens, including *Pseudomonas aeruginosa*, *E. coli*, *Enterobacter* species, *Staphylococcus aureus*, *Klebsiella* species, *T. glabrata*, and *C. albicans*. Routine cleaning of denture cups with a weak bleach solution can prevent contamination and reduce the risk for denture-associated oral infections.

Dental Plaque, Dental Caries, and Pulpal Infections. Dental bacterial plaque can increase the risk of local and systemic infection, and efforts should be directed at keeping bacterial plaque accumulation as low as possible. A clear need exists to maintain the highest compliance with effective oral hygiene protocols for mechanical plaque removal (e.g., brushing, flossing), augmented with topical antimicrobial regimens (e.g., chlorhexidine) as needed.

Deep dental decay at risk for infecting the pulp should be stabilized before therapy to prevent the risk of pulpal infection and pain during therapy. Pulpal/periapical infections can have a significant effect on cancer chemotherapy and may be difficult to manage in patients receiving chemotherapy; considerable attention should be paid to stabilizing infections before medical management. Careful and complete diagnostic tests should be performed to determine pulpal vitality and endodontic status. The clinician should distinguish osteolytic periapical infections and endodontic failures versus noninfectious periapical conditions, such as apical scars, metastatic cancer lesions, or leukemic infiltrates that mimic periapical infection. If an endodontic procedure is necessary, it is prudent to allow enough time to assess infection stabilization and treatment success before cancer chemotherapy begins. Prophylactic antibiotics may be indicated if the risk for subsequent infection is considered clinically significant. If the periapical and pulpal disease is associated with nonrestorable teeth, every effort should be made to extract these teeth as soon as possible and allow maximal time for healing before cancer treatment begins.

Temporary materials can be placed until the patient has recovered from cancer therapy. Incipient minimal decay can be treated with fluorides and sealants until more definitive therapy can be completed.

Invasive dental and surgical procedures should be undertaken only with a clear understanding of a patient's immune and coagulation status. Table 50-2 presents guidelines for antibiotic and platelet support. Every case should be individually assessed, and the patient's physician and other appropriate specialists should be consulted before the clinician renders care. Extractions should be as atraumatic as possible, and efforts should be instituted to promote rapid stabilization and healing. Socket sites should be debrided and copiously irrigated. Consideration should be given to obtaining primary closure with conservative alveolectomy. In general, an acceptable time interval for initial healing before starting chemotherapy is 10 to 14 days. If less time is available, more vigorous supportive care and more frequent follow-up evaluations may be necessary. If documented infection is associated with the teeth scheduled for extraction, antibiotics (ideally chosen with the benefit of sensitivity testing) should be administered for at least 7 to 10 days after the extraction.

If extraction of teeth with endodontic infections is impossible for medical reasons, the clinician may consider providing initial endodontic therapy (open and broach) and sealing antimicrobial medicaments in the root canal and pulpal chamber. Antibiotics should be administered for 7 to 10 days. Extraction of the tooth can be performed after the patient's medical status has stabilized at or near normal. Appropriate treatment to eliminate the risk of infection is important because pathogens can readily disseminate directly from the dental pulp into periapical tissues and then into the systemic circulation.

Periodontal Infections. Periodontal infection can be a major concern for cancer chemotherapy patients. Sites with preexisting periodontal disease in immunosuppressed patients can flare up, resulting in an acute infection. Improved protocols for managing immunosuppressed patients can reduce this risk. The signs and symptoms of periodontal disease may be decreased in immunosuppressed patients or patients with hematologic malignancies, which can lead to underrecognition of the degree of periodontal disease. In addition, extensive ulceration of sulcular epithelium, which may be present with periodontal disease, is not directly observable, yet may represent a significant entry point for a future disseminated infection by various organisms. Bacteremias from colonizing organisms have been noted to develop in these patients. In patients with leukemic gingival infiltrates, the enlargements shrink with appropriate chemotherapy, which permits improved hygiene care.

Chronic periodontal disease may develop into acute periodontal infections with associated systemic sequelae during neutropenia.[29,40,65] Dental disease prevention programs have been shown to reduce the risk of potential oral sequelae associated with cancer therapy, with complications being pre-

TABLE **50-2**

Management Suggestions Relative to Invasive Dental Procedures

MEDICAL STATUS	GUIDELINE	COMMENTS
Patients with chronic indwelling venous access catheters (e.g., Hickman)	Regimens recommended by American Heart Association for infective endocarditis prophylaxis are often used	There is no clear scientific proof detailing infectious risk for these lines after dental procedures; this is not an evidence-based practice
Neutrophils		Order CBC with differential
≥1500/mm^3	Prophylactic antibiotics for mild neutropenia are usually unnecessary	Other indications for prophylaxis may be present
<1500/mm^3	Antibiotic prophylaxis should be considered, especially <1000/mm^3; regimens recommended by American Heart Association for infective endocarditis prophylaxis are often used; clinical judgment is crucial—if infection is present or neutropenia is severe, more aggressive antibiotic therapy may be indicated, based on consultation with an infectious diseases specialist	If organisms are known or suspected, appropriate adjustments to antibiotic regimens should be made based on sensitivities
Platelets*		Order platelet count and coagulation tests
>75,000/mm^3	No additional support needed	
40,000-75,000/mm^3	Platelet transfusions are optional for surgical procedures; consider administering preoperatively and 24 hr later based on clinical course; platelet support is generally not required for hygiene and restorative procedures	Use techniques to promote establishing and maintaining control of bleeding (e.g., sutures, pressure packs, minimize trauma)
<40,000/mm^3	Platelets should be transfused 30 min before surgical procedure; obtain platelet count immediately, and transfuse regularly until bleeding risk is no longer present; dental hygiene procedures, including curettage, can be done with counts >25,000/mm^3	In addition to above, consider using hemostatic agents (e.g., microfibrillar collagen, topical thrombin, fibrin glues); monitor sites carefully

*Assumes that all other coagulation parameters are normal and that platelet counts will be maintained at or above the specified level until initial stabilization/healing has occurred.
CBC, Complete blood count.

vented, reduced in severity, or alleviated.[8] When acute periodontal infection is diagnosed, broad-spectrum antibiotic therapy should be considered while culture results are pending. Local therapy may include chlorhexidine rinsing or irrigation with effervescent agents (e.g., hydrogen peroxide, which can release oxygen locally) that may affect anaerobic bacteria colonizing the periodontal pocket and gentle mechanical plaque removal (dental brushing and flossing); placement of local periodontal antibacterials (minocycline microspherules) may also be considered. The key to reducing the risk of significant gingiva-associated infections (and bleeding) is to perform dental prophylaxis before myelosuppression and to maintain excellent oral hygiene throughout treatment.

Oral hemorrhage

Hemorrhage from oral tissues in patients receiving cancer therapy can result from thrombocytopenia, loss of coagulation factors from disseminated intravascular coagulation or liver disease, mucosal infections (including gingivitis and periodontitis), and trauma. Spontaneous mucosal petechiae and gingival bleeding may be observed when the platelet count decreases to less than 20,000/mm^3. Damage to mucosal tissues, such as damage resulting from oral HSV infections, increases the risk of bleeding. Trauma associated with oral function can also induce minor hemorrhage.

Oral hemorrhage in cancer patients with thrombocytopenia is rarely a debilitating complication, although its occurrence can be alarming to patients, caregivers, and family. Local measures center on forming an adequate clot and protecting the clot until healing has occurred. Direct pressure applied by moist gauze or gauze soaked in topical thrombin can be used. A vasoconstrictor such as epinephrine can help with initial control, but rebound vasodilation can occur as the drug's effect wears off. Clot-forming agents, such as those made from microfibrillar collagen hemostatic products (Avitene Hemostat, INSTAT), fibrin glue, and chitosan (HemCon), can also be used to organize and stabilize clots. Platelet transfusions are usually not required except for patients whose platelet counts are profoundly suppressed, resulting in insufficient clot formation and repeated significant bleeding episodes. Aprotinin or aminocaproic acid can be used adjunctively to promote coagulation, especially when platelet transfusions are marginally effective in controlling bleeding.

Gastrointestinal effects—nutritional disturbances, nausea, and emesis

A frequent and often significant site of toxicity of cancer chemotherapy is the GI tract. As it does with the oral mucosa, chemotherapy can damage the rapidly proliferating mucosal lining of the stomach and intestines. The resulting mucositis can lead to significant discomfort (cramping, pain), diarrhea, ulceration, and disruption in the absorption of nutrients. In addition, gastric injury plus CNS toxicity from chemotherapy can cause patients to have frequent and profound nausea and emesis. This complication can significantly affect the patient's quality of life during and after cancer chemotherapy.[4,61]

In addition to the effect of emesis on the quality of life is the negative influence on oral nutrition intake and the potential damage to oral tissues after emesis; the pH of oral tissues can decrease to approximately 2.0. In the presence of mucositis, the exposure of compromised mucosa to this acidic fluid can potentially damage the tissues further. Also, the vigorous tongue movements usually associated with chemotherapy-associated emesis can result in increased trauma to the tongue

and floor of the mouth as these tissues move against incisal and occlusal surfaces.

Protocols to reduce or prevent nausea and vomiting during chemotherapy have become remarkably effective. Often initiated prophylactically, these therapies can minimize the problem and ensure patient comfort. Strategies often combine approaches that target the GI mucosa and the CNS nausea and vomiting centers.[1,36] The nausea and vomiting associated with chemotherapy can result in adverse conditioning such that normal smells, tastes, and other associated stimuli can induce nausea and vomiting—even just driving by the clinic or hospital where the therapy was administered can be a trigger. Patients may even develop an aversion to swallowing their own saliva, tooth brushing, or wearing removable dental appliances. These conditions may also trigger a heightened gag reflex. Systematic deconditioning strategies can generally help control or eliminate this problem and allow for the resumption of routine oral care.

HEMATOPOIETIC CELL TRANSPLANTATION

Myeloablative HCT is one of the most aggressive forms of cancer therapy. Patients are given supralethal doses of chemotherapy with or without total body irradiation. The patient's stored hematopoietic stem cells or stem cells from the best available human leukocyte antigen–matched donor are infused into the patient to restore bone marrow function and reestablish an immune system. Oral complications frequently associated with HCT are similar to complications noted in patients undergoing high-dose chemotherapy. Mucositis, salivary gland dysfunction, infections, taste dysfunction, and bleeding are common acute oral complications in the first 4 weeks after transplantation. Risk of oral infection slowly declines over the first several months as neutrophil and macrophage counts recover, although oral candidiasis and reactivation of HSV and VZV can occur in susceptible patients for many months after engraftment. Full immune recovery takes up to 6 months after autologous transplantation and 12 months after allogeneic transplantation.

The severity of mucositis is related to the type of conditioning regimen used. Oral mucosal healing partially depends on the rate of engraftment (especially following the neutrophil counts). Mucositis tends to heal more slowly in allogeneic transplant patients (versus autologous/syngeneic transplant recipients) because of post-transplantation prophylaxis for acute graft-versus-host disease (GVHD) (see later).

Oral infections noted in HCT recipients are similar to infections seen in immunosuppressed patients receiving high-dose chemotherapy without transplantation. Use of prophylactic fluconazole reduces the incidence of oral and disseminated candidal and other fungal infections. The risk for reactivation of latent HSV and the risk for reactivation or acquisition of CMV are very high in the early period after HCT. Prophylaxis with acyclovir for HSV and the use of CMV-negative blood products with ganciclovir for CMV have significantly reduced the frequency and effect of these infections. Risk of oral bacterial infection has decreased over the past decade, which may be attributable to oral hygiene protocols and improved antibiotic prophylactic and treatment protocols. Opportunistic gram-negative bacterial pathogens, such as *P. aeruginosa*, *Neisseria* species, and *E. coli*, and gram-positive cocci, such as staphylococci and streptococci, remain a concern.

GVHD is an immune-mediated disease that occurs after transplantation and results from immunologic reactions and damage mediated by donor-derived lymphocytes and cytokines against the patient's tissues. GVHD is potentially lethal. In the oral cavity, GVHD mimics numerous, naturally occurring autoimmune disorders (e.g., lichen planus, lupus erythematosus, scleroderma, Sjögren's syndrome). Oral acute GVHD can become apparent 7 to 21 days after transplantation and is characterized by mucosal erythema, atrophy, ulceration, and (later) hyperkeratotic striae and plaques.[74] Chronic oral GVHD manifests similarly and becomes apparent more than 100 days after transplantation. Topical steroid rinses/creams/gels and topical azathioprine can help reduce symptoms and promote healing of ulcerations, but resolution generally depends on successful systemic therapy with prednisone, cyclosporine, mycophenolate, tacrolimus, and other immunosuppressive agents. Cutaneous GVHD has been shown to be responsive to treatment with psoralen plus ultraviolet A (PUVA).[39] Intraoral PUVA therapy with UVA light sources that can directly expose oral mucosal surfaces has also been reported to help manage oral GVHD lesions.[66] GVHD can also damage salivary glands with resulting xerostomia and mucoceles involving major and minor salivary gland tissue.[58]

Patients with long-term salivary gland dysfunction are at increased risk for dental decay. For these patients, the dental professional should promote excellent dental plaque removal, prescribe 1.1% neutral sodium fluoride toothpastes or gel with daily brush-on or gel tray protocols, and promote low sugar intake. Tables 50-3 and 50-4 list dental management suggestions for patients who have received HCT, according to type of HCT and time since transplant.

Other late complications of HCT include recurrence of the primary malignancy, occurrence of second primary or secondary cancers (especially in long-term survivors), and viral infections, especially VZV. Dental and facial skeletal growth abnormalities have been noted in children younger than 12 years receiving transplants, primarily resulting from damage induced by conditioning regimens, especially total body irradiation. Children frequently show delayed exfoliation of primary teeth, which correlates with the delayed or arrested development of succeeding permanent teeth. Teeth developing after transplantation often exhibit short, conical-shaped roots. Skeletal changes in jaws generally are manifested as decreased jaw length and reduced alveolar ridge height (the latter most likely from decreased root length).[15]

ORAL COMPLICATIONS OF RADIATION THERAPY FOR CANCER

Radiation therapy is a primary treatment modality for head and neck cancer. The oral complications of radiation therapy arise from direct damage to progenitor cells of epithelium, parenchyma, and bone and from vasculitis and endarteritis that adversely affect the oral mucosa, salivary glands, musculature, bone, and connective tissue. These injuries directly or indirectly result in clinical consequences that manifest as mucositis, taste loss, infection, xerostomia, rampant dental decay, soft tissue necrosis, bone necrosis, and fibrosis of oral and perioral tissue including skin and muscles (Box 50-3).

Current changes in the management of the primary disease, including accelerated fractionation of radiation therapy, hyperfractionated radiation schedules, and addition of specific kinds of chemotherapy to the radiation therapy protocols, have been associated with an increased incidence and severity of many of the oral complications. Conversely, the improvement in diagnostic imaging coupled with intensity modulated radiation therapy has significantly decreased the scope and severity of many oral complications.

The importance of dentistry in the overall management of patients with head and neck cancer receiving radiation therapy is well established. The elimination of dental disease and establishment of oral care protocols to maintain maximal oral health must be part of patient assessment and care before

radiation therapy. During and after radiation therapy, dental involvement is dictated by the specific care needs of the patient, who may require more frequent assessments and earlier interventions than most general dental patients.

Detailed oral and dental assessment is necessary to identify conditions that should be treated before radiation therapy. Sites of potential mechanical irritation should be eliminated. Dental treatment such as extractions can delay the start of therapy if undertaken late in the preradiation evaluation phase. Early referral and coordination between oncologists and the dental team can reduce this problem. Attempts to reduce the risk of osteoradionecrosis (described later) generally involve extraction of nonrestorable or questionable teeth, root tips, and periodontally involved teeth in the planned radiation field with enough time before the start of radiation therapy to allow for adequate initial healing. If time permits, asymptomatic periapical radiolucent lesions can be managed. Endodontics can be performed and completed after radiation, if managed expertly. Providing the patient with a detailed review of oral hygiene, oral care during radiation therapy, and oral care after radiation therapy are important components of long-term care.

Acute Reactions

Acute reactions arise from direct toxicity to tissues in the radiated treatment volume. They generally become apparent shortly after the start of radiation therapy and worsen throughout the course of therapy. After the cessation of therapy, although most complications resolve, some can remain and evolve into chronic conditions.

BOX **50-3**

Oral Complications of Radiation Therapy

ACUTE	CHRONIC
Oral mucositis	Xerostomia
Infection	Dental caries

Radiation-induced oral mucositis

Epidemiology. Almost all patients treated with radiation therapy for head and neck cancer develop some degree of oral mucositis. In more recent studies, severe oral mucositis occurred in 29% to 66% of all patients receiving radiation therapy for head and neck cancer.[18,82] The incidence of oral mucositis was especially high in (1) patients with primary tumors in the oral cavity, oropharynx, or nasopharynx; (2) patients who also received chemotherapy; (3) patients who received a total dose greater than 50 Gy; and (4) patients who were treated with hyperfractionation radiation schedules (e.g., more than one radiation treatment per day).

Morbidity. Mucositis is the major source of treatment-related morbidity in patients receiving radiation therapy for head and neck cancer. These patients are often unable to continue eating by mouth because of mucositis pain and receive nutrition through a gastrostomy tube or intravenous line. Patients with oral mucositis are significantly more likely to have severe pain and weight loss of 5% or more.[18] In one study, approximately 16% of patients receiving radiation therapy for head and neck cancer were hospitalized because of mucositis.[81] Of the patients receiving radiation therapy for head and neck cancer, 11% had unplanned breaks in radiation therapy because of severe mucositis.[81] Oral mucositis is a major dose-limiting toxicity of radiation therapy to the head and neck region.

Pathogenesis and clinical appearance. The pathogenesis of radiation-induced oral mucositis is believed to be generally similar to the pathogenesis of chemotherapy-induced mucositis. The clinical appearance is also similar. In radiation mucositis, lesions are limited to the fields of radiation. With commonly used fractionated dose levels of approximately 200 cGy/day, mucosal erythema is noted 1 to 2 weeks after the start of therapy, followed by ulceration in the third or fourth week. Lesions progress throughout the course of therapy and heal within 4 to 8 weeks after completion of therapy.[42,43]

The principal factors affecting the development and severity of radiation mucositis are dose, fraction, and duration of radiation. Marked individual variability is seen, however. When the primary radiation beam strikes metallic dental restorations and appliances, a secondary backscatter radiation is produced. Backscatter radiation is of lower energy than the primary beam and travels only a short distance. Tissues that directly contact these metal surfaces are exposed to the primary beam and the additional backscatter radiation, increasing the total absorbed dose of radiation and potentially causing more mucosal breakdown. Consequently, removable dental appliances should be taken out during treatment sessions. Metal fixed restorations are usually not removed; efforts to hold tissues away from metal surfaces (e.g., using vinyl mouth guards or cotton rolls) have been reported anecdotally to reduce mucosal damage.[86]

Management. Management strategies described previously for chemotherapy patients are generally also useful for cancer patients undergoing head or neck radiation. In addition, two radiation-specific issues emerge:

1. Radiation injury is oral site–specific and depends on dosage and portals of therapy.
2. Duration of radiation-induced oral mucositis typically extends for 2 to 8 weeks after the cessation of therapy compared with the approximate 5 to 14 days observed in chemotherapy patients. Extended radiation treatment protocols produce more significant damage to mucosal tissues and submucosal vasculature and connective tissues, which accounts for this difference.

An additional, more global issue needs to be addressed for head and neck cancer patients receiving radiation therapy. Because the primary cause of oral cancer is tobacco and alcohol abuse, continuation of these habits escalates risk. Research has shown that patients who do not stop smoking after primary therapy for oral cancer are at increased risk of recurrence or second primary lesions. Patients with head and neck cancer should be encouraged and supported in efforts to cease tobacco use permanently. In addition, more severe mucositis occurs in patients who smoke and consume alcohol during radiation therapy; they should be strongly encouraged to discontinue such activities.

Infection during radiation therapy

Radiation therapy to oral tissues can compromise local immunity because of damage to oral mucosa, tissue-based white blood cells, immune cells migrating into oral tissues during radiation therapy, and loss of salivary function. Systemic immunity generally remains intact, however. The pattern of infections seen in head and neck radiation patients is characterized primarily by *Candida* infections. Viral and significant bacterial infections are uncommon.

Candidiasis is the most common oropharyngeal infection in patients undergoing radiation therapy.[60] Patients receiving head and neck radiation therapy are frequently colonized with *Candida* and show an increase in quantitative counts and clinical infection. Although the contribution of *Candida* to oral mucositis associated with radiation therapy is unclear, candidiasis may increase the discomfort of mucositis. Treatment of oral candidiasis during radiation therapy has primarily focused on the use of topical antifungals such as nystatin and clotrimazole. Compliance can be a problem with these topical antimicrobial agents for patients with mucositis because of irritation, nausea, pain (nystatin solutions), and difficulty in dissolving the medication forms (nystatin pastilles and clotrimazole troches) owing to hyposalivation. Topical antifungals, especially nystatin, may have limited efficacy, especially in patients immunosuppressed because of concomitant chemotherapy. In such patients, systemic antifungals such as fluconazole and ketoconazole can be used.

Salivary gland dysfunction

Salivary gland tissue is particularly sensitive to radiation. During the first several weeks of radiation therapy, painless enlargement of salivary glands may be noted. Over the following weeks, this swelling generally resolves. Shortly after the start of radiation, changes in salivary flow rate and saliva

composition are often noted. The serous acini are more susceptible to radiation damage than mucous acini, which in addition to reducing flow rates also results in saliva having a thicker, more mucous character. Patients report the sensation of dryness and having more difficulty clearing secretions. During the first several weeks of radiation therapy, salivary flow rates modestly recover over days of rest (i.e., over weekends) only to decline rapidly during the succeeding 5 days of therapy. After several weeks of therapy, the ability of salivary glands to recover at all is lost, and flow rates steadily decrease over the course of therapy. When radiation doses to salivary glands exceed approximately 25 to 30 Gy, the ability for glands to recover is significantly limited.

Amifostine is a prodrug that is dephosphorylated in tissues to a pharmacologically active free thiol metabolite. This thiol metabolite can scavenge reactive oxygen species generated by exposure to radiation. The effects of intravenous amifostine on xerostomia and mucositis secondary to head and neck radiation therapy were studied in an open-label phase III trial.[9] There was a significant reduction in the incidence of grade 2 or higher acute and late xerostomia in the amifostine group, as assessed by nonblinded investigators. There was no significant difference in the incidence or severity of mucositis between the two groups. Based on these results, intravenous amifostine has been approved by the U.S. Food and Drug Administration (FDA) to reduce the incidence of moderate-severe xerostomia in patients undergoing postoperative radiation treatment for head and neck cancer, in which the radiation port includes a substantial portion of the parotid glands. Intravenous amifostine must be administered within 30 minutes of radiation therapy and is associated with significant side effects, including transient hypotension and nausea and vomiting. Although subcutaneous delivery of amifostine has been reported to have reduced side effects, this route of delivery of amifostine for this indication has not been approved by the FDA as of this writing.

Taste dysfunction

Shortly after the start of external-beam radiation therapy to oral fields, including the tongue and posterior oropharyngeal tissues, patients often begin to report diminishing senses of taste and smell. A total dose of more than 30 Gy reduces the acuity of all taste sensations.[13] Direct damage to the microvilli and outer surface of the taste cells, damage to nerves supplying taste cells, xerostomia, and mucosal infection all may affect taste. In most instances, taste acuity recovers by 6 months after radiation therapy,[69] but some patients are left with residual hypogeusia. Treatment with zinc sulfate is often tried in various populations with taste changes, despite inconsistent evidence of its efficacy. A more recent phase III double-blind, placebo-controlled study did not show any benefit from zinc sulfate in patients with taste changes secondary to radiation therapy.[30] Palliative measures, such as chewing sugar-free flavored gum, may be beneficial to some patients.

Late Reactions

Late oral complications of radiation therapy primarily represent residual effects from direct damage to the vasculature, salivary glands, mucosa, connective tissue, and bone in the irradiated field. The most common patient symptoms are related to hyposalivation. The types and severity of pathologic changes are directly related to the total dose of radiation, the size of fractions administered, and the duration of treatment. Irradiated mucosa shows epithelial atrophy, disrupted vascular supply, and submucosal fibrosis, all of which result in an atrophic, friable mucosa. Fibrosis in skin, muscle, and joint tissue results in limited jaw function and trismus. In salivary glands, loss of acinar cells, alteration in duct epithelium, gland fibrosis, and fatty degeneration occur. In bone, hypervascularity and hypocellularity result in an increased risk of osteoradionecrosis.

Salivary gland dysfunction

Bilateral exposure of the major salivary glands to tumoricidal doses of radiation predictably results in xerostomia. Individuals who receive total radiation doses greater than 30 Gy are at risk for profound xerostomia if all the major glands are in the field. As the total dose of radiation increases, saliva production decreases. Some salivary function may recover within 6 months after radiation, but in most cases the loss of function is permanent, and strategies to prevent oral complications related to xerostomia need to be continued indefinitely.

Xerostomia results in a loss of oral mucosal lubrication, reduced pellicle formation (with subsequent reduced resistance to abrasion and chemical damage), and decreased remineralization of hard dental tissue. Changes in antimicrobial proteins (e.g., lactoferrin, lactoperoxidase, statins, and defensins) and pH also affect the microbial population, resulting in a more cariogenic microflora.

Stimulation of salivary gland function. The treatment of radiation-induced salivary gland hyposecretion should begin with an initial assessment of residual function by measurement of whole resting and stimulated saliva volumes. If salivary glands have remaining functional tissue, residual function may be stimulated naturally (i.e., through taste) or with the use of cholinergic or other agents capable of improving gland function. Sugar-free chewing gum and candy may help stimulate salivary flow from residual major and minor salivary gland cells that were spared from exposure or able to recover from the irradiation. Citric acid is considered to be the strongest "natural" tastant for stimulation of salivary glands, making sugar-free lemon candies a reasonable choice for patients with dry mouth. (Many of the "sugar-free" candies use sorbitol as a sweetener. Because this sugar can pass through the GI tract without being absorbed, patients who consume large quantities of sorbitol may have diarrhea.) Xylitol is another artificial sweetener often found in sugar-free candies. The advantage of xylitol over other sweeteners is the additional benefit of anticaries activity.[31]

Salivary secretion is caused mainly by the release of acetylcholine from parasympathetic nerves, acting via muscarinic acetylcholine receptors on salivary secretory cells. In the presence of functional secretory cells, cholinergic agonists such as pilocarpine and cevimeline are able to stimulate salivary secretion. Pilocarpine tablets have been approved by the FDA for (1) the treatment of symptoms of dry mouth from salivary gland hypofunction caused by radiation therapy for cancer of the head and neck and (2) the treatment of symptoms of dry mouth in patients with Sjögren's syndrome. The recommended initial dose of pilocarpine tablets is 1 tablet (5 mg) taken three times a day. Dosage can be titrated according to therapeutic response and tolerance. The usual dose range is 3 to 6 tablets or 15 to 30 mg/day, not to exceed 2 tablets per dose. At least 6 to 12 weeks of uninterrupted therapy with pilocarpine tablets may be necessary to assess whether a beneficial response has been achieved.

Cevimeline is a newer cholinergic agent that has a similar mechanism of action as pilocarpine. Cevimeline tablets have been approved by the FDA for the treatment of symptoms of dry mouth in patients with Sjögren's syndrome. The recommended dose of cevimeline hydrochloride is 30 mg taken three times a day. There is insufficient safety and efficacy information to support doses greater than 30 mg three times a day. Pilocarpine and cevimeline tablets are contraindicated in patients with uncontrolled asthma, in patients with known hypersensitivity to either agent, and in patients in whom

contraction of the pupil is undesirable (e.g., in acute iritis and in narrow-angle [angle-closure] glaucoma).

The most frequent adverse effects associated with these sialogogues are due to their general mechanism of action and include sweating, nausea, rhinitis, diarrhea, chills, flushing, increased urinary frequency, dizziness, and asthenia. Taking these medications with food can reduce the frequency and severity of these side effects. If a patient sweats excessively while taking these medications and cannot drink enough liquid, the patient should consult a physician because dehydration may develop. Patients should also be informed that these drugs may cause visual disturbances, especially at night, which could impair their ability to drive safely. These medications should be used with caution in patients with a history of cardiovascular disease because they can potentially alter cardiac conduction and heart rate. They should also be used with caution in patients with controlled asthma, chronic bronchitis, or chronic obstructive pulmonary disease because they can potentially increase airway resistance, bronchial smooth muscle tone, and bronchial secretions. Bethanechol is an older cholinergic agonist that is approved by the FDA for the management of urinary retention. Some studies have indicated that it may be beneficial in patients with salivary dysfunction secondary to radiation therapy for head and neck cancer.[19,35]

Palliation of xerostomia. Saliva substitutes and oral lubricating agents may be used when stimulation of salivary function is impossible. Most commercial products are more viscous than saliva, do not mimic the changing viscosity after secretion of saliva, and do not contain salivary enzymes and antibodies. Most products currently available are based on carboxymethylcellulose solutions; animal mucins have been incorporated in some European products. Acceptance of these palliative products can vary, and comparative trials have identified patient-preferred products.[25] Most commercial products have not been subjected to controlled clinical study.

One line of xerostomia products (Biotene/Oral Balance; Laclede, Inc., Rancho Dominguez, Calif.) includes salivary enzymes that may improve oral health and not merely increase moisturization. A double-blind, placebo-controlled crossover trial of Oral Balance gel and Biotene toothpaste in patients with xerostomia after radiation therapy found that the palliative effects of these products were superior to the effects of placebo (carboxymethylcellulose gel and regular toothpaste). No effect on oral colonization by *Candida* species and cariogenic oral microflora was seen, however, with use of these topical agents for 2 weeks.[20] In contrast, another placebo-controlled, single-blind study reported that use of the Oral Balance gel for 4 weeks decreased the number of periodontal-associated bacteria and candidal species identified in saliva.[59] Because saliva substitutes generally have a limited duration of activity, they have to be administered repeatedly, creating problems in patient acceptance and cost. Patients commonly discontinue these products and instead rely on frequent sipping of water.

Dental caries

Salivary gland dysfunction increases the risk of dental caries because of such factors as a shift to a more cariogenic flora, decreased titers of salivary antimicrobial substances, and loss of mineralizing components. Management of decay secondary to decreased salivary flow must address each component of the caries process. Oral hygiene techniques to remove bacterial dental plaque must be scrupulously maintained. Hyposalivation should be managed whenever possible, and sialogogues should be used if effective. The tooth structure may be made more caries-resistant by the use of topical fluorides (gels and varnishes) and remineralization may be enhanced by the combined use of fluorides and remineralizing products. The use of trays for home-based fluoride application is believed to be more effective because of increased contact time. Compliance with fluoride trays may be poor,[26] however, and brush-on fluoride gels can also be effectively used. The two forms of topical fluoride that are commonly used are stannous fluoride and neutral sodium fluoride. Stannous fluoride can cause staining with persistent use, but this tooth discoloration can generally be removed through standard professional dental cleaning.

The high-risk caries secondary to xerostomia is significantly influenced by shifts in resident oral flora, especially increased colonization by *Streptococcus mutans* and *Lactobacillus* species. Ideally, laboratory assessments to quantify cariogenic organisms should be done before proceeding with the use of antimicrobials. Topical fluorides may reduce levels of *S. mutans*, but they may not decrease the numbers of lactobacilli. Chlorhexidine rinses can help control the numbers of *S. mutans*; *Lactobacillus* species are more resistant.[21] If the underlying risk factors are not controlled, rapid recolonization by cariogenic organisms occurs, necessitating continuing use of topical chlorhexidine and fluoride. Because of ionic interactions, fluoride (negatively charged ions) bonds with chlorhexidine (positively charged molecules), and use of the two agents should be separated by several hours. In addition, tooth remineralization products high in calcium phosphate and fluoride have been developed and have shown useful in vitro effects that are supported by clinical experience.

Late oral infections

Oral infections occurring after radiation therapy are usually not a major clinical problem for patients recovering from acute radiation toxicities. Oral infections at this time are primarily associated with overgrowth or high carriage rates of bacterial and yeast organisms that are usually attributable to risk factors imposed by reduction or loss of normal salivary function.

Bacterial infections. The shift in predominant bacterial species colonizing dental surfaces is noted to involve bacteria associated with dental caries. Other than bacterial infections associated with dental caries and endodontic disease, mucosal bacterial infections are generally not a significant clinical problem. Unless chlorhexidine is used continuously to control gram-positive bacteria in dental plaque, increased colonization of mucosal surfaces by gram-negative organisms is not noted.

Candidiasis. With continuing xerostomia, oral candidiasis can persist and may cause discomfort and altered taste. The treatment of choice has been primarily topical antifungal agents. Systemic antifungals may have some benefit, however, when topical agents are unacceptable or ineffective. Nystatin is commonly used, but has limited effectiveness. Better topical antifungal drugs currently available include clotrimazole and amphotericin B. These agents can be applied topically as rinses, troches (or pastilles), or creams—particularly if the patient wears dentures. When prescribing topical antifungal drugs, the clinician should note the presence of sucrose in the product because frequent use of products with sucrose, especially in patients with xerostomia, can promote caries. Limited compliance with the topical agents may be overcome with systemic azoles (e.g., ketoconazole, fluconazole) that can be taken once a day for clinically symptomatic infections and then once a week for prophylaxis.

Tissue necrosis

Any oral tissues included in the field of radiation can be irreversibly damaged and potentially be at risk for postradiation soft tissue and bone necrosis. The late toxic effects to oral

mucosa and bone result from endarteritis and vascular changes that produce a relatively hypervascular, hypocellular, and hypoxic tissue that is unable to repair or remodel itself effectively if trauma occurs. In addition, connective tissue changes can compromise tissues and result in soft tissue necrosis. Where necrosis occurs in tissues over bone, the subsequent exposure of bone can lead to osteoradionecrosis. Risk for tissue necrosis (soft tissue and bone) increases as the dose and volume of tissue irradiated increase, with most cases of osteoradionecrosis reported in sites that have received greater than 55 Gy.[76]

Osteoradionecrosis results from the vascular changes that occur in bone and from damage to the cells of the bone (osteoblasts, osteocytes, and osteoclasts). Although the mineralized portion of bone is unaffected by radiation, the destruction of the cellular elements of bone and the hypovascularization result in minimally viable bone that is unable to remodel or repair itself. The posterior mandible is the most common site involved with osteoradionecrosis, although necrosis can occur in any irradiated area, including the maxilla. Symptoms and signs may include discomfort or tenderness at the site, bad taste, paresthesia and anesthesia, fistula formation, and secondary infection. Pathologic fracture can occur from extensive tissue involvement. The risk of necrosis is lifelong, increases with time, and may occur many years after radiation. As long as a risk for dental or periodontal disease or trauma in irradiated fields exists, so does the risk of osteoradionecrosis. This condition is usually initiated by trauma (e.g., denture trauma) or surgical procedures, but it may also be idiopathic, occurring spontaneously with no identifiable cause. Although the lesions may become secondarily infected, osteoradionecrosis is not primarily an infectious process. The overall risk of developing osteoradionecrosis has been estimated to be 2.6% to 15%.[23]

Prevention of osteoradionecrosis begins with preradiation dental stabilization or management of dental disease. The goals are to eliminate the need for dental surgery after radiation and to prevent future infection or trauma in the irradiated areas. Teeth in high-dose fields with questionable prognosis, particularly because of periodontal or endodontic disease or in patients who are unlikely to maintain acceptable oral health, should be extracted before radiation therapy. If possible, 14 days should be allowed for healing; some authors have suggested 21 days.[23] Surgery should be performed carefully to reduce the degree of trauma to the bone, using primary closure if possible, eliminating infections, and supporting the general health of the patient.

When osteoradionecrosis develops, management includes avoidance of further local irritants, discontinuation of dental appliances if they encroach on the lesion, maintenance of nutritional status, and cessation of smoking and alcohol consumption. Topical antibiotics (e.g., tetracycline) or antiseptics (e.g., chlorhexidine) may reduce the potential for local irritation by the microbial flora. For chronic localized osteoradionecrosis, this treatment along with regular follow-up care may be the best approach. Every attempt should be made to promote mucosal coverage of the exposed bone. Appropriate analgesics should be provided.

If worsening pain, infection, and osteoradionecrosis progression are noted, hyperbaric oxygen therapy (HBO_2) is recommended. HBO_2 has been shown to increase oxygenation of irradiated tissue, induce angiogenesis, and promote osteoblast repopulation and fibroblast function. HBO_2 is usually prescribed as 30 to 60 "dives" at 100% oxygen at 2 to 2.5 atm of pressure.[57] If surgery is needed, postsurgical HBO_2 of 10 dives is recommended. Bone sequestra may be managed with local resection or, in severe cases involving the mandible, mandibulectomy. The mandible can be reconstructed to provide continuity for esthetics and function. In one general cancer clinic, postradiation extractions performed with expert surgery resulted in only 5% of extractions showing delayed healing.[23] This record suggests that when extractions are performed by experienced clinicians, HBO_2 might be reserved for patients in whom osteoradionecrosis develops. However, most centers accept prophylactic HBO_2 as the standard of care prior to any surgical intervention in the post-radiation fields.

Taste changes

Taste and smell dysfunction can be a chronic disability after exposure to radiation. As noted earlier, taste acuity generally recovers over the 2- to 4-month period after the end of radiation treatment. Some individuals are left with permanent hypogeusia, however. The efficacy of zinc supplementation in helping to recover the sense of taste is controversial. If the patient's sense of smell is intact, eating pleasure can be enhanced by trying to make food as "aromatic" as possible (e.g., by warming food) and adding spices to help enhance the taste experience. Nutritional counseling may be necessary to ensure adequate nutritional intake if patients are unable to maintain adequate calorie levels because eating is not enjoyable.

Nutrition

Loss of appetite is common because of radiation-induced complications such as sore mouth, xerostomia, taste loss, dysphagia, nausea, and vomiting. Eating becomes pleasureless and may be painful, resulting in selection of foods that do not aggravate the oral tissues, often at the expense of adequate nutrition. Nutritional complications and deficiencies may be avoided by modifying the texture and consistency of the diet; by adding between-meal snacks to increase protein and caloric intake; and by administering caloric, vitamin, and mineral supplements. High-calorie and protein liquid dietary supplements can be used to augment diets to maintain body weight and ensure adequate nutritional intake. Nutritional counseling is advisable during and after therapy. Nasogastric feeding tubes or percutaneous endoscopic gastrostomy may be required when swallowing is impeded or impossible. After treatment and after mucositis has resolved, nutritional counseling must consider any long-term complications that may be present, including xerostomia, increased caries risk, altered ability to chew, difficulty in forming the food bolus, and dysphagia. Consideration must be given to taste, texture, moisture, and caloric and nutrient content.

Temporomandibular Dysfunction

Musculoskeletal syndromes may arise because of fibrosis of skin and muscles after radiation and surgery, mandibular discontinuity after surgery, and parafunction (clenching/bruxism) associated with the emotional stress caused by the disease and its treatment. Limitation of jaw opening is related to radiation exposure of the lateral pterygoid muscles. Mandibular stretching exercises and prosthetic aids to help reduce the severity of the fibrosis should be instituted before restriction of movement has occurred. Therapy of mandibular dysfunction may include occlusal stabilization appliances, physiotherapy, exercises, trigger-point injections, analgesics, muscle relaxants, tricyclic antidepressants, and other pain management strategies.

SUMMARY

The oral cavity is highly susceptible to the direct and indirect toxic effects of cancer chemotherapy and therapeutic ionizing radiation. Stabilization of oral health before treatment and supportive oral and dental care are crucial components of the patient's overall management, affecting all phases of therapy.

Oral complications occurring during and after therapy can profoundly add to the suffering of the patient, adversely affect the success of therapy, and significantly increase the overall cost of care. Oral care should be preventive and therapeutic to minimize oral and associated systemic complications.

Oral complications of chemotherapy are generally acute (i.e., during therapy) and resolve shortly after the cessation of therapy. Ionizing radiation can cause not only significant intratherapy oral complications, but also permanent toxic effects. Consequently, the dentist must clearly understand the specifics of the proposed therapy and the potential oral problems based on the patient's current oral health and develop a plan that covers all phases of therapy.

Future research should be targeted at developing strategies and technologies to address the quality of life and oral function (1) to reduce the incidence and severity of oral mucositis; (2) to improve infection prevention, detection, and treatment; (3) to prevent salivary gland dysfunction; and (4), specifically for radiation therapy patients, to reduce the incidence and severity of chronic oral complications.

CHAPTER 51

Drugs of Abuse

CHARLES S. BOCKMAN AND PETER W. ABEL

Drug abuse can be defined as an inappropriate use of a drug for a nonmedical purpose. Drug abuse is considered to cause harm to the individual abuser and to society as a whole. Many variables not directly related to a drug can influence whether a given individual becomes a drug abuser. Many experts argue that cocaine possesses the greatest potential for abuse based on its pharmacologic characteristics alone. For individuals who try nicotine, the risk of developing an addiction is approximately twice that for individuals who try cocaine, however.[7] This statement is not meant to infer that the pharmacologic abuse potential of nicotine is twice that of cocaine; rather, some psychosocial factors are equally important in affecting onset and continuation of drug abuse and addiction. It is beyond the scope of this chapter to discuss these factors related to drug users and their environment; this chapter concentrates solely on the pharmacologic aspects of drugs of abuse.

A wide variety of different types of drugs and other chemical substances are subject to abuse. Anabolic steroids are abused by bodybuilders and other athletes to add muscle mass and enhance athletic performance. The most commonly abused groups of drugs are those that act on the central nervous system (CNS) to alter perception. This chapter focuses on drugs that are abused because they have effects in the CNS that are perceived by some individuals as desirable.

HISTORIC PERSPECTIVE

Natural products such as hemp flowers, opium, and coca leaves have been used for thousands of years for their ability to cause pleasurable sensations or other alterations in consciousness. Other than alcohol, the first major drugs of abuse in the United States were cocaine and opioids. Throughout the nineteenth century, unregulated opium use led to a plethora of patent medicines containing opium derivatives. As a result, many middle-class Americans became dependent on opium because of promiscuous use of such preparations. Nevertheless, social attitudes toward drug abuse remained relaxed until after the Civil War. The widespread use of morphine by injection for dysentery, malaria, and pain resulted in such large numbers of morphine-addicted veterans that morphine dependence became known as "soldier's disease."[10]

The chemical isolation of the alkaloid cocaine in 1859 was followed by a rapid increase in the use of that drug. It was enthusiastically promoted for various disorders, and by the turn of the twentieth century, oral abuse of cocaine in the form of patent medicines and tonics was widespread. The manufacturers of Coca-Cola did not stop using cocaine-containing syrup in their soft drink until 1903, after 17 years in production.

In the early 1900s, the mass media developed the myth of cocaine-crazed renegades committing heinous crimes against society. Opioid dependence was still prevalent, and morphine was the major opioid of abuse. During this period, federal laws were enacted to control the widespread drug abuse problem. The introduction of the Pure Food and Drug Act in 1906, the Harrison Narcotic Act in 1914, and the Narcotic Drugs Import and Export Act in 1922 and the enforcement of these acts by law enforcement officials led to the virtual disappearance of cocaine abuse by the 1930s. The increased cost and reduced street availability of cocaine helped lead to the increase of amphetamine as a stimulant drug of abuse. Intravenous (IV) heroin use was also becoming popular, and by 1935 it was as widely abused as morphine. Between World Wars I and II, addiction began to be widely equated with criminality.[10] In the case of marijuana, sensationalized accounts of murders perpetrated by individuals under the influence of the "killer weed" led to the passage of the Marihuana Tax Act of 1937, which effectively banned its production, distribution, and sale.

In the 1960s, drug abuse began to make major inroads into middle-class society. The baby-boom generation began experimenting with lysergic acid diethylamide (LSD) and marijuana. Epidemic amphetamine abuse developed during the 1960s, peaking in 1967 with 32 million legal prescriptions written for amphetamines that suppress appetite and lead to weight loss. To combat the rising tide of drug abuse, the Comprehensive Drug Abuse Prevention and Control Act was enacted in 1970 and replaced previous laws in this area. This act classified drugs into five schedules according to their abuse liability and provided a graded set of penalties for violation of regulations relating to the manufacture, sale, prescription, and record keeping of drugs of abuse. A summary of the abuse potential and examples of drugs falling under this act are provided in Table 55-5. This act is the major regulatory legislation controlling drugs of abuse (see Chapter 55).

In the early 1970s, cocaine was rediscovered as a recreational drug by the young, upwardly mobile, affluent generation. This second cocaine epidemic necessitated a redefinition of the picture of the typical drug abuser as an unemployed, minority male criminal. The 1993 National Household Survey on Drug Abuse reported that 70% of illicit drug abusers are employed, 80% are white, and 75% live in areas outside of the city.[43] As of 2006, the characteristics of the typical drug abuser remain similar to those of 1993.[44]

In 1983, a glut in the world market for cocaine combined with the development of a smokable, inexpensive, and very addictive form of the drug called "crack" brought the third cocaine epidemic to the inner cities, where availability of powdered forms of the drug was limited because of its cost.

In the 1990s, the preparation of a smokable form of methamphetamine led to the widespread abuse of this stimulant, called "ice" and "crank" on the street. More severe abuse patterns than had ever been seen before emerged with the appearance of these smokable, freebase forms of cocaine and methamphetamine. Smoking these drugs results in a more rapid onset of action and a more intense effect, conferring on them more abuse liability than other forms of these drugs that must be sniffed or taken orally. The abuse potential of these drugs increased so dramatically with this mode of administration that drug seeking became more paramount to this population of abusers than it previously had been. Equally insidious was the emergence of clandestine laboratories that make "designer drugs," synthetic substances that are inexpensive to produce and difficult to detect. These include the amphetamine analogue 3,4-methylenedioxymethamphetamine (MDMA) (otherwise known as "ecstasy") and "China white," a synthetic opioid analogue of fentanyl with 1000 to 2000 times its potency.

The economic effect of these new patterns of abuse can be felt in hospital emergency departments and in board rooms across the United States. Although cocaine and methamphetamine abuse has generally declined since the 1980s, the incidence of cocaine-related and methamphetamine-related medical emergencies has increased threefold since 1981.[6] This increase may reflect the increased toxicity of smokable drug preparations because smoking leads to a greater concentration of drug in the body than other routes of administration. Potential costs of illicit drug use in the workplace include payment for substance abuse treatment programs, loss of productivity from absenteeism, accidents, disability claims, theft, and employee screening for drug use. Among full-time workers, 43% reported that tests for illicit drug or alcohol use occurred at their place of employment during the hiring process; in the employed 18- to 64-year-old age group, 8% reported positive for an illicit drug in the previous month.[37]

In general the incidence of illicit drug use has declined modestly since 1975.[31,32] In 1979, 51% of American high school seniors reported using marijuana annually; that figure decreased to 32% in 2007. Similar trends were reported for cocaine (6% in 1975 and 5% in 2007), hallucinogens (8% in 1975 and 5% in 2007), barbiturates and other sedative-hypnotics (10% in 1975 and 6% in 2007), heroin (1% in 1975 and 1% in 2007), inhalants (3% in 1976 and 4% in 2007), and amphetamines (16% in 1975 and 9% in 2001). There are some important exceptions to the decline in illicit drug use since the 1970s. Although overall amphetamine use has decreased, annual use of the smokable preparation of methamphetamine has increased from 1.5% in 1990 to a peak in 2004 (3.5%), followed by a decline to 1.7% in 2007. A noteworthy increase in MDMA use from trace levels in 1985 to 3.5% in 1995 to 4.5% in 2007 reflects the current upward trend in overall use of so-called "club drugs." In addition, an emerging trend indicates that nonmedical use of prescription drugs such as clonazepam (Klonopin), methylphenidate (Ritalin), and oxycodone (OxyContin) is extremely prevalent with 15% of high school seniors reporting recreational use of at least one prescription medication within the past year.

DRUG ABUSE CHARACTERISTICS AND TERMINOLOGY

The term *addiction* refers to a compulsion to take a drug on a continuous or periodic basis to experience its psychoactive effects.[4] For addiction to exist, the abuser must have a mental obsession to continue drug administration to produce pleasure. Additional characteristics of addiction, which may or may not be present, are dependence and tolerance. When the administration of a drug is discontinued or, in the case of certain drugs, significantly reduced, *dependence* leads to the appearance of a characteristic and specific group of symptoms, termed a *withdrawal* or *abstinence syndrome*.[28] *Tolerance* exists when administration of the same dose of a drug has progressively less effect. This decreased response to the effects of a drug requires that increasingly larger doses of a drug be given to produce the same pharmacologic actions. The development of tolerance depends on the dose of the drug and the frequency of its administration. Tolerance is caused by compensatory responses that act to decrease the body's response to a drug. The cellular basis for drug tolerance may be related to a decrease in receptors for the drug, a reduction in enzyme activity associated with signal transduction pathways, or other effects. *Cross-tolerance* is the phenomenon whereby chronic use of a drug produces tolerance to that drug's effects and to other drugs that produce the same effect. Cross-tolerance may be observed among drugs of similar or different chemical types. A related but different phenomenon is *cross-dependence*, which refers to an ability of one drug to substitute for another drug, usually in the same class, in a dependent individual without precipitating a withdrawal syndrome.

On the basis of common pharmacologic actions and of cross-tolerance and cross-dependence, the major drugs of abuse can be divided into distinct categories: opioid analgesics; general depressants of the CNS, including sedative-hypnotics and antianxiety drugs; cocaine, amphetamines, and related psychomotor stimulants; hallucinogens; marijuana; and inhalants. Table 51-1 lists the major abuse characteristics of these six drug groups—the degree of addiction and dependence and tolerance development commonly associated with

TABLE **51-1**

Abuse Characteristics of Drug Groups

	PSYCHOLOGICAL DEPENDENCE	PHYSICAL DEPENDENCE	TOLERANCE

the abuse of each drug group. In the following discussion, each drug group is described in terms of three major factors: (1) the pharmacologic effects produced by the drug group; (2) the abuse characteristics of the drug group, including addiction, tolerance, dependence, withdrawal, and other characteristics; and (3) the toxicity caused by the drug group and how it is treated.

ABUSE OF OPIOID ANALGESICS

Opioid analgesics most commonly abused include heroin, morphine, and, among health care professionals, meperidine and fentanyl. In addition to these agonists, various other synthetic and semisynthetic derivatives are subject to abuse. These agents differ from each other in their abuse characteristics, their onset and duration of action, the intensity of their effects, and, to some extent, the pattern of their abuse. Many of the mechanisms involved in the analgesic response to opioids also produce euphoria or a perceived state of well-being, and much research has been generated in an attempt to develop efficacious analgesics that are not euphoric and have less abuse potential. Although this research has led to a greater understanding of the physiologic characteristics of pain, at present no opioids or other types of analgesics are superior to morphine. In the following discussion, morphine is considered the prototype for this group, unless another drug is specifically mentioned.

Pharmacologic Effects

In the following discussion, the subjective effects of opioids are the effects observed in individuals who are opioid abusers. Although opioids produce similar pharmacologic effects in most individuals (see Chapter 20), not everyone reports the subjective effects of warmth, contentment, orgasm, and euphoria. In nonabusing individuals, the nausea and vomiting caused by opioids are construed as unpleasant and may obfuscate many of the reinforcing characteristics of these drugs. Many individuals view the mental clouding produced by opioids as an undesirable inability to concentrate, whereas addicts find this quality appealing. Most important, because opioids are the mainstay in the treatment of moderate-severe pain, it is relevant to know that in the therapeutic setting little substantive evidence suggests that effective pain management with opioids in individuals leads them to develop into opioid abusers.

For individuals who abuse opioids, the IV administration of heroin causes an immediate overwhelming sense of warmth that permeates the abdominal area and that has been described as orgasmic. Nausea, vomiting, and histamine release occur soon after, causing a sense of itching, reddening of the eyes, and a decrease in blood pressure. Feelings of increased energy with talkativeness ("soapboxing") alternate with periods of relaxation or tranquillity ("coasting"). This intense euphoria may last several minutes. The depressant effects on the CNS then appear and include mental clouding, decreased visual acuity, and sedation accompanied by a feeling of heaviness in the extremities. The abuser has no motivation to participate in physical activity; the individual appears to be asleep, but only the head and facial muscles are relaxed ("nodding"). This period is followed by episodes of light sleeping accompanied by vivid dreaming. Feelings of anxiety and worry are absent, and a pervasive sense of contentment is present. Taken together, the early euphoric period followed by the sedation and sleeping may last 3 to 5 hours.

Abuse Characteristics

The development of tolerance is a characteristic feature of all opioid agonists. Regardless of whether opioids are administered in a therapeutic setting or are self-administered, repetitive use leads to tolerance or a reduction in response, such that a greater dose of drug is required to achieve the same effect that was produced on initial administration of the drug. Tolerance develops most readily when opioids are given in large doses at short intervals or during constant infusion of the drug; the phenomenon can be observed within days after drug therapy has begun. Tolerance or desensitization to the effects of opioids develops at the cellular level and may be viewed as a homeostatic response by the cell to constant exposure to an agonist. Because the development of tolerance to the effects of opioids is a physiologic phenomenon, it inevitably occurs in patients after repeated drug administration. The development of tolerance is not a predictor of whether the patient will become an opioid abuser.

Because most fatalities resulting from opioid overdose are caused by respiratory depression, the prescribing physician must understand that tolerance develops similarly to the respiratory depressant effect and to the analgesic and euphoric effects of opioids. This fact has important ramifications for the clinician, who may be wary about administering 10 times the normal dose of morphine for adequate pain control in a patient who has developed tolerance to the analgesic effects. Out of concern for the respiratory depressant or addictive properties of morphine, the clinician may not provide adequate pain control even though the patient has developed a similar degree of tolerance to the respiratory depressant and euphoric effects of morphine. Because of this use-induced decrease in the ability of opioids to suppress respiration, considerable tolerance to the lethal effects of opioids may develop. Tolerance to the respiratory effect of opioids is rapidly lost during abstinence, however, and death may result if an addict returns to the previously maintained dosage after withdrawal has been completed.

Similar to tolerance, dependence on opioids is also a result of repeated administration of an agonist and occurs for all opioids. Dependence results from cellular adaptation caused by uninterrupted agonist occupation of opioid receptors. Normal function of the individual now requires the presence of an opioid drug at its receptor. When the drug is removed from the receptor during drug withdrawal, an acute withdrawal syndrome ensues. The intensity of the withdrawal syndrome is related to the degree of dependence. As with tolerance, dependence develops most rapidly and to the greatest extent when the opioid receptors are constantly occupied. No outward signs of dependence are observed until the drug is withdrawn.

Withdrawal symptoms in an opioid-dependent individual include rhinorrhea, lacrimation, vomiting, sweating, yawning, diarrhea, irritability, restlessness, chills, piloerection ("cold turkey"), mydriasis, hyperventilation, tachycardia, hypertension, tremors, and involuntary muscle movements. In general, the appearance and severity of withdrawal signs depend on the duration of action of the opioid being taken. Signs of withdrawal in a heroin-dependent individual appear approximately 6 hours after the last dose, increase in intensity over the next 36 to 72 hours, and subside after about 1 week. In contrast, dependence on a long-acting opioid, such as methadone, results in a mild but protracted withdrawal syndrome with delayed onset. A withdrawal syndrome can also be precipitated in dependent individuals by displacing the opioid from the receptor with an antagonist (naloxone), an agonist-antagonist (pentazocine), or a partial agonist (buprenorphine). Death from opioid withdrawal is rare; however, when it does occur, it is because of cardiovascular collapse from dehydration and acid-base imbalance.

The development of dependence to opioids is a physiologic response seen in all individuals; it does not predict whether they become abusers. In patients who become dependent, the dose of opioid can be decreased by 50% every

other day and eventually stopped without overt signs of withdrawal.

Addiction to opioids is significant, as exemplified by the high relapse rate among addicts after withdrawal. The euphoria, tranquillity, and abdominal effects, described as orgasmic, promote abuse of opioids. The rapidity with which opioids penetrate the CNS to cause their psychoactive effects correlates with their ability to cause addiction. Opioid addicts prefer the "rush" sensation produced by the rapid onset of psychoactive effects characteristic of IV administration over the slower onset of effects produced by other routes of administration. Heroin is preferred because its high lipid solubility confers rapid penetration into the brain and an intense effect. Conversely, orally administered methadone for control of chronic pain has much less potential for creating addiction.

Addiction to opioids occurs independently from tolerance and physical dependence and is a result of an addict craving the feelings produced by opioids. This craving may even occur before, or in the absence of, the development of tolerance and dependence. The fact that discontinuance of opioids may precipitate a withdrawal syndrome may provide an incentive to continue their use, however. Because of the short duration of action of heroin, a dependent addict oscillates between feelings of euphoria and sickness related to withdrawal and exhibits drug-seeking behavior. Drug-seeking behavior is manifested by pleas, complaints, demands, and other activities directed toward obtaining the drug to alleviate the discomfort caused by drug withdrawal. An individual may become dependent on the psychological effects of opioids, however, before developing fear of withdrawal.

Patients in need of pain control should not be denied adequate opioid medication because they show evidence of tolerance or exhibit withdrawal symptoms if the medication is stopped, as these signs do not indicate addiction. In addition, a patient who is in pain and receiving opioids does not respond the same way a psychologically dependent addict responds to opioids. Patients who are able to self-administer their opioid analgesic take the drug solely to reduce the pain, do not increase the dose greatly over time, and stop administration when the pain goes away.[24]

Toxicity

In acute opioid overdose, the classic triad of coma, respiratory depression, and pinpoint pupils is common to all opioid agonists (except meperidine, in which case the pupils may be dilated in tolerant individuals). Hypoventilation leads to marked hypoxemia and cyanosis, and acute pulmonary edema evidenced by a pink, frothy sputum may occur, especially with heroin overdose. Nausea and vomiting may be prominent. Hypotension, as a result of cerebral ischemia, develops gradually and may eventually lead to circulatory shock. Convulsions do not occur with most opioids, although they have been reported in children with codeine overdose, in addicts in response to meperidine, and in cases of propoxyphene poisoning.

The treatment of choice is rapid IV administration of 0.4 mg of naloxone, repeated if necessary at 2- to 3-minute intervals. Dramatic improvement occurs within minutes, with enhanced ventilation and dilation of the pinpoint pupils. The patient must be closely monitored because the antagonist's effect lasts only 1 to 4 hours. Monitoring is especially important with methadone overdose because respiratory depression may last 48 hours. If vital signs return to normal, no attempt should be made to arouse the patient with additional naloxone because if the patient is an opioid addict, large doses of the antagonist may precipitate an acute withdrawal syndrome.

The toxic effects of chronic abuse of opioids are minimal. Other than constipation, addicts with a stable supply of drug, individuals enrolled in a methadone maintenance program, or patients taking opioids long-term for pain control have few difficulties as long as they continue taking the drug. Many addicts share unsterile needles and equipment, however, which increases their risk of contracting acquired immunodeficiency syndrome (AIDS), hepatitis, skin abscesses, deep infections, and endocarditis.

When the supply of an addict's preferred drug is compromised, the addict may substitute substances of unknown content and potency or drugs thought to have a similar effect. Many addicts like the effects caused by IV injection of the agonist-antagonist pentazocine with the antihistamine tripelennamine. The talc contained in the crushed tripelennamine tablet has caused deaths as a result of lung emboli. Overdose leading to death may occur when an addict injects a purer sample than that to which he or she is accustomed or a sample containing a much more potent opioid, such as those seen with China white in the 1980s and fentanyl in the 1990s. Unexpected toxic effects also occurred in the late 1970s and early 1980s, when "bathtub chemists" trying to synthesize potent opioids produced a compound contaminated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which caused Parkinson-like symptoms in many young abusers (see Chapter 15). Abuse of prescription opioid analgesics has also resulted in unexpected deaths. In the late 1990s and early 2000s, deaths from overdosage resulted when individuals crushed tablets of the controlled-release formulation of oxycodone to make the entire dose available for intranasal or IV administration.

Opioid withdrawal or detoxification of heroin addicts or other opioid-dependent individuals can be managed with methadone because cross-dependence exists between it and other opioids.[36,45] Because methadone and all other opioid analgesics act at opioid receptors, methadone can be substituted for the opioid being abused without precipitating a withdrawal syndrome. By substituting longer acting methadone for a short-acting opioid such as heroin, the addict is spared the undesirable effects of withdrawal because the opioid receptor remains occupied. Methadone can be withdrawn from the addict over weeks. Methadone, with its long duration of action, produces a protracted but tolerable withdrawal syndrome.

The α_2-adrenoceptor agonist clonidine can also be used alone or in combination with methadone to assist in the detoxification of an opioid-dependent individual. Many of the unpleasant effects experienced during opioid withdrawal, such as nausea, vomiting, sweating, tachycardia, cramps, and hypertension, are caused by hyperactivity of the autonomic nervous system. Clonidine, through its action at α_2 adrenoceptors in the brain, suppresses the outflow of sympathetic nervous system activity, reducing the discomfort of opioid withdrawal.

Although management of acute opioid withdrawal is easy, the recidivism rate (i.e., the number of addicts who return to abusing opioids) is very high. Methadone maintenance therapy can also be used in the long-term treatment of opioid abuse. The pharmacologic basis of methadone maintenance depends on its oral effectiveness, long duration of action, and the development of cross-tolerance between it and other opioids, particularly heroin. Tolerance to the effects of opioids is mediated at the cellular level and develops to any opioid acting at the same receptor.

The first step in maintenance therapy is to provide an oral dose of methadone that is not sedating but prevents signs of withdrawal. Maintenance therapy is performed at a government-regulated clinic and is feasible because of the long duration of action of methadone. Patients function normally and do not have the "rush" associated with other routes of administration. If the patient relapses into opioid abuse, the development of cross-tolerance between methadone and heroin or other agents results in a blockade or diminution of the euphoric effect of the abused substance, removing the

reinforcing properties of the abused agent. Although the patient is now dependent on methadone, withdrawal from a long-acting opioid results in a mild but protracted abstinence syndrome with delayed onset. The dose of methadone is gradually reduced until the patient is opioid-free. Methadone maintenance therapy is effective only if the patient wants to quit abusing opioids and if, over the time of the therapy, the patient breaks the psychological dependence on opioids.

In 2000, Congress passed the Drug Addiction Treatment Act (DATA), allowing certified physicians to prescribe narcotic medications for the treatment of opioid addiction. DATA produced an important paradigm shift that allowed for the treatment of addiction to opioids such as heroin to occur in physicians' offices, rather than limiting it to highly stigmatized government-regulated methadone clinics. Buprenorphine, an agent now being used under this new legislation, is a long-acting partial agonist that acts on the same receptors as heroin and morphine; it relieves opioid cravings in mildly to moderately addicted individuals and produces less respiratory depression and withdrawal symptoms than the full agonist methadone.[21]

ABUSE OF SEDATIVE-HYPNOTICS

Drugs in the sedative-hypnotic group are general CNS depressants and include sedative-hypnotic and antianxiety drugs (discussed in Chapter 13). Older sedative-hypnotic drugs, including barbiturates, glutethimide, and the widely abused but no longer approved drug methaqualone, have substantial abuse potential. Benzodiazepines and related drugs are now the most commonly used sedative-hypnotic and antianxiety drugs. Although these newer drugs have significant abuse potential, they are less frequently abused than the older sedative-hypnotic agents. Sedative-hypnotic drugs are readily available from illicit sources and by prescription abuse when large amounts of the drugs are accumulated by drug abusers visiting different prescribers.

Pharmacologic Effects

The signs of intoxication with sedative-hypnotic and antianxiety drugs are similar to signs produced by alcohol—drowsiness, impairment of motor coordination, ataxia, and slurred speech. Sluggishness, difficulty in reasoning, mood swings, and irritability are also seen. Subjective effects include sensations of well-being, euphoria, and sometimes stimulation. The next day the abuser may experience nervousness, anxiety, tremor, headache, and insomnia. The exact constellation of effects depends on the dose of the drug, the route of drug administration, the frequency of administration, and the user's expectations.

Abuse Characteristics

The degree of addiction with sedative-hypnotic drugs depends on the dose of the drug, the frequency of administration, and the duration of drug use. Sedative-hypnotic drugs differ in onset and duration of action (short-acting and long-acting barbiturates and benzodiazepines are available). Addiction is most commonly associated with abuse of short-acting drugs, such as secobarbital, pentobarbital, oxazepam, and lorazepam. Dependence on longer acting agents, such as phenobarbital and chlordiazepoxide, is less common.[3,22] Dependence occurs only rarely with intravenously administered ultrashort-acting sedative-hypnotics because they cannot be taken frequently enough to maintain adequate plasma concentrations.

For benzodiazepines, drugs with a higher affinity for the BZ_2 benzodiazepine receptor subtype (e.g., alprazolam) seem to have a greater potential for abuse than drugs with a higher affinity for the BZ_1 benzodiazepine receptor.[30] Initial exposure to sedative-hypnotics may occur when the drug is prescribed to relieve anxiety or insomnia. The dose is slowly increased, and the abuser may become preoccupied with obtaining and using the drug. So-called date rape drugs, such as γ-hydroxybutyrate, a metabolite of γ-aminobutyric acid, and the prescription benzodiazepine flunitrazepam ("roofies") are also subject to misuse. Both drugs have similar effects as sedative-hypnotics; however, their rapid oral absorption, onset of action, and ability to cause anterograde amnesia have resulted in their surreptitious use as sedatives to facilitate rape of unwitting individuals.

In contrast to opioids, sedative-hypnotics do not induce dependence unless increased doses of drugs are taken over a long period (≥1 month). The onset and severity of the abstinence syndrome also depend, in part, on the dose and the duration of drug use. Minimal withdrawal symptoms are elicited by abrupt withdrawal from chronic daily use of 400 to 500 mg of pentobarbital or secobarbital.[20] With chronic use of larger doses, progressively more severe symptoms of withdrawal can be precipitated, even by abruptly reducing the accustomed dose by half. Although withdrawal from daily doses of 600 to 800 mg of secobarbital after 1 month produces a minor withdrawal syndrome, withdrawal from daily doses of 800 to 900 mg after 2 months or more produces major withdrawal symptoms. Another important determinant of the onset, severity, and duration of the withdrawal syndrome is the half-life of the specific drug. Drugs with relatively short half-lives (8 to 30 hours) tend to produce a severe withdrawal syndrome that develops quite rapidly. Drugs with longer half-lives (40 to 100 hours) produce a slower onset but less severe withdrawal syndrome of long duration.

The withdrawal syndrome after cessation of sedative-hypnotics resembles that seen after alcohol withdrawal. After a usually symptomless period (8 to 18 hours after the last dose), the individual exhibits increasing symptoms of anxiety, insomnia, agitation, and confusion. Anorexia, nausea and vomiting, sweating, and muscle weakness are also seen. Coarse tremors in the face and hands; dilation of the pupils; and increases in respiratory rate, heart rate, and blood pressure may occur. Orthostatic hypotension and syncope may also occur. These symptoms become more severe during the first 24 to 30 hours of drug withdrawal. By the third or fourth day, major manifestations of abstinence may develop, which include delirium, hallucinations, agitation, hyperthermia, convulsions, and nonspecific symptoms of anxiety. Symptoms associated with benzodiazepine withdrawal also occur; these are persistent tinnitus (≤8 months), muscle twitching, paresthesias, visual disturbances, and confusion and depersonalization.[38] Reports of xerostomia and pain in the jaws and teeth have particular dental significance.[8]

Muscle fasciculations and enhanced deep reflexes may progress to frank seizures. One or more grand mal convulsions lasting less than 3 minutes may occur, with consciousness being regained within 5 minutes. In some cases, status epilepticus may ensue. The prolonged postictal stupor typical of epileptic seizures is not seen, but confusion may persist for 1 or 2 hours. Delirium develops gradually over 2 to 4 days and is heralded by a period of insomnia. Delirium is characterized by confusion, disorientation of time and place, nightmares, and vivid auditory and visual hallucinations. Paranoid delusions with extreme fear and agitation may develop, especially at night ("night terrors"). The symptoms terminate spontaneously after a prolonged period of sleep. This withdrawal psychosis may be caused by rebound rapid eye movement sleep, which, having been suppressed during the period of intoxication, intrudes into the waking state. During the phase of delirium, body temperature is elevated. A continuous marked hyperthermia is a life-threatening problem that, if not immediately and vigorously treated, may (along with agitation) lead to fatal exhaustion and cardiovascular collapse.

After the acute withdrawal syndrome, recovery is gradual but complete after approximately 8 days, although residual weakness may be noted for 6 to 12 weeks. Abrupt withdrawal from large doses of sedative-hypnotics can precipitate a severe, life-threatening withdrawal syndrome that has a significant mortality rate. The withdrawal syndrome from sedative-hypnotics may be more severe than withdrawal caused by opioids.

Tolerance develops to sedative-hypnotic drugs, and partial cross-tolerance also occurs among the various drugs in this class. Tolerance is usually complete to doses of short-acting barbiturates of up to 500 mg/day, but doses of greater than 800 mg/day are associated with signs of intoxication. The onset of tolerance to benzodiazepines in humans develops slowly, beginning in 3 to 5 days, with maximal tolerance in 7 to 10 days.[38] The mechanisms of tolerance to these drugs are unclear. Much of the tolerance to large doses of short-acting barbiturates is associated with hepatic enzyme induction that results in enhanced barbiturate elimination. This metabolic tolerance plays less of a role for benzodiazepines, for which cellular tolerance, a decreased responsiveness of neuronal pathways in the CNS, seems to play a more prominent role.

Toxicity

Ingestion of large doses of sedative-hypnotic drugs may be life-threatening. Coma may develop with progressive deterioration of respiration and blood pressure. The victim exhibits hypoxia, cyanosis, shock, hypothermia, and anuria. Death is usually from cerebral anoxia caused by respiratory failure. Therapy is mainly supportive, consisting of oxygen administered by artificial respiration and fluids or pressor agents (or both) to maintain circulation. For barbiturates, osmotic diuretics with sodium bicarbonate are also used to alkalinize the urine and hasten elimination of the drug. The benzodiazepine receptor antagonist flumazenil has been used specifically to block toxic effects in the treatment of acute benzodiazepine overdose.

Withdrawal from chronic therapeutic abuse of sedative-hypnotic drugs is associated with drug craving, nausea and abdominal cramps, tachycardia, palpitation, and generalized seizures. Panic attacks and disorientation may occur, progressing to paranoid psychosis with aggression, delusions, and visual hallucinations.[8,38] Coma and respiratory depression cause a significant mortality rate. Treatment includes substitution with a long-acting sedative-hypnotic drug, such as phenobarbital, followed by a modest daily reduction in the maintenance dose.[26] Seizures represent a medical emergency and are treated by immediate administration of diazepam, pentobarbital, or carbamazepine. Withdrawal from sedative-hypnotic drugs should be carried out in a hospital setting because life-threatening complications may develop.

Other Sedative-Hypnotic Drugs

Various other sedative-hypnotic drugs may be classified according to chemical structure into aldehyde derivatives (chloral hydrate, paraldehyde), 1,2-propanediol carbamates (meprobamate), and heterocyclics (glutethimide, methyprylon, methaqualone). All drugs in these groups produce patterns of intoxication, tolerance, dependence, and addiction that are similar to the patterns produced by barbiturates and benzodiazepines. All these drugs exhibit some degree of cross-tolerance and can suppress the abstinence symptoms of other depressants of the CNS.

ABUSE OF AMPHETAMINES, COCAINE, AND OTHER PSYCHOMOTOR STIMULANTS

Psychomotor stimulants include analogues of phenylethylamine (*d*-amphetamine and methamphetamine), a group of amphetamine derivatives in which the terminal amine nitrogen is part of a heterocyclic group (methylphenidate, phendimetrazine) or a diethylated group (diethylpropion), and cocaine. The chemical structures of some of these drugs are shown in Figure 51-1. Amphetamines and methylphenidate are generally used for treatment of narcolepsy and attention-deficit/hyperactivity disorder; phendimetrazine and diethylpropion are anorectics. These drugs are available on the street and by prescription. Cocaine is the most widely abused member of this class. The chemical structure of cocaine is shown in Figure 51-2. It has been estimated that 3 million Americans abuse the various forms of cocaine. Generally, the effects of and abuse patterns associated with the individual drugs in this group are quite similar.

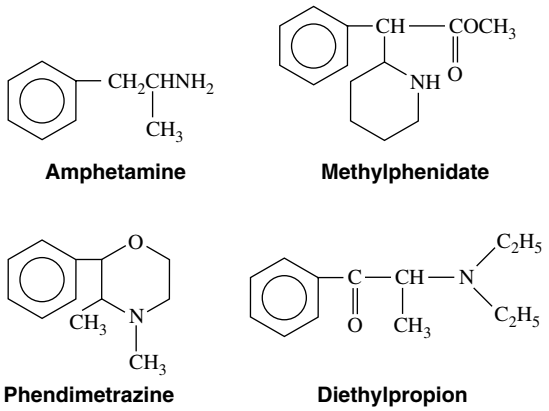

FIGURE **51-1** Structural formulas of amphetamine and related stimulant drugs.

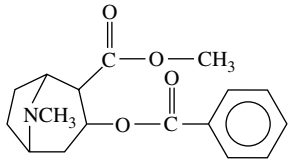

FIGURE **51-2** Structural formula of cocaine.

Amphetamine and Related Drugs

Pharmacologic effects

Single oral doses of amphetamine and related drugs produce wakefulness, reduced fatigue and reaction times, and improved performance of psychomotor tasks, especially in sleep-deprived individuals. Feelings of enhanced well-being, moderate exhilaration, and euphoria are common. Judgment may be impaired, and irrational behavior may occur. These drugs can cause signs of increased peripheral adrenergic nerve activity, such as an increase in blood pressure, tachycardia, mydriasis, sweating, and constipation. These effects probably result from the release of norepinephrine from central and peripheral neurons or the blockade of neuronal uptake of norepinephrine at these sites. High oral doses of CNS stimulants induce feelings of cleverness, enhanced abilities, aggressiveness, and fearlessness and may cause a manic "high," paranoid rage, violent diarrhea, and vomiting.

Abuse characteristics

Patterns of oral use are usually intermittent and involve lower doses causing milder effects. Oral amphetamines have been abused by students who want to study through the night and by truck drivers who want to stay awake for long hauls. Amphetamine abusers also take these drugs intranasally, intravenously, and by smoking. IV administration of methamphet-

amine results in a markedly pleasurable rush described as an expanding, flashing, vibration feeling, or a total body orgasm. IV administration of amphetamines is more apt to promote repeated use than oral administration. Because the euphoric effect of IV methamphetamine is long, it can be injected every 3 hours to maintain its euphoric effect.

The standard hydrochloride salt form of methamphetamine can be converted into its freebase, resulting in a form of the drug called "ice" or "crank" that can be administered by smoking cigarettes laced with the drug. Smoking methamphetamine in its freebase has become the most popular abused form of this drug in recent years. Because smoking the drug is a more acceptable route of administration, the easy availability of this form of the drug has been suggested to be responsible for the more recent increase in its abuse. The onset of effects and the intensity of the euphoria produced by smoking "ice" are reported to be at least as great as those seen when methamphetamine is injected intravenously. Both chemical forms of the drug are usually taken continuously for 2 to 5 days, during which time the abuser does not sleep or eat. This is called a "run" or "binge." The next stage is the "crash," during which the abuser sleeps for 24 to 48 hours. This stage is often followed by hunger, depression, dysphoria, and restlessness.

The degree of addiction and abuse potential is high for all the drugs in this group. Individuals dependent on these drugs have a very strong compulsion to engage in drug-seeking behavior. Marked tolerance to the stimulant effects of amphetamine develops readily. Although the therapeutic dose of amphetamine is 10 to 15 mg, abusers may inject intravenously 2 g/day. The mechanism of tolerance is unknown but has been attributed to the depletion of central catecholamine stores with replacement by p-hydroxynorephedrine, a metabolite of amphetamine that may function as a false neurotransmitter in adrenergic nerves.

Dependence on amphetamine is not easily demonstrable because it may be difficult to differentiate true withdrawal symptoms from the body's response to prolonged sleep and food deprivation and enhanced physical activity. Withdrawal from the drug after a "run" is followed, however, by a prolonged sleep and then by a ravenous appetite, fatigue, apathy, and depression. This complex of symptoms is interpreted as evidence of dependence. In humans, the depression associated with amphetamine withdrawal is correlated with a CNS reduction in 3-methoxy-4-hydroxyphenylglycol, a norepinephrine metabolite, which indicates that CNS catecholamines are depleted. This finding provides a neurochemical mechanism to explain the depression caused by drug withdrawal.

Toxicity

Acute severe overdose, although uncommon, is characterized by CNS and cardiovascular stimulation. Coma and convulsions occur, which may develop into status epilepticus. These convulsions may be controlled with IV diazepam. Cardiac arrhythmias and hypertension, occasionally precipitating subarachnoid hemorrhage or intracerebral hematomas, may lead to cardiovascular collapse. Enhanced autonomic activity, including hyperthermia and dilated pupils, may also be seen.

A chronic amphetamine abuser typically displays anxiety, akathisia, volatile mood, headaches, and cramps. In addition, the abuser frequently shows signs of mental and physical fatigue, poor personal hygiene, and facial twitching. Of particular interest to dentistry are the worn teeth and chewed tongue that result from continuous oral movements. Chronic stimulant abuse leads to stereotypy, psychosis, and overt violence. Stereotypic compulsive behavior is characterized by pleasurable curiosity and fascination with detail. Compulsive, repetitive activity develops, such as cleaning an immaculate home or disassembling and reconstructing mechanical objects. Chronic abuse can cause a drug-induced paranoid psychosis that resembles acute paranoid schizophrenia. Psychosis may develop within 1 to 5 days after beginning drug use and usually lasts 6 to 7 days. The most common symptoms are delusions of persecution; auditory, tactile, and especially visual hallucinations; and hyperactivity. Anxiety, agitation, aggressiveness, and depression are often observed. Paranoia, hallucinations, and terror reactions lead to hostility and difficulty in controlling rage. Amphetamine abusers display a high incidence of unpremeditated, unprovoked, and bizarre acts of violence and assaultive and even homicidal behavior.

After amphetamine use is discontinued, confusion, delusions, and loss of memory may persist for several weeks or months. Treatment of toxicity is based on enhancing the elimination of the drug from the body. Acidification of the urine with ammonium chloride increases the rate of urinary excretion of amphetamine and causes rapid reduction of psychotic symptoms.[5]

Cocaine

The leaves of the coca plant, which contain up to 1.8% of the pure alkaloid, are the primary source of cocaine. The Andean Indians have chewed coca leaves, mixed with an alkaline substance to promote release of cocaine, for many years. Although peak blood concentrations of 95 ng/mL are achieved, little drug-induced euphoria is reported among Andean Indians who chew coca leaves. The leaves are used to make cocaine paste (30% to 90% cocaine), which is converted to pure cocaine hydrochloride, primarily in South America. Many samples of street cocaine apparently contain adulterants such as amphetamines, mannitol, or lidocaine. The local anesthetic procaine shares some characteristics with cocaine and can produce euphoria. Procaine powder is frequently used to cut cocaine and, mixed with mannitol or lactose, is sold as cocaine.

Pharmacologic effects

Cocaine is a local anesthetic that produces adrenergic effects by blocking neuronal uptake of norepinephrine. Pharmacologic responses to cocaine are mainly cardiovascular and are similar to those of amphetamine. Cocaine produces a dose-related tachycardia and increase in blood pressure, especially systolic. The onset of action is 2 to 5 minutes by the IV route and approximately 30 minutes by the intranasal route. In both cases the cardiovascular response dissipates over roughly 30 minutes. In IV doses of 32 mg, cocaine promotes a moderate mydriasis and hyperglycemia, but no effects on the electrocardiogram, respiratory rate, or body temperature.[47]

As a recreational drug, cocaine uniformly causes euphoria and signs of CNS stimulation. The subjective effects of cocaine include elation, arousal, and alertness. Garrulousness and enhanced friendliness facilitate social interaction in group settings. Hunger and fatigue are suppressed. The user has a subjective feeling of increased mental agility. As is true of amphetamine, performance may be enhanced in sleep-deprived, but not in rested, subjects. Cocaine can delay ejaculation, which together with heightened sensory awareness and elevated mood, enhances the sexual experience. The orgasmic rush produced by IV cocaine use may become a substitute for coitus. This essentially pleasant high is produced by doses of about 100 mg, 25 mg, and 10 mg of cocaine by the oral, intranasal, and IV routes, respectively.[47]

Negative subjective effects occur in 3% of intoxications in the early stages of abuse, but occur in 82% of compulsive cocaine abusers. The euphoric effects of the drug are followed by restlessness, irritability, and psychomotor agitation. Hyperexcitability and paranoia may occur. Chronic, high-dose cocaine abuse may result in aberrant sexual behavior, such as

marathons of promiscuity. Men may have reduced libido, with an inability to maintain an erection or to ejaculate. Women may be unable to achieve orgasm.[14]

Abuse characteristics

Although ingested cocaine can have stimulant effects, it is rarely taken orally. The intranasal route ("snorting") is more commonly used by cocaine abusers. Cocaine hydrochloride usually is inhaled as a "line" of powder containing 20 to 30 mg of the drug. It produces a maximum effect in 15 to 20 minutes and a duration of effect lasting 1 hour or more. Nasal mucosal vasoconstriction and paralysis of membrane cilia prevent complete absorption by this route, and measurable cocaine remains on the nasal mucosa for 3 hours after use. Snorting of cocaine in solution produces effects in 5 to 15 minutes that last 2 to 4 hours. The euphoric effect of cocaine is less intense when the intranasal route is used compared with IV injection or smoking the drug.

When cocaine is injected, the IV route is preferred over the intramuscular or the subcutaneous route because local vasoconstriction delays the onset of action by the latter routes. IV injection produces an intense orgasmic rush in approximately 1 minute that lasts 30 to 40 minutes. Abusers average 16 mg of cocaine per injection in a recreational setting. Cocaine is also used intravenously with heroin. The mixture, referred to as a "speedball," is used to attenuate the excessive stimulation caused by large doses of cocaine.

The smoking of cocaine requires conversion of the hydrochloride salt of the drug to the freebase form. The salt form, when heated, decomposes before the vaporization temperature is reached. The freebase volatilizes at temperatures of approximately 90° C and is not destroyed by heating. Smokers may manufacture their own freebase by dissolving the salt in an alkaline solution and extracting the alkaloid with a solvent such as ether. Since the mid-1980s, the freebase form has become commonly available as "crack," a form of freebase melted down into crystalline balls that can be smoked. Crack may be smoked in cigarettes or by heating with an alcohol flame in a pipe. Because the lung-brain circulation time is only 8 seconds, and the inhalation route bypasses the liver, the effects of smoking cocaine base are just as rapid and intense as IV cocaine and last approximately 20 minutes. Smokers average 100 mg of base with each smoke, increasing to 250 mg with rapid tolerance development. Smoking may be repeated every 5 minutes, with intake in compulsive abusers totaling 1.5 g/day. Smoking freebase cocaine has become the most popular method for administration of this drug, and similar to methamphetamine freebase, the freebase form of cocaine has contributed significantly to the increase in its abuse.

Used intranasally as a low-dose recreational drug, cocaine produces moderate addiction. High-dose IV or inhalation use produces compulsive behavior characterized by loss of control over drug use and an inability to stop the drug despite repeated attempts. Cocaine shares with other addictive drugs a reinforcing property that results in rapid acquisition of self-administration behavior. This reinforcing property may result from activation of a CNS dopaminergic reward system with cell bodies located in the ventral tegmentum projecting to the nucleus accumbens. Cocaine enhances dopaminergic activity at the latter site by blocking dopamine uptake by nerve endings. This endogenous reward system is normally activated by responding to physiologic imperatives such as hunger, thirst, and sex drive. Cocaine directly stimulates this reward circuitry, dominating motivation for essential physiologic needs. Rats given free access to IV cocaine take the drug in preference to food and die of starvation in a few weeks.

Significant tolerance does not develop with occasional cocaine use because of the short half-life of the drug. Frequent use resulting in constant cocaine concentrations in the body does cause tolerance, however. Acute tolerance to subjective and cardiovascular effects is observed within 1 hour after repeated IV doses. Dependence occurs primarily in compulsive, high-dose cocaine abusers. With chronic cocaine use, CNS dopamine depletion may occur, resulting in adverse symptoms during periods of abstinence. Withdrawal results in depression, dysphoria, social withdrawal, craving for the drug, appetite disturbances, tremor, and muscle pain. Such withdrawal phenomena may be severe enough to prevent some abusers from stopping the drug, even though toxic delirium may develop with continued drug use. Oral diazepam has been useful in treating withdrawal anxiety; psychotherapy or cautious use of tricyclic antidepressants is recommended for prolonged depression.

Toxicity

Medical complications of cocaine abuse most often involve the CNS and the cardiovascular system.[14] The CNS effects include a toxic psychosis, similar to that caused by amphetamine, which often develops in chronic, heavy abusers of cocaine. The syndrome is characterized by intense anxiety, inability to concentrate, stereotyped compulsive behavior, paranoid delusions, and violent loss of impulse control. Hallucinations may develop that are typically tactile, with sensations of insects burrowing under the skin or snakes crawling over the body. Such psychotic crises are reported in 10% of intoxications in compulsive abusers. Acute depression with suicidal ideation also may develop. Longer term personality changes include a tendency to paranoia with features of depression, reduced frustration threshold, difficulties in impulse regulation, and social maladjustment.

Cardiovascular complications of cocaine include cardiac arrhythmias, with sinus and ventricular tachycardia, ventricular fibrillation, and fatal cardiac arrest. Acute myocardial infarction is a particular hazard among abusers with preexisting coronary artery disease because of the increased systolic blood pressure, heart rate, and myocardial oxygen consumption engendered by cocaine.[25] Abrupt increases in arterial blood pressure, occurring within minutes of intranasal use of cocaine, have resulted in subarachnoid hemorrhage, particularly in individuals with aneurysms of cerebral vessels. One case of fatal rupture of the ascending aorta was reported in an individual with preexisting chronic hypertension who had smoked freebase cocaine. Acute cardiac events may occur even with recreational intranasal use of cocaine in individuals without predisposing cardiac disease.[29]

Hepatotoxicity, with clinical findings of elevated titers of serum transaminases and jaundice, has been reported in chronic cocaine abusers. Such liver damage may occur in plasma cholinesterase–deficient individuals, in whom cocaine metabolism is shunted through hepatic oxidative pathways, resulting in the production of cytolytic superoxides.[34] A significantly increased rate of spontaneous abortion has been noted in pregnant women. Because cocaine can cross the placental barrier, infants born to cocaine abusers may exhibit tremulousness. Frequent intranasal use leads to chronic rhinitis and rhinorrhea, atrophy of the nasal mucosa, loss of sense of smell, and necrosis and perforation of the nasal septum. These changes, occurring as a result of chronic ischemia, should alert the clinician to possible intranasal cocaine abuse. Bruxism and temporomandibular joint disorders are also more frequent in cocaine abusers.

Death from cocaine overdose usually is attributable to generalized convulsions, respiratory failure, or cardiac arrhythmias. Deaths have occurred with each route of cocaine administration and may be so rapid that treatment comes too late. Because cocaine is metabolized by plasma esterases, individuals with low cholinesterase activity are at high risk of cocaine fatality.[14] Treatment of cocaine overdose is symptomatic.

CNS stimulation can be treated with IV diazepam, ventricular arrhythmias can be treated with IV lidocaine, and respiratory depression can be treated with oxygen and positive-pressure ventilation.

ABUSE OF HALLUCINOGENS

Hallucinogens are defined as drugs that alter perception, mood, and thought without changes in consciousness or orientation. These drugs are also referred to as *psychotomimetics* because some of their effects mimic naturally occurring psychoses or as *psychedelics* because of their use by some people to induce mystical experiences. These drugs are claimed to provide the abuser with enhanced insight and self-knowledge, leading to new ways of looking at life and new insights into personal relationships.

Psychedelic Hallucinogens

Psychedelic hallucinogens can be divided into different chemical classes. The chemical structures of some psychedelic hallucinogens are shown in Figure 51-3. The lysergic acid derivative LSD is a semisynthetic chemical that does not occur in nature. LSD is a commonly used hallucinogen and has become the standard with which other hallucinogenic substances are compared. Drugs derived from tryptamine include the synthetic compound dimethyltryptamine and its derivative, psilocin, and the naturally occurring phosphorylated form of psilocin, psilocybin. The third class of hallucinogens includes amphetamine analogues such as MDMA and mescaline. Mescaline and psilocybin produce effects that are nearly the same as those produced by LSD. MDMA has stimulant effects similar to those of amphetamine and some psychedelic effects similar to those of LSD. Because MDMA possesses mild psychedelic and stimulant properties, it has become popular in club or dance settings, where it can enhance the light and sound experience and enable users to dance vigorously for extended periods. Under these conditions of prolonged physical exertion, MDMA can cause dangerous levels of dehydration and hyperthermia.

Pharmacologic effects

Symptoms associated with the LSD experience occur sequentially, with somatic symptoms developing first, followed by perceptual and mood changes, and then by psychic or psychedelic phenomena.[50] Within a half hour of ingestion of LSD, a feeling of inner tension develops, accompanied by somatic symptoms of mild sympathetic stimulation and motor alterations. The individual feels dizzy, weak, vaguely numb, and nauseated. Marked mydriasis is accompanied by an increase in blood pressure and pulse rate, tremor, hyperreflexia, and, at high doses, ataxia. These somatic effects are soon submerged by perceptual and psychic effects, which begin approximately 45 minutes after the drug is taken. Some individuals experience euphoria, elation, serenity, or ecstasy, whereas in others the initial tension may progress to anxiety and depression, evoking a panic reaction. A paranoid rage reaction occasionally occurs, although most subjects tend to be passive, quiet, and withdrawn.

Abuse characteristics

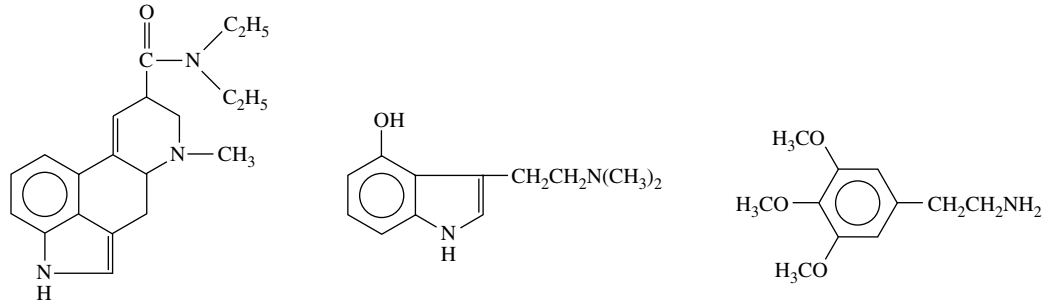
The subjective effects of LSD are highly dependent on the psychological makeup of the individual, the environmental influences at the time of the drug experience, the expectations of the individual, and the size of the dose. Distortion of sense perception is the most specific symptom of the LSD experience, affecting all modalities but especially vision. Colors seem unusually bright and vivid, and objects appear distorted and seem to undulate and flow. Fixed objects appear to shift from near to far; fine surface details appear in deep relief; and colorful, dreamlike images occur as vivid streaming filmstrips even with the eyes closed. Frank visual hallucinations are rare, but visual illusions are common, as when a spot on the wall is mistaken for a face. There are distortions of body image, enhanced auditory perception, and, more rarely, alteration of other sensory modalities. Time sense is distorted; it is often described as stopping or going backward. Synesthesias are common, so that music may be experienced visually, or colors may be "heard."

The changes in sensory perception are soon followed by the psychedelic "trip." Subjects may experience depersonalization, and the separation between the self and the environment melts away. The user has a sense of profound insight, revelation, and expanded consciousness. This loss of self is interpreted as a "good trip" by psychedelic drug abusers, but occasionally loss of control and fear of self-disintegration foster panic and even attempts at self-destruction. The individual remains oriented and alert throughout the experience and often remembers all events during the "trip" even months later.

In general, use of these drugs is not associated with marked dependence, and no clear withdrawal syndrome has been reported. If addiction develops at all, it is mild and infrequent. Tolerance to the effects of LSD is not common but has been reported, and cross-tolerance is seen among members of the psychedelic hallucinogens. With repeated use, tolerance to LSD develops within 1 week but lasts only a few days after discontinuance of the drug.

Toxicity

The adult human lethal dose of LSD has been estimated to be 2 mg/kg, although no deaths caused directly by LSD overdosage have been reported. Adverse psychological reactions to hallucinogens are common.[51] Panic reactions or "bad trips"



Lysergic acid diethylamide **Psilocin** **Mescaline**

FIGURE **51-3** Structural formulas of representative hallucinogenic drugs.

are relatively frequent and are related to an overdose of the drug. Often, companionship and reassurance, or "talking down," is sufficient to control this reaction; if this is insufficient, other treatments include sedation with oral diazepam. Acute depression or psychotic reactions can also occur. Ingestion of 50 mg results in hyperactivity, psychosis, amnesia, upper gastrointestinal tract bleeding, and coma.

Approximately 1 in 20 LSD abusers has "flashbacks," in which episodic visual disturbances resembling previous LSD experiences occur during abstinence from the drug.[2] This alteration is now called *hallucinogen persisting perception disorder*.[4] This disorder may occur months after the previous trip and last a few minutes to a few hours. It is thought to be caused by a drug-induced permanent change in the visual system. This disorder is treated in the same way as panic reactions. In addition, prolonged psychotic states may be precipitated by LSD use, requiring long-term hospitalization and treatment with antipsychotic drugs.[41]

Deliriant Hallucinogens

The ketamine derivative phencyclidine, also called PCP or "angel dust," is a synthetic drug that produces a unique state characterized by delirium, hallucinations, insomnia, and agitation. PCP produces what is called a "dissociative state" because it is said to dissociate the mind from the body without loss of consciousness. The drug was investigated in 1958 as an anesthetic in humans, but was subsequently abandoned because of severe postanesthetic dysphoria and hallucinations. Derivatives of PCP, such as thienyl and N-ethyl analogues, are also available on the street. The chemical structure of PCP is shown in Figure 51-4.

Pharmacologic effects

To produce its effects, PCP binds to receptors in the CNS that are associated with the N-methyl-D-aspartate acid (NMDA) type of glutamate receptor. NMDA receptors mediate some of the CNS effects of the excitatory amino acid glutamate. The PCP binding site resides within the NMDA-gated Ca^{++} channel complex, where PCP acts as a noncompetitive antagonist at the NMDA receptor and inhibits some of the CNS effects of glutamate. Receptors that bind PCP have been identified in the CNS in the limbic system and frontal cortex, areas involved in memory, emotion, and behavior. PCP has also been reported to cause dopamine release and to inhibit the active reuptake of dopamine into dopaminergic nerves. This inhibition enhances and prolongs the effects of dopaminergic nerve stimulation.

With lower doses, PCP abusers usually remain alert and oriented, while exhibiting euphoria, agitation, or bizarre behavior. Individuals may be irritable or mute and rigid, stare suspiciously, and exhibit impaired reasoning. They are easily provoked to anger and may exhibit violent behavior. The dissociative state, coupled with effects on limbic-mediated emotional control, may provoke feats of superhuman strength, causing harm to self and others. Inappropriate behavior, such as strolling down a street nude, may occur.[51] Detachment, disorientation, stupor, and coma may also occur, but are more common at higher doses.

Abuse characteristics

Currently, the most common route of administration of PCP is by smoking, in which the drug is mixed with tobacco or marijuana. At the burning tip of a cigarette, PCP is converted to 1-phenyl-1-cyclohexene (PC), which is largely inactive. In smoking PCP cigarettes, approximately 40% of the dose is received by the smoker as PCP and approximately 30% as PC. Some abusers snort PCP powder or ingest it mixed with alcoholic beverages or in pill form. A small percentage of abusers inject the drug intravenously. Urine and serum concentrations of PCP do not correlate with the state of intoxication. PCP disappears from urine 2 to 4 hours after a single use (largely because of sequestration in fatty tissues), but it may be detected in the urine of chronic abusers for 30 days.[13,49]

Most PCP use is intermittent rather than chronic. Some PCP abusers develop addiction to the drug, although this is less common than with the drugs of abuse previously discussed. No clearly defined dependence on PCP has been identified, but withdrawal from chronic use has been reported to result in depression, irritability, confusion, and sleep disturbances along with a strong craving for the drug.

Toxicity

Symptoms of acute intoxication appear 15 to 30 minutes after ingestion. Marked analgesia, shivering, salivation, bronchospasm, urinary retention, hypertension, tachycardia, and hyperpyrexia result. Nystagmus is observed in approximately two thirds of intoxications. Grimacing, localized dystonias, and tremor may progress to grand mal seizures or status epilepticus at doses greater than 70 mg, which also produce deep and prolonged coma with loss of protective reflexes that may last for 1 week or more. Death has been attributed to intracranial hemorrhage, status epilepticus, and respiratory failure. Life-threatening hyperthermia may also develop, sometimes in association with hepatic necrosis. Individuals under the influence of PCP act violently with some regularity, and accidents, including drownings, have been documented in many cases. Acute treatment centers on acidification of the urine to hasten renal excretion of PCP. IV diazepam is used to control seizures and the agitated or excited state caused by the drug. Prolonged psychotic episodes may require treatment with antipsychotic drugs.

ABUSE OF MARIJUANA

Marijuana is ground-up leaves and flowers from the hemp plant, *Cannabis sativa*, and is one of the most frequently abused drugs in the United States. A cannabinoid known as Δ-9-tetrahydrocannabinol (THC) (Figure 51-5) seems to be the main psychoactive ingredient. Preparations of marijuana vary widely in their THC content, depending on the variety and part of the plant used and the environment in which the plant is raised. Stalk fibers from any variety of hemp contain no psychoactive agents,[46] and the type of hemp plant from which stalk fibers are used commercially in the production of rope, twine, cord, and clothing is virtually drug-free because

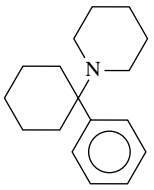


FIGURE **51-4** Structural formula of phencyclidine.

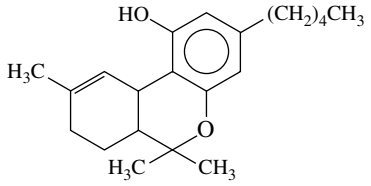

FIGURE **51-5** Structural formula of Δ-9-tetrahydrocannabinol.

it is grown under conditions that favor high fiber and low THC content. Conversely, more potent samples of marijuana are made from the younger, topmost leaves of hemp varieties that can contain approximately 5% THC by weight. Another component of the C. *sativa* plant that is commonly abused is an extract called *hashish*. In contrast to marijuana, which is ground-up plant material, hashish is an extract containing only the THC-rich resin that is secreted by the hemp plant. Hashish is more potent than marijuana, and it can contain 12% THC by weight. Marijuana and hashish are usually smoked in the form of cigarettes or from a pipe.

Pharmacologic Effects

Early theories on the mechanism of action of THC in causing effects in the CNS suggested that THC interacted with the lipid component of neuronal membranes affecting their permeability to crucial ions. With the identification[16] and cloning[40] of a cannabinoid receptor and the discovery that an arachidonic acid derivative, anandamide, may be the endogenous ligand for the cannabinoid receptor,[17] it is now agreed that THC acts stereospecifically with a G protein–coupled, transmembrane-spanning receptor. Although the physiologic role of the cannabinoid receptor and its putative ligand remains undefined, these receptors are located in the cerebellum, hippocampus, and basal ganglia.[23]

Intoxication with marijuana is unique, causing changes in mood, motivation, and perception that are similar to some of the effects caused by amphetamines, LSD, alcohol, sedative-hypnotics, and opioids. Within minutes of inhaling marijuana smoke, the typical abuser reports feelings of euphoria, uncontrollable laughter, depersonalization, alterations in judgment of time and space, and sharpened vision. Mild visual hallucinations may occur, particularly when the eyes are closed. Similar to LSD, the abuser knows that these visual disturbances are drug-induced. Later, the abuser experiences generalized feelings of well-being, relaxation, and tranquillity that may last 2 to 3 hours. The abuser experiences a reduction in attention span, difficulty in thinking and concentrating, and impairment of short-term memory. All these effects are considered desirable by the abuser and are described as "mellowing out." Many abusers report that the feelings of intoxication, dreaminess, and sedation can be more easily suppressed voluntarily than the equivalent effects produced by alcohol. The sedative-hypnotic property of marijuana facilitates the onset of sleep and resembles the effects caused by CNS depressants. This property of marijuana is in sharp contrast to the effects of LSD and other hallucinogens. Although it is generally agreed that a dose-related impairment in psychomotor performance occurs, many experienced abusers exhibit no such decrement in their performance; perhaps this is why no clear correlation has been shown between blood concentrations of THC and an individual's ability to drive a car.[27]

Physiologic effects of smoking marijuana occur within a few minutes, peak in their action in approximately 20 minutes, and wane over 2 to 3 hours.[11] Moderate marijuana use causes reddening of the eyes in association with a euphoric high that is followed by drowsiness.[18,27,42] Autonomic effects of marijuana include xerostomia, tachycardia, reduced peripheral resistance, and in large doses, orthostatic hypotension.[42] These effects may be deleterious in individuals with ischemic heart disease or cardiac failure.[27] Marijuana does not affect respiratory rate, blood glucose concentrations, or pupillary diameter[42]; however, marijuana does reduce intraocular pressure.

Studies of the potential therapeutic uses of dronabinol, the nonproprietary name of THC, show it to be effective in treating some conditions. Oral administration of dronabinol has been approved as an antiemetic in cancer patients undergoing chemotherapy and as an appetite stimulant in patients with weight loss resulting from AIDS-related anorexia. Smoking marijuana may also have beneficial effects in the treatment of weight loss in patients with AIDS. Whether smoking marijuana has an advantage over orally administered dronabinol in the treatment of AIDS-related anorexia remains to be determined. Although THC is effective in reducing intraocular pressure in patients with glaucoma, its psychoactive properties make THC less desirable than other forms of drug therapy for this indication.

Abuse Characteristics

In humans, the development of tolerance to marijuana is most apparent among heavy chronic abusers and is evidenced by increases in the amount of drug used over time. Although chronic use of marijuana has a long history, whether dependence on marijuana develops in humans remains controversial. Abrupt withdrawal of marijuana from chronic abusers has been reported to cause sleep disturbances, decreased appetite, nausea, and vomiting.[42] Whether these alterations in normal function are alleviated by the readministration of marijuana has not been shown, and this is necessary to prove that constant exposure to marijuana causes the development of dependence. Although the magnitude of addiction to marijuana is difficult to quantify, marijuana clearly possesses some abuse potential because it is the most commonly used illegal drug in the United States. Perhaps the lack of understanding of the abuse potential of marijuana is related to the fact that few individuals ever seek treatment for marijuana addiction, combined with the knowledge that the extensive and frequent use of this drug has led to few reports of severe toxicity.

Toxicity

Although few reports exist of adverse effects caused by acute administration of marijuana, the most common adverse reaction usually seen in naïve abusers is an acute nonpsychotic panic reaction characterized by anxiety and fear of losing one's mind. Many inexperienced elderly abusers interpret the THC-induced tachycardia combined with the psychological effects of THC as evidence that they are dying. Both of these conditions are best treated with authoritative reassurance or antianxiety agents of the benzodiazepine class. Very high doses of THC may result in self-limiting toxic delirium, acute paranoia, and psychotic episodes.

Chronic use of marijuana seems to cause no functional changes in the CNS; however, heavy smokers may be prone to chronic bronchitis, airway obstruction, poor dentition, and squamous cell metaplasia (similar to smokers of tobacco). Contamination of marijuana with *Aspergillus*[33] or the herbicide paraquat can lead to severe pulmonary damage in abusers. Chronic, intensive use of 5 to 18 marijuana cigarettes weekly is reported to reduce testosterone concentration and cause oligospermia in men.[35] Other studies of shorter exposures to marijuana have not confirmed these findings, although they do show that secondary sexual characteristics in very young abusers can be suppressed by marijuana.[27] Teratogenic effects of THC are known to occur in animals; no such reports exist for humans smoking marijuana. Anecdotal reports suggest marijuana use produces an amotivational syndrome, which is described as an affliction of young abusers of marijuana who drop out of social activities and show little interest in school, work, or other goal-directed activities. Laboratory studies and cross-cultural analyses of marijuana smokers in countries where marijuana use is acceptable do not support the contention that THC use leads to psychosocial deterioration.[39] Others have suggested that the lifestyle and goals of an abuser of any kind of illicit drug may more satisfactorily explain the amotivational syndrome.

ABUSE OF INHALANTS

Modern awareness of the consciousness-altering effects of inhaled compounds began with the discovery of anesthetic agents such as ether, chloroform, and nitrous oxide in the early nineteenth century. Today this list also includes halothane and other halogenated compounds. The use of general anesthetics is discussed in Chapter 18. Although nitrous oxide, halothane, and other volatile anesthetics are usually available only to medical or health care personnel, nitrous oxide can also be found in restaurant supply stores as a propellant for making whipped cream and packaged in small metal canisters called whippets. Although ether and chloroform are no longer used as anesthetics, they are available through chemical supply houses.

In addition to volatile anesthetics, three other main classes of inhalants are subject to abuse. The first are volatile solvents, which include glue, paint thinners, cleaning fluids, degreasers, and gasoline. The generalized depressant effects on the CNS caused by these solvents are mediated by ingredients such as trichloroethylene, benzene, toluene, naphthalene, hexane, heptaene, and acetone. This class of inhalants is widely abused because of ready availability.

The second class of inhalants includes aerosol propellants such as methanol, ethanol, and isopropanol used in spray paint and cooking sprays. Trichlorofluoromethane and other fluorocarbons used as refrigerants may also be abused. The alcohols are less rewarding than other volatile solvents, and ethanol is more prone to be abused by the oral route of administration.

The third class includes organic nitrites, which include amyl, butyl, and isobutyl nitrite. Amyl nitrite is used as a vasodilator in the treatment of angina pectoris (discussed in Chapter 26) and is packaged in mesh-enclosed glass ampules designed to be crushed between the fingers, allowing for inhalation of the vapors for relief of the pain of angina. Amyl nitrite ampules are commonly referred to as "poppers" because of the popping sound resulting from their being broken. Amyl nitrite and isobutyl nitrite are perceived to be sexual enhancers, which increases their abuse potential. Although amyl nitrite is available only by prescription, isobutyl nitrite is used as a room deodorizer and can be purchased from shops that sell drug paraphernalia under the names "Locker Room," "Doctor Bananas," and "Rush."

Pharmacologic Effects

With the exception of the organic nitrites, all the abused inhalants have a generalized depressant effect on the CNS similar to that of volatile general anesthetics. Low doses of these agents first produce signs of stimulation followed by depression, unconsciousness, and, with larger doses, death. The desirable effects of these compounds—euphoria, perceptual distortions, ataxia, giddiness, and slurred speech—occur within seconds of inhalation and last 5 to 45 minutes. Undesirable effects may be experienced during use and for variable periods afterward and include coughing, vomiting, rhinitis, photophobia, irritation of the eyes, tinnitus, nausea, and sneezing. The vasodilatory action of the organic nitrites is immediate and produces a feeling of warmth and lightheadedness that is commonly referred to as a "head rush." The "head rush" is brief and is considered desirable; however, it may result in loss of consciousness as a consequence of postural hypotension if the drug is inhaled while standing. Headaches commonly occur after use of organic nitrites and are caused by vasodilation of cerebral blood vessels.

Abuse Characteristics

The euphoria, disinhibition, and general feelings of drunkenness are thought to be the reinforcing characteristics of inhaled CNS depressants; abusers take these agents repeatedly, suggesting addiction to them. Few controlled studies have been performed on the development of tolerance to solvents, aerosols, and nitrites. Because solvents, aerosols, ethanol, barbiturates, and benzodiazepines share many of the same pharmacologic effects, however, considerable interest remains in whether cross-tolerance exists among these agents. There is little evidence that signs of abstinence occur in individuals when inhalants are withdrawn, suggesting that dependence is not part of the experience of these abusers.

Toxicity

Ascribing the toxic effects of an abused inhalant to an individual agent is difficult because the toxic effects of inhaled solvents and aerosols may be caused by more than one substance and because solvents typically contain several volatile compounds or may be tainted with heavy metals such as lead and cadmium. The major health risks associated with acute use of anesthetic gases and volatile liquids are sudden death from asphyxiation, respiratory depression, or arrhythmia-induced cardiopulmonary arrest. Halogenated hydrocarbons, such as trichloroethylene, are particularly likely to cause arrhythmias.

Repeated abuse of inhalation agents may lead to toxic effects caused by chronic exposure. Industrial solvents are known to cause liver and kidney damage, sensory and motor neuropathies, bone marrow suppression, and pulmonary disease. The toxic effects of chloroform on the liver and kidney are so well known that chloroform has not been used as an anesthetic for decades and has been eliminated from commercially available products. Continuous exposure to nitrous oxide can cause megaloblastic anemia, methemoglobinemia, and, rarely, peripheral neuropathy. In industrial settings where chronic exposure to organic nitrites occurs, cases of methemoglobinemia have been reported; however, this is rare in abusers of these compounds.

POLYDRUG ABUSE

Drug abuse problems are often compounded by the practice of taking two or more drugs in combination or in sequence. Polydrug abusers may seek additive or potentiated effects (e.g., the simultaneous use of alcohol and another sedative) or the modulation or termination of effects (e.g., the sequential use of amphetamines and barbiturates). Approximately 20% of chronic alcoholics abuse other drugs, especially barbiturates, antianxiety drugs, and marijuana. Primary heavy abusers of marijuana frequently use amphetamines or psychedelic agents, whereas heroin addicts are particularly apt to abuse amphetamines, cocaine, hallucinogens, and barbiturates. Most patients in methadone maintenance programs apparently are polydrug abusers. When multiple drug dependencies develop, the withdrawal syndrome becomes difficult to treat and is associated with a significantly enhanced mortality rate.

IMPLICATIONS FOR DENTISTRY

Certain signs may alert the dentist to the possible parenteral abuse of drugs. Telltale cutaneous lesions may result from chronic hypodermic administration of drugs of abuse. These lesions include acute septic complications, such as subcutaneous abscesses, cellulitis, and thrombophlebitis, and chronic cutaneous complications, including skin tracks and infected lesions, which occur most commonly in the thigh or antecubital or deltoid regions. Skin tracks result from frequent, multiple injections that produce chronic tissue inflammation.

These are typically linear or bifurcated erythematous lesions that become indurated and hyperpigmented. Another sign that may alert the clinician to the problem of drug abuse is the presence of an ill-defined febrile illness. This finding often reflects a low-grade bacteremia resulting from the injection of drugs.

In ascertaining whether a patient is abusing drugs, the dentist cannot depend on being able to identify a particular personality type, recognize cutaneous lesions (which may be concealed under clothing), or diagnose a mild febrile illness. Rather, the dentist must rely on careful and thorough questioning of the patient and on the skillful use of a well-designed medical history questionnaire. Drug abuse is a subject of considerable importance to dentists because they are occasionally the unwitting target or victim of drug abusers' need to secure drugs. Also, drug abuse among health professionals has a long history, numerous medical and dental abnormalities are associated with drug abuse, and interactions may occur between drugs that dentists customarily prescribe and drugs the patient is abusing.

Dentists as a Target of Drug Abusers

Inevitably, drug abusers, through pretense and subterfuge, attempt to obtain drugs from dentists. The dentist should be aware of any patient who complains of pain from pulpitis or an abscess and who refuses endodontic or surgical intervention. An opioid abuser may claim to be allergic to codeine or pentazocine in an effort to obtain more positively reinforcing drugs, such as meperidine, morphine, or hydrocodone.[1] As a general defense against drug abusers, the dentist should never let patients know where such drugs are kept, never leave prescription pads out where they may be taken, and avoid the use of prewritten prescription forms.

Drug Use Among Dentists

Dentists are not immune to the hazards of drug abuse. Similar to physicians, they may be in greater danger of developing drug dependencies than the general population because of the ready accessibility of opioid analgesics and sedative-hypnotic drugs. Opioid addiction among medical personnel is much higher than that of the general population. One form of drug abuse common among dentists and other health professionals is the inhalation of nitrous oxide. Evidence suggests that the pleasurable effects of nitrous oxide inhalation can lead to a craving for the drug in some individuals.[9] The abuse potential of nitrous oxide coupled with the ease of availability of the drug contributes to its relatively frequent abuse by dentists.

Medical and Dental Complications of Drug Abuse

The most common and serious medical complications in drug-abusing patients are AIDS, endocarditis, and hepatitis. IV drug abusers are at risk of AIDS. Sharing needles for IV injections spreads the AIDS virus. IV drug abusers are responsible for a significant number of AIDS cases among heterosexuals.

Bacterial endocarditis in drug abusers is most commonly caused by *Staphylococcus aureus*, which seems to derive from an increase in endogenous pathogens in the addict rather than from contaminated drugs or drug paraphernalia. In drug-abusing patients, the disease often affects the tricuspid valve, which is unusual in nonabusers. *Pseudomonas* endocarditis, although less common, primarily involves the tricuspid valve and has an overall mortality rate of 50%. *Candida albicans* infects the left-sided valves and is almost invariably fatal. Candidiasis may be disseminated to skin, eyes, bones, or joints.

Viral hepatitis is often seen among drug abusers and is probably transmitted by contaminated needles. The disease is usually mild, but individuals displaying early signs of elevated prothrombin time, fever, elevated leukocyte count, or encephalopathy have a poor prognosis. In 50% to 80% of cases, the acute infection results in chronic inflammatory hepatic disease.

Opioid drugs have been reported to depress the immune system by interacting with opioid receptors on T lymphocytes and leukocytes. Other drugs of abuse have also been suggested either to suppress or to enhance the activity of the immune system. Whether the development of infectious diseases in drug abusers is caused by a direct effect of these drugs on the immune system is unknown.

Specific dental complications of drug use include rampant caries and rapidly progressing periodontal disorders, probably resulting from nutritional deficiencies and neglect of personal hygiene. Xerostomia with an enhanced rate of dental caries has been reported in individuals who abuse opioids, amphetamines, sedative-hypnotic drugs, and marijuana. In other studies, opioid and marijuana use do not seem to reduce the rate of salivary secretion, however.[19,48] Self-mutilation has occurred among drug abusers; teeth may be deliberately damaged in an effort to obtain drugs. Long-term cocaine and amphetamine abusers may develop facial tics and bruxism, which result in a traumatized tongue and worn teeth.[12] These subjects may also chronically rub the tongue along the inside of the lower lip, producing ulcers on the abraded tissues.[12]

Drug Interactions in Drug Abuse

Drug interactions in drug abusers are not unique, but depend on the drug of abuse.[15] Barbiturates and other sedative-hypnotic drugs induce hepatic cytochrome P450 enzyme activity. Abusers of such substances may be resistant to the therapeutic effects of corticosteroids, oral anticoagulants, and many CNS depressants because the metabolism of these drugs is enhanced by enzyme induction. Opioid abusers generally show tolerance to other opioid analgesics. The dentist should beware of giving pentazocine to such patients because this and other agonist-antagonists may precipitate an acute withdrawal syndrome in opioid-dependent patients. Marijuana may intensify CNS depression produced by barbiturates, general anesthetics, and other CNS depressant drugs. The sympathomimetic effects of cocaine, amphetamine, and marijuana may be enhanced by drugs used in dental practice. Administration of local anesthetics containing epinephrine or gingival retraction cords impregnated with epinephrine may enhance tachycardia and elevations in blood pressure caused by these drugs.

Pain Control and Drug Abusers

Drug abusers may be more anxious and fearful of dental procedures and may have a lower pain tolerance than patients who do not abuse drugs. To counteract these fears, abusers may take their favorite drug of abuse before dental appointments. If the dentist knows that the drug abuser has taken such a drug, the dental procedure should be rescheduled, and the patient should be counseled to avoid drug use before the next visit. Complicating this picture is that tolerance to sedative drugs and local anesthetics has also been reported, particularly in parenteral drug abusers. These patients may need larger amounts of these drugs for pain-free dental treatment. Larger doses of sedatives and local anesthetics carry the risk of enhanced adverse effects caused by these drugs.

Treatment of pain and anxiety in a recovering or reformed substance abuser presents a problem to the dentist.[9] Whether the patient has abused alcohol or other drugs in the past, proper dental care demands a preoperative evaluation of the patient's personal attitude toward drug treatment. Many of these individuals refuse mood-altering drugs, and such wishes must be respected. As a rule, it is best never to administer a drug, or another of its class, that has previously been abused by the patient. In cases in which anxiety is predominantly somatic (e.g., tachycardia, breathlessness, and tremulousness),

oral propranolol may be valuable. Intraoperative pain control can be accomplished with local anesthetics, but systemic exposure to epinephrine should be minimized in patients being treated with neuronal uptake pump inhibitors such as desipramine for postdependence depression. Postoperative pain can usually be adequately controlled with nonsteroidal anti-inflammatory drugs.

CHAPTER 52

Toxicology

HARRELL E. HURST AND MICHAEL D. MARTIN

Toxicology is a basic science that is concerned with information regarding poisonous substances and their toxic actions. This discipline draws on biology, chemistry, and medicine to coordinate knowledge regarding toxic materials. Toxicology strives to understand key features of biology relevant to adverse interactions of chemicals with living systems. A principal objective is to promote the safe use of chemicals, particularly among humans, whether encountered as medicines, as food additives or contaminants, as industrial materials, as household products, or in the environment. Topics of interest to toxicologists include analysis of toxic agents, identification of toxic effects, elucidation of mechanisms of toxicity, management of poisoning, characterization of potential chemical risks, forensic and legal applications, and timely application of knowledge to prevent potentially disastrous consequences of chemical use.

The toxicology of therapeutic agents is integral to their pharmacologic characteristics and is described in appropriate chapters of this text. This chapter reviews general principles of toxicology, summarizes key organ systems that are susceptible to toxic effects, and outlines prevention and management of acute poisoning. Toxic materials not described elsewhere in the text are reviewed, and relevant topics related to dental practice are discussed.

GENERAL PRINCIPLES

All chemical substances can cause harm or kill if encountered at sufficiently large concentrations over crucial periods of time. This statement embodies insight articulated by Paracelsus in the sixteenth century that dose is the major determinant of toxicity. A subset of substances has relatively specific toxic effects, however. These are considered very harmful based on human experience and are considered poisons or toxins. Beyond this base of experience exists a vast number of uncharacterized, potential toxicants. As of 2007, the Chemical Abstracts Service[10] reported counts of more than 32 million organic and inorganic substances, 245,000 inventoried or regulated substances, and some 15 million commercially available chemicals. Because many of these are potentially toxic, this array dictates that toxicologists use some means of triage toward assessment of potential toxicants. At present, selection of chemicals for toxicologic testing is dictated by their potential for use, by funding of basic research on the chemicals, and initial evidence of their specific adverse effects.

The ultimate aim of toxicologic science in society is to guide safe use of chemicals. The definitions in Box 52-1 can assist in understanding and promoting concise communication in the approach to this objective. Safety is a negative entity—that is, the absence of threat of injury. As such, safety cannot be proved directly. Society often simplistically considers chemicals "safe" or "toxic." Such naive characterization can preclude the rational judgment that enables safe uses of chemicals. Critical judgment requires understanding of the distinction between the terms *toxicity* and *hazard* to enable assessment of risks (see Box 52-1). Toxicologic assessment promotes safety by defining hazardous situations of use so that the unsafe use of chemicals can be avoided.

A primary concern of toxicology is evaluation of risk. All useful chemicals have some degree of risk associated with their use. Toxicologic science has developed testing paradigms to define toxicity to assess potential risk. Benefits also must be considered relative to the risk of use. A high degree of risk may be acceptable when benefits are great (e.g., use of toxic but potentially life-extending drugs such as chemotherapeutic agents). Otherwise, risk may be unacceptable for less essential uses (e.g., food coloring). In contrast to the science inherent in testing methods, judgment of risk acceptability involves policy. Such judgment invokes economic, social, and ethical values and should consider factors such as needs met by a chemical under consideration, alternative solutions and their risks, anticipated extent of use and public exposure, effects on environmental quality, and conservation of natural resources.

Within such considerations is an issue of major importance to toxicology and to society in general, which is determination of cause-and-effect relationships. This objective of epidemiologic studies is elusive for chronic diseases, such as many types of cancer. Such diseases may involve confounded potential causes, such as chemical or viral exposure and genetic susceptibility factors. Uncritical publication of unscientific observations or incomplete studies leads the public to inappropriate conclusions, which should be characterized more correctly as hypotheses. Adequate processes for determination of causation, as opposed to simple unrelated association or correlation, require scientific discipline and judgment based on considerable experience.

The criteria developed by Sir Austin Bradford Hill[36] provide a sound basis for consideration of causal relationships and should be considered a touchstone for expert opinion regarding cause and effect (Box 52-2). None of these criteria should be considered as absolutely essential, and they cannot be considered as proof of causal relationships. Their careful application during evaluation of potential cause-and-effect relationships can assist, however, in organizing knowledge toward a weight-of-evidence judgment and may provide an alternative interpretation for consideration.

Dose-Response Relationships

As mentioned earlier, the relationship between dose and toxic response is the fundamental axiom of the science of toxicol-

BOX 52-1

Definitions Relevant to Principles of Toxicology

Safety	Condition of being secure from threat of danger, harm, or injury
Toxicity	Property of grave harmfulness or deadliness associated with a chemical that is expressed on biologic exposure
Hazard	Threat of danger directly related to circumstances of use of a chemical
Risk	Expected frequency of occurrence of an adverse effect in a given situation

BOX 52-2

Hill Criteria for Consideration of Causal Relationships

CRITERION	EXPLANATION
Strength of association	Observed magnitude of the association compared with other relevant observations should be considered as a primary indicator in assessment of cause and effect
Consistency	Association of cause and effect can be observed repeatedly by others under appropriate circumstances
Specificity	Particular conditions produce the effect, or a specific group is affected. Bounds of causal relationship should be delimited
Temporality	Causation generally occurs before effect, whereas correlational effects can vary in temporality
Biologic gradient	Demonstration of a fundamental dose relationship provides convincing evidence of cause and effect
Plausibility	Some basis in previous knowledge provides a means of common understanding (remember, however, that all phenomena were novel at some point)
Coherence	Care should be taken that interpretation of cause and effect does not unduly conflict with scientifically established facts of biology and medicine
Experiment	Manipulation of accessible variables in the potential cause-and-effect relationship has an effect
Analogy	Previously understood examples provide basis for formulation of testable hypotheses

From Hill A: The environment and disease: association or causation? *Proc Roy Soc Med* 58:295, 1965.

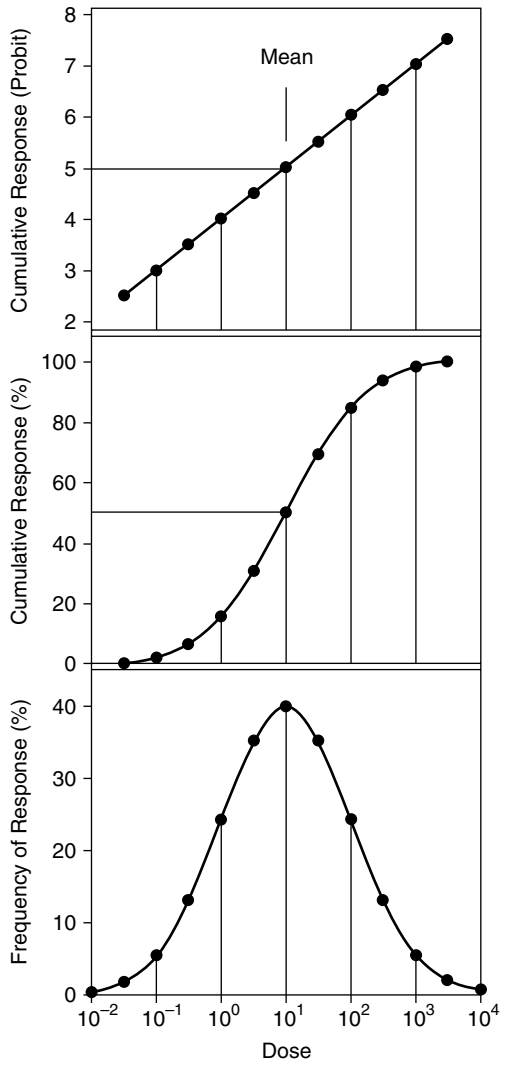

FIGURE **52-1** Various techniques for graphic display of quantal response versus dose data, including frequency of response (*bottom panel*), cumulative response (*middle panel*), and cumulative response linearized by probit transformation (*top panel*).

ogy. Studies are designed to ascertain dose-response functions associated with specific adverse effects. When simple all-or-nothing criteria, such as death, are used, quantitation of response is simple. More often, objectives require more subtle means of assessment, however, that are less readily quantified. Beyond simple indication of the quantity of material required for the toxic effect, dose-response relationships provide strong evidence of the causal relationship between the observed effect and the chemical under study, as noted previously.

Figure 52-1 presents three modes of display of idealized dose-response data to illustrate and describe the dose required for median response in subjects tested. These data are typical of quantal or all-or-nothing responses such as lethality. In this example, the dose axis is logarithmically spaced, and the data describe a log-normal distribution. Responses that arise from mass action, such as reversible occupancy of receptor by drugs, often are most easily plotted on a logarithmic axis. Alternatively, effects caused by limited biologic capacity, such as irreversible enzyme inhibition, can exhibit abrupt threshold-like effects and may be more easily analyzed on a linear dose axis. The rule is to plot the data to see what type axis is most applicable.

The *lower panel* of Figure 52-1 indicates distribution of responses across the dose axis, with a mean of 10 and standard deviation (SD) of one $\log_{10}$ unit. Response percentages include approximately 68.3% within ±1 SD of the mean, 95.5% within ±2 SD, and 99.7% within ±3 SD of the mean. The distribution indicates hypersusceptibility for individuals at the lowest doses and resistant responders at the highest doses.

Such a plot gives a convenient way to visualize the distribution of responses across dose within the test groups.

The *middle panel* of Figure 52-1 plots the cumulative response versus dose across all treated groups. Here the response data are practically linear in the range from –1 SD to +1 SD for these ideal data. This plot provides convenient, accurate estimation of dose required for a 50% response, such as the median lethal dose (LD_{50}). Real data are rarely so well behaved, however, because too few animals may be included for adequate definition of the sigmoid curve. Another disadvantage is that the sigmoid curve presents difficulty in estimating doses that elicit extremes of response, such as 1% or 99%.

An alternative presented in the *top panel* of Figure 52-1 uses the probit transform[45] for the cumulative response. Probit units are derived by conversion of cumulative response percentages to units of deviation from the mean. The scale uses normal equivalent deviation units (NED), for which the mean is arbitrarily set to a NED value of 5 to give positive values along the axis. As is evident in the example, the probit transform linearizes the extreme values of the response function, which allows accurate estimation of doses affecting 1% or 99% of subjects exposed. In addition, the probit transform facilitates determination of the slope, which enables comparison of the dose-response function with other agents or responses.

Such plots are inadequate in dealing with issues of societal risk, however, for which policy often requires estimation of exposure posing a theoretic risk of 1 in 1 million, otherwise described as a 10^{-6} risk factor. Practical problems intervene, including the impracticality of experimental studies involving sufficient animals to define adequately the dose-response function at low response levels. A classic toxicologic experiment conducted at the National Center for Toxicological Research illustrates this point. Officially termed the *ED_{01} Study,*[33] this experiment examined in detail the response function of mice treated with low doses of the experimental carcinogen 2-acetylaminofluorene. The study, sometimes termed the *megamouse study,* involved more than 24,000 mice to determine, with precision, the dose effective in producing a 1% tumor rate. This work advanced toxicologic understanding of the complexity of genotoxic and proliferative cellular events in chronic cancer bioassays. It also exhibited logistic difficulties in conducting statistical studies of low incidence and illustrated gaps in the evolving understanding of chemically induced cancer.

Factors That Change Dose-Response Relationships

Dose-response relationships can vary with many factors, including differences within and among individuals. As described in Chapter 3, factors responsible for dose-response variations within an individual over time may include age and nutritional status, environmental influences, functional status of organs of excretion, concomitant disease, and various combinations of factors. Changes in pharmacokinetics of toxicants are a frequent basis for altered dose-response relationships. Known influences include increased toxicant bioactivation by enzyme induction,[31] such as occurs in certain variants of cytochrome P450[13] with exposure to phenobarbital or polychlorinated biphenyls. Conversely, inhibition of metabolic clearance is possible with interacting chemicals, increasing the pharmacodynamic action of drugs and chemicals.

Cytochrome P450 variant 3A4 is an important enzyme in human drug metabolism, and its presence in the gut and liver subjects it to inhibition by many drugs and dietary components, such as grapefruit juice.[19] Conversely, substances are often less toxic by the oral route when administered with food as a consequence of less rapid absorption. The time and frequency of administration can be important in altering dose-response relationships through functional changes. Many compounds induce tolerance on repeated administration, whereas others can become more toxic with closely repeated administration. Receptor densities and sensitivity may vary with time or as a consequence of previous exposure. An example of the latter is the well-known tolerance that develops to long-term administration of opioids.

Responses among individuals differ as a consequence of different genetic traits, a subject of intense interest as knowledge emerges from the Human Genome Project, and use of efficient molecular techniques and transgenic animals becomes widespread in research. Recognition and understanding of relevant aspects of human diversity derived from functional genomic research offer potential for therapeutic gains.[26] The rationale is to use appropriate drugs in patients best suited to benefit, and to reduce use in patients with genetic traits that might result in toxicity. These efforts have spawned new terms, including *pharmacogenetics,* representing characterized genetic differences in drug metabolism and disposition, and *pharmacogenomics,* used to describe the broad spectrum of genes that affect drug response. A summary is available[25] that describes progress in determining genetic polymorphisms relevant to drug action and disposition. Known variants linked to altered drug effects in humans include phase I cytochrome P450 enzymes, phase II enzymes such as N-acetyltransferases and glutathione-S-transferases, small molecule transporters, drug and endogenous substrate receptors, and ion channel variants. Chapters 2 and 4 provide additional information on these topics.

Similar advances are likely to be applied to understand genetic differences that result in toxic effects aside from those that arise during drug therapy. Approximately 400 million individuals worldwide exhibit a heritable deficiency in the cytoplasmic enzyme glucose-6-phosphate dehydrogenase. Because this enzyme is essential to the cell's capacity to withstand oxidant stress through production of reducing equivalents, sensitive individuals with this enzymatic deficiency have chemically mediated hemolytic anemia when exposed to oxidants.[6]

Of particular importance to the interpretation of toxicologic studies are interspecies differences, which may confound understanding and interpretation of results from animal models. Well-known differences in physiology, metabolic rates, pharmacokinetics of toxicant metabolism and excretion, and sites of toxicant action mediate these interspecies differences. Advances involving physiologically based pharmacokinetic modeling and use of predictive, mechanistically based biomarkers offer promise of augmenting, or in some cases obviating, conventional toxicity testing.

Acute Versus Chronic Toxicity

Toxicity can be classified by the amount of time required for development of the adverse effect. For this purpose, the term *acute* describes toxicity with a sudden onset, whereas *chronic* describes a long latency or duration. In epidemiology, this classification typically describes the time between exposure and onset of toxicity. Intoxication is an acute effect that results from ingestion of a large quantity of ethanol over a brief time. Alternatively, the progressive diffuse architectural damage to the liver known as cirrhosis occurs over years with chronic ethanol exposure. In experimental toxicology, these terms are used to refer to experimental paradigms involving the duration of treatment or exposure. *Acute testing* typically describes a single treatment, whereas *chronic toxicity testing* usually involves dosing or feeding a chemical over the lifetime of a species, as in a rodent carcinogenicity bioassay.

If exposure occurs repeatedly at intervals more frequent than the time required to eliminate a toxicant, the material accumulates in the body throughout the duration of exposure. Although each exposure may be less than toxic, accumulation

may produce toxic concentrations if exposure continues for sufficient time. The primary determinant is the rapidity of elimination relative to the frequency and magnitude of exposure. Slowly eliminated toxicants, such as lipophilic chemicals or materials readily bound in tissues, have the greatest potential for accumulation.

Chronic toxicity may exhibit little or no apparent relationship to acute toxicity. In such cases, understanding of cause and effect requires careful study. Of the many examples of chronic toxicity, carcinogenesis currently is of greatest concern in society. Precancerous cellular changes occur and develop slowly and may remain undetected over long periods. Periodic dental examinations often play a significant role in detection of cancers of the oral cavity. Knowledge of patient habits with adverse potential health effects, such as the link between tobacco use and occurrence of oral lesions,[75] assists the dental practitioner in being vigilant against such chronic toxicity.

Chemically Related Toxicants

Understanding of chemical toxicity requires knowledge of related chemicals that may be present as impurities because of manufacturing or exist as a result of environmental effects. A classic example is 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin, or TCDD), which was discovered in the herbicide mixture known as Agent Orange used in the Vietnam War. Although dioxin existed at low part-per-million levels in the herbicide mixture, the extreme toxicity of this contaminant in certain species created grave concern for contaminated areas. This concern led to a ban on the use of the herbicide 2,4,5-trichlorophenoxyacetic acid because TCDD is formed through a condensation reaction involving two molecules of 2,4,5-trichlorophenol. Dioxin also can be formed from other sources, such as combustion of municipal waste, iron ore sintering, and wood pulp and paper mills. The toxic actions of TCDD are mediated through its binding to the aryl hydrocarbon nuclear receptor,[57] which regulates transcription of genes encoding cytochrome P450 enzymes in the CYP1A subfamily and several other genes that regulate cell growth and differentiation. Despite its extreme toxic potential in some species, epidemiologic studies regarding the effect of TCDD exposure on humans have been inconclusive to date.

The consequences of metabolism of drugs and chemicals after ingestion are extremely important. The following example illustrates the importance of understanding toxic effects relative to drug metabolism. Terfenadine is a nonsedating histamine H_1 receptor antagonist that was widely used for relief of symptoms of seasonal allergy. This drug was removed from the market because studies revealed cardiotoxicity when terfenadine was given with erythromycin.[93] The toxic interaction was traced to the antibiotic's inhibition of the high-affinity oxidative enzyme system CYP3A in human liver and intestinal membranes.[19] This interaction inhibited normal clearance of terfenadine, and the abnormally elevated concentrations produced toxicity in the form of a prolonged QT interval and the cardiac arrhythmia torsades de pointes. This antihistamine has been replaced with its active metabolite, fexofenadine, which apparently does not elicit this toxicity (see Chapter 22).

Local Versus Systemic Effects

Toxic effects can occur at a site of exposure, such as dermal contact, or at some site remote from the point of chemical contact or entry. Local effects dependent on applied concentration are usually diminished by dilution with physiologic fluids and diffusion within tissue away from the site of application. The toxic effect depends on the nature of the interaction at the local site. If the effect is caused by reversible interaction with a receptor, such as that of a local anesthetic, toxicity is attenuated by diffusion, and the system is returned to a more normal state as the drug dissociates from receptors. For toxicants that act through destruction of normal cellular architecture, such as a caustic agent, return to normality requires repair of membranes and cellular structures.

Systemic effects are facilitated by transport within the body fluids and may be influenced by metabolism. Depending on whether biotransformation activates a protoxicant or detoxifies a toxicant, the effects of systemic processing can increase or attenuate toxicity. Compounds may be more or less toxic by the oral route than by other means of systemic exposure, as the first-pass effect of intestine or liver serves to activate or remove toxicants before distribution in the systemic circulation. Alternative systemic exposures, such as inhalation, are not modulated in this manner because systemic exposure occurs directly.

Target Organ Systems

Most toxic chemicals exhibit specificity in their action on target tissues or organs because these targeted biologic systems reach crucial points in which their physiologic functions are interrupted under the influence of the chemical. This section presents crucial physiologic systems and their characteristics that are important in understanding organ-specific toxicity.

Nervous system

Given the primary importance in control of integrated function, the central nervous system (CNS) is a target of paramount importance for many toxicants. Individual neurons exhibit high metabolic rates and are unable to rely on anaerobic glycolysis. These characteristics make these cells susceptible to toxicants that adversely affect cellular respiration and energy production and lead to neuronal damage when central or peripherally acting toxicants interrupt neuronal metabolism, cerebral circulation, oxygen-carrying capacity of blood, or pulmonary ventilation.

A remarkable cell-selective neurotoxicant is 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), an impurity discovered[42] after attempted illicit synthesis and injection of a meperidine analogue. This compound is a protoxicant for 1-methyl-4-phenylpyridinium, which is formed by monoamine oxidase and concentrated by high-affinity carrier into dopaminergic neurons. The molecular target of 1-methyl-4-phenylpyridinium is reduced nicotinamide adenine dinucleotide dehydrogenase, and the interaction blocks the cellular respiratory exchange of electrons in mitochondria of cells. Its toxic actions result in destruction of dopaminergic neurons in the substantia nigra (see Chapter 15). Death of these cells produces symptoms strikingly similar to Parkinson's disease, leading to loss of willful motor actions.

Loss of integrity of neuronal cell metabolism can alter neuronal architecture, particularly the myelin sheath of peripheral neurons. Such effects are common to many forms of toxicity expressed in the nervous system. Various compounds, such as tri-*o*-cresyl phosphate, acrylamide, and metabolites of hexane, cause degeneration of long axons that control neuromuscular activities. Termed *distal axonopathy*,[39] this toxicity involves a "dying back" or retrograde degeneration of distal axons and leads to loss of control of motor functions such as gait. Other effects, such as sensory neuropathy and paresthesia, can result from similar effects of toxicants on small sensory fibers.

Blood and hematopoietic system

Because of the crucial roles of the elements of blood in delivering oxygen and maintaining immune function, toxic effects on blood or the hematopoietic system can be life-threatening. Of these, perhaps no poisoning is more common, preventable, or treatable with timely therapy than the toxic interaction of

carbon monoxide (CO) with hemoglobin (Hb). This interaction blocks the vital oxygen-carrying capacity by formation of carboxyhemoglobin (CO-Hb). Characteristics of CO and its toxic effect on various tissues sensitive to anoxia have been concisely reviewed.[86] Details of treatment, which involves displacement of Hb-bound CO with oxygen, are provided in the comprehensive text *Medical Toxicology*.[89] In mild (CO-Hb <30%) or moderate (CO-Hb 30% to 40%) cases, therapy includes use of 100% oxygen by nonrebreathing mask until CO-Hb is less than 5%. Severe poisoning can mandate hyperbaric use of oxygen to hasten the exchange.

Another toxic effect that alters the oxygen-carrying capacity of erythrocytes is the formation of methemoglobin. In this toxicity, the heme iron is oxidized from the ferrous (Fe^{++}) to ferric (Fe^{+++}) state by exposure to oxidizing chemicals such as nitrites or aromatic amines.[92] As with CO-Hb, methemoglobin is incapable of carrying molecular oxygen to tissues. Although the effects of resultant anoxia are similar, the treatment differs. The treatment involves use of methylene blue, as a precursor to its metabolite leukomethylene blue, a cofactor that enables erythrocytes to reduce methemoglobin in the presence of reduced nicotinamide adenine dinucleotide phosphate (NADPH). This therapy has complications of potential hemolysis for treatment of infants and individuals with glucose-6-phosphate dehydrogenase deficiency[92] because this enzyme is essential in the production of NADPH.

Other adverse actions affect the blood-forming cells of the bone marrow. Such effects can cause loss of immune functions mediated through leukocytes, as noted with induction of agranulocytosis during treatment with thioamide antithyroid drugs, such as propylthiouracil. Although rare, this adverse effect is devastating because it leaves the patient susceptible to sepsis. Aplastic anemia is a complication of therapy with the antiepileptic drugs felbamate and carbamazepine. This condition is very serious because the marrow loses the ability to produce cells. This potential effect requires vigilance for signs of blood dyscrasias and requires laboratory monitoring of blood cell counts during the first months of treatment.

Other adverse effects on the hematopoietic system include overexpression of certain types of cells, such as that noted in the development of acute myelogenous leukemia from benzene. Benzene is a toxicant commonly encountered in petroleum distillates such as gasoline and is considered a causative agent in human leukemia, probably through an active hydroquinone[38] or benzoquinone[53] metabolite. The process of leukemia development seems to involve preferential selection and clonal expansion of stem and progenitor cells through interaction of the toxic benzene metabolites by multiple independent genetic and epigenetic factors.

Respiratory system

The effect of toxicants on the respiratory tract is largely determined by the area of intimate cellular exposure to inhaled chemicals. Such contact is dictated by the structure of the conducting airways and the physical and chemical properties of the toxicant. Larger particles and more water-soluble compounds deposit in the upper regions of the respiratory tract, whereas very fine particles and less soluble gases reach more deeply into the lungs.

Compounds that are rapidly absorbed or highly caustic generally affect the nasal passages. Formaldehyde has a detectable pungent odor at concentrations greater than 0.5 ppm and is highly irritating to the nasal passages. The nasopharyngeal region serves as a filter for particles 10 to 30 μm in diameter. Many of these particles are cleared upward by mucociliary action. Highly water-soluble gases, such as sulfur dioxide, dissolve in moisture present in the upper respiratory membranes and form irritating sulfurous acid. Less soluble compounds, such as oxides of nitrogen and ozone, penetrate more deeply into lung and generally exert effects at membranes in the smallest airways or alveoli. Particles smaller than 5 μm may travel well down into the bronchiolar region, whereas fine particles of 1 μm nominal size reach the alveolar region.[91]

Lung toxicity typically involves damage to the delicate architecture vital for efficient gas exchange. Because lung tissues contain many cytokines and immunologic mechanisms for particle clearance and tissue repair, inflammation is a common result of inspired toxic gases such as ozone. With severe acute injury, an exudative phase may progress to pulmonary edema, which alters ventilation, diffusion of oxygen and carbon dioxide, and perfusion. Severity depends on the extent of damage to bronchiolar and alveolar cells and the resolution of inflammation through mitogenic or fibrinogenic processes.

Chronic injury to the lung may result from inhalation of fine particles. Phagocytic mechanisms attempting to remove insoluble particles may produce tissue scarring and interstitial fibrosis, in which collagen fibers replace normal membranes and occupy alveolar interstitial space. This kind of injury is common with inhalation of silicate particles such as asbestos.[64] These actions produce inflexible tissue, diminish surface area, and lead to poor surfaces for gas exchange. Another chronic lung toxicity is emphysema; its major cause is cigarette smoking. This toxic effect produces distended, enlarged air spaces that are poorly compliant but without fibrosis. The pathogenesis of this condition is not fully understood, but an imbalance between proteolytic activities of lung elastase and antiproteases seems to be involved.[3] Lung cancer became a major concern with the increase in popularity of smoking; this health scourge of today was a rare disease a century ago. Smoking is believed to be the most important risk factor for this disease, presenting a 10-fold and 20-fold increase in risk for average and heavy smokers.[91]

Organs of excretion

The primary organs of toxicant elimination are the liver and kidneys. The liver provides the major site for metabolic transformation, rendering compounds generally more water-soluble and subject to more efficient excretion in urine by the kidney. The unique physiologic features of each organ provide crucial characteristics that are susceptible to toxic actions and subsequent adverse consequences of impaired function.

The liver possesses remarkable capabilities for regeneration. Hepatotoxicity often results in necrosis and loss of the vital capacities of the liver, however. Essential functions include protein synthesis, nutrient homeostasis, biotransformation, particle filtration, and formation and excretion of bile. Impaired production of proteins such as albumin, clotting factors, and lipoproteins may cause hypoalbuminemia, hemorrhage, and fatty liver. Toxic actions that alter glucose synthesis and storage often lead to hypoglycemia and confusion, whereas effects on cholesterol uptake may produce hypercholesterolemia. Altered biotransformation or biliary excretion of endogenous substrates such as steroid hormones or bilirubin may affect a wide variety of hormonal functions or cause jaundice.

As previously noted, various membrane and cytosolic enzymes in the liver provide the essential metabolic functions of oxidation and glucuronide, sulfate, and mercapturate conjugation for removal of toxicants. These reactions usually detoxify compounds, but occasionally metabolic products exhibit enhanced toxicity. Interactions can occur among effects of toxicants within the liver through induction of enzymes or depletion of metabolic resources. Acetaminophen

has been widely used as an over-the-counter analgesic without adverse effects on the liver at therapeutic doses. In circumstances of glutathione depletion, however, which occurs with large acetaminophen overdose, malnutrition, or CYP2E1 induction by long-term ethanol use, a reactive electrophilic intermediate forms in sufficient amounts to produce covalent adducts that severely damage the liver (see Chapter 21).

The kidney plays a vital role in regulating extracellular fluid and excreting soluble wastes through filtration of blood, concentration of wastes, and elimination. To accomplish these vital functions, nephrons are composed of vascular, glomerular, and tubular components. The kidneys possess metabolic and regenerative capabilities, but these resources lead to renal failure when overwhelmed. Nephrotoxicity can be classified as acute or chronic. Acute renal failure can be caused by hypoperfusion from renal vasoconstriction, as elicited by the antifungal amphotericin B, or hypofiltration through glomerular injury resulting from cyclosporine and aminoglycosides. Numerous compounds, including nonsteroidal anti-inflammatory drugs, various antibiotics, and heavy metals, cause acute renal failure by nephritis, acute tubular necrosis, or obstruction. Causes of chronic renal failure from many of these toxicants include nephritis from inflammatory and immunologic mechanisms and papillary necrosis through ischemia or cellular injury. Compensatory mechanisms may include hypertrophy and induction of metallothionein synthesis in response to heavy metal exposure.

PREVENTION AND MANAGEMENT OF POISONING

Prevention of chemical toxicity is a responsibility of the entire community. Governmental agencies and private corporations must act in concert to minimize toxic hazards in the workplace and the environment. In the home, parents have a responsibility to protect children from harm as they explore their surroundings. Numerous sources of information are available to aid families in protecting against accidental poisoning. Steps can be taken by practitioners to limit the possibility of accidental poisoning. Patients should be encouraged to keep all medications out of the reach of children, and drugs should always be kept in child-resistant containers. Information on the label of a prescribed drug should be understandable and include the name of the agent and clear directions for use. The prescribing physician or dentist should always indicate the purpose of the medication in the label information on the prescription. This procedure helps reduce confusion about drugs in the medicine cabinet and facilitates rapid identification of the drug involved in cases of accidental ingestion. Patients should be instructed to discard unused medication rather than attempt self-medication with drugs remaining from a previous course of therapy.

Diagnosis and treatment of poisoning are the purview of the physician. Principles of therapy for poisoning are summarized in Box 52-3 and apply to the management of any drug overdose. A dentist may be called on to provide emergency treatment of acute poisoning, however, within the practice environment or because of training as a health care professional.

Principles of Therapy for Poisoning

Summon help

When acute poisoning is evident, help should be sought through the emergency 911 telephone service if available. For less critical situations, the community poison control center provides an invaluable service. These centers are equipped with extensive files describing the signs and symptoms of poisoning and recommended methods of treatment for most toxic substances distributed within the United States. Poison control centers can be reached by telephone on a 24-hour basis, and phone numbers are usually published inside the cover of telephone directories. If the toxic reaction is serious, expert medical assistance should be sought immediately. In addition, most major medical centers have drug information centers that provide information to practitioners about drugs and drug interactions.

BOX 52-3

First Aid for Poisoning

1. Summon help
2. Stabilize the patient
3. Evaluate the cause
4. Terminate absorption
5. Consider specific antidotes
6. Enhance elimination
7. Provide for supportive care

Stabilize the patient

Supportive therapy should be provided. Because hypoxia and shock are two common manifestations of serious toxicity, respiration and circulation must be monitored and assisted if required. For convulsions, physical protective measures may suffice along with the administration of oxygen to help avoid hypoxia. Intravenous diazepam is a drug of choice for pharmacologic control of continuing seizures.

Evaluate the cause

Proper therapy to eliminate exposure to the toxin or reverse its effects depends on identifying the poison. Questioning the victim or the victim's associates, searching for empty containers, or looking for physical signs on the patient (e.g., miosis or needle tracks for opiate or opioid overdose, burn marks in the mouth for ingestion of caustic chemicals) can be important in establishing the cause of poisoning.

Terminate absorption

Any obvious means of contact with the poison should be removed. For dermal exposure to chemicals, removal of contaminated clothing and repeated washing with soap and water are indicated. With ingested compounds other than petroleum products and corrosive substances, vomiting can be induced, but only in a conscious patient. Vomiting should not be induced for poisoning by petroleum products or agents producing loss of consciousness because of the risk of aspiration. Likewise, corrosive damage to the esophagus and gastric perforations may result from corrosive substances if emesis is induced. Modern practice is to avoid inducing vomiting because it does not reliably remove ingested poisons. Gastric lavage can be used by qualified personnel if care is taken to avoid aspiration of stomach contents by the victim. Prevention of absorption of many drugs within the gastrointestinal tract can be achieved by activated charcoal (10 to 50 g in water), and cathartics may be used to hasten the exit of drugs from the intestine. The merits and limitations of gastrointestinal decontamination measures have been reviewed in detail.[15]

Consider specific antidotes

Specific antidotes are available to treat poisoning by certain classes of compounds. Antidotes may be useful in preventing

the absorption of ingested agents (e.g., Ca^{++} salts for F^-), increasing their rate of elimination (e.g., dimercaprol for inorganic mercury), blocking specific receptors (e.g., naloxone for morphine), or blocking other toxic activity (e.g., N-acetyl cysteine for acetaminophen overdose). One specific antidote should be remembered by dentists. For ingestion of toxic amounts of fluoride, which might occur with prescribed tablets or with topical liquids or gels, the local antidote to prevent absorption is Ca^{++} (in milk, calcium lactate, calcium gluconate, or lime water). If necessary, 2 to 10 mL of 10% calcium gluconate may be injected intravenously to bind fluoride and overcome hypocalcemia. Dentists who use benzodiazepines and opioid analgesics for conscious sedation must be familiar with the use of flumazenil and naloxone, respectively, to reverse respiratory depression caused by these drugs (see Chapters 13 and 20).

Enhance elimination

Measures to facilitate elimination of toxicants are in the realm of emergency care physicians; they are mentioned briefly here for completeness. The renal excretion of weak electrolytes can often be accelerated by appropriate modification of urinary pH. Administration of an osmotic diuretic in conjunction with large volumes of water is helpful in promoting urinary excretion and reducing the renal concentration of nephrotoxic poisons. In some instances, peritoneal dialysis or hemodialysis may be useful.

Provide for supportive care

Medical assessment of poisoning and continuing treatment, as needed, should be provided by physicians, nurses, and staff in an appropriate health care facility. Professionals with a full range of medical treatment resources may be required to address additional sequelae during the course of recovery.

OCCUPATIONAL SAFETY IN DENTISTRY

Although dentistry is considered to be relatively "occupationally safe," numerous potentially hazardous substances are used in the dental office or laboratory. In addition, dental environments may provide exposure to radiation or to blood-borne pathogens. Since 1988 the Occupational Safety and Health Administration (OSHA) has been writing, implementing, and enforcing regulations designed to ensure that employees are informed of hazardous materials in their work environment and given appropriate instruction in the risks and handling of these materials. The primary components of this program include (1) labeling of containers for materials, (2) on-site maintenance of material safety data sheets for materials used in the workplace that contain hazardous chemicals, and (3) employee education and training. For dentistry, OSHA regulations and guidelines include potential exposures to blood-borne pathogens and biologic agents in addition to chemicals. To assist in fulfilling the requirements of OSHA regulations, the American Dental Association has published several helpful documents on OSHA, including a step-by-step guide to compliance and a video OSHA refresher course.[2]

To meet OSHA regulations, drugs and chemicals must be labeled with the name of the chemical, appropriate risk warnings regarding the chemical, and name and address of the manufacturer or other responsible party. If a hazardous material is transferred to another container at any time other than for immediate use, an appropriate label must be affixed to the new container.

Material safety data sheets are central to the safety program and are the primary source of risk and hazard information. These sheets are required to be provided by the manufacturer on request and must identify the hazardous substances included in the preparation, the physical and chemical characteristics, the fire and explosion danger, and other health hazard data. Material safety data sheets must also provide information on handling, storage, cleanup, disposal, and emergency and first aid procedures. These sheets must be present in the workplace and available to employees at all times. Dentists are required to provide appropriate training for employees in the use and management of hazardous substances when they are hired, whenever new hazardous substances are brought into the workplace, and when new information regarding the use of existing substances becomes available.

SPECIFIC TOXICANTS

The toxic effects of several classes of substances are presented. Agents that illustrate general principles presented earlier and that have public health importance or importance in the practice of dentistry are described.

Metals

Metals as a class are toxic primarily because of their ability to bind with biologic structures such as thiol groups in enzymes and other proteins. The major effect in humans is the inhibition of enzyme function. Because of this binding affinity, the effect of metals may be widespread in the organism, but usually a primary or most sensitive system in which clinical manifestations may be detected is evident. Metals as a class are important because of their ubiquitous nature in modern medicine and technology and in nature. Two metals of importance in public health and dental practice are mercury and lead.

Mercury

Mercury is present virtually everywhere in the environment. An estimated 2700 to 6000 tons is released annually from the oceans and the earth's crust into the atmosphere. An additional 2000 to 3000 tons is released through human activities, including the burning of fossil fuels. Mercury exists in three chemical classes: elemental mercury (Hg^0), which is a liquid at room temperature and is used as a primary component in dental amalgam; inorganic mercury salts; and organic mercury salts. Inorganic mercury salts may exist as mercurous (Hg^+) or mercuric (Hg^{++}) forms. Of the many organic forms of mercury, methylmercury is the most important toxicologically because of its ability to permeate membranes and the blood-brain barrier, its potency for biologic damage, and its widespread use in human activities.[58]

Mercury toxicity provides an interesting example of several important toxicologic principles. The first is that a single substance may produce differing effects depending on presentation to the organism. Hg^0 is essentially nontoxic when ingested because of a lack of absorption in the gastrointestinal tract. It may be toxic, however, when injected subcutaneously.[76] In addition, because of its high vapor pressure, it vaporizes readily and is easily inhaled. When inhaled, Hg^0 is absorbed readily into the blood, with absorption rates estimated at 74% to nearly 100% of inhaled dose.[29,37] When in the blood, it is oxidized and is available for binding to enzymes and other proteins, producing toxic effects. Another important principle exhibited by mercury is that when a substance can exist in different chemical forms, the forms may present strikingly different health effects. Organic mercury typically produces signs of toxicity that are neurologic in nature, whereas inorganic salts often produce gastrointestinal destruc-

tion and, secondarily, nephritis. These effects are discussed further subsequently.

Inorganic mercury salts are used widely in industry; mercuric chloride is an example of a mercury compound with a wide variety of industrial uses. These compounds, in contrast to organic mercury compounds, are not well absorbed through the gastrointestinal tract and do not readily cross biologic membranes when absorbed. Only approximately 10% of an inorganic mercury dose is absorbed through the gastrointestinal tract compared with more than 90% of an ingested dose of methylmercury. Nevertheless, inorganic salts such as mercuric chloride are severely corrosive to tissue and when absorbed produce toxic effects through binding of enzymes. Inorganic mercury compounds have been used medicinally and applied dermally in makeup for hundreds of years until recent times; calomel (a cathartic) and mercurochrome (an antiseptic) are common examples. Virtually all such uses have been discontinued.

Organic mercury compounds represent the most important form of mercury from a toxicologic perspective. This is particularly true of methylmercury because of its widespread use and because it is a by-product of many industrial processes. Organic mercury is known to accumulate in the food chain, and this is particularly evident in seafood, where the pelagic and top-level predators accumulate significant amounts of methylmercury in their flesh.

A number of tragic, inadvertent organic mercury poisonings have occurred in modern times. Two incidents are particularly well documented. From 1932-1968, the Chisso Corporation, a company located in Kumamoto, Japan, dumped an estimated 27 tons of mercury compounds into Minamata Bay. Kumamoto is a small town approximately 570 miles southwest of Tokyo. The town consists of mostly farmers and fisherman whose normal diet included fish from the bay. Symptoms of methylmercury poisoning unexpectedly developed in thousands of these people. The illness became known as Minamata disease. Methylmercury has also been widely used to prevent grain spoilage through its antifungal effect. The second major outbreak occurred in the early 1970s when more than 500 people died and many others were made severely ill in Iraq when grain seed treated with methylmercury was inadvertently ground into flour and consumed. In both of these instances, because organic mercury readily crosses the blood-brain and placental barriers, a significant number of fetal deaths and teratogenic results occurred.

Hg^0 is the form of concern in dentistry because it is a primary component of dental amalgam, constituting approximately 50% by volume of the material. The greatest risk of exposure from Hg^0 is by inhalation of the vapor. Hg^0 vapor is highly lipid-soluble and readily crosses membranes; this gives it ready access to the CNS and other body components, where it is easily oxidized to the mercuric form. Acute, high-level exposure to Hg^0 vapor produces corrosive inflammation of the upper and lower respiratory tract and nephrotoxic and CNS effects. Long-term exposure to low or moderate levels of Hg^0 vapor damages enzymes and structural proteins in the CNS, resulting in blockage of neuromuscular and synaptic transmission. Figure 52-2 shows the currently known range of effects based on urinary mercury concentrations. Urinary mercury concentration is considered a reasonable indicator of recent Hg^0 exposure, but because mercury is sequestered in organ systems, urinary mercury concentration is not a true indicator of total body burden.[49] Although the three forms of mercury (inorganic, organic, and elemental) produce differing toxicologic effects, the two major target organs of any mercury exposure are the CNS and the kidneys.

Although the earliest indicators of CNS effects of mercury exposure are not always clinically evident, they are measurable with neurobehavioral testing.[7,20] As exposure increases, behavioral changes may be noticed, such as irritability, memory disturbances, personality changes, drowsiness, or depression. Fine muscle tremors are noted, especially of the fingers, eyelids, and lips, and this loss of neuromuscular control increases as exposure levels increase. Renal damage in the form of tubular necrosis increases in a dose-dependent manner. Oral manifestations of mercury intoxication include hypersalivation, gingivitis, and gingival discoloration. Cases of periodontal destruction with tooth loss have been reported at high levels of exposure.[51] Also present at high levels of exposure is a yellow-brown discoloration of the lens of the eye.

Mercury in dentistry

Since the introduction of mercury amalgam into dentistry in the early nineteenth century, concerns about its safety have been expressed from time to time. Claims of toxic effects cover virtually the entire spectrum of disease, and a vocal "antiamalgam" contingent currently exists. Much of the confusion regarding the potential health effects of mercury exposure from dental sources is caused by false claims and by flawed studies used to support these claims by antiamalgam proponents. Two areas of potential concern have been the subject of more recent and ongoing studies. One is the potential occupational risk to dental personnel working with dental amalgam, and the other is to the consumer or patient who has mercury amalgam placed in the teeth as a treatment.

OSHA and the National Institute for Occupational Safety and Health have recognized the need to set occupational thresholds over which exposure to mercury must not occur. These organizations have set a threshold limit value of 50 µg of Hg^0 per cubic meter of air as a time-weighted average based on a 40-hour work week.[17] The World Health Organization has set a more restrictive threshold limit value of 25 $\mu g/m^3$.[22] Hg^0, which is readily vaporized, can achieve concentrations of 2000 $\mu g/m^3$ in a closed room. Studies of ambient air mercury concentrations in dental offices have shown that, under conditions of careless handling of mercury, the occupational threshold levels can be exceeded.[69] These high con-

centrations may occur after contamination through accidental spills of Hg^0.

Studies examining occupational exposure among dental personnel show that certain practices in dental offices—now considered outmoded—are the most significant contributors to occupational exposure. These practices include the use of squeeze cloths to express mercury from amalgam; dispensing mercury from a central supply, which leads to accidental spills; and the use of office-prepared capsules.[50] Neurobehavioral changes have been noted in dentists exposed to mercury.[20] Modern dental offices that have good hygiene practices with respect to mercury pose minimal risk to dental personnel, however. Excellent hygiene remains vital to preventing unnecessary mercury exposure.

With regard to mercury exposure that patients receive from the placement of amalgams in the course of treatment, anecdotal claims of disease states of every sort attributed to such exposure have been reported. Although rare individuals may be sensitive to very low level mercury exposure, little or no valid scientific evidence supports such claims in the general population. An important reason for the controversy is the reliance of some individuals on false claims and dubious studies about the dangers of dental amalgams. To date, no scientific studies have supported a health risk from dental amalgams to patients in whom these restorations have been placed.[48,52]

Two large-scale, randomized, prospective clinical trials have been completed that studied the effect of mercury exposure from dental amalgam in children.[5,16] These studies each included more than 500 children who were randomly assigned to dental treatment groups that would receive either amalgam or resin composites for necessary restorations in posterior teeth,. The subjects were followed annually for 5 years in the study by Bellinger and colleagues[5] and 7 years in the study by DeRouen and colleagues.[16] Outcome measures included comprehensive batteries of neurobehavioral tests including IQ testing, neurologic examinations including nerve conduction velocities, and renal function tests. Although there were measurable differences in urinary mercury concentrations between the amalgam and nonamalgam treatment groups, there were no significant differences found for any of the outcome measures between groups, indicating that the level of mercury exposure from routine dental treatment with amalgam does not present an important health risk for neurologic or renal outcomes.

A study of 1663 adults participating in the ongoing Air Force Health Study of Vietnam-era veterans to determine possible associations between amalgam exposure and neurologic abnormalities found no association between amalgam exposure and neurologic signs or clinically evident peripheral neuropathy.[41] The body of evidence also indicates no detectable negative effect on general health at the levels of mercury exposure produced by the presence of dental amalgam fillings except in rare cases of allergy to amalgams.[17] Following the mercury hygiene guidelines listed in Box 52-4 minimizes any exposure to patients beyond that which results from the amalgam itself.

BOX 52-4

Recommended Guidelines for Minimizing Mercury Exposure in the Dental Environment

1. Use precapsulated amalgam preparations only. Reclose disposable capsules after use.
2. Do not use squeeze cloths for expressing mercury from amalgam mix.
3. Monitor office levels of Hg^0 yearly or whenever contamination is suspected.
4. Use exposure badges that sample the air for Hg^0 concentration.
5. Provide periodic urinary mercury concentration testing for personnel.
6. If "free" mercury (rather than precapsulated) must be used to mix amalgam, store it away from heat in unbreakable, tightly sealed containers.
7. Store amalgam scrap in a sulfide solution (e.g., used x-ray fixer) or under water.
8. Do not touch amalgam with bare hands.
9. Use a rubber dam for restorative procedures.
10. Use a high-velocity vacuum when manipulating the amalgam and vacuum and water spray when removing old amalgam restorations.
11. In the event of a mercury spill (even a small one), use a mercury spill cleanup kit (commercially available). Do not vacuum the spill because this hastens the volatilization of the mercury into the air.

Lead

Lead has been a toxicologic problem for humans from the earliest times. It was found in early utensils and food storage and preparation vessels. It has been used extensively in plumbing, contaminating drinking water. Occupational exposures to lead occur in miners, smelters, and lead acid battery workers, but the most common chronic exposure is through diet. Perhaps the best recognized sources of lead exposure are from lead-based paint and combustion products of tetraethyl lead antiknock compound added to gasoline before the change to unleaded gasoline. Although Congress produced legislation limiting the lead concentration in paint to 0.06% in the 1970s, many older buildings still contain significant amounts of lead-based paint with very high concentrations of lead. A relatively small chip of this paint may contain 100 mg of lead. When consumed by a child, this amount exceeds the daily allowable intake by a factor of at least 30.[34] Because lead compounds that were included in paint formulas have a sweet taste, young children have frequently consumed these paint chips. (The condition of eating unnatural foods is called *pica*.)

Adults absorb approximately 10% of dietary lead, although children may absorb significantly larger amounts. With normal renal function, absorbed lead is primarily excreted by the kidneys. In the body, lead primarily concentrates in the hard tissues such as bone and teeth. Similar to mercury, lead produces toxic effects primarily by binding with proteins necessary for cellular function. Toxic signs exhibited at various blood levels are illustrated in Figure 52-3. One early effect of lead exposure is inhibition of the heme biosynthetic pathway. Intermediary products of heme biosynthesis called *porphyrins* are excreted in the urine in a characteristic pattern indicative of lead poisoning.[68]

Chronic lead poisoning, known as *plumbism*, produces a spectrum of effects depending on the duration and severity of exposure. A microcytic hypochromic anemia may be produced early in exposure and cause lethargy and weakness. Neurologic effects may produce restlessness, irritability, hyperactivity, and impaired intellect. Chronic low-level lead exposure can produce deficits in gross and fine motor development and in cognitive and intellectual development. Early detection and management of lead exposure is crucial to prevent these permanent effects in children.[47] Peripheral neuropathies may be seen and are manifested as wristdrop, footdrop, and muscular weakness. Gastrointestinal signs such as intestinal spasms may progress to severe abdominal cramping with increased or continued exposure.

The greatest threat from lead poisoning is encephalopathy, which occurs more often in children. Early neurologic

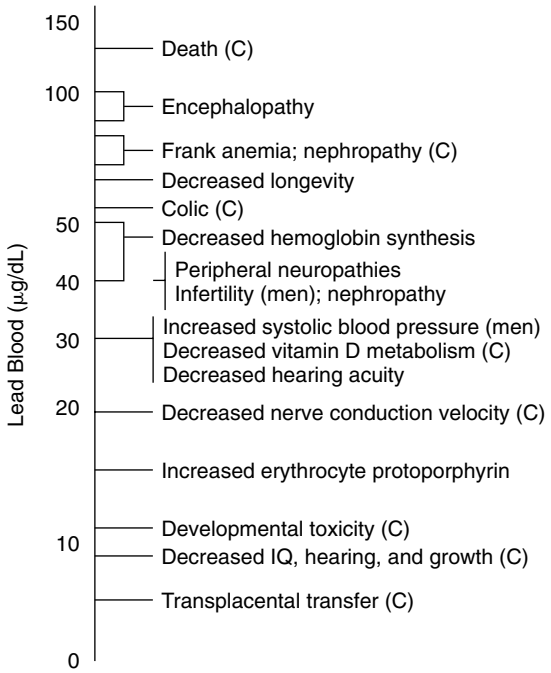

FIGURE **52-3** Signs and symptoms of lead toxicity relative to concentrations in blood. Children are represented at the more sensitive end of the designated ranges. *(C)*, Denotes observations in children. (Adapted from Ellenhorn M, Schonwald S, Ordog G, et al: Metals and related compounds: lead. In Cooke D, editor: *Ellenhorn's medical toxicology: diagnosis and treatment of human poisoning*, ed 2, Baltimore, 1997, Williams & Wilkins.)

signs and symptoms develop as described earlier and progress to delirium, convulsions, and coma. One fourth of patients with lead encephalopathy do not survive, and 40% of survivors are left with severe neurologic dysfunction.[66,70] Lead is toxic to the kidney, and reversible tubular damage and irreversible interstitial fibrosis may be seen. Long-term exposure to lead is classically associated with a blue-black line that appears along the gingival margin. This deposit of lead sulfide is known as Burton's lines, and although associated with lead exposure, it may also be caused by exposures to other metals, such as silver, iron, or mercury.

For treatment, removal of the subject from the source of lead exposure is paramount. Depending on the blood lead levels, chelation therapy is instituted according to protocols[23] for the treatment of lead poisoning recommended by the U.S. Centers for Disease Control and Prevention and the American Academy of Pediatrics. Succimer, edetate calcium disodium, dimercaprol, and penicillamine all are effective, but differ in advantages of routes of administration and specificities relative to other essential trace metals.

Iron

The pharmacologic features of iron are discussed in Chapter 30. Iron is a heavy metal that is required to sustain life and is commonly used therapeutically. The daily adult consumption of iron is equivalent to approximately 15 to 40 mg of elemental iron, only a portion of which is absorbed. An allowance of 10 mg/day is recommended for children, with small additional increments during puberty to account for rapid growth. Inappropriate levels of exposure can lead to significant toxicity, however. Iron toxicity can be either chronic or acute. More than 2000 cases of iron poisoning are reported in the United States each year. Chronic toxicity seems to be more common in individuals who have a genetic predisposition to absorb excessive amounts of iron taken orally. Pathologic changes include hemosiderin accumulation in the liver and spleen and hemochromatosis. Deferoxamine, a drug that selectively chelates iron (especially the ferric form) and removes iron from hemosiderin, is used to treat chronic toxicity.

Acute toxicity occurs most frequently in children, in whom accidental ingestion is most likely to occur.[27] The lethal dose of ferrous sulfate for a 2-year-old is approximately 3 g. The first signs of acute oral toxicity occur in the gastrointestinal tract. Vomiting and diarrhea are common. The vomitus may appear brown, and the stool may be bloody. Gastric scarring can also occur. Acidosis and shock occur a few hours later. A delayed phase, occurring 24 to 48 hours later, is characterized by convulsions, cardiovascular collapse, and coma. Treatment consists of evacuation of the stomach contents by lavage or induction of vomiting. Support of the cardiovascular system and kidneys by maintaining blood pressure, plasma volume, and correction of acidosis is often necessary. Deferoxamine given intravenously or intramuscularly is effective in chelating iron after it is absorbed. Deferoxamine is not well absorbed by the oral route, and oral administration is ineffective in preventing absorption of iron from the gastrointestinal tract.

Treatment of poisoning: heavy metal chelators

Chelators are compounds that form complexes with metal ions. The word *chelator* is derived from the Greek word *chele*, meaning "claw." A chelator molecule binds a metal ion by two or more polar functions, such as sulfhydryl, carbonyl, amino, or hydroxyl groups. These form bonds similar to the bonds of the protein functional units attacked by metal ions. Through this action, chelators spare endogenous ligands and promote excretion of metals as the chelator-metal complexes. Dimercaprol, succimer, and penicillamine are drugs currently marketed to promote the excretion of mercury, lead, and other metals. A few additional agents are available to treat poisoning by metals other than mercury, such as edetate calcium disodium for lead and cadmium and deferoxamine for iron. Structures of these chelators are shown in Figure 52-4. Selectivity for metal ions varies among chelators. Some, such as edetate, aggressively remove vital nutrient metals, such as calcium and zinc. Such selectivity is important in the choice of the chelator, which should be matched for the heavy metal and circumstances of therapy. Selectivity of chelators for specific heavy metals is presented in Table 52-1.

Dimercaprol (2,3-dimercapto-1-propanol) was developed during World War II as an antidote for the arsenical gas lewisite, and it was formerly known as British antilewisite. Subsequently, dimercaprol was found to be an active chelator of various heavy metals. Dimercaprol is prepared as a 10% solution in a peanut oil vehicle (beware of peanut allergy!) and must be injected intramuscularly. It is maximally effective when given shortly after an acute exposure to mercury; however, it is valuable even in chronic mercurialism. Dimercaprol is used with edetate calcium disodium in protocols for treatment of lead poisoning.[23] The drug is usually injected two to three times a day initially, with doses tapering off to once or twice a day over about 10 days. The dimercaprol-mercury complex (actually two dimercaprol molecules to a single mercury atom) is excreted in the urine, which must be kept alkaline to avoid dissociation of the conjugate.

Succimer (meso-2,3-dimercaptosuccinic acid) is structurally similar to dimercaprol. This drug has the advantage of being effective after oral administration and being less toxic than dimercaprol. Succimer is more water-soluble and is the drug of choice for the treatment of lead poisoning because it is more specific for lead chelation than edetate calcium disodium and removes fewer essential minerals such as calcium, copper, iron, and zinc. The dose for lead chelation is 10 mg/

TABLE **52-1**

Metals and Chelators That Enhance Excretion

METAL	CHELATOR	OTHER NAMES	ADMINISTRATION
Arsenic	Succimer; dimercaprol	Dimercaptosuccinic acid, DMSA; 2,3-dimercapto-1-propanol, BAL	Oral; IM
Cadmium	$CaNa_2$ EDTA	Edetate calcium disodium	IV infusion
Copper	D-Penicillamine	3-Mercapto-D-valine	Oral
Iron	Deferoxamine		IM
Lead	Succimer; dimercaprol + $CaNa_2$ EDTA; D-penicillamine		Oral; IM + IV infusion; oral
Mercury	Succimer; dimercaprol; penicillamine		Oral; IM; oral

IM, Intramuscular; *IV,* intravenous.

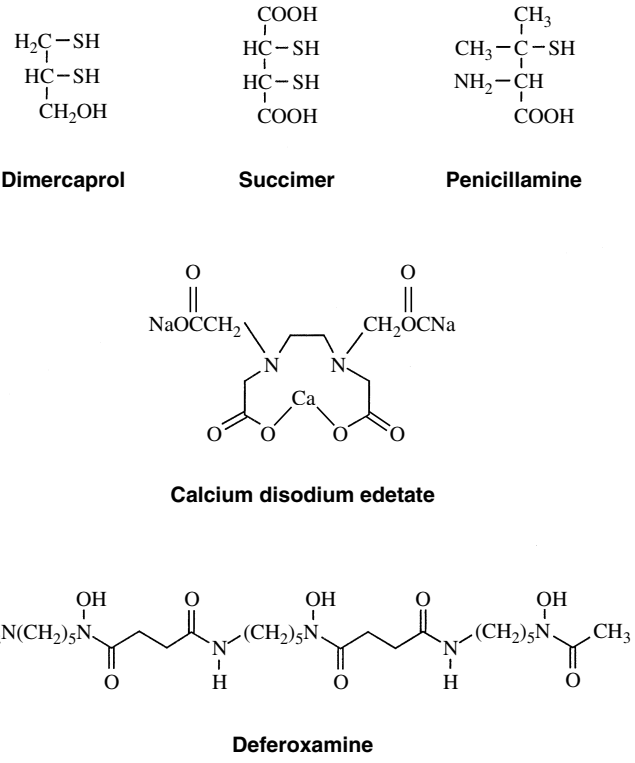

FIGURE **52-4** Chemical structures of chelating agents.

kg every 8 hours for 5 days, then 10 mg/kg every 12 hours for 14 days. In animal studies, succimer was more effective than dimercaprol in alleviating acute toxicity and preventing distribution of orally administered mercury from mercuric chloride, particularly to the brain. In addition, oral administration was more efficient than parenteral administration in reducing retention and organ deposition of oral mercuric chloride, probably because of decreased intestinal uptake.

Penicillamine (3-mercapto-D-valine) is a highly effective chelator of copper and is of primary importance in the management of Wilson's disease (hepatolenticular degeneration). Although less effective against other metals, penicillamine is often a useful drug for asymptomatic patients with a moderate body burden of metal because it is orally effective. In general, 1 to 2 g/day is administered as needed for therapy of mercury poisoning. The penicillamine-mercury complex (also involving two drug molecules for each mercury atom) is excreted in the urine.

Edetate calcium disodium complex is a chelator for divalent and trivalent metals that can displace calcium from the molecule. Typically, these metals include lead, zinc, cadmium, manganese, iron, and mercury. Edetate calcium disodium is poorly absorbed from the gastrointestinal tract and is given intramuscularly or intravenously. Edetate calcium disodium must be used carefully according to suppliers' protocols because it can produce nephrotoxicity. Edetate calcium disodium can aggravate symptoms of severe lead poisoning, such as cerebral edema and renal tubular necrosis, and in high doses can lead to severe zinc deficiency.

Deferoxamine is a specific chelating agent for iron. It is available only for parenteral administration. The preferred route is intramuscular; acute iron intoxication treatment involves 1 g as an initial dose, followed by 500 mg every 4 hours for two doses and additional doses of 500 mg every 4 to 12 hours as needed based on clinical response.

Treatment of mercury poisoning

Therapy depends on the type of mercury poisoning. Exposure to elemental or inorganic mercury can be treated with dimercaprol (higher mercury levels) or penicillamine (lower mercury levels). Hemodialysis may be needed to protect the kidney. Succimer is also effective. For short-chain organic mercurials such as methylmercury, chelation therapy is ineffective, and dimercaprol is contraindicated because it concentrates mercury in the brain. Hemodialysis is ineffective. Methylmercury can possibly be bound in the gut with a polythiol resin.

Gases

Perhaps no other toxic pollution issue stirs such universal concern as air pollution because gaseous pollutants are dispersed over broad regions, and inhalation exposure is insidious. Significant regulatory effort is devoted to decreasing air pollutants by the Clean Air Act, and general information on topics important in the control of air pollution is available from the Internet.[78] The U.S. Environmental Protection Agency (EPA) uses six "criteria pollutants" as indicators of air quality and has established a maximum concentration for each to preclude adverse effects on human health. The four gaseous criteria pollutants are discussed subsequently; the remaining two are airborne lead and fine particulate material that is 10 μm or smaller in diameter.

Carbon monoxide

The origin of CO, a colorless, odorless gas, is incomplete combustion of carbon. The toxicity of CO results from its combination with Hb and exclusion of oxygen from this vital oxygen transfer mechanism. CO exhibits an affinity for Hb 210 to 300 times that of oxygen, and the resultant complex

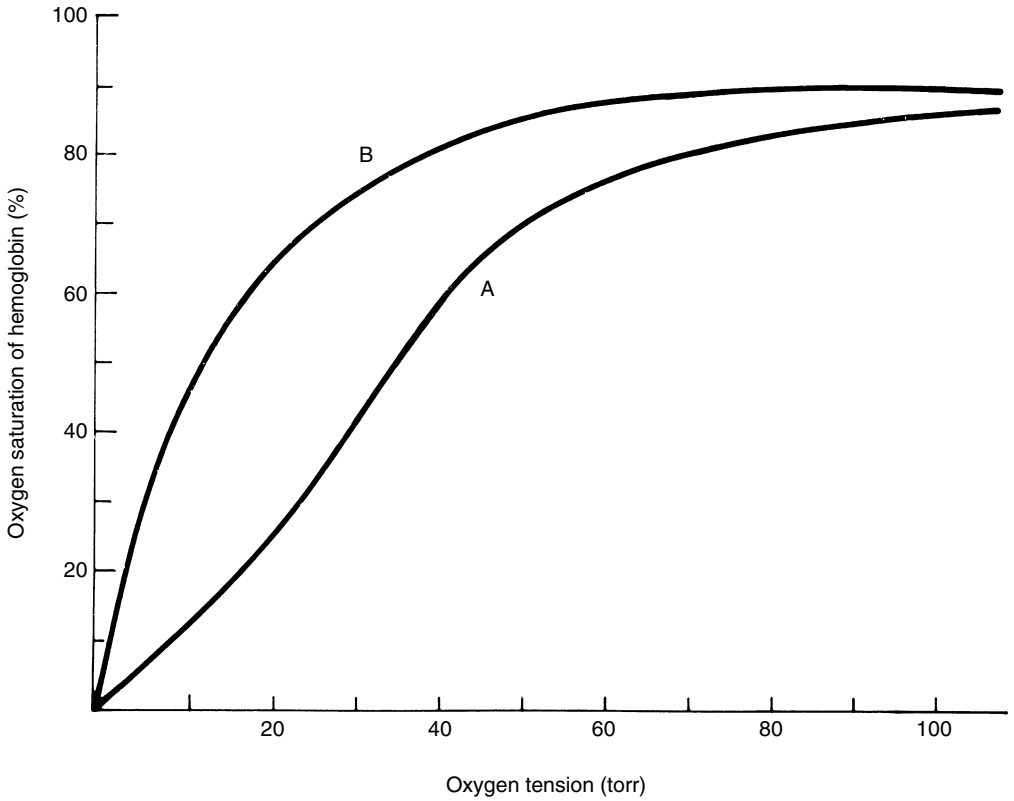

FIGURE **52-5** Effect of carbon monoxide on oxygen dissociation. C*urve A* represents the normal desaturation curve for oxyhemoglobin and shows that half of the bound oxygen is made available to tissues as the oxygen tension (Po_2) decreases to slightly more than 30 mm Hg (~30 torr). In the presence of 50% carboxyhemoglobin *(curve B)*, Po_2 must decrease to a hypoxic value of 10 mm Hg before a similar percentage of oxygen is released from hemoglobin binding sites.

with reduced heme iron, CO-Hb, is incapable of combining with oxygen.[86] The relationship between CO air levels and CO-Hb in blood can be predicted by the Coburn-Foster-Kane equation[72]; typical symptoms associated with varying CO-Hb levels are presented in the review by Von Burg.[86] The effect of CO-Hb on oxygen dissociation is shown in Figure 52-5.

Ozone

Ozone (O_3) is an odorless, colorless gas composed of three oxygen atoms. Typically, O_3 is not emitted into the air, but is created at ground level by photochemical reactions among nitrogen oxides and volatile organic compounds in the presence of heat and sunlight. O_3 occurs naturally in the stratosphere (approximately 10 to 20 miles above the earth) and forms a protective barrier that absorbs the sun's harmful ultraviolet rays. In the earth's lower atmosphere and at ground level, O_3 is considered unhealthy because of its oxidative effects. Because of its relative insolubility, inspired O_3 is carried deep into the lung, where it oxidizes membranes in the alveoli. O_3 irritates lung airways and causes inflammation, reduced lung capacity, and increased susceptibility to respiratory illnesses such as pneumonia and bronchitis. Other symptoms include wheezing, coughing, and pain with deep breathing. Oxidation products arising from O_3 reactions with lung proteins or lipids initiate numerous cellular responses, including generation of cytokines and expression of adhesion molecules. These responses promote an influx of inflammatory cells to the lung in the absence of a pathogenic challenge, resulting in modification of cellular tight junctions, increased lung permeability, and development of edema.[55] Individuals with preexisting respiratory problems, such as asthma or chronic obstructive pulmonary disease, are most vulnerable. Repeated exposure to O_3 pollution for several months may cause permanent lung damage.

Sulfur dioxide

Sulfur dioxide (SO_2) is a colorless gas with a pungent, irritating odor. SO_2 is used as a preservative of fruits and vegetables, a disinfectant in wineries and breweries, and a bleaching agent in paper and textile industries. It is generated as an air pollutant by industry, such as high-sulfur coal-fired electric power plants, and is largely responsible for the environmental and public health impact of acid rain.[44] In contrast to the properties and site of impact of O_3, SO_2 is highly soluble in aqueous fluids and affects the upper respiratory tract. On dissolution, it forms sulfurous acid, which is extremely irritating to the nasopharyngeal and respiratory tracts. Acute exposure causes dryness of the nose and throat and a decrease in tidal respiratory volume. Coughing, sneezing, choking, and nasal discharge occur. In dentistry, chronic exposure at levels causing these symptoms has been associated with dental caries and gingival and periodontal disorders. Patients noted rapid dental destruction, loss of restorations, and increased sensitivity of teeth to temperature change.[87]

Nitrogen oxides

Nitrogen dioxide (NO_2) is a brownish, highly reactive gas that is present in all urban atmospheres. The major mechanism for the formation of NO_2 in the atmosphere is the oxidation of the primary air pollutant nitric oxide (NO). Mixtures of nitrogen oxides (NO_x) play a major role, together with volatile organic hydrocarbons, in complex atmospheric reactions that

produce O_3 and are important precursors to acid rain. NO_2 is relatively insoluble in aqueous media and decomposes in water to form nitric acid (HNO_3) and NO, a potent vasodilator. When inspired, it reaches deep into the lungs. NO_2 can cause bronchitis, pneumonia, hemorrhagic pulmonary edema, and diffuse alveolar damage. Exposure also seems to reduce resistance to respiratory infections. Acute exposure to nitrogen oxides causes a relatively rare condition known as *silo filler's disease*. Most cases involve young, otherwise healthy farm workers who enter silos freshly filled with corn silage without adequate ventilation. The most common presenting feature is dyspnea, but the disease was fatal in 5 of 20 reviewed cases.[94]

Liquids and Vapors

The organic liquid that presents the greatest risks to humans is ethanol. The toxicologic profile of this compound is unique among organic liquids and is presented in detail with other aliphatic alcohols in Chapter 43. Considered in this section are the organic solvents, including hydrocarbons and chlorinated compounds, and methyl methacrylate (because of its common use in dentistry). Figure 52-6 shows structures of the compounds discussed here.

Solvents

Although transient exposure to solvents may occur in the home, more significant exposure most commonly occurs in the workplace. Exposure most often occurs through inhalation; absorption through the skin is also a common route of exposure. Absorption from the gastrointestinal tract is variable. Compounds that are well absorbed, such as benzene or toluene, can produce significant systemic toxicity. Others, such as naphtha or gasoline, are not as well absorbed. A major risk from ingestion is the potential for pneumonitis as a result of emesis and aspiration.

Regardless of the site of absorption, the great lipid solubility of this group of compounds allows them to cross the blood-brain barrier readily. Individuals exposed to high concentrations of organic solvents usually exhibit profound CNS depression. Chronic exposure to lower concentrations of these chemicals produces toxic effects characteristic of the individual compounds.

Chlorinated solvents

Dichloromethane, otherwise known as methylene chloride, is a common solvent in paint remover and is used for liquid-liquid extraction in laboratories. Acute toxicity is caused by CNS depression, and fatalities have resulted from exposure. Symptoms include mental confusion, fatigue, lethargy, headache, and chest pain. Dichloromethane is metabolized to carbon monoxide. Evidence of its carcinogenicity, obtained in mice, seems to be related to toxic metabolites formed by glutathione-S-transferase and may be specific to the very high activity and localization of this enzyme in this species.[35]

Carbon tetrachloride is metabolized in the liver to a highly reactive metabolite (a free radical) that, in the presence of oxygen, reacts with proteins and lipids. The resulting hepatotoxicity may take days to develop and is accompanied by severe renal toxicity. Compounds that increase the rate of carbon tetrachloride biotransformation, such as cytochrome P450 enzyme inducers, increase the danger of toxicity. Substances that inhibit its metabolism are protective.

In a similar manner, perchloroethylene (also known as tetrachloroethylene) has been found to produce reactive metabolites that are thought to produce renal toxicity. This compound has also been associated with an increased risk of oral, laryngeal, and esophageal cancer in workers occupationally exposed to dry-cleaning processes that use perchloroethylene.[85]

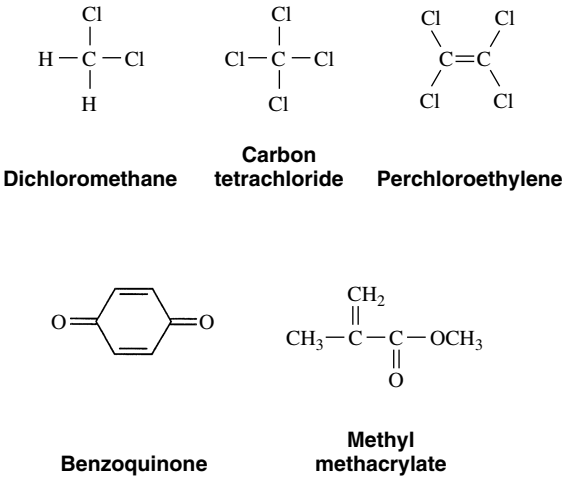

FIGURE **52-6** Chemical structures of chlorinated solvents, the benzene metabolite benzoquinone, and the acrylic plastic monomer methyl methacrylate.

Benzene

Benzene is another widely used industrial solvent commonly encountered in petroleum distillates such as gasoline. Benzene is considered a causative agent in human leukemia, probably through active hydroquinone or benzoquinone metabolites formed at oxidation.[38]

Methyl methacrylate

Methyl methacrylate is widely used in dentistry for the production of prosthetic devices and in orthopedic medicine as a luting agent. Although properly cured polymers from methyl methacrylate seem to be biologically inert, numerous adverse effects have been associated with the monomer. Exposure to the monomer can lead to toxicity and allergic reactions.[14] A slight, transient decrease in blood pressure has occasionally been reported when methyl methacrylate was used to cement orthopedic devices. The assumption in these cases was that the effects were caused by absorption of the monomer into the patient's vasculature. Adverse effects have also been reported by personnel in operating rooms, where, because of improper mixing, concentrations of more than 200 ppm have been measured. Surgeons have developed contact dermatitis and paresthesias,[30] and nurses have reported dizziness, nausea, and vomiting.

A survey of dental laboratories suggests that these were exposed to more moderate concentrations (≤5 ppm) of the monomer,[12] although peak concentrations can be double that amount.[56] Although the concentrations to which dental technicians are exposed are moderate, a study of dental technicians suggested that cutaneous absorption of the monomer, a result of dipping the fingers in the liquid to smooth and improve the finish of the polymer surface, caused a localized slowing of nerve conduction.[67] Other studies have found more generalized neuropathies attributed to methyl methacrylate exposure in dental technicians.[18,65] In addition, cutaneous reactions have been reported from monomer and "cured" methacrylate polymer.[46,59]

Numerous studies have confirmed more recently that dental resins and composites release methyl methacrylate and many similar plastic components that are known to have the potential for endocrine-disrupting effects.[1,40,74,88] The term *endocrine-disrupting* refers to alterations in the natural biosynthesis, metabolism, or receptor occupancy of hormones such as estrogen and testosterone. Many of these endocrine-disrupting compounds found in dental filling materials are

uncured monomers, such as bisphenol A (BPA) and bisphenol A glycidylmethacrylate (Bis-GMA), and chemically related compounds such as phthalates.

Although little is definitively known about the effects of low-dose exposure of these components of dental composites and sealants, evidence exists of the potential for detectable effects on human metabolic systems. Much of this evidence is from animal model and human in vitro studies, and little or no research has been reported that uses in vivo studies to examine these potential effects. Potential systemic effects on the organism of endocrine disruption are wide-ranging and biologically important. These may include developmental defects, behavioral effects, fertility problems, and tumorigenic effects. There have been no safety studies or randomized clinical trials in humans to examine the potential effects of low-dose exposures to these substances, such as one might get from dental sources, but available data suggest that such exposures produce minimal effects, if any.

Pesticides

Pesticides represent a unique segment of the chemical market because these products are designed and produced for their toxic effects. Considerable efforts have been devoted to the concept of selective toxicity, in which products are developed with the objectives of toxic action on pests, while affording some advantage to other species. In the United States, pesticides are regulated under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA),[80] which delegates regulatory authority to the EPA. Before a pesticide can be legally used, it must be registered with the Office of Pesticide Programs (OPP). Pesticide registration is the process by which the EPA examines the ingredients of a pesticide; the site or crop on which it is to be used; the amount, timing, and frequency of its use; and storage and disposal practices. The EPA OPP evaluates each pesticide to ensure no adverse effects on humans, nontarget species, or the environment under specified use before initial registration; older, previously registered pesticides undergo reregistration to assess health effects as new information becomes available.

Depending on the toxicity of the marketed product, pesticides are registered for general public use or are classified for restricted use only by a certificated pesticide applicator or under the direct supervision of a certified applicator. Pesticides are restricted from residential or institutional use if the product, as diluted for use, has an oral LD_{50} of 1.5 g/kg or less and restricted for other uses if the product, as diluted for use, has an oral LD_{50} of 50 mg/kg or less.

Certain pesticides have been banned or severely restricted for export or import through the auspices of the United Nations Environment Programme and the Food and Agriculture Organization, which developed internationally accepted guidelines for exchange of information on banned or severely restricted industrial chemicals and pesticides. These guidelines eventually evolved into the United Nations Rotterdam Convention on the Prior Informed Consent Procedure, which lists banned and restricted pesticides.[77]

The Food Quality Protection Act[81] of 1996 amended FIFRA to require evaluation of pesticide safety with consideration of potential aggregate exposures from nondietary and dietary routes. From this mandate, pesticide registrations are being revised. The current status of pesticides is available electronically via a website[82] that the EPA OPP maintains with extensive information regarding pesticide use, regulation, data sources, consumer alerts, and educational materials. The EPA OPP also has supported production of a manual, available electronically,[62] that is designed to provide health professionals with current information regarding health hazards of pesticides.

Insecticides

Most insecticides in common use by the public today fall into two classes based on their mode of toxic action: anticholinesterases, characterized by their inhibitory action on acetylcholinesterase, and pyrethroid insecticides, so named after their origin as pyrethrum extract from flowers of the genus *Chrysanthemum*. Organochlorine insecticides, such as DDT, were widely used from 1945-1969, but have been banned for use in the United States because of their adverse effects, including their biologic and environmental persistence, biomagnification through diet in lipid tissues of higher organisms, demonstrated interaction with estrogen receptors, and enzyme-inducing properties.

The anticholinesterase insecticides are analogues of organophosphate or methylcarbamate esters. Representative structures are shown in Figure 52-7. The mechanism of action of anticholinesterase drugs is described in greater detail in Chapter 8. These compounds inhibit the hydrolytic action of the neurologically essential enzyme system, acetylcholinesterase.[54,61] Anticholinesterases interact with the enzyme in a manner similar to the endogenous substrate, but with turnover numbers several orders of magnitude smaller than the substrate, acetylcholine. This interaction leaves the enzyme phosphorylated or carbamylated and inactive regarding physiologic function. Poisoning results in great overabundance of acetylcholine at cholinergic receptors on autonomic nerves, at the neuromuscular junction, in the adrenal medulla, and in the CNS.

Approximately 100 organophosphate-class insecticides are currently in use in the United States. Many are analogues of phosphorothioic acid; these are activated preferentially in insects to phosphate homologues by oxidative mechanisms. A classic example of differences in toxicity of thio versus oxo organophosphate homologues is exhibited by parathion (rat oral LD_{50} 13 mg/kg)[32] versus paraoxon (rat oral LD_{50} 1.8 mg/

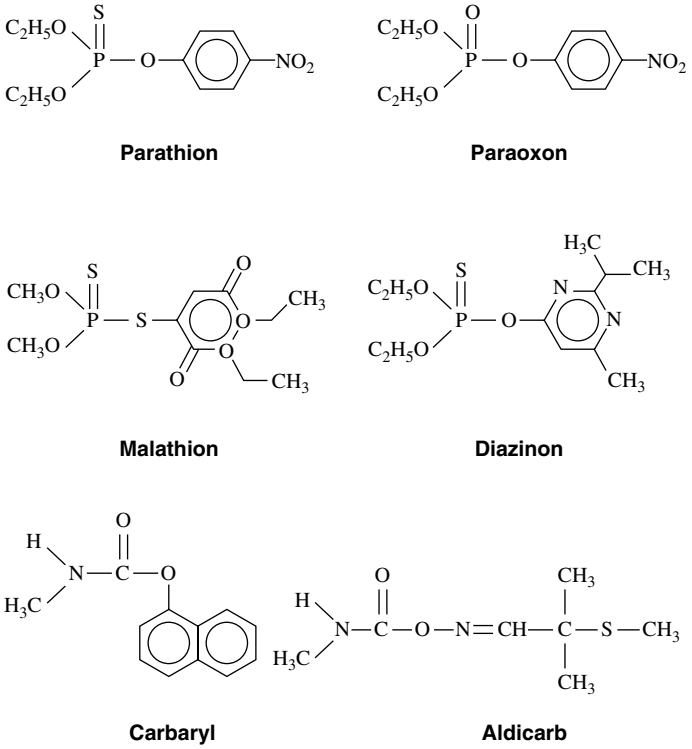

FIGURE **52-7** Chemical structures of organophosphate and methylcarbamate anticholinesterase insecticides.

kg).[60] The venerable compound malathion has been used widely for nonagricultural applications, whereas chlorpyrifos, diazinon, parathion, and terbufos are now restricted to use only by certified applicators.

Of some 22 methylcarbamates in use, carbaryl (rat oral LD_{50} 250 mg/kg)[84] has been used most widely in home and garden applications. It is relatively nontoxic to mammals but is highly toxic to honeybees. In contrast, aldicarb, a methylcarbamate designed with molecular dimensions based on acetylcholine, is much more toxic to mammals (LD_{50} approximately 1 mg/kg).[63] Aldicarb is available only to certified applicators; it is applied to the soil and taken up for systemic action in plants. Treatment of acute anticholinesterase poisoning by either organophosphates or methylcarbamates involves liberal use of anticholinergic drugs, particularly atropine, to antagonize muscarinic cholinergic signs. Pralidoxime has been used successfully to reverse cholinesterase inhibition when used early in cases of organophosphate poisoning, but may aggravate poisoning with methylcarbamate insecticides.[43]

The pyrethroids consist of a group of natural or synthetic compounds that modify properties of ion channels in nerves. Pyrethroids maintain Na^+ channels open for prolonged periods, leading to hyperexcitation of the nervous system. These compounds elicit repetitive nerve activity, particularly in sensory nerves, along with membrane depolarization, enhanced neurotransmitter release, and eventual block of excitation. These actions occur as a consequence of prolongation of Na^+ ion current in voltage-dependent Na^+ channels. The pyrethroids have remarkably selective toxicity for insects relative to mammals. They are largely contact insecticides with rapid "knock-down" properties.

Natural pyrethroids (pyrethrin I, pyrethrin II) are short-lived as a consequence of rapid oxidation and photodegradation in the environment and are rapidly hydrolyzed or oxidized when taken orally. These properties have resulted in rapid acceptance with minimal risk from use, but disadvantages are short duration of action and expense of natural product isolation. Synthetic pyrethroids are designed to be more persistent. These include two types, determined by the presence or absence of a cyano function; two examples are shown in Figure 52-8. Of these, permethrin is stable to light and has low toxicity in adult mammals, but is more toxic to neonates with undeveloped hydrolytic and oxidative mechanisms (rat oral LD_{50} 1500 mg/kg for adults, 340 mg/kg for 8-day-old rats).[9] Other synthetic analogues substituted with a cyano group are more toxic. Cypermethrin, a cyano homologue of permethrin, enables comparison of the effect of the cyano modification (rat oral LD_{50} 250 mg/kg for adults, 14.9 mg/kg for 8-day-old rats).[9] Occupational exposure to pyrethroid insecticides leads to temporary paresthesia and respiratory irritation. Treatment is generally supportive.

Organochlorine insecticides, previously used extensively, are now only of historic importance in the United States, but some are still used in other regions of the world because of their low cost, stability, and efficacy. Figure 52-9 shows structures of some of these organochlorine insecticides. The Nobel Prize for Physiology and Medicine in 1948 was awarded to Paul Mueller, who discovered the insecticidal properties of the prototype, DDT. DDT is a member of the dichlorodiphenylethane subclass of organochlorine insecticides, but is now restricted under the UN PIC (Prior Informed Consent) procedure.[77] The chlorinated cyclodiene structure subclass includes chlordane, dieldrin, and heptachlor, which also are restricted under the UN PIC procedure. Chlordecone and mirex represent another unique subgroup of cagelike, highly chlorinated C10 structures that are restricted from use. The hexachlorocyclohexane-type compounds include lindane, a specific insecticidal isomer that is still used in Kwell shampoo and topical creams as an ectoparasiticide and ovicide for crab and head lice and in certain home and garden pest control products.

The toxic actions of organochlorines, similar to pyrethroids, alter conduction in the ion channels of nerves. DDT alters Na^+ and K^+ ion permeability, Na^+-dependent and K^+-dependent adenosine triphosphatase (ATPase) and Ca^{++}-dependent ATPase functions, and inhibition of calmodulin in nerves. These actions reduce the rate of nerve membrane repolarization and increase sensitivity to small stimuli. The chlorinated cyclodienes are different because their actions seem to be more localized within the CNS. These compounds inhibit Na^+-dependent and K^+-dependent ATPase and Ca^{++}-dependent ATPase and act as γ-aminobutyric acid antagonists, eliciting uncontrolled neurotoxic excitation.[21]

Fumigants

Fumigants may be gases, volatile liquids, or solids that release toxic gas on treatment with water or acid. Typically, fumigants are not selective in toxicity; rather, they are used for their asphyxiant, highly reactive, or cytotoxic properties. Examples of gaseous fumigants include carbon dioxide, which is a relatively nontoxic asphyxiant; ethylene oxide, largely used as a sterilizing agent in the health care industry; and methyl bromide, previously in wide use as a soil fumigant but undergoing phaseout because it is an ozone-depleting agent. Liquids include ethylene dibromide, bromochloropropane, 1,3-dichloropropene, and formaldehyde. Solids that liberate toxic gases for fumigation are zinc phosphide and aluminum phosphide, which produce toxic phosphine. Many fumigants form covalent adducts with important protein structures, including enzymes. 1,2-Dibromo-3-chloropropane, perhaps the best-known occupational testicular toxin, has been banned because of this action. Toxic effects of fumigants have been reviewed with particular attention to mutagenic activities.[28]

Herbicides

Herbicides are the most widely used type of pesticides. Given the broad use of these pesticides with apparently low relative risk in normal use, some herbicides in common use are presented, with selection based on high usage or significant toxicity where evident. Research efforts by crop scientists in recent decades have produced diverse structures, many of which offer selective toxicity against weeds, while sparing economic crops. An example is the use of herbicides in "no-till" production of grains, in which fields are sprayed to kill grasses, and seeds are planted without the need for plowing fields. Structures of some herbicides are illustrated in Figure 52-10.

Atrazine is a member of the class of chemically similar compounds known as the triazine herbicides that block photosynthesis in plants. Atrazine is one of the most widely used agricultural pesticides in the United States. Approximately 80 million pounds of the atrazine active ingredient are applied annually to control broadleaf weeds in field corn and sorghum, in lawns and turf, and after production of wheat. Epidemiologic studies of workers exposed in chemical plants and farming populations have not shown a significant incidence of disease related to atrazine use, and little acute toxicity is evident in suicide attempts with atrazine. Atrazine has undergone review, however, for re-registration by the EPA Health Effects Division.[79] This decision for re-review was based on the high volume of use, persistence of atrazine in surface and ground water, and more recent research indicating that atrazine diminished secretion of hypothalamic gonadotropin-releasing hormone in rats. Previous work[11] had indicated that atrazine given by gavage in high doses altered luteinizing hormone and prolactin serum levels in two strains of female rats by altering the hypothalamic control of these hormones. Subsequent studies at more relevant concentrations in amphibians did not find that atrazine adversely affected amphibian gonadal development.[79]

Glyphosate has broad-spectrum herbicidal activity, sometimes called "total kill," against a wide range of weeds. Glyphosate kills plants by inhibiting an essential plant enzyme involved in biosynthesis of aromatic compounds, which is absent in nonplant life forms. As a result, under normal use glyphosate is practically nontoxic to mammals, aquatic organisms, and avian species. Irritation of the oral mucous membrane and gastrointestinal tract was frequently reported with ingestion of the concentrate. Other effects recorded were pulmonary dysfunction, oliguria, metabolic acidosis, hypotension, leukocytosis, and fever. Various reviews, which indicated absence of toxicity in long-term animal studies of glyphosate, have been summarized.[90]

Chlorophenoxy compounds, typified by 2,4-dichlorophenoxyacetic acid (2,4-D) and 2-(2-methyl-4-chlorophenoxy)propionic acid, are used to control broadleaf weeds. They act as stimulants of uncontrolled growth in plants by mimicking and disrupting the actions of plant growth regulators such as indole acetic acid. In animals 2,4-D exhibits various mechanisms of toxicity, including uncoupling of oxidative phosphorylation, damage to cell membranes, and disruption of acetyl coenzyme A metabolism. Ingestion of large doses can cause nausea, gastrointestinal hemorrhage, hypotension, muscular twitching and stiffness, metabolic acidosis, and renal failure. Significant dermal exposure and occupational inhalation are associated with progressive sensory and motor peripheral neuropathy.[8] One analogue, 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), was removed from use in the United States in 1979 because of its contamination with the toxic by-product, 2,3,7,8-tetrachlorodibenzodioxin, as previously noted. Agent Orange, the notorious herbicide used in the Vietnam War, was a 50:50 mixture of 2,4-D and 2,4,5-T.

Nitrophenolic compounds formerly used as herbicides, such as dinitrocresol and dinitrophenol, are highly toxic to humans and animals, with LD_{50} values in the range of 25 to 50 mg/kg.[62] These stimulate energy metabolism in mitochondria by uncoupling oxidative phosphorylation; this leads to hyperthermia, causing profuse sweating, fever, thirst, and tachycardia. Because of this toxicity, the registrations for herbicidal uses of dinitrocresol and dinitrophenol and similar compounds have been canceled. In contrast, certain dinitroaminobenzene herbicides, including butralin, oryzalin, and pendimethalin, and fluorodinitrotoluidine derivatives, such as benfluralin, dinitramine, fluchloralin, and trifluralin, do not uncouple oxidative phosphorylation or generate methemoglobinemia. These herbicides inhibit cell division in plants. Acute oral LD_{50} values are equal to or greater than that of fluchloralin (1550 mg/kg), and some are greater than 10,000 mg/kg.

Paraquat is the most important dipyridyl herbicide for consideration because it has delayed, severe, and specific pulmonary toxicity. Paraquat exhibits its particular and unique toxicity (LD_{50} in humans of approximately 3 to 5 mg/kg)[62] in part because of its selective accumulation in lung tissue by a diamine transport system located in the alveolar epithelium. In addition, paraquat is involved in a single-electron cyclic

FIGURE **52-11** Treatment of cyanide poisoning. Cyanide *(CN^-)*, whether inhaled or ingested, combines with ferric ions *(Fe^{+++})* in cytochrome oxidase to inhibit cellular respiration. Therapy is aimed at eliminating cyanide from the cells by a two-step process: (1) Sodium nitrite *($NaNO_2$)* is administered intravenously to oxidize the iron in hemoglobin from the ferrous *(Fe^{++})* to the ferric state; the methemoglobin that is formed competes for cyanide, freeing cytochrome oxidase from attack by cyanide. (2) Cyanide is inactivated by the administration of sodium thiosulfate *($Na_2S_2O_3$)* to yield thiocyanate *(SCN^-)*, which is readily excreted in the urine. Experimentally, these steps reduce the lethal potency of cyanide by 80%.

reduction-oxidation reaction that attacks unsaturated lipids in membranes to form lipid peroxides.[71] The oxidative destruction and subsequent fibrotic lesions developed during reparative processes lead to severely diminished lung function, anoxia, and death days after ingestion of paraquat. The comprehensive treatise by Ellenhorn and associates[24] presents pharmacokinetic plots indicating likely survival or death based on blood concentrations versus time after ingestion.

Predicides

Predicides are pesticides used to control predatory animals such as coyote, fox, and wild dog populations that are likely to prey on livestock, poultry, or endangered species or that are vectors of communicable diseases. Sodium cyanide, which liberates hydrogen cyanide, is one such predicide, and this is the only current registered use for sodium cyanide as a pesticide. Because of its extreme toxicity, sodium cyanide is restricted to use only by trained applicators. Cyanide inactivates cellular oxidative phosphorylation by binding to the Fe^+ in the cytochrome a-a_3 complex. The inability of cells to use oxygen, particularly in the brain and heart, is rapidly lethal to warm-blooded animals. Therapy for poisoning involves treatment with 100% oxygen and rapid provision of an alternative, less critical source of Fe^{+++} for cyanide binding. This is accomplished by inducing methemoglobinemia by administering amyl nitrite or sodium nitrite. This is followed by treatment with sodium thiosulfate solution to assist conversion of cyanide to thiocyanate by the mitochondrial enzyme rhodanese (Figure 52-11).

Rodenticides

Various compounds have been used to attack rodents. Some are quite toxic to rodents, humans, and wildlife through acute exposure, whereas others require multiple doses to elicit significant toxicity. Most of these act as anticoagulants, and their structures are shown in Figure 52-12. The oldest, warfarin, is a coumarin derivative that has been used as a rodenticide since 1950. Warfarin derives its action through antagonism of vitamin K action as a cofactor in synthesis of coagulation factors (see Chapter 31). Warfarin exhibits LD_{50} values in the range of 9 to 100 mg/kg in rats, with females being more susceptible.[4] Other multiple-dose anticoagulants are derivatives of 1,3-indandione. These include diphacenone (LD_{50} approximately 2.5 mg/kg) and chlorophacinone (LD_{50} approximately 6.2 mg/kg).

Resistant strains of rodents have emerged, which has led to development of new hydroxycoumarin derivatives (so-called "superwarfarins") that are much more potent and do not require repeated doses to kill. Brodifacoum (LD_{50} approximately 0.5 mg/kg) and bromadiolone (LD_{50} approximately 0.7 mg/kg) are characterized as single dose in use.[4,83] Necropsies after poisonings support the diagnosis of coagulopathy with findings of hemoperitoneum, hemothorax, and pulmonary hemorrhage. Because of the increased potency and increased duration of action in some of these newer rodenticides, poisoning has occurred in pets, wildlife, and exposed humans.[73] Treatment is based on assessment of prothrombin time, which should be monitored at 24 hours and 48 hours after ingestion. If prothrombin time is elevated at these times, treatment with phytonadione (phylloquinone, vitamin K_1) should be instituted with continued assessment of prothrombin time over 4 to 5 days.[62] Other compounds in use as single-dose rodenticides include strychnine, zinc phosphide, and bromethaline, which is a dinitroaniline derivative that uncouples oxidative phosphorylation.

CHAPTER 53

Geriatric Pharmacology

MARC W. HEFT AND ANGELO J. MARIOTTI

With the demographic change that has resulted in a "graying" of the population, a compelling interest in the health and health concerns of older adults has arisen. The increasing incidence and prevalence of systemic diseases among older adults, especially chronic diseases, and the concomitant increase in medication use have provided the impetuses for the subspecialty of geriatric pharmacology. Although it has long been apparent that some reduction of drug dosage is appropriate because children are smaller than adults, it was not understood until more recently how elderly patients differ from younger adults. Some misconceptions about aging are widely held, such as the idea that senility or a progressive increase in blood pressure are normal outcomes of aging. Geriatric pharmacology did not emerge out of a specific incident, as occurred with the thalidomide disaster, which highlighted the fetus as an area of special concern for the pharmacologist. Rather, the field of geriatric pharmacology has developed out of changes in demographics that have been accompanied by an increasing knowledge of and sensitivity to the special physiologic, pharmacologic, pathologic, psychological, economic, and emotional problems of older adults.

In 2008, the elderly—individuals 65 years old or older—numbered 38.9 million and represented 12.8% of the U.S. population[60]; by 2030, they are expected to represent 20% of the population and number approximately 72 million. Not only is the total ≥65 years group growing faster than the population as a whole, but between the years 2003 and 2030 the group 85 years old and older is expected to increase from 4.7 million to 9.6 million.[61]

Of special interest to dentists is the fact that the newer cohorts of older adults are and will be in better oral health than before.[21,43] The rate of edentulousness has declined,[39,62,63,70] and the number of retained teeth among dentate adults has increased.[29,37,39,62,63] With this trend among dentate older adults has emerged an understanding that this population has similar needs for routine restorative and periodontal treatments as younger adults.[20,29,63] An increasing number of elderly individuals will need the kind of dental treatment that was formerly rare in elderly patients. This treatment requires, among other things, antianxiety drugs, analgesics, local anesthetics, and anti-inflammatory drugs. The dentist will be confronted by an increasing number of ambulatory, community-dwelling elderly patients with a significant burden of systemic disease and medication use.

Normative aging studies have shown that healthy elderly individuals are substantially and measurably different from their younger counterparts. More recently, pharmacologists have begun to appreciate how these changes affect the pharmacokinetics and pharmacodynamics of drugs.

As people age, they are more likely to be seen at the dental office with various diseases, especially chronic diseases, for which they take numerous drugs that are strong in effect and potentially toxic. Americans 65 years old and older take a disproportionately high percentage of all drugs prescribed.[13,44] Studies of ambulatory populations indicate that although 80% to 90% of older adults take at least one medication, most take two or more. The most commonly used drugs are agents affecting the cardiovascular system, analgesic and anti-inflammatory drugs, psychotherapeutic medications, and gastrointestinal preparations such as laxatives and antacids. Approximately 40% of the medications are prescribed to patients to be taken "as necessary," with an average of three drugs per patient.[47,50]

The number of medications prescribed to individuals of any age increases the risk of adverse drug reactions, drug interactions, and other health-related problems associated with the use and misuse of medications.[27,47,50] Potential problems in older adults are compounded by age-related physiologic changes that may place these individuals at greater risk. The misuse of medications among elderly patients is considered a major health care problem.[19,41,50] Finally, many segments of society, not the least important of which are health care providers, have become sensitized to the nonmedical problems common among elderly individuals (loneliness, depression, poverty, poor nutritional status) and have come to understand how these can complicate therapeutic management.

This chapter presents a view of geriatric pharmacology that deals mainly with alterations in drug responsiveness that can be attributed directly to aging. The psychosocial factors that indirectly influence the way elderly individuals use and react to drugs are addressed only briefly.

PHYSIOLOGIC CHANGES ASSOCIATED WITH AGING

Studies of the aging process in community-dwelling, healthy (presumed disease-free) individuals have provided insights into the process of biologic aging. These studies have been either cross-sectional studies, in which different-aged individuals are assessed at the same point in time, or longitudinal studies, in which the same individuals are assessed at different times as they "age in place." Although the former studies are easier and quicker to complete, they limit inferences to age differences rather than age-related changes because of the limitations in controlling for and measuring individual differences in biology and behavior. Results of cross-sectional and longitudinal studies have reported a gradual decline in performance from the third decade through the seventh and eighth

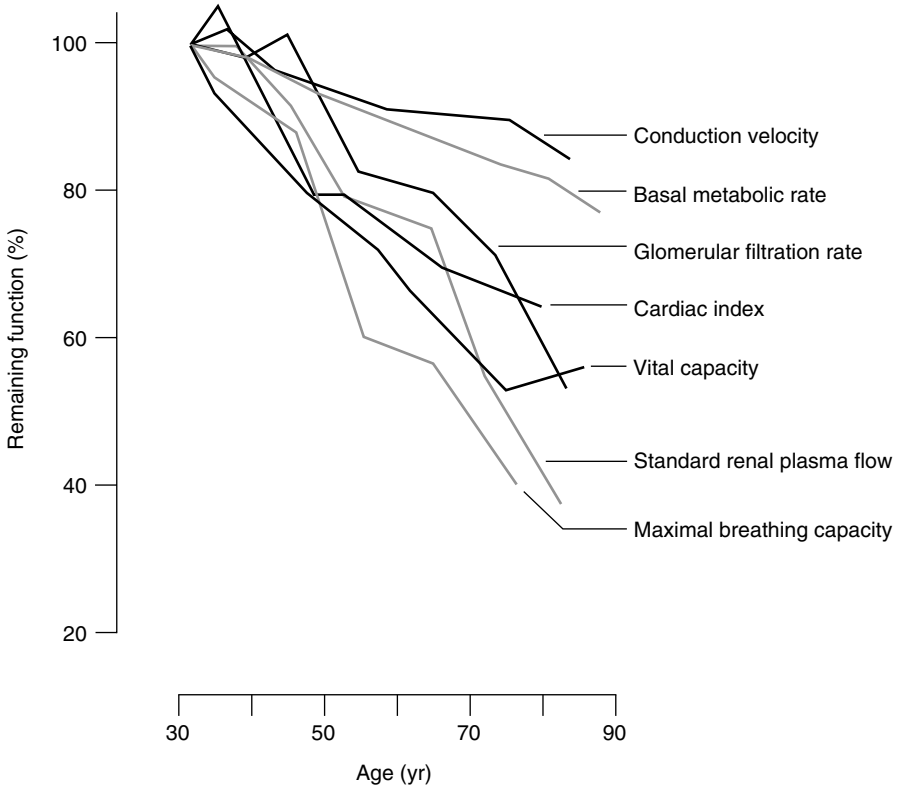

FIGURE **53-1** Influence of age on measures of physiologic function beginning at age 30 (100% of remaining function). (From Miller RD: Anesthesia for the elderly. In Miller RD, editor: *Anesthesia*, ed 2, New York, 1986, Churchill Livingstone.)

decades in a broad range of physiologic functions, including renal function, pulmonary function, cardiac function, and nerve conduction velocity (Figure 53-1).[54]

Findings from these studies have shown that (1) broad individual intersubject differences exist in the rate of aging; (2) not all organ systems age at the same rate; (3) the pattern of age-related declines in organ systems can vary among individuals; (4) with increasing age, greater variability in measures of organ function occurs among individuals within an age cohort; (5) age-associated declines are greater in more complex integrative functions (e.g., maximum breathing capacity) than in basic functions (e.g., the velocity of propagation of a nerve impulse along a nerve); and (6) the latency and capacity for achieving adaptive responses are greater and smaller for older individuals compared with younger individuals. Variability is a cardinal feature of the aging process. At least some of the apparent decline in functioning may reflect changes in lifestyle rather than chronologic aging per se (e.g., declining muscle mass associated with the adaptation of a more sedentary lifestyle).

Table 53-1 summarizes age-related changes in drug disposition that have potential importance to drug use. These alterations affect the absorption, distribution, biotransformation, and excretion of drugs; the specific features of these changes are considered later. A well-documented decline in homeostatic competence occurs in elderly individuals, which accounts for the increased incidence of postural hypotension with age,[10] the increasing sluggishness of thermoregulation, and the fact that elderly individuals are less able to compensate rapidly for the hypotensive effects of an antihypertensive drug.[24] Elderly individuals undergo physiologic changes that can be characterized as normal concomitants of the aging process, but they also experience changes related to disease and medication. Aging represents an interplay among the physiology of aging, disease, and the cumulative effects of behavioral and lifestyle choices (e.g., sedentary living and tobacco use versus regular exercise and abstention from tobacco); as a result, the elderly population is a more heterogeneous population than that of children between birth and puberty.[65]

NONPHYSIOLOGIC ASPECTS OF AGING

Multiple Disease States

Elderly individuals have more health problems, especially chronic diseases and conditions, than younger individuals. Table 53-2 lists the most prevalent chronic conditions among older adults. Some of these diseases are degenerative (e.g., cataracts, detached retina), others are caused by cumulative exposure to environmental contaminants (e.g., cases of chronic obstructive pulmonary disease and cancer), and still others are the consequence of changing metabolic processes commonly seen in aging (e.g., decreased bone density with increasing age). Older adults have an increased incidence of all varieties of heart disease (e.g., arrhythmias, myocardial infarction, valvular disease), renal disease, atherosclerosis, arthritis, diabetes, osteoporosis, and various gastrointestinal problems. They also experience declines in humoral-mediated and cell-mediated immune responses (leading to a decreased resistance to infectious diseases) and various sensory and musculoskeletal impairments. More than four out of five individuals 65 years old and older have at least one chronic illness, and multiple coexisting conditions are common. The leading chronic health conditions for this age group are arthritis, hypertensive disease, and heart disease.[2,12]

Although elderly individuals represent less than 13% of the population, they account for 30% of hospitalizations[23] and 32% of drug use.[17] The symptoms of disease in older adults may often manifest differently in elderly individuals compared with younger individuals. Infections are sometimes manifested by tachycardia instead of fever in older individuals. Transient or episodic symptoms may be forgotten, misreported, or misinterpreted.

TABLE **53-1**

Summary of Age-Related Changes That Affect Drug Disposition in Older Adults

PHARMACOKINETIC PROPERTY	PHYSIOLOGIC CHANGE	POSSIBLE INFLUENCE ON DRUG EFFECT
Absorption	↑Gastric pH	Increased absorption of drugs inactivated by stomach acid
	↓Absorptive surface	Minor effect
	↓Splanchnic blood flow	Minor effect
	↓Gastrointestinal motility	Minor effect
Distribution	↓Cardiac output	Impaired delivery of drugs to organs of greater acute elimination; effects on CNS
	↓Total body water	Increased concentration and effect of drugs distributed in body water
	↓Lean body mass	Increased concentration and effect of drugs distributed in lean body mass
	↓Plasma albumin	Increased effect of, and interaction between, drugs extensively bound to albumin
	↑α_1-Acid glycoprotein	Minor effect
	↑Body fat	Increased sequestration of lipophilic drugs in fat
Metabolism	↓Hepatic mass and enzyme activity	Decreased phase I metabolism of some drugs
	↓Hepatic blood flow	Decreased metabolism of drugs normally rapidly cleared by the liver
Excretion	↓Renal blood flow	Decreased renal elimination of water-soluble drugs and metabolites
	↓Glomerular filtration rate	Decreased renal excretion of water-soluble drugs and metabolites
	↓Tubular secretion	Decreased renal elimination of drugs and metabolites actively secreted into urine

CNS, Central nervous system.

TABLE **53-2**

Rank Ordering and Prevalence of Selected Reported Chronic Conditions

	PREVALENCE BY AGE (IN YEARS)		
CONDITION	**65-74**	**>75**	**ALL AGES**
Arthritis	444.7	550.4	129.9
Hypertension	372.6	373.6	121.5
Hearing impairment	273.7	380.7	90.8
Heart disease	271.8	333.6	84.1
Chronic sinusitis	176.2	167.8	139.7
Cataract formation	118.1	246	25.3
Deformity or orthopedic impairment	151.4	176.6	111.6
Diabetes	95.2	87.8	25.8
Visual impairment	67.4	127.6	34.7
Tinnitus	89.4	75.1	26.4

Prevalence data (no. cases/1000 persons) from Adams PF, Hardy AM: *Current estimates from the National Health Interview Survey, 1988. Vital and health statistics,* Series 10, No. 173, Hyattsville, MD, 1989, US Department of Health and Human Services.

Numerous studies have shown that older adults, because of the higher prevalence of chronic disease, are the principal consumers of drugs.[44,48] Their use of over-the-counter and prescription medications for the treatment of chronic diseases has dual implications. These agents can provide a cure or palliative treatment of a disease in a nontoxic and economical manner. Because of the age-related changes in physiologic status and age-dependent and age-related diseases,[9] however, medications can induce adverse reactions that can be a major source of morbidity or mortality.[27,49]

Adverse Drug Reactions

The incidence of adverse drug reactions among older adults is much greater than among younger individuals; this increase is related mostly to polypharmacy (multiple drug use). Other important factors in the occurrence of adverse drug reactions include multiple diseases (especially chronic diseases), hepatic or renal insufficiency, small body size, malnutrition, and previous drug reactions. Important adverse reactions include side effects (e.g., dry mouth with tricyclic antidepressant medication), drug allergy (e.g., pruritus or hives), and toxic reactions (e.g., digitalis toxicity).[35] Toxic reactions are especially important in older adults and may be caused by a broad range of potential pharmacodynamic changes (age-related changes in drug sensitivity) or pharmacokinetic changes (including decreased renal function and changes in lean body mass and water content).

Adverse drug reactions can be categorized into two principal groups: unexpected and unpredictable versus predictable and preventable. An unexpected, unpredictable reaction is an unwanted consequence of drug administration that occurs at appropriate doses for prophylaxis, diagnosis, or therapy. Examples of such reactions include allergic responses, idiosyncratic reactions, and secondary pharmacologic effects. In contrast, predictable, preventable drug reactions involve an unwanted consequence of drug administration that occurs because of failure in decision making by the health care provider. Failure by the physician or dentist to choose the appropriate agent can occur, as in prescribing the wrong drug for a disease or prescribing a drug with known potential adverse effects in a susceptible patient.

Because most adverse drug reactions are preventable, the clinician should be aware of the patient's medical history, drug history, current list of medications (over-the-counter and prescribed), the pharmacologic characteristics of each agent used, and any abnormal physiologic factors that can affect drug action. Although the incidence of adverse reactions increases among older patients in part because of polypharmacy, actions of a single powerful agent can produce severe

TABLE **53-3**

Age-Related Increased Risk of Toxicity with Commonly Prescribed Dental Agents

DRUG	INCREASED RISK FOR ELDERLY PATIENTS
Clindamycin	Diarrhea and colitis
Metronidazole	Toxic plasma concentrations (patients >70 yr old)
Cephalosporins	Impaired clotting mechanisms and bleeding problems
NSAIDs	Compromised renal and gastrointestinal function
Opioid analgesics	Increased plasma half-life, respiratory depression
Glucocorticoids	Muscle wasting and osteoporosis with long-term therapy
Benzodiazepines	Impaired memory and decrements in psychomotor performance

adverse reactions for elderly patients. Many drugs commonly prescribed by dentists can produce various harmful reactions in patients. As illustrated in Table 53-3, various drug classes can be of potential risk to older patients. Cephalosporins commonly prescribed to treat infections can produce deleterious effects. Cefoperazone, cefamandole, and cefotetan can prolong prothrombin time and partial thromboplastin time, which can impair hemostasis.[16,46] Other antibiotics, such as clindamycin, can markedly increase the incidence of gastrointestinal problems such as diarrhea and colitis in patients older than 60 years.[26,45]

In addition to antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs) can cause morbidity in elderly patients. NSAIDs are commonly used for postoperative pain control in dental practice; however, NSAID use among older adults can be problematic, as documented by associations of NSAID intake with impaired renal function, gastrointestinal toxicity, or hypertension.[1,7,28] Traditional alternatives to NSAIDs have included the use of cyclooxygenase-2 (COX-2) inhibitors such as celecoxib. Because NSAIDs inhibit the COX-1 and COX-2 pathways, the use of selective COX-2 inhibitors provides anti-inflammatory and analgesic properties with less gastrointestinal toxicity.[55] Although drugs with COX-2 selectivity do not have the same adverse gastrointestinal effects of NSAIDs, more recent results showing other adverse reactions with COX-2 agents have brought concern that an increased risk of heart attack, thrombosis, and stroke may be associated with these agents (e.g., rofecoxib [Vioxx] was removed from the market in 2004 because of these issues).

Another dilemma encountered by older adults that complicates their dental treatment plan involves medications that may cause xerostomia. Drug-induced xerostomia is a concern because (1) older adults take prescription and nonprescription medications at a higher rate than the general population, (2) numerous medications have xerostomic potential (>400 medications have been implicated), and (3) the oral health sequelae of xerostomia are consequential. Xerostomia induced by sympathomimetics, diuretics, anticholinergics, tricyclic antidepressants, antihistamines, anti-Parkinson drugs, psychotropic agents, cardiovascular agents, and muscle relaxants can greatly impair oral health and function.[57] Potential sequelae of xerostomia include rampant dental caries, periodontal problems, difficulty in speech and swallowing, mouth soreness, impaired denture retention, greater likelihood of oral infection, and altered sense of taste.[18,42]

Polypharmacy is a special attribute of drug use among older adults. One fourth of hospitalized patients older than 65 years receive six or more drugs daily[56]; older adults average 13 prescriptions per year[32]; and approximately 90% of patients 75 years old and older take drugs regularly, with more than one third taking three or more drugs daily.[33] The major consequence of multiple drug use is an increased incidence of adverse drug reactions. These adverse drug reactions result from many factors, including incorrect identification of medications, multiple prescriptions from more than one health provider (because of a lack of awareness or communication among providers), and the use of medications prescribed for someone else.

Because most adverse drug reactions are preventable, dentists should take advantage of available resources to minimize the likelihood of these untoward sequelae. Consultation with other health professionals (including physicians and pharmacists) or use of a comprehensive drug reference book assists in determining the appropriate drug and dose schedule. In addition, computer-based data retrieval systems and newsletters can keep the dentist informed regarding appropriate drug selection. Finally, the dentist should always be aware and concerned about the onset of new symptoms that do not normally arise from the anticipated course of the disease process but do occur after dental treatment.

Adverse drug reactions in older adults are largely preventable. A sound approach to avoiding adverse drug reactions involves (1) understanding the physical and psychosocial changes that occur in older adults, (2) knowing the pharmacokinetics and pharmacodynamics of the medications a patient is taking and medications the dentist is planning to use or prescribe, (3) evaluating the existing prescription drug burden of a patient when considering further prescription needs, (4) prudent drug monitoring, and (5) careful record keeping.

Patient Compliance

Patient compliance can be a major source of medication errors. Ample evidence exists that a substantial percentage of elderly patients make serious or potentially serious medication errors.[22] Failure to comply with drug regimens consists of omitting medications; using medications not prescribed by the physician or dentist; and making errors of dosage, sequence, and timing. Problems especially identified with elderly patients that contribute to compliance errors include poor comprehension and memory, deficits in vision and hearing, financial restrictions, inability to cope with the environment, self-neglect, cultural attitudes, and physical obstacles to getting medications out of the bottle (particularly child-resistant containers) and self-administering them. Whenever possible, unnecessary medications should be eliminated, and drugs with simplified dosing schedules should be selected. Prescription strategies by the dentist, including written instructions, use of drugs that require fewer doses per day (e.g., doxycycline instead of tetracycline), selection of less expensive generic alternatives, and packaging of drugs in easy-open daily dosing boxes, may increase the likelihood of compliance.

Psychosocial Factors

Any discussion of geriatric pharmacology would be incomplete without mention of the various psychosocial and economic challenges that frequently confront elderly individuals. Although elderly individuals no longer inevitably have a serious reduction in income, 10.5% live in poverty, and elderly single women (14% are below the poverty line) are worse off than men or couples. Poverty rates are higher for elderly African Americans (25%) and Hispanics (24%) than for elderly whites (9%).[59] Elderly individuals may also live in increasing isolation, away from families, children, and spouses, and have depression, loneliness, and sometimes senility. They

also receive three times as many prescriptions for psychotropic drugs as do younger people, even though they are more vulnerable to the adverse effects of these drugs and take twice as long to recover from the adverse effects than do young patients.[31]

This constellation of factors places older adults at risk for many problems, including inadequate diet, poor nutrition, unintentional weight loss, forgetfulness and inattention to medical and pharmacologic needs, and an inability or lack of desire to fill prescriptions and take them as directed. One widely held belief about elderly adults is that their nutritional status is compounded by losses in salivary secretory ability and taste acuity that are presumed to occur with aging and naturally interfere with the enjoyment of food. Although some studies showed a decrease in parotid gland secretion, salivary amylase activity and morphologic age-related changes in the salivary gland, most studies have not found a diminution of salivary flow in older individuals,[4,5] and the decline in gustatory function is at most modest among elderly individuals.[69] Pathologic aging may have an adverse effect on salivary function, and many of the drugs and treatments to which an older individual is subject can cause xerostomia of varying degrees of severity.

PHARMACOLOGIC CHANGES ASSOCIATED WITH AGING

Two basic mechanisms have been developed to explain age-related differences in drug effects.[35] The pharmacodynamic mechanism suggests that changes in drug responsiveness account for such differences.[8,25] These changes presumably involve either an alteration in the number or activity of receptors on the target cell or a change in intracellular responses to receptor activation. Documentation in support of this mechanism is modest, involving only a few drug classes. The more widely accepted pharmacokinetic mechanism suggests that age differences in drug response are related to changes in drug disposition as a result of alterations in drug absorption, distribution, metabolism, excretion, or combinations of these processes. A general review of these factors with particular regard to aging is provided.

Pharmacokinetics of Drugs

Absorption

Most medications prescribed to patients living independently are taken orally. These medications are absorbed through the gastrointestinal tract. The documented age-related alterations that might predispose older adults to potential declines in absorption are increased gastric pH, decreased absorptive surface, decreased gastric emptying, decreased splanchnic blood flow, and impaired intestinal motility.[6,40] Little evidence exists, however, to support an age-related decline in absorption.[25] Decreased stomach acidity could improve absorption of drugs normally inactivated by stomach acid. An important consideration for patients of all ages is the possible interaction of medications with food. The absence of food in the gastrointestinal tract improves the efficiency of absorption of some drugs, such as erythromycin. The absorption of other medications is relatively unimpaired.[35] Although food-drug interactions are not a problem of aging per se, they are important in older adults, who have a heavier medication burden.

Distribution

The distribution of a drug to potential receptor sites occurs after absorption of the drug through the gastrointestinal tract and then into the bloodstream. Distribution is influenced by body composition (lean body mass, body water, and adipose tissue mass), plasma protein binding (particularly albumin), and blood flow to organs. The documented age-related changes that might affect drug distribution in older patients include decreased lean body mass, decreased body water, increased body fat, decreased cardiac output, and decreased albumin level.[40]

The change in lean body mass may reflect other factors, including a potential lifestyle change in physical activity or dietary change, rather than an aging effect per se; nevertheless, this consistent finding in older adults must be considered when evaluating a patient. The net effect is a decrease in lean body mass and total body water and an increase in total body fat. The respective volumes of distribution for water-soluble medications and fat-soluble medications are decreased and increased.[40] Water-soluble drugs, such as acetaminophen, ethanol, digoxin, and cimetidine, are distributed in a smaller volume in older individuals and have higher concentrations at the same dose.[25,40] Similarly, more lipid-soluble drugs, such as diazepam and lidocaine, are more widely distributed (yielding a lower concentration at the receptor site) and have a longer terminal half-life in older adults.[25,40]

Although decreased plasma titers of albumin are probably not a concomitant of aging, they may accompany chronic disease seen in an aging population. A decrease in plasma albumin increases the availability of highly bound drug, effectively increasing the drug concentration at the receptor. A higher concentration of free drug in the plasma has been shown for salicylic acid, metronidazole,[36] and phenytoin, but not for warfarin.[64] Theoretically at least, in situations of reduced plasma albumin, therapeutic and toxic effects should be achieved at lower blood concentrations for drugs that are extensively protein bound.[68] This effect may be especially important with malnutrition. Many drugs have no documented age-related difference in protein binding; two examples are diazepam and penicillin G.[14]

Metabolism

The metabolism of most drugs begins with the obligatory passage through the liver after absorption from the gastrointestinal tract. Hepatic metabolism depends on hepatic blood flow, the liver enzymes responsible for biotransformation of the drug, and genetic factors that influence the hepatic enzyme system.[35,40] The reported age-related declines that might be responsible for altered drug disposition include decreased liver mass and decreased hepatic blood flow.[40] Biologic variability, drug use, behavioral factors (e.g., smoking or alcohol use), or a combination of these factors may exert a greater effect than age on hepatic metabolism.

The documented age-related effects may impair the efficiency of the phase I pathways of metabolism—oxidation, reduction, and hydrolysis. The phase II pathways of glucuronidation, acetylation, and sulfation are unaffected.[40] For drugs that are rapidly cleared by the liver, the rate-limiting step in biotransformation is the hepatic blood flow. The metabolism of drugs with high clearance, such as propranolol, is reduced when hepatic blood flow is reduced. Caution should be exercised with concurrent administration of drugs (e.g., some antiarrhythmic medications) that may reduce hepatic blood flow. For drugs with low clearance, metabolism depends on the efficiency of the hepatic enzyme systems. Some benzodiazepines (e.g., desmethyldiazepam) that depend on microsomal oxidation have a prolonged half-life, whereas others (e.g., lorazepam) that undergo conjugation are unaffected by age.

The clinician should also consider the route of administration when assessing the potential for hepatic metabolism. The preceding discussion presumes the oral route of administration, which involves the absorption of the drug from the gastrointestinal tract and then transport through the liver via the hepatic portal circulation. The parenteral route of admin-

istration may eliminate the liver as the organ primarily influencing disposition of the drug.

Excretion

The elimination of drugs by the kidney provides the eventual pathway for removal of most medications. The documented age-related changes that might impair kidney function and excretion include decreased renal blood flow, decreased glomerular filtration rate, and decreased tubular secretion.[40] Renal function is typically evaluated by the creatinine clearance, which has been reported to decline by approximately one third between the ages of 20 and 90 years in the ambulatory, community-dwelling volunteers of the Baltimore Longitudinal Study on Aging.[52] More recent data from the same study have shown, however, that for approximately one third of older subjects, renal function did not decline, and quite variable declines occurred among other older subjects.[34] These latter data underscore the need to establish adequate dosing schedules for medications based on blood concentrations, rather than interpretation of age-adjusted "normative" data.

Drugs that are eliminated primarily unchanged in the kidney include digoxin, gentamicin, amantadine, lithium, nadolol, and lisinopril. Dosages for drugs with a high therapeutic index, such as penicillins and cephalosporins, are usually not adjusted for older adults (in the absence of renal disease or polypharmacy). Dosages for medications with active metabolites, such as the benzodiazepines diazepam and flurazepam, should be adjusted.[25]

The response of elderly patients to drugs is affected by alterations in renal drug clearance and the fact that altered renal function may make them more sensitive to the nephrotoxicity of drugs such as NSAIDs and aminoglycosides. Conversely, the decreased activity of the renin-angiotensin system may blunt the effects of drugs that inhibit renin secretion, such as β-adrenergic blocking agents and angiotensin-converting enzyme inhibitors, diminishing their therapeutic effectiveness in the treatment of hypertension.[38]

The complex and potentially serious alterations in kidney function mandate that consideration be given to renal excretory capacity when prescribing drugs to elderly patients. Although a diminution in renal function that is related to age does occur, kidney disease is not restricted to elderly patients.

Pharmacodynamic Changes

Studies investigating age-related changes in pharmacodynamics are difficult to pursue, and, consequently, scant data exist in this area. Available evidence suggests no global age-related changes in drug sensitivity. Increased sensitivity to certain benzodiazepine anxiolytic medications and decreased sensitivity to β-adrenergic agonists and antagonists have been reported in older individuals.

There are several possibilities for pharmacodynamic alterations in drug reactivity with aging, including a change in the number of receptors, a change in their affinity for the drug, or a change in tissue responsiveness to drug-receptor binding. Discovering which of these possibilities accounts for a particular reaction is difficult because it requires knowledge of receptor number, binding affinity, and quantitation of the sequential steps after the drug-receptor interaction to the final observed response. Experimental evidence exists that one or more of these changes does occur with several groups of drugs, but interpretation of the results of some of these experiments is confounded by the fact that elderly individuals also show decreases in homeostatic competence, speed of performance, thermoregulation, and immunocompetence.

Changes in sensitivity to β-adrenergic agonists and antagonists have been reported in many studies. With the production of cyclic adenosine 3′,5′-monophosphate by lymphocytes as an indicator of responsiveness to isoproterenol in young and old individuals, a decrease in adenylyl cyclase occurs in normal subjects 67 to 90 years old compared with subjects 18 to 27 years old.[15] Sensitivity of young men to isoproterenol and propranolol was shown to be greater than in elderly men, but the well-documented increase in the blood concentration of norepinephrine in elderly individuals may possibly create competition for receptor sites.[66] In a series of investigations involving rat myocardial and human lymphocytic β-adrenergic function, a decreased responsiveness of the β receptors to catecholamines was found, along with decreased adenylyl cyclase activity, but no decline in receptor density.[53]

Increased sensitivity to central nervous system depressants is a recognized fact. In tests involving nitrazepam, age-related decrements in psychomotor performance were described and linked to pharmacodynamic, not pharmacokinetic, changes.[11] Elderly patients who were given diazepam for a surgical procedure required lower doses than younger patients to reach the same level of sedation.[51] This observation has been confirmed in other studies for diazepam and temazepam.[58] Determination of the minimum alveolar concentration for isoflurane showed an 18% decrease in anesthetic requirement in older adults compared with young adults; similar results have been obtained with other anesthetics.[67] In contrast to the generalization that brain function in elderly individuals seems to be inherently more susceptible to disruption by anesthetic drugs, the greater sensitivity of older patients to etomidate seems to result from a decreased initial distribution of the anesthetic after intravenous injection.[3]

In addition to pharmacodynamic changes, the genetic characteristics of an individual may also influence the behavior of drugs in elderly patients. The apparent volume distribution of the acetylator phenotype of isoniazid decreases significantly with age.[30] Pharmacogenetics for elderly patients is important because genetically determined enhancement or impairment of drug action in the body can amplify the toxicity of a drug or diminish the efficacy of a drug.

IMPLICATIONS FOR DENTISTRY

Elderly patients differ from younger patients in ways that have the potential to affect responses to drugs. Changes potentially affecting pharmacokinetics and pharmacodynamics occur during aging, but at this stage in the development of the science of geriatric pharmacology, remarkably few instances of problems with drugs that arise directly from these changes have been documented. Responses to drugs in elderly patients are confounded by multiple medications; pathologic states; compliance errors; and various psychological, sociologic, and economic difficulties that beset older individuals. Some precautions appropriate to dentistry are as follows:

1. Elderly patients usually take more prescription and nonprescription drugs than the general adult population. Drug interactions and adverse drug reactions are more likely to occur with this polypharmacy. The dentist should take a careful history of the patient's medical and pharmacologic status and update it at regular intervals during treatment.
2. Elderly patients are more sensitive than young adults to the depressant effects of drugs. The dosages of analgesics, antianxiety drugs, sedative-hypnotics, and general anesthetics may need to be reduced.
3. Because of the known loss in homeostatic competence, drugs that alter blood pressure, heart rate, and smooth muscle tone should be used with caution in elderly patients. Conversely, immunosenescence may dictate more aggressive antibiotic therapy than normal for the prevention and treatment of infections.

4. Elderly patients are more susceptible to orthostatic hypotension than younger adults. Special attention is called for when elderly patients go from a reclining posture in the dental chair to a standing position.
5. A decline in renal function occurs in healthy elderly patients, and an even greater decrease occurs in patients with kidney disease. This fact should be considered when prescribing drugs whose principal route of elimination is the kidney. Conventionally, dosage intervals are increased in such circumstances, but the dose of the drug or drugs may have to be reduced.
6. The dentist should be aware of the psychosocial considerations for elderly patients and be sensitive to such problems as the expense of the medications and the possibility of forgetfulness and poor compliance. Special packaging, clear labeling, simplified dosage regimens, and recruiting a responsible relative or friend to monitor drug therapy may improve compliance.

CHAPTER 54

Drugs for Medical Emergencies

MORTON B. ROSENBERG

Every dentist can expect to be involved in the diagnosis and treatment of medical emergencies during the course of clinical practice. These emergencies may be directly related to dental therapy, or they may simply occur by chance in the dental environment. In studies surveying the incidence and type of medical emergencies in dental practice, 95.6% of the respondents reported such emergencies. Although most of the reported emergencies were minor (e.g., 53% were syncopal episodes), life-threatening or major emergencies were also described.[14,33] Many medical emergencies occur during the administration of local anesthesia and during painful procedures such as extractions and pulp extirpation.[35] The potential need for acute medical intervention during dental treatment may be increased for practitioners treating a high percentage of elderly patients, patients with special needs, or medically compromised patients, and practitioners using minimal, moderate, or deep sedation and general anesthesia.

It has been postulated that the incidence of medical emergencies in dentistry as a whole is increasing.[34] This increase may be attributed to the following factors:

1. *Increasing age of the general population*. As the number of elderly individuals in the general population increases, the likelihood of encountering a medical emergency as a result of the physiologic and pathologic changes associated with aging also increases. In addition to the normal deterioration of major organ systems that occurs with age, elderly patients are more likely to exhibit chronic clinical manifestations of organ derangement (e.g., angina pectoris, congestive heart failure, chronic obstructive lung disease) that may become acute during the dental visit and require intervention. Elderly patients take more prescription and over-the-counter drugs than young patients, and the effects of these compounds can be significantly different from the effects seen in younger patients. The pharmacokinetics of many drugs are altered by aging; pharmacodynamic and physiologic changes also may result in greater sensitivity to many drugs, especially central nervous system (CNS) depressants (see Chapter 53).[11]
2. *Effect of medical advances*. Advances in the diagnosis and treatment of many medical conditions have permitted an increasing population of compromised patients to survive and seek comprehensive dental treatment. Pharmacologic advances in such diverse areas as cancer, cardiovascular disease, and psychiatric illness and surgical advances such as organ transplants, cardiac valve replacements, coronary artery revascularization, pacemakers, and automatic implantable cardioverter-defibrillators have significant ramifications for dental therapy and can be directly related to acute medical problems in the dental office. In general, the growing number of medically stabilized yet chronically ill patients seeking dental treatment is paralleled by a concomitant increase in the incidence of medical emergencies during dental treatment. Dental advances such as intraosseous implants and comprehensive periodontal treatment combined with extensive restorative dentistry leading to "lifelong dentistry" are attracting older, less healthy patients into the dental environment.
3. *Pharmacologic therapies*. Therapeutic choices for dentists are constantly increasing with the introduction of new generations of antibiotics, analgesics, local anesthetics, and sedative drugs. Each new drug has its own inherent indications, contraindications, and possible side effects. These drugs also have the capacity to interact with each other and with other drugs the patient may be taking for medical conditions. Such drug interactions have the potential to elicit acute adverse reactions during the dental appointment.[36] The growing popularity of herbal supplements and other alternative medical therapies has implications that are just being realized and studied. Many of the side effects of these alternative medical therapies, such as antihemostatic, hypotensive, and hypoglycemic properties, can directly affect dental treatment.[29]
4. *Drug abuse*. Substance abuse is a fact of life in modern society. Many dental patients "premedicate" themselves with prescribed or illicit CNS depressants before dental therapy. These drugs may present acute problems by themselves or interact with drugs administered or prescribed by the dentist.

EMERGENCY PREPARATION

Many chronic medical conditions, such as asthma, congestive heart failure, coronary artery disease, and cerebrovascular disease, may become acute medical emergencies when exacerbated by the stress of the dental appointment. Stress, anxiety, fear, and phobia may cause other minor stress-related emergencies, such as syncopal episodes and hyperventilation syndrome. A thorough preoperative evaluation, meticulous detail to achieving profound local anesthesia in a safe manner, consideration of nonpharmacologic stress reduction protocols, and the use of pharmacologic sedative techniques to minimize pain, fear, and anxiety help reduce this risk.

Preoperative evaluation includes the use of a medical history questionnaire, oral history, review of systems, physical examination, vital signs, and appropriate laboratory tests and consultations. This evaluation should determine the risk/benefit ratio of the contemplated procedure, what drugs

BOX **54-1**

Medical Emergencies of Relevance to Dental Practice

Syncope
Hyperventilation
Angina pectoris
Myocardial infarction
Hypertension
Hypotension
Hemorrhage
Cerebrovascular accident
Grand mal seizure
Insulin shock/diabetic coma
Asthma
Anaphylaxis/other allergic reactions

should be used or avoided, the potential for a medical emergency, and the type of monitoring best suited for the particular patient.

EMERGENCY PREPAREDNESS

Although almost any medical emergency can occur during the course of dental treatment—which means that dental personnel must be prepared to provide effective basic life support (BLS) and seek emergency medical services in a timely manner—dentists must be able to diagnose and treat common medical problems (e.g., syncope or hyperventilation syndrome) definitively and respond effectively to certain less common (or even rare) but potentially life-threatening emergencies, especially emergencies that may arise as a result of dental treatment (e.g., anaphylactic reaction to an administered drug).[9] These emergencies are listed in Box 54-1.

Many factors determine the degree of preparedness for medical emergencies needed in a specific dental practice, but all dental offices must be ready at some minimal level.[30] The use of local anesthesia is an indication for the dentist to be prepared to handle medical emergencies, as evidenced by the following language in product literature approved by the U.S. Food and Drug Administration: "Dental practitioners who employ local anesthetic agents should be well versed in diagnosis and management of emergencies that may arise from their use. Resuscitative equipment, oxygen and other emergency drugs should be immediately available for immediate use."[6] An overall emergency preparedness plan, as outlined in Box 54-2, is essential for every dental practice. Implicit in Box 54-2 is the necessity to develop a team approach in preparing for and responding to medical emergencies in the dental office, with each staff member (receptionist, dental auxiliary, dental hygienist, and dentist) responsible for a specific role.

Preparedness must be individually tailored according to the type of patient treated (e.g., young, healthy patients in an orthodontic practice versus medically compromised patients in a periodontal practice), location (an urban setting where emergency help is close at hand versus a rural location where there may be a significant delay until help arrives), and training (whether the dentist and staff are capable of performing advanced emergency procedures and protocols). Although a comprehensive guide to the pathophysiologic characteristics, prevention, diagnosis, and management of specific medical emergencies is beyond the scope of this chapter, several sources for this purpose are listed in the general references. In practices where sedation or general anesthesia is administered, advanced emergency training and equipment are required and often promulgated by state dental practice acts.

EMERGENCY DRUGS

Although many medical emergencies may be properly treated without the use of drugs, every dental office must contain an emergency kit with drugs appropriate to the training of the individual dentist, the patient being treated, and the type of procedures being performed.[2,18] No drug can take the place of a properly trained health professional and support staff in diagnosing and treating emergencies. Nevertheless, the design and purchase of an appropriate emergency kit often play an integral role in dictating the course and outcome of emergency treatment.

Besides determining which drugs should be included in an emergency kit, the dentist must understand that he or she must maintain the knowledge base to use them. In the midst of a medical emergency, with the patient by definition in an acutely abnormal or even critical situation, there is no time to begin reading labels, leafing through emergency texts, or administering drugs as suggested by a brochure in the emergency kit. In addition, there is a significant difference between the theoretic knowledge of how to treat an emergency and being able to put such cognitive skills to practical use. Constant review and training keeps the dental team sharp. Regular continuing education in medical emergencies, review of new advances in pharmacology, certification and recertification in BLS and advanced cardiac life support (ACLS), and emergency drills are the best methods to prepare for emergencies.

Many states mandate certification in BLS for dental licensure, and in offices that use deep sedation/general anesthesia, training in ACLS is a standard of care. Without prompt attention to the *ABCDs* (*a*irway, *b*reathing, *c*irculation, *d*efibrillation) of cardiopulmonary resuscitation (CPR), drugs are of

little value. The advent of automatic external defibrillators has made early defibrillation an integral part of the BLS "chain of survival" for the treatment of cardiac arrest. Since January 1998, health care provider CPR courses conducted by the American Heart Association include a mandated module on automatic external defibrillator application and use.[7] Some states have begun to mandate the presence of an automatic external defibrillator in general dental offices.

The role of drugs and the type of intervention that should be attempted by a dentist during a medical emergency are controversial issues. If any consequence of dental treatment is foreseeable and results in harm, liability may be imposed.[41] Emergency drugs are generally powerful, rapidly acting compounds. The correct approach to the use of drugs in any medical emergency should be essentially supportive and conservative. In a review covering the use over a 2-year period of 8500 emergency drug systems purchased by dentists, a 0.75% incidence of use was reported.[47]

Emergency kits either can be organized by the individual practitioner or can be purchased commercially. Many dentists are uncomfortable choosing and purchasing individual drugs for their emergency kits, and the purchase of a high-quality, commercially available emergency drug kit modified for dentistry can provide consistent drug availability (i.e., periodic drug updating) in an organized fashion.

There is a general tendency to overequip basic dental emergency kits with drugs that are beyond the needs and expertise of many general dentists. The drugs placed in an office emergency kit should include only drugs familiar to the dentist. Only one agent should be included for each particular need. The fewer drugs in an emergency kit, the easier it is to know their proper use, especially during an emergency.[37] Many authors, state boards of dental registration, commercial vendors, and professional groups have suggested the composition of dental medical emergency kits.[32] The composition of these kits varies greatly and depends on the training and philosophy of emergency care of the creator, whether the kit is dental specific, and whether sedation or anesthesia is used. The definitive pharmacologic features of these drugs are discussed in other chapters.

TABLE **54-1**

Critical Emergency Drugs

DRUG	INDICATIONS	PREPARATIONS
Oxygen	For use in all medical emergencies in which hypoxemia may be present	Steel cylinders (green); E tanks, 690 L
Epinephrine	Acute allergic reactions, acute asthma (not responding to adrenergic inhaler)	Ampules, 1 mg; vials, 1 and 30 mg; syringes, 0.3 and 1 mg
Nitroglycerin	Angina pectoris, acute myocardial infarction	Tablets (sublingual), 0.15, 0.3, 0.4, and 0.6 mg; spray, 0.4 mg/actuation
Albuterol	For bronchodilation	Aerosol, 90 µg/actuation
Glucose	Hypoglycemic episode	Various oral/transmucosal preparations (orange juice, cake icing, cola)
Aspirin	For reducing platelet aggregation	Chewable aspirin, 81-325 mg

Critical Emergency Drugs

All dentists must keep certain drugs readily available in the office in fresh supply for immediate administration (Table 54-1). Dentists must know reflexively when, how, and in what doses to give these specific agents for acutely life-threatening situations.

Oxygen

Oxygen is a primary, if not the primary, emergency drug indicated in any medical emergency in which hypoxemia may be present. These emergencies include, but are not limited, to acute disturbances involving the cardiovascular system, respiratory system, and the CNS. In a hypoxemic patient, breathing enriched oxygen elevates the arterial oxygen tension, which improves oxygenation of peripheral tissues. Because of the steepness of the oxyhemoglobin dissociation curve, a modest increase in oxygen tension can significantly alter hemoglobin saturation in a hypoxemic individual. Hypoxemia leads to anaerobic metabolism and metabolic acidosis, which often adversely affect the efficacy of emergency pharmacologic interventions.

Oxygen can be delivered to a spontaneously breathing patient by full facemask, nasal cannula, or nasal hood. Dental offices also must have the capacity to deliver oxygen via positive-pressure ventilation. Controlled ventilation may be accomplished with the use of a bag-valve-mask device (consisting of a mask, self-inflating bag, and nonrebreathing valve) or with a manually triggered oxygen-powered breathing device (consisting of a mask connected by a valve activated by a lever and high-pressure tubing to the oxygen supply). Each method of providing positive-pressure ventilation requires practice for effective use. Providing a seal around the nose and mouth while ventilating the patient can be difficult with the bag-valve-mask device. The oxygen-powered device is easier to use, but care must be taken not to inflate the stomach. Both techniques are preferred, however, over mouth-to-mouth, mouth-to-nose, or mouth-to-mask techniques.[3] Airway adjuncts such as oropharyngeal and nasopharyngeal airways, endotracheal equipment, laryngeal mask airways, and the means of establishing an emergency airway by cricothyrotomy and transtracheal ventilation can be useful or even lifesaving in the hands of a trained and experienced health professional. Without appropriate training, however, their use may prove deleterious in an acute emergency.

Although oxygen toxicity may occur after prolonged therapy with high concentrations of oxygen, it is not an issue during clinical resuscitation. This statement is true even for the rare patient whose respiratory drive depends on hypoxemia because of chronically elevated carbon dioxide concentrations. If clinically indicated, oxygen should never be withheld during any medical emergency.[8] Inspired oxygen concentrations depend on the delivery system used (Box 54-3).

BOX **54-3**

Inspired Oxygen Concentration with Different Delivery Systems

DELIVERY SYSTEM	INSPIRED OXYGEN CONCENTRATION (%)
Spontaneous breathing	
Nasal cannula	25-45
Facemask	40-60
Positive-pressure ventilation	
Mouth-to-mouth	17
Mouth-to-mask (oxygen flow to mask of 10 L/min)	80
Bag-valve-mask	75-95
Manually triggered, oxygen-powered breathing device	75-95

TABLE **54-2**

Primary Emergency Support Drugs

CATEGORY	REPRESENTATIVE DRUG	PREPARATIONS
Anticonvulsant	Diazepam (Valium)	Ampules and syringes, 10 mg; vials, 10, 20, and 50 mg
Corticosteroid	Hydrocortisone sodium succinate (Solu-Cortef)	Vials, 100, 250, 500 mg, and 1 g
Antihistamine	Diphenhydramine (Benadryl, Benahist, Nordryl)	Ampules, 50 mg; vials, 50, 100, 300, and 500 mg
Respiratory stimulant	Aromatic ammonia spirit (Aromatic Ammonia Aspirols)	Ampules, 0.4 mL

Epinephrine

Epinephrine is the most important injectable drug in the dental emergency kit. Epinephrine is an endogenous catecholamine with α-adrenergic receptor–stimulating and β-adrenergic receptor–stimulating activity. It is the drug of choice for the management of the cardiovascular and respiratory manifestations of acute allergic reactions. The beneficial pharmacologic actions of epinephrine when used in resuscitative dosages include bronchodilation, increased systemic vascular resistance, increased arterial blood pressure, increased heart rate, increased myocardial contractility, and increased myocardial and cerebral blood flow.

For the effective treatment of acute allergic reactions, epinephrine must be administered as soon as the condition is diagnosed. The drug can be injected subcutaneously, 0.3 to 0.5 mL of a 1:1000 solution, or intramuscularly (for a more serious emergency). Epinephrine should be available in preloaded syringes or autoinjectors for immediate use. The intravenous route (slow infusion) is also advocated, but it may induce or exacerbate ventricular ectopy, especially in patients receiving digitalis.

Because of its profound bronchodilating effects, epinephrine is also indicated for the treatment of acute asthmatic attacks unrelieved by sprays or aerosols of β_2-adrenergic receptor agonists. Epinephrine may also be instilled directly into the tracheobronchial tree by an endotracheal tube with good results.[19] Epinephrine is one of the major vasoactive compounds indicated for use during cardiac arrest because of its ability to elevate coronary perfusion pressure.[3,42]

Nitroglycerin

Although nitroglycerin is available in many preparations—long-acting oral and transmucosal preparations, transcutaneous patches, and intravenous solutions—the appropriate forms for the dental office are the sublingual tablet or translingual spray. Nitroglycerin is the treatment of choice for acute angina pectoris. It acts primarily by relaxing vascular smooth muscle, dilating systemic venous and arterial vascular beds, and leading to a reduction in venous return and systemic vascular resistance. These actions all combine to reduce myocardial oxygen consumption. One tablet or spray (0.4 mg) should be given initially. This dose may be repeated twice at 5-minute intervals to a total dose of three administrations. Relief should occur within 1 to 2 minutes; if the discomfort is not relieved, the diagnosis of evolving myocardial infarction must be considered.[53]

Contraindications to the administration of nitroglycerin include patients who are hypotensive and patients who have taken sildenafil (Viagra) recently. The combination of nitroglycerin and sildenafil can lead to profound hypotension and unconsciousness.

Bronchodilator

Inhalation of a β_2-adrenergic receptor agonist, such as metaproterenol, terbutaline, or albuterol, is used in the treatment of acute bronchospasm encountered during asthma and anaphylaxis.[39] Use results in bronchial smooth muscle relaxation and the inhibition of chemical mediators released during hypersensitivity reactions. Albuterol or levalbuterol is an excellent choice because either has fewer cardiovascular side effects than other bronchodilators.

Glucose

Glucose preparations are used to treat hypoglycemia that results either from fasting or insulin/carbohydrate imbalance in a patient with diabetes mellitus. If the patient is conscious, oral carbohydrates, such orange juice, a chocolate bar, cake icing, or a cola drink, act rapidly to restore circulating blood glucose. If the patient is unconscious, and acute hypoglycemia is suspected, intravenous administration of 50% dextrose solution or intravenous or intramuscular administration of glucagon (which increases blood glucose by its effects on liver glycogen) is the treatment of choice. There is no place for insulin in the dental office.

Aspirin

The antiplatelet properties of aspirin have been shown to decrease myocardial ischemia dramatically when administered to patients during an evolving myocardial infarction; aspirin has no substitute for this indication. Contraindications to aspirin use include patients with aspirin intolerance and patients with severe bleeding disorders.[24]

Primary Support Drugs

Primary support drugs are helpful for treating medical emergencies that are usually not acutely life-threatening (Table 54-2). Although dentists do not have to include these drugs in the emergency kit, they all are useful, particularly for situations in which the dentist is familiar with their use and

where emergency medical services may not be immediately available.

Anticonvulsant

Seizures that may require acute medical intervention may be associated with epilepsy, hyperventilation episodes, cerebrovascular accidents, hypoglycemic reactions, or vasodepressor syncope. Local anesthetic overdoses or accidental intravascular injection may also require the administration of an anticonvulsant. Current management of a seizure that interferes with ventilation or persists for longer than 5 minutes includes the use of an intravenous benzodiazepine such as diazepam or the water-soluble benzodiazepine midazolam, which may also be administered intramuscularly.[38,40,48]

Corticosteroid

Corticosteroids are used in the definitive management of acute allergic reactions and acute adrenal insufficiency. The onset of even an intravenous corticosteroid such as hydrocortisone sodium succinate is delayed, but the drug can be useful in halting the progression of a major allergic or anaphylactoid reaction.[46] The dentist may encounter what initially appears to be a syncopal episode but is actually the more serious problem of acute adrenal insufficiency in a patient taking long-term systemic corticosteroids to treat a chronic medical condition or a patient with primary adrenal insufficiency such as Addison's disease. For this life-threatening emergency, prompt diagnosis, BLS techniques, and infusion of corticosteroids are needed.[21]

Antihistamine

Antihistamines such as diphenhydramine are useful in the treatment of minor or delayed allergic reactions and as adjuncts in the management of an acute allergic or anaphylactoid reaction. Adverse effects of antihistamines include CNS depression resulting in sedation, thickening of tracheobronchial secretions, and decreased blood pressure.

Respiratory stimulant

Aromatic ammonia is a pungent, noxious irritant to the mucous membranes and stimulates the respiratory and vasomotor centers of the medulla. It is used as a general arousal agent during syncopal episodes.

Drugs for Advanced Cardiac Life Support

ACLS is the standard of care for comprehensive resuscitation by health care providers with advanced skills and training. Cardiac arrest and sudden cardiac death are major causes of mortality. Pharmacotherapy plays an important role in the management of these patients; guidelines for ACLS provide recommendations for specific drug therapies. These guidelines are constantly reviewed and updated and are now subdivided into ACLS[22] and pediatric advanced life support.[23] Included in this training is the use of many antiarrhythmic and vasoactive drugs (Table 54-3).[10] Training in ACLS is necessary for dentists administering deep sedation or general anesthesia and is often required by state law for providers of moderate sedation. State regulations should be consulted to determine which of the drugs described here must be available in locations where sedation or anesthesia is administered. The greatest changes in the newest ACLS guidelines are reduced emphasis on additional medications, rhythm checks, and any maneuver that interprets chest compressions for more than 10 seconds and the increased emphasis on searching for and addressing the cause for sudden cardiac arrest (Table 54-4).

Pulseless arrest rhythms are divided into shockable and nonshockable rhythms. Shockable rhythms are ventricular fibrillation (VF) or ventricular tachycardia (VT). In VT/VF, definitive therapy consists of basic CPR with electrical shocks. Drug therapy may be administered via intravenous, intraosseous, and endotracheal routes. If VT/VF persists, vasoactive drugs such as epinephrine or vasopressin or both are recommended to facilitate defibrillation. Antiarrhythmics such as amiodarone or lidocaine are also indicated. Nonshockable pulseless arrest rhythms include asystole and pulseless electrical activity. Drug therapy includes epinephrine and vasopressin. If pulseless electrical activity or asystole persists, atropine should be given.

TABLE **54-3**

Advanced Cardiac Life Support Drugs

DRUG	INDICATION
Antiarrhythmics	
Lidocaine	Ventricular tachycardia, pulseless ventricular tachycardia or ventricular fibrillation
Amiodarone	Pulseless ventricular tachycardia or ventricular fibrillation, supraventricular tachycardia (most forms)
Procainamide	Intermittent/recurrent ventricular tachycardia
Verapamil, diltiazem	Atrial flutter or atrial fibrillation, supraventricular tachycardia
Adenosine	Supraventricular tachycardia
Atropine	Bradycardia, asystole, certain types of atrioventricular block
Magnesium sulfate	Torsades de pointes, ventricular fibrillation (if hypomagnesemia is present)
β Blockers (e.g., propranolol)	Atrial flutter or atrial fibrillation, supraventricular tachycardia, refractory ventricular tachycardia
Inotropes	
Epinephrine	Anaphylactic shock, asystole, pulseless electrical activity, pulseless ventricular tachycardia or ventricular fibrillation, bradycardia
Vasopressin	Pulseless ventricular tachycardia or ventricular fibrillation
Norepinephrine	Refractory hypotension
Dopamine	Bradycardia, hypotension
Dobutamine	Congestive heart failure
Isoproterenol	Refractory symptomatic bradycardia, long QT syndrome
Digoxin	Atrial flutter, fibrillation, heart failure
Inamrinone	Refractory congestive heart failure
Milrinone	Refractory congestive heart failure
Vasodilators/Antihypertensives	
Nitroprusside	Hypertension, acute heart failure
Nitroglycerin	Hypertension, acute heart failure, anginal pain
Others	
Sodium bicarbonate	Hyperkalemia, metabolic acidosis with bicarbonate loss, hypoxic lactic acidosis
Morphine	Acute pulmonary edema, pain, and anxiety
Furosemide	Acute pulmonary edema
Thrombolytic agents (e.g., alteplase, streptokinase)	Acute thrombosis

TABLE **54-4**

Advanced Cardiac Life Support Classification of Core Drugs (2005)

DRUG	RHYTHM INDICATION	DOSE	CLASS RECOMMENDATION	COMMENTS
Adenosine	SVT	6 mg	I	Must be administered rapidly. May be repeated at dose of 12 mg for 2 additional doses. In patients taking carbamazepine or dipyridamole, or in cardiac transplant recipients, use initial dose of 3 mg
Amiodarone	Pulseless VT or VF	300-mg IV bolus	IIb	No dilution required. May repeat with 150 mg IV in 3-5 min
	Stable VT	150 mg	IIb	To avoid hypotension, administer over 10 min. Dose may repeated as needed to a maximum 2.2 g/24 hr. One option is to follow the bolus with a continuous 1 mg/min for 6 hr, then reduce to 0.5 mg/min for 18 hr. Supplementary boluses of 150 mg can be repeated every 10 min as necessary for recurrent or resistant arrhythmias
Atropine	Symptomatic bradycardia	0.5 mg IV or IO	IIa	Maximum dose of 3 mg
	Asystole	1 mg IV or IO	Indeterminate	Repeat every 3-5 min, 3 mg maximum
	PEA	1 mg IV or IO	Indeterminate	Repeat every 3-5 min, 3 mg maximum, only indicated if rate is slow
Diltiazem	Atrial fibrillation	0.25 mg/kg	IIa	May repeat dose in 15-20 min at 0.35 mg/kg. Administer over 2 min. Bolus is followed by infusion at 5-15 mg/hr
	SVT	0.25 mg/kg	IIb	May repeat dose in 15-20 min at 0.35 mg/kg. Administer over 2 min. Bolus is followed by infusion at 5-15 mg/hr
Dopamine	Symptomatic bradycardia	2-10 µg/kg/min	IIb	Administer as a continuous infusion
Epinephrine	Pulseless VT or VF	1 mg IV or IO	IIb	Repeat every 3-5 min
	Symptomatic bradycardia	2-10 µg/min infusion	IIb	Administer as a continuous infusion
	PEA	1 mg IV or IO	IIb	Repeat every 3-5 min
	Asystole	1 mg IV or IO	IIb	Repeat every 3-5 min
Ibutilide	Atrial fibrillation	1 mg if ≥60 kg, 0.01 mg/kg if <60 kg	IIb	Administer over 10 min. Dose may be repeated 10 min after completion of first dose
Lidocaine	Pulseless VT or VF	1-1.5 mg/kg IV or IO	Indeterminate	Repeat doses of 0.5-0.75 mg/kg may be given every 5-10 min (maximum dose of 3 mg/kg). Continuous infusion rate is 1-4 mg/min
	Stable VT	0.5-0.75 mg/kg IV or IO	Indeterminate	Repeat doses of 0.5-0.75 mg/kg may be given every 5-10 min (maximum dose of 3 mg/kg). Continuous infusion rate is 1-4 mg/min
Magnesium	Pulseless VT or VF associated with torsades de pointes	1-2 g IV or IO	IIa	If pulse absent, dilute in 10 mL of 5% dextrose in water, and administer over 5-10 min. If pulse present, mix in 50-100 mL of 5% dextrose in water, and administer over 5-60 min
Procainamide	Stable VT	20 mg/min	IIa	Administer until arrhythmia is suppressed, hypotension occurs, QRS widens >50% from baseline, or total of 17 mg/kg has been administered. Maintenance infusion rate is 1-4 mg/min
	Atrial fibrillation	20 mg/min	Not rated	Administer until arrhythmia is suppressed, hypotension occurs, QRS widens >50% from baseline, or total of 17 mg/kg has been administered. Maintenance infusion rate is 1-4 mg/min. Avoid use in patients with impaired left ventricular function

IO, Intraosseous; *IV,* intravenous; *PEA,* pulseless electrical activity; *SVT,* supraventricular tachycardia; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

TABLE **54-4**

Advanced Cardiac Life Support Classification of Core Drugs (2005)—cont'd

DRUG	RHYTHM INDICATION	DOSE	CLASS RECOMMENDATION	COMMENTS
Vasopressin	Pulseless VT or VF, PEA or asystole	40 U IV or IO	Indeterminate	May be given once. May replace first or second dose of epinephrine
Verapamil	SVT	2.5-5 mg IV	IIa	Administer over 2 min. Dose of 5-10 mg may be repeated in 15-30 min (total dose 20 mg). Alternative dosing is 5 mg every 15 min (total dose 30 mg)

From Emergency Cardiovascular Care Committee, Subcommittees and Task Forces of the American Heart Association: 2005 American Heart Association Guidelines for cardiopulmonary resuscitation and emergency cardiovascular care, *Circulation* 112 (Suppl 24):IV-1-IV-203, 2005.
IO, Intraosseous; *IV,* intravenous; *PEA,* pulseless electrical activity; *SVT,* supraventricular tachycardia; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

Symptomatic bradycardia is defined as a heart rate less than 60 beats/min combined with symptoms such as hypotension, altered mental status, chest pain, syncope, or other signs of shock. Besides basic CPR, atropine doses or epinephrine, dobutamine, or dopamine infusions may be indicated depending on the degree of atrioventricular (AV) block followed by transcutaneous pacing if these medications are ineffective.

Symptomatic tachycardia is defined as a heart rate greater than 100 beats/min combined with symptoms of shock. Treatment can range from immediate synchronized cardioversion to drug therapy. Treatment for stable patients is based on the classification of the rhythm into narrow-complex or wide-complex tachycardia. Vagal maneuvers, administration of adenosine, or administration of second-line drugs such as calcium channel blockers or β blockers may be considered. These drugs should not be used for Wolff-Parkinson-White syndrome.

Regular, wide-complex tachycardias (QRS >0.12 second) include VT, supraventricular tachycardia with aberrancy, and tachycardias associated with or mediated by accessory pathways. Immediate synchronized cardioversion is performed for unstable supraventricular tachycardia owing to reentry, unstable atrial fibrillation, unstable flutter, and unstable monomorphic VT. Adenosine is recommended for wide-complex tachycardias that are believed to be supraventricular tachycardia. If the tachycardia is VT, and the patient is stable, an antiarrhythmic drug, such as amiodarone or procainamide, may be given.

Antiarrhythmic agents

Beyond defibrillation, which is the only proven intervention to achieve return of spontaneous circulation in patients experiencing VF, antiarrhythmic drugs have been advocated as adjunctive treatments potentially to normalize abnormally depolarizing and conducting myocardial cells.[1] Amiodarone is recommended for the treatment of VF or pulseless VT unresponsive to other measures. Amiodarone is a complex drug that acts on Na^+, K^+, and Ca^{++} channels and has α-adrenergic and β-adrenergic–blocking properties. In the emergency setting, it is administered as an intravenous bolus of 150 mg over 15 minutes followed by a maintenance infusion of 1 mg/min for the next 6 hours with a maximum cumulative dose of 2.2 g over 24 hours. The patient should be monitored carefully for hypotension and bradycardia.

Lidocaine, a class IB antiarrhythmic, acts by inhibiting the ion flux via Na^+ channels and has been used for years for pulseless VT/VF. It has been relegated more recently to an alternative drug for the treatment of VF and pulseless VT, but still has utility as an alternative to amiodarone when amiodarone is unavailable.[51]

The 2005 ACLS guidelines no longer recommend the use of procainamide for the suppression of pulseless VT/VF. It may be useful for patients who have been resuscitated and are still unstable despite doses of amiodarone or lidocaine.[16] Bretylium is no longer advocated for the treatment of VT and VF.[22,28]

Verapamil and diltiazem are nondihydropyridine Ca^{++} channel blockers that inhibit extracellular Ca^{++} influx through slow Ca^{++} channels, inhibiting automaticity in the sinoatrial node and conduction via the AV node. Verapamil is used to terminate reentrant tachyarrhythmias that require AV nodal conduction for their continuation and to control the ventricular rate in patients with atrial fibrillation or flutter or multifocal atrial tachycardia. Diltiazem is used for the same indications, but seems to produce less myocardial depression than verapamil.[49] Because of its narrow safety margin, digitalis has been largely superseded by Ca^{++} channel blockers and β blockers to manage acute atrial fibrillation.[20,22]

Adenosine is an endogenous purine nucleoside that acts by temporarily depressing AV and sinus node activity. It is an important drug for controlling AV nodal reentrant tachycardia and junctional tachycardias.[13] Bolus administration is indicated for paroxysmal supraventricular tachycardia.

Atropine inhibits cholinergic responses that decrease heart rate and systemic vascular resistance and is used to increase heart rate during periods of symptomatic sinus bradycardia resulting from excessive parasympathetic nervous system activity. It is also administered for asystole and slow pulseless electrical activity with the assumption that excessive vagal stimulation was responsible for the cardiovascular collapse. Because atropine can increase myocardial oxygen demand, precipitate tachyarrhythmias, and expand the zone of infarction, it must be used carefully in patients with presumptive myocardial infarction.[50]

Hypotensive patients may require a continuous infusion of a powerful inotrope or vasopressor for hemodynamic support. Typical infusions include epinephrine, dopamine, dobutamine, phenylephrine, norepinephrine, or vasopressin.

Mg^{++} replacement is advocated when hypomagnesemia is present. Hypomagnesemia can precipitate polymorphic VT (torsades de pointes) and VF.[5]

β-Adrenergic blockers, such as atenolol, metoprolol, propranolol, and esmolol, may enhance the benefits of thrombolytic agents in patients receiving these agents and have been shown to reduce the incidence of VF in post–myocardial infarction patients not receiving thrombolytic agents. These drugs are also used to control the ventricular rate in the presence of atrial tachyarrhythmias. Adverse effects of β-adrenergic blockers relate to their actions on the cardiac conduction system and to exacerbation of bronchospasm in patients with preexisting lung disease.[54]

Vasoactive drugs

In the absence of adequate circulation, vasoconstricting drugs such as catecholamines or vasopressin may enhance organ perfusion by increasing arterial and aortic pressures, resulting in desirable increases in cerebral and coronary perfusion pressures, while reducing blood flow to visceral and muscle tissues. Indications for their use include ischemic heart disease, acute heart failure, cardiogenic shock, and cardiac arrest.

Epinephrine is currently the preferred initial catecholamine recommended in ACLS for pulseless VT/VF, asystole, and pulseless electrical activity. arrest. The benefits of epinephrine in this application are its ability to cause vasoconstriction, to act as a cardiotonic, and to facilitate cardiac perfusion during CPR, thus increasing the success of defibrillation.[45]

Vasopressin causes peripheral vasoconstriction by stimulation of vasopressin receptors located in skin and skeletal muscle and vasopressin receptors located in the mesenteric circulation, resulting in shunting of blood to vital organs.[1] In addition, vasopressin potentiates the effects of catecholamines, enhancing vasoconstriction and resulting in greater coronary perfusion, which leads to more effective CPR and greater survival.[52]

Hypotensive patients may require a continuous infusion of a powerful inotrope or vasopressor for hemodynamic support. Typical infusions include epinephrine, dopamine, dobutamine, phenylephrine, norepinephrine, or vasopressin.

Norepinephrine is indicated in patients with low peripheral resistance and severe hypotension. Under these conditions, the drug is a potent vasoconstrictor and inotropic agent. Sloughing and necrosis of tissues may occur if extravasation occurs during administration. Dopamine is a chemical precursor of norepinephrine and has α_1-adrenergic–stimulating and β_1-adrenergic–stimulating properties. Specific dopaminergic receptors also contribute to the drug's cardiovascular pharmacologic characteristics. Indications for dopamine include certain types of shock, such as that associated with heart failure.[8,43] Dobutamine is a synthetic catecholamine and potent inotrope used in the treatment of heart failure when signs and symptoms of shock are absent.[8,43] Inamrinone and milrinone are nonadrenergic cardiotonic agents that also cause vasodilation with hemodynamic effects similar to dobutamine. They increase cardiac function and induce peripheral vasodilation.[26] Calcium chloride was initially thought to be beneficial during resuscitation by increasing myocardial contractility, but studies have shown that high concentrations of Ca^{++} may be detrimental.[12]

Vasodilators

Intravenous nitroglycerin permits controlled titration in relaxing vascular smooth muscle. This drug may cause severe hypotension when administered to a hypovolemic patient.[25] Sodium nitroprusside is an extremely potent, rapidly acting, direct peripheral vasodilator. It is used for the treatment of acute heart failure and hypertensive emergencies.[44]

Sodium bicarbonate

Sodium bicarbonate is administered to correct metabolic acidosis occurring during protracted resuscitative efforts. The use of this drug should be guided by blood gas analysis if possible.[15]

Diuretics

Diuretics such as furosemide are used for their venodilating and diuretic effects for the treatment of acute pulmonary edema and cerebral edema after cardiac arrest.

Morphine

Morphine is the opioid of choice to manage ischemic chest pain and acute pulmonary edema. The drug is titrated in small intravenous doses to avoid respiratory depression.

Thrombolytic agents

Thrombolytic therapy is often instituted early in evolving myocardial infarction to promote fibrin digestion and clot dissolution. Many studies are being conducted with streptokinase, urokinase, anistreplase, and alteplase to determine their respective roles in the early treatment of myocardial infarction.[17]

Supplementary Drugs

Supplementary drugs are additional emergency drugs that must be available when certain sedative or anesthetic drugs are administered. They include drugs that are used to reverse untoward effects of anesthetics and others that are used to treat specific medical conditions that may occur during anesthesia.

Naloxone is a specific opioid antagonist that reverses opioid-induced respiratory depression. It is mandatory in practices where parenteral opioids are administered.[31] Flumazenil is a specific benzodiazepine antagonist that reverses sedation and respiratory depression resulting from benzodiazepine administration.[27] Succinylcholine is used to overcome laryngospasm during deep sedation/general anesthesia by relaxing skeletal muscle controlling the vocal cords. It should be used only by practitioners with advanced anesthesia training. Dantrolene arrests the syndrome of malignant hyperthermia, a genetically transmitted disorder of excessive Ca^{++} release in skeletal muscle occurring during general anesthesia in which succinylcholine or volatile inhalation anesthetics are routinely administered.[4]

The use of parenteral vasopressors to treat hypotension is sometimes indicated during anesthesia. Some vasopressors, such as methoxamine and phenylephrine, increase blood pressure by causing peripheral vasoconstriction selectively, and others, such as ephedrine and mephentermine, act by a combination of peripheral vasoconstriction and cardiac stimulation.

CHAPTER 55

Prescription Writing and Drug Regulations

VAHN A. LEWIS

PRESCRIPTION

A *prescription* is a written or verbal order for medication to be used for the diagnosis, prevention, or treatment of a specific patient's disease by a licensed physician, dentist, podiatrist, or veterinarian. In some states, a prescription may also be written by appropriately trained optometrists, physician's assistants, and registered nurses. A prescription is a legal document for which the prescriber and the pharmacist are responsible. Prescriptions are subject to state, federal, and local regulations.

The writing of a prescription is one step in many that must be properly performed to initiate a course of therapy (Figure 55-1). This process starts with establishing a proper prescriber-patient relationship, which includes patient identification, proper diagnostic procedures, presentation and discussion of a treatment plan to the patient, availability of counseling, and follow-up care. These fundamental concepts have been reasserted more recently by the medical profession with respect to online prescribing for patients who are unknown to the practitioner. A prescription is prima facie evidence in court that such a relationship exists. Selection of therapy requires a multitude of factors to be considered: factors related to the patient (e.g., has difficulty swallowing tablets) and the therapeutic goal (cure or symptom control); evaluation of drug interactions; recognition of the various relationships among the patient, prescriber, and insurance companies and governmental bodies (that may establish guidelines or limits on payment for medications); and the medication costs and whether the patient can afford to buy it. Prescribing outside the proper prescriber-patient relationship is unprofessional conduct.

Prescribing should be done in a thoughtful and deliberate way, and the conditions for error-free prescribing must be ensured. In 1999, The Institute of Medicine report "To Err is Human" documented an increasing frequency of medical errors.[9] The report analyzed the nature of errors and categorized them into slips, lapses, and mistakes. Slips and lapses occur when the prescriber knows the correct procedure, but fails to perform it properly. Mistakes result from incorrect understanding of the correct course of action.

Slips and lapses can be influenced by the conditions under which the prescribing is done, interruptions during the writing of the prescription, or writing an incorrect drug name from memory, although the intended drug choice was sound. In this regard, several suggestions were made, including standardizing prescribing rules, using automated prescriber drug order entry systems and pharmaceutical software, having necessary patient information available at the point of care, and improving the patient's knowledge about his or her treatment. Some areas in which errors often occur include poor handwriting, incorrect calculation of pediatric drug doses, look-alike drug name mix-ups, prescriptions for drugs to which the patient is allergic or intolerant, and inappropriate dosage forms. There is a relationship between increased admissions (practitioner overloading) and increased errors. New errors also occur as new therapeutic entities are introduced. Surveys of prescriptions find errors not only within single prescriptions, but also between multiple prescriptions for the same patient in the form of drug interactions or incompatibilities.

Legal Categories of Drugs

Drugs may be categorized according to legal restrictions governing their use as over-the-counter (OTC), prescription, or controlled drugs. As determined by the U.S. Food and Drug Administration (FDA), a prescription drug is one that requires a prescription to be dispensed by a pharmacist, whereas an OTC drug can be purchased without a prescription. The 1997 FDA Modernization Act changed the indication of a prescription drug to "RX only." Several state laws refer to prescription drugs as "dangerous" drugs, meaning that they are unsafe for use except under the supervision of a practitioner licensed to administer them. Drugs such as antibiotics, local anesthetics, and systemic corticosteroids are examples of prescription drugs.

Drugs with an abuse potential, called *controlled substances*, have additional restrictions placed on their use. The Drug Enforcement Administration (DEA) of the Department of Justice is responsible for identifying and regulating such drugs. Controlled substances may be OTC, prescription, or unavailable for medical use. Examples of controlled drugs include cough remedies with codeine, opioids such as morphine that are characterized as having medical use, and opioids such as heroin that are said to have no accepted medical use. Most controlled substances have their principal site of action in the central nervous system. The widely abused anabolic steroids are an important exception to this rule and are controlled substances.

OTC agents are deemed to be safe and effective without professional guidance when used according to their labeled instructions. Examples of OTC, or nonprescription, drugs include some nonopioid analgesics, cold remedies, vitamins, topical antibiotics, and topical corticosteroids. These medications are manufactured under the same quality control standards that apply to prescription drugs; their safety and effectiveness are also monitored by the FDA.

As a result of legislative changes during the 1990s (Table 55-1), several additional sources of treatments have become more available. Dietary supplements may contain "dietary ingredients," which can include vitamins, minerals, herbs, amino acids, enzymes, organ tissues, metabolites, extracts, or

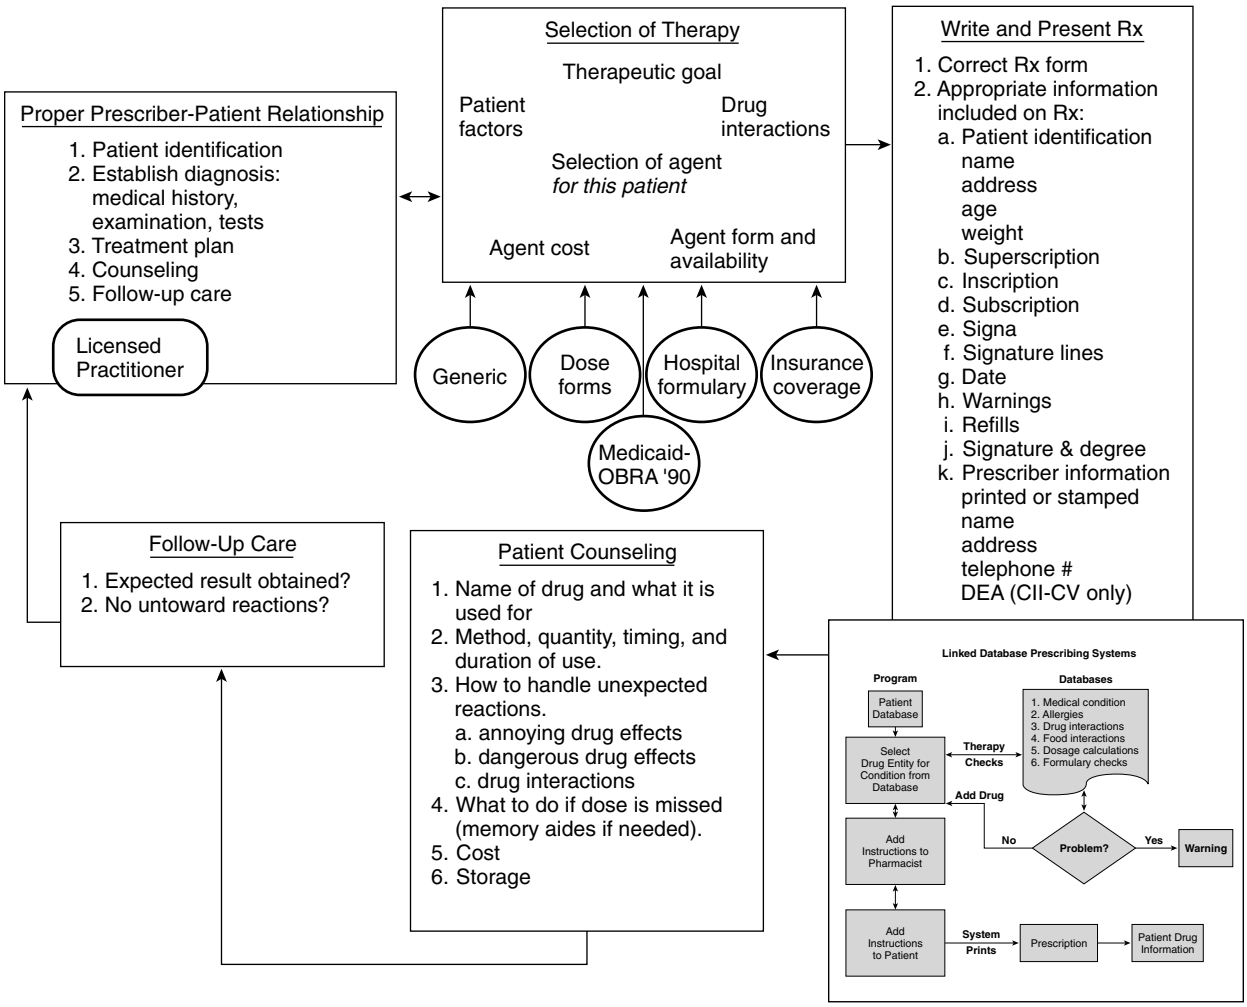

FIGURE **55-1** Steps involved in proper prescribing. After selecting the correct therapy, the prescriber must fill out the various components of the prescription to meet professional and legal requirements established by state, federal, and professional organizations. The next step is to present the prescription to the patient and provide the name of the drug and what it is being prescribed for, how to take it, what kinds of untoward effects the patient might expect, and what the patient should do about them if they occur. Some discussion of storage and cost of the medication may be included when indicated. After the presentation of the prescription, it is still important to monitor the progress of the patient. If the therapeutic goals are not being achieved, the process may need to be started over. *OBRA*, Omnibus Budget Reconciliation Act.

concentrates. These products must be labeled as dietary supplements. The manufacturer is responsible for (1) truthful information, (2) nonmisleading information, and (3) ensuring that the dietary ingredients in the supplements are safe. Manufacturers do not need to register with the FDA or obtain FDA approval. Complementary and alternative medical approaches may use "biologicals," which can include herbal remedies, special diets, or food products used for therapy. Herbs are defined as plants or plant products that produce or contain chemicals that act on the body.

The National Center for Complementary and Alternative Medicine sponsors many projects to investigate the potential therapeutic value of treatments such as St. John's wort, shark cartilage, and glucosamine. The goal is to determine whether these treatments can aid in the treatment of various disorders. This Center is also concerned with assessing the value of nondrug therapies and nontraditional medical systems such as acupuncture, Eastern medicine, and homeopathic medicine. The FDA can provide guidelines for the therapeutic claims made for these various products through the Center for Food Safety and Applied Nutrition, whose role is primarily educational. The United States Pharmacopeia (USP) has developed a Dietary Supplement Verification (DSV) Program. For a dietary supplement to bear the USP-DSV seal, it must include its ingredients on the label; indicate the strength and amounts of ingredients; prove that the product is shown to be absorbable when taken; and document that it has been screened for heavy metals, microbes, and pesticides and been manufactured in safe, sanitary, and controlled conditions. (See Chapter 56 for a more complete review of herbal products and alternative medicine.)

A new class of drugs has been created by the Combat Methamphetamine Epidemic Act of 2005, which created restrictions for the sale of ephedrines and phenylpropanolamine from retail stores. These products require the buyer to present identification and limit the monthly quantities that can be purchased.

Single-Entity Versus Combination Prescriptions

A single-entity prescription is one written for a preparation with only one active ingredient, the agent that produces the desired effect (e.g., ibuprofen, 600-mg tablets), in contrast to

TABLE **55-1**

Federal Laws Regulating Drugs and Prescribing

LAW	EFFECT
Pure Food and Drug Act 1906 (Wiley Act)	Prohibited mislabeling and adulteration of drugs[26]
Opium Exclusion Act of 1909	Prohibited importation of opium
Amendment (1912) to the Pure Food and Drug Act	Prohibited false or fraudulent advertising claims
Harrison Narcotic Act of 1914	Established regulations for use of opium, opiates, and cocaine (marijuana added in 1937)
Food, Drug and Cosmetic Act of 1938	Required that new drugs be safe and pure (but did not require proof of efficacy); enforcement by FDA[27]
Durham-Humphrey Amendment of 1951	Vested in the FDA the power to determine which products could be sold without prescription
Kefauver-Harris Amendments (1962) to the Food, Drug and Cosmetic Act	Required proof of efficacy and safety for new drugs and for drugs released since 1938; established guidelines for reporting information about adverse reactions, clinical testing, and advertising of new drugs
Comprehensive Drug Abuse Prevention and Control Act (1970), Controlled Substances Act, as amended	Outlined strict controls in the manufacture, distribution, and prescribing of habit-forming drugs; established programs to prevent and treat drug addiction[32]
Orphan Drug Amendments of 1983	Amended Food, Drug and Cosmetic Act of 1938, providing incentives for the development of drugs to treat conditions suffered by <200,000 patients in the United States.[33]
Drug Price Competition and Patent Restoration Act of 1984 (Waxman-Hatch Act)	Abbreviated NDA for generic drugs; required bioequivalence data; patent life extended by amount of time delayed by FDA review process; cannot exceed 5 extra yr or extend >14 yr post-NDA approval; authorized abbreviated NDA
Omnibus Budget Reconciliation Act of 1990	Deepened governmental involvement in prescription writing through legislation relating to "best discount prices," rebates, formularies, and pharmacy reimbursements; placed restrictions on payment for prescriptions for barbiturates and benzodiazepines
Generic Drug Debarment Act of 1991 and the Food, Drug, Cosmetic and Device Enforcement Amendment of 1991	Increased penalties for abuses of generic drug regulations
1992 Expedited Drug Approval Act	Allowed accelerated FDA approval for drugs of high medical need; required detailed postmarketing patient surveillance
1992 Prescription Drug User Fee Act	Required manufacturers to pay user fees for certain NDAs; FDA states review time for new chemical entities has decreased from 30 mo in 1992 to 20 mo in 1994[31]
1994 Dietary Supplements and Health Education Act	Required dietary supplement manufacturers to ensure that a dietary supplement is safe before it is marketed; FDA is responsible for taking action against any unsafe dietary supplement product after it reaches the market; generally, manufacturers do not need to register with FDA or get FDA approval before producing or selling dietary supplements; manufacturers must ensure that product label information is truthful and not misleading[25]
North American Free Trade Act (1994) and General Agreement on Tariffs and Trade (1948), World Trade Organization (1995)	Necessitated harmonization of pharmacopeias and drug regulations between trading partners
1996 Health Insurance Portability Accountability Act (HIPAA)	Standardized third-party payment for medical treatment and increased confidentiality and privacy for patient information maintained in medical databases[20]
1997 FDA Modernization Act	Replaced "legend" with label "Rx only"; allowed manufacturer to discuss off-label uses of drugs with practitioners; revised accelerated track approval for drugs that treat life-threatening disorders; made provisions for pediatric drug research; revised interaction of agency with individuals doing clinical trials[6]
2005 Combat Methamphetamine Epidemic Act	Establishes new regulations for the sale of ephedrine, pseudoephedrine, and phenylpropanolamine that differ from the Control Substance V regulations by not requiring sale in a pharmacy
U.S. Troop Readiness, Veterans' Care, Katrina Recovery, and Iraq Accountability Appropriations Act of 2007	Established requirement for the use of tamper-resistant written prescriptions for Medicaid prescription reimbursement. Prescriptions must have three tamper-resistant features

NDA, New Drug Application.

a combination prescription, which calls for a preparation with more than one active ingredient (e.g., aspirin, 230 mg; acetaminophen, 150 mg; caffeine, 30 mg; and hydrocodone bitartrate, 5 mg). Many combination formulations are available precompounded, in a single fixed-dosage form, and may be prescribed in the same manner as a single drug (e.g., acetaminophen and hydrocodone tablets).

When the combination is a rational one (as is the combination of a nonopioid and an opioid analgesic for enhanced pain relief), the ease of prescribing and using the preparation may justify its selection. Too frequently, however, unnecessary drugs (e.g., caffeine) or inappropriate combinations (e.g., the mixing of two nonopioid analgesics) are used. Fixed-dosage formulations prepared by the manufacturer are not subject to dosage adjustment to suit the needs of the individual patient. Differences in the half-lives of the individual agents may lead to ineffective or excessive action of one or more of the drugs. Nevertheless, at certain times therapeutic

advantages can be obtained by using a combination drug to reduce confusion related to taking numerous individual medications at irregular times.

Drug Names and Generic Substitution

As discussed in Chapter 3, any drug may be identified by more than one designation in various references, texts, and package inserts. Of special interest here are nonproprietary and proprietary names. The nonproprietary name is also referred to as the *generic name*. This name is selected by the U.S. Adopted Names Council. The steady increase in the number of new drugs and the marketing of existing drugs by different manufacturers are making similarities between different drug names an increasing challenge. The practitioner must be vigilant in prescribing the correct agent and spelling drug names correctly. Because, with few exceptions, individual drugs have only one nonproprietary name, it is this name by which the drug is primarily identified. Nonproprietary names may differ among countries, however. The same agent may also have many proprietary or trade names, which are given to it by the various manufacturers or marketers to identify their brand of the drug. In advertisements and labeling with the trade name, the nonproprietary name of the drug must also be prominently identified.

In recent years, governmental regulatory agencies have had a strong tendency to encourage or mandate the prescription and dispensation of drugs by nonproprietary name.[15] The principal motivation for these regulations is to control rapidly increasing drug costs. Currently, all states and the District of Columbia have repealed their existing antisubstitution laws and replaced them with drug substitution laws permitting or, in some states, requiring the pharmacist to dispense generic drugs (preparations containing the same active chemicals in identical amounts, but sold under the common nonproprietary name), unless specifically prohibited by the prescriber. Also, the federal government has instituted "maximum allowable cost" programs in an effort to contain the cost of prescription drugs to the consumer by limiting prescription by proprietary name. These programs require the prescriber to certify the necessity of prescribing a specific brand of drug rather than its nonproprietary counterpart. According to the FDA, the savings may range from 30% to 80%.[28]

Equivalence: Chemical, Pharmaceutical, Biologic, and Therapeutic

If two brands of the same drug are to be considered for substitution, the basis for identifying them as equivalent must be carefully defined.[12] Drug products that contain the same amounts of the same active ingredients in the same dosage forms and meet current official compendium standards are considered chemical equivalents. Pharmaceutical equivalents are drug products that contain the same amounts of the same therapeutic or active ingredients in the same dosage form and meet standards based on the best currently available technology. This description means that pharmaceutical equivalents are formulated identically and must pass certain laboratory tests for equivalent activity, including dissolution tests when appropriate, by standards set for various classes of drugs.

Bioavailability refers to the extent and rate of absorption of a dosage form as reflected by the time-concentration curve of the administered drug in the systemic circulation. Bioequivalent drugs are drugs that, when administered to the same individual in the same dosage regimen, result in comparable bioavailability. Insofar as the extent of absorption is concerned, pharmaceutical equivalence presumably ensures biologic equivalence.

Therapeutic equivalents are chemical or pharmaceutical equivalents that, when administered to the same individual in the same dosage regimen, provide essentially the same efficacy (and toxicity). Therapeutic equivalency can be shown only by controlled human clinical trials, which are expensive and time-consuming. In the absence of contradictory clinical evidence, drugs that are bioequivalent are assumed to be therapeutically equivalent.

Chemically equivalent drugs may not share comparable bioavailability. Problems of bioequivalence can arise from many areas. First, although the amounts of the therapeutic ingredients may be the same in two dosage forms, the preparations may contain different binders, diluents, stabilizers, preservatives, and various other pharmacologically inactive ingredients to give them their physical form. Second, the pressure used to compress the mixture into the tablet or capsule dosage form may vary and alter the dissolution rate. For suspensions or solutions, the methods used to dissolve, disperse, or suspend the drug in a liquid formulation may differ. Third, the quality control, age, purity, and physical consistency of any of the chemical constituents contained in different formulations of chemically equivalent products can differ. All these various and sometimes poorly controlled factors can influence the rate at which the product disintegrates or dissolves in the gastrointestinal tract, affecting absorption of the active ingredients.

Variations in bioavailability have been shown to be responsible for some treatment failures with certain categories of drugs. Approximately 5% of drug products pose challenges to generic drug manufacturers. Drugs with poor bioavailability, high lipid solubility, nonlinear pharmacokinetics, or narrow therapeutic ranges cause difficulty; examples include steroids, digitalis glycosides, anticoagulants, thyroid preparations, theophylline, antineoplastic drugs, and anticonvulsants. Advanced or complex dosage forms with coatings or layers are also difficult to match. Drugs with potential bioavailability problems that are likely to be used by dentists include the various dosage forms of erythromycin, diazepam, and ibuprofen.

To facilitate the wider use of generic drugs, the FDA has published a list of all FDA-approved drugs that it regards as therapeutically equivalent, entitled *Approved Drug Products with Therapeutic Equivalence Evaluations* (also known as the *Orange Book*).[16] This source can be used as a guide to identifying less expensive generic alternatives that pharmacists can substitute for a brand name product designated the "reference listed drug," that is, the innovator drug. This list indicates drugs that are considered therapeutically equivalent (termed a *positive formulary*), designated with a rating beginning with the letter *A*; drugs that may not be therapeutically equivalent (termed a *negative formulary*), designated with a starting letter *B*; and drugs about which the agency has not yet made a determination (blanks). The FDA's policy is to consider pharmaceutically equivalent drugs as therapeutically equivalent unless scientific evidence to the contrary exists. In the *Orange Book* (available on the Internet[5]), the reference-listed drug, therapeutically equivalent rating, and generic drug rating are provided in tabular form. If a generic oral dosage form preparation is considered therapeutically equivalent, it is given the designation of *AB* (the second letter, *B* in this case, refers to the class of dose form). At the time of this writing, 96% of ibuprofen tablets were judged *AB*, 100% of diazepam tablets were *AB*, and all erythromycin ethyl succinate suspensions were considered *AB*.

Although FDA recalls of generic drugs greatly outnumber recalls of brand name drugs, most American pharmaceutical firms follow Good Manufacturing Practice regulations and are inspected periodically by the FDA for compliance with quality control standards. In addition, many generic products are manufactured and distributed by the same company that markets the original proprietary drug. For these reasons, a generic product should not be assumed to be inferior to its

brand name counterpart. It is left to the practitioner to know the properties of the drugs used and to decide whether to prescribe by trade or nonproprietary name. If the condition being treated is not serious or life-threatening, and if the therapeutic index of the drug category being prescribed is not critical, a generic drug can save the patient a substantial amount of money, and the drug should be prescribed by its nonproprietary name.

Component Parts of the Prescription

A complete, ideal prescription comprises several parts, each of which provides specific information about the prescriber, the patient, and the drug. The patient's full name and address are required on prescriptions for DEA-controlled substances. Including the patient's age may be required and is especially desirable on prescriptions for children younger than 12 years, permitting the pharmacist to confirm the dosage. The name and full address of the prescriber are necessary. The telephone number may be required and is usually included as a convenience to the pharmacist. The date on which the prescription is written and signed is always desirable and is required on prescriptions for DEA-controlled substances or in states in which prescriptions expire.

The symbol *Rx*, known as the *superscription*, is generally understood to be an abbreviation of the Latin *recipe*, meaning "take thou," but was probably derived from the ancient Roman symbol for Jupiter and used in the physician's prayer for the survival of the patient.

The inscription provides specific information about the drug preparation: (1) the name of the drug, which can be either the nonproprietary or the proprietary name, or possibly both, with the proprietary name following the nonproprietary name in parentheses, as with pentazocine (Talwin), and (2) the unit dosage or amount of the drug in milligrams (e.g., penicillin VK 500 mg) or other appropriate unit of measure (e.g., penicillin G 250,000 U) and the dosage form (e.g., tablets, suspension, sprinkles). If the prescription is for a liquid preparation, the individual unit of dosage is usually contained in a teaspoonful or 5 mL (e.g., amoxicillin 125 mg/5 mL). The inscription should provide an unambiguous identification of the drug and any other ingredients that the pharmacist must assemble to fill the prescription order. Drug products are available in unique strengths and dosage forms. When prescribing, a product, strength, and dosage form that is available to the pharmacist should be designated. The inscription should be written just below and to the right of the superscription.

Several sources of drug information should be available during selection of drug therapy (also discussed in Chapter 3). Good sources for identifying the drug, dosage form, and dose include *The Physicians' Desk Reference, Facts and Comparisons, Mosby's Drug Reference for Health Professions,* and *ePocrates Rx*. In addition, it is valuable to have a compilation of drug interactions available to screen for possible adverse interactions. A book such as *Drugs in Pregnancy and Lactation* by Briggs and colleagues[2] is helpful when a course of therapy is being planned for women of childbearing potential and for pregnant or nursing women. The American Pharmacists Association's *Handbook of Nonprescription Drugs* may be useful if the practitioner is uncertain whether an OTC drug might affect therapy. References on herbal drugs and dietary supplements may also be useful (see Chapter 56).

Additional sources of drug information are available as computer software programs, compact disks, and personal digital assistant programs and on the Internet. Electronic resources can have advantages if the text is accompanied by a sophisticated search engine. An innovation in prescribing is the concept of "linked database prescribing" (Figure 55-2). This type of system has the potential to reduce several sources of prescribing errors, such as poor handwriting, selection of the wrong drug name (selection is based on therapeutic classification), nonexistent product strengths and dosage forms, orders for drugs to which patients are allergic, and therapeutic incompatibilities. Other errors such as dosing and patient instruction errors could also be reduced by appropriately designed systems.

Although this concept seems to have a bright future, implementation would be challenging for professional, technical, and legal reasons. If patient data are entered into such a system, the system would need to comply with the Health Insurance Portability and Accountability Act of 1996 (HIPAA). Specialties such as dentistry may use drugs in a different way than the drugs are generally used in medicine; this can lead to false rejections or warnings for valid prescrip-

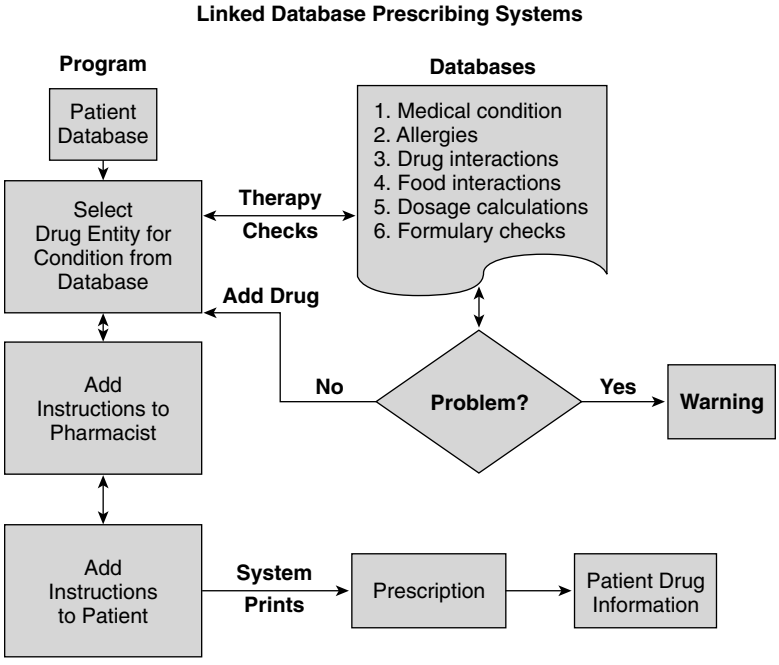

FIGURE **55-2** The complex process of prescribing can be facilitated by a linked database prescribing system. These systems can assist the prescriber by putting patient, drug, drug interaction, and formulary information at the prescriber's fingertips. The systems can provide warnings when problems are discovered. Current systems leave the instructions to the pharmacist and patient up to the prescriber. Written drug information for the patient is frequently generated automatically.

tions. Who would be responsible for programming and maintaining the quality of the databases? Who would pay for the use of such a system? An example of a linked database prescribing system is C*linical Pharmacology,* an Internet-based program created by Gold Standard Multimedia.

The next part of the prescription is the subscription. The subscription is the prescriber's directions to the pharmacist regarding fulfilling the inscription. Because almost all drugs used by dentists are available in precompounded form, the subscription is usually brief, including the following:

1. The quantity and dosage form of the drug to be dispensed; that is, the number of tablets or capsules or the volume of a liquid preparation needed for a course of therapy (e.g., "dispense 28 tablets"). This direction is written, preferably in Arabic numerals, for an appropriate amount of the drug as determined by the manner in which it would be used by the patient and the amount of time the patient would need it. The prescriber also considers the toxicity and abuse potential of the drug and the cost to the patient. For DEA-controlled drugs, the quantity must be written in numbers and spelled out (in English, not Latin) to avoid alteration. (Without this precaution, 15 is easily changed to 45, 75, or 150.) Alternatively, the prescription must have a check-off box for the range of doses that includes the amount to be dispensed. In any prescription, no greater quantity of drug than is needed should be ordered. In some cases the amount prescribed should be limited to prevent obscuring symptoms, such as prescribing analgesics for 3 or 4 days rather than the 7 to 10 days common for antibiotics. If multiple appointments are anticipated, it may be more cost-effective to write the amount to reflect several appointments. The subscription should be written on the line below the last line of the inscription.
2. The number of authorized refills of the prescription. The number and its time limitation are specified for DEA-controlled drugs, but are otherwise left to the discretion of the practitioner. Some state laws dictate, however, that prescriptions expire at the end of each year. If refill directions are not authorized by the prescriber, no refills may be dispensed. With controlled substances, care should be taken to devise a refill authorization system that is not easily altered, such as crossing out all except the desired number in a series (e.g., 0, 1, 2, 3). The refill instructions are usually physically located below the transcription (described later) of the prescription.
3. Directions to the pharmacist to list the medication on the container label. The current trend in most states is to require the pharmacist to identify medications on the label unless such identification is not considered to be in the patient's best interest and is specifically prohibited by the prescriber. Identifying the drug can prevent allergic reactions or adverse interactions with other medications and misuse of the unused portion of the prescription. It may be especially helpful in directing the management of victims of drug poisoning. When present, this information is often physically located below the transcription on the prescription.

The transcription, or signature—from the Latin *signa*, meaning "label" or "let it be labeled," and indicated on the prescription by "Label:" or "Sig:"—is the prescriber's directions to the patient that appear on the medicine container. At one time, such directions were uniformly written in Latin, but modern practice is to use English. Latin abbreviations are still used by many clinicians in prescriptions and progress notes to save time (Table 55-2); however, such gains are minor in general dental practice and may contribute to prescription errors (e.g., "q4h" instead of "qid" represents a 50% dosage increase). Figure 55-3 depicts the same signature for an analgesic medication, one written entirely in English and the other written in Latin abbreviations. Items written in the transcription are transferred onto the prescription bottle label by the pharmacist, so they should be complete but concise.

TABLE **55-2**

Latin Abbreviations Used in Prescription Writing

ABBREVIATION	LATIN	ENGLISH
ad lib.	*ad libitum*	at pleasure
a.c.	*ante cibum*	before meals
aq.	*aqua*	water
b.i.d.	*bis in die*	twice a day
caps.	*capsula*	capsule
c̄	*cum*	with
d.	*dies*	a day, daily
disp.	*dispensa*	dispense
gtt.	*guttae*	drops
h.	*hora*	hour
h.s.	*hora somni*	at bedtime
non rep.	*non repetatur*	do not repeat (or refill)
no.	*numerus*	number, amount
p.c.	*post cibum*	after meals
p.r.n.	*pro re nata*	as needed
q.h.	*quaque hora*	every hour
q.4h.	*quaque quarta hora*	every 4 hours
q.i.d.	*quater in die*	four times a day
Sig.	*signa*	let it be labeled, label
stat.	*statim*	immediately
tab.	*tabella*	tablet
t.i.d.	*ter in die*	three times a day

Label: Take two tablets immediately. Take one or two tablets every 4 hours as needed for relief of pain.

Sig: Tab 2 stat. Tab 1 or 2 q.4h. p.r.n. for relief of pain.

FIGURE **55-3** Sample of the same transcription or signature (instructions to the patient) written in English and with Latin abbreviations.

The phrase "use as directed" should not be used. Rather, the transcription should be explicit and include (1) the route and method (e.g., take, instill, or insert); (2) the number of dose forms to be taken each time (e.g., take two tablets); (3) how frequently to administer the medication (e.g., every 6 hours or at bedtime); (4) for what length of therapy (e.g., for 7 days or until all taken); (5) for what purpose (now required by law in some states; e.g., for an analgesic, "to relieve pain" or "for pain"); and (6) any special instructions (e.g., shake well before using or refrigerate). The instructions to the patient should be consistent with the patient characteristics, drug, and dosage form. Prescriptions written for children should use the verb *give* instead of *take* to indicate that the parent or guardian is to administer the drug. Enteric-coated drugs should be swallowed whole to ensure that the coating is still intact when the drug reaches the stomach. Directions for suspensions should include the phrase "shake well then take …" to ensure administration of a uniform dose. The transcription should be located on the next line after the subscription. (The arrangement of information on the prescription is by custom, but by

observing this order the practitioner is less likely to omit an essential part of the instructions.)

The handwritten signature and professional degree of the prescriber convey the authority of the prescriber to order the medication and of the pharmacist to fill the prescription. Although all prescriptions should be signed, a signature is required by law only for certain controlled substances (Schedule II drugs); other prescriptions may be telephoned to a pharmacy, where the pharmacist writes them down. When it appears, the dentist's signature is followed by the prescriber's professional degree rather than preceded by "Dr." as the abbreviation for "Doctor." If several dentists work in a clinic that uses the same prescription form, several states require that the prescriber's name be mechanically printed or stamped on the prescription on an extra line under the signature line. Most state dental practice acts specify that prescriptions may be written only for patients under active care. Many state laws stipulate that only the classes of drugs directly involved with dental treatment may be prescribed by the dentist. Another form of identifier needed on some prescriptions is the National Provider Identifier (NPI), which was established by HIPAA (see Table 55-1). The NPI serves as a unique provider identifier for all electronic prescribing and billing.[3]

Finally, the prescriber's DEA registration number must appear on any prescription for a controlled or scheduled drug in compliance with the Controlled Substances Act of 1970. This number should not be routinely entered on prescriptions that do not require it, however, to prevent its use by potential drug abusers.

Many states have their own acts related to controlled substances. If state, federal, or local regulations governing any drug or procedure differ, the most stringent of the regulations applies. The state and federal certificates of registration must be renewed periodically. DEA registration is not required of practitioners in the military or the Public Health Service or of recent graduates in internship or residency programs; in the latter case, the institutional DEA registration number may be used.

After the prescribing of the drug, but before the prescription is filled, the pharmacist evaluates the prescription again. The pharmacist has responsibility to the patient and the practitioner to check the prescription for possible errors in drug selection, dosage form and dosage, and patient instructions.

Increasingly, prescriptions are being filled at sites remote from where the patient lives. Prescriptions may be mailed or in some cases submitted by the telephone or Internet to a pharmacy. Remote pharmacies may be used to obtain medications at a better price or may be required by insurance carriers. In some cases, these pharmacies may not be in the United States.

The FDA is charged with regulating the production of prescription drugs from development to distribution. It has set standards that require compliance during drug development (e.g., New Drug Application [NDA]), labeling (package inserts), drug manufacturing (i.e., Good Manufacturing Practices), and drug distribution and postmarketing surveillance (e.g., MedWatch). The FDA is challenged, however, by limited funding (Prescription Drug User Fee Act), changes in international agreements (the North American Free Trade Agreement [NAFTA] and the General Agreement on Tariffs and Trade [GATT]), changes in public attitudes toward regulation of medications (1994 Dietary Supplements and Health Education Act), increased threats to drug and food safety (bioterrorism, "mad cow disease"), and the use of the Internet to market drugs.

Mail order pharmacies

For long-term medications where the cost is covered by an insurance company, patients may be directed to submit the prescription to a central pharmacy if the company is to cover the cost. The medication is shipped to the patient by domestic mail, and if the shipment crosses state or national borders, the medications must comply with FDA requirements.

Internet prescriptions

The development of Internet drug distribution has added an additional area of challenge for the control of the drug supply. Many of the solicitations for drug sales over the Internet are illegal, and the FDA has moved to close such practices.[23] These sites may come and go, however, before the FDA can act. The medications sold may be of unknown quality and may come from distant sources. Cursory Internet health histories may not properly reflect the patient's health status or may not be reviewed by qualified personnel. Drugs can be used more safely when appropriate medical histories are obtained and considered by practitioners during the prescribing process. In addition, if a patient has an adverse reaction to a drug obtained from a distant source, recognizing and treating adverse reactions may be difficult. There is also a potential financial risk to the patient when using the Internet because the seller may be unknown to the buyer. *Caveat Emptor* ("Buyer beware") is very much the operating principle for these transactions. To help reduce some of the risks associated with the use of Internet pharmacies, the National Association of Boards of Pharmacy has developed a voluntary certification program called *Verified Internet Pharmacy Practices Site* (VIPPS). A VIPPS seal of approval indicates that the pharmacy complies with state licensing and additional requirements, including the patient's right to privacy.

Reimportation of Drugs

Technically, no unapproved drugs may be imported into the United States. Travelers and immigrants may feel more comfortable, however, taking medications they are familiar with from their home countries. The FDA and U.S. Customs Service regulate drug importation for personal use by guidance documents used for interpreting the various laws administered by the FDA.[29] Small quantities of medications unavailable in the United States, intended to continue a course of treatment begun in a foreign country, may be allowed to enter. The FDA narrows the scope of such drug importations to small amounts (generally less than a 3-month supply) for personal use. If the product's use is properly identified, it is not for a serious condition, and it is deemed not a health risk, it can be approved. If it is an unapproved product for treatment of a serious illness for which treatment is unavailable domestically, not for commercial sale, and not deemed to pose an unreasonable risk, and the patient can document that a physician is responsible for the patient's care, it may be approvable. These provisions were prompted by the concerns for patients with acquired immunodeficiency syndrome who were willing to assume the greater risk of non–FDA-approved drugs to treat their often fatal condition.

Commercial importation or reimportation of drugs into the United States is illegal without FDA approval. The Medicine Equity and Drug Safety Act of 2000 permits reimportation of drugs manufactured in the United States back into this country. Before the law can go into effect, however, it needs the approval of the U.S. Health and Human Services Secretary. So far, approval has not been given. The concern is that when a drug is out of the United States it is no longer subject to U.S. laws, and its composition cannot be guaranteed. Although most foreign governments have departments that regulate drugs sold to their own populations, many do not regulate businesses that market drugs to countries beyond their borders. There is a valid concern that for drug entities imported from various sources, assembled into a dosage form in one country, and then sold in another, there would be no

way to ensure the purity, safety, efficacy, or proper labeling of the result.

Agents from the FDA may cooperate with the U.S. Customs Service to enforce the Federal Food, Drug and Cosmetics Act with respect to medications that are carried or mailed into the United States. In a pilot survey program, hundreds of packages containing drugs were detained. Some of these packages failed to declare medications properly, which could result in Customs penalties. If the recipient cannot show the FDA that the shipment is in response to valid prescriptions or letters of instruction from a physician, drugs can be destroyed or returned to their source.

There are examples of seized drugs that were previously banned from the United States for safety concerns being illegally imported into the United States. In some cases, labeling for the imported drugs fails to mention offending agents contained in the container. Drugs that are outright counterfeits have been discovered. Control over the manufacturing of imported products is unknown, and they are sometimes contaminated with bacteria or other "filth." In some cases, drugs that are older than their expiration date are received, resulting in subtherapeutic blood concentrations or, in worst cases, toxicity from a degraded drug.

The cost savings of using drugs from foreign sources can be substantial, however. A prescription that may cost more than $100 to fill in the United States may be available from Canada for less than half that amount and may be available from India for pennies per dose. Mexico is also a source for low-cost medicines. In many cases, these foreign drugs are just as effective as the more expensive versions available in the United States. For patients taking lifesaving medications and who have no insurance or have a fixed or low income, their choice may be between no medication or cheaper imported drugs. Programs have been developed for physicians licensed to practice in the United States and Canada to write prescriptions for busloads of patients who get their prescriptions filled in Canada and then return to the United States. The more recent decline in the value of the dollar has reduced some of these savings; nevertheless, there are still considerable savings in buying outside the United States. In other cases, "storefront" pharmacies have opened that receive prescriptions in various cities in the United States, fax them to Canadian pharmacies for filling, and then deliver the medications to the patients by mail. The FDA has judged the latter operations to be illegal commercial importers and has moved to shut them down.

Noncompliance

A subject of current interest regarding directions on prescriptions is patient compliance or, more accurately, noncompliance. Twenty-five percent to 60% of all patients fail to take medications as intended by their physicians. Noncompliance includes such practices as improper or inappropriate timing of doses or premature discontinuation of the medication. The many possible reasons for patient noncompliance may involve a lack of knowledge or understanding of the drug or the purpose for which it was prescribed, misinformation from nonmedical sources, negative patient attitudes toward illness or "taking drugs," development of an adverse effect, economic factors, or inadequate communication (instruction and emphasis) by the practitioner.

Patient compliance is probably improved when the prescriber explains the condition for which the patient is being treated, what the alternative treatment regimens are, and the anticipated benefits of the selected drug treatment.[13] After the drug therapy is selected, patients should be informed of the name of the drug and, in layman's terms, its therapeutic purpose. This information helps the patient recognize the importance of each prescription. Specific instructions on drug use should include how and when to take the medication, how much to take, and when to expect the benefits. The patient should also be made aware of possible adverse reactions and side effects. Some side effects such as drowsiness may be disturbing and interfere to an extent with daily living, but do not require discontinuation of therapy. Other adverse reactions, such as acute allergic reactions, require immediate discontinuation of therapy. Finally, drug and food interactions should be mentioned. The patient should be given an opportunity to ask questions or clarify the instructions.

A logical presentation of this information, as given in the preceding paragraph, improves instruction recall and understanding of the instructions.[18] For patients on a strict budget, a discussion of drug costs may be important. Little is accomplished by prescribing a drug that the patient is unable or unwilling to buy. The patient should also be informed of what to do if a dose is missed and whether the drug should be taken immediately or at the next dosing interval. It is also useful to tell the patient about any special storage requirements, such as the need for keeping the drug refrigerated (emulsions) or at room temperature (syrups). Practitioners need to familiarize themselves with the instructions for use and storage of the medications they prescribe because these instructions can vary among dosage forms and preparations of the same drug entity.

Patient information sheets for numerous drugs, especially newly approved agents, are available online from the FDA.[30] These sheets may be downloaded and given to patients to help address many of the informational issues that can influence compliance.

The prescription enhances the physician-patient relationship and contributes to patient compliance if care is used in presenting it. Writing a prescription in English and in the patient's presence and then explaining it, in addition to improving compliance, may equip the patient to detect any errors that may occur in prescribing or filling the prescription.

Because few patients are able to recall oral instructions accurately, the labeled directions should be specific. Failure to be specific can provide the basis for malpractice lawsuits. If the patient has many prescriptions or has a special difficulty with oral instructions, a written reminder should accompany the prescription.

Patient compliance may also be improved by selecting drugs that need to be taken only once or twice daily instead of agents that have to be administered more frequently. When multiple drug therapy is necessary, combination products, when appropriate, are helpful in reducing the "confusion over pill profusion," as is prescribing drugs with distinctive physical characteristics (e.g., a red tablet, a white tablet, and a capsule instead of three white tablets).

Prescription Format and Pad Forms

Prescriptions should be written concisely, accurately, and legibly. Ink, indelible pencil, or typing is required for prescriptions for Schedule II drugs and is preferable for all prescriptions. Use of "gel" pens to write prescriptions to prevent washing away of the original prescription information is recommended because gel pen ink is absorbed into a paper's fibers and resists its removal by chemical solvents. These pens are widely available. With the advent of safe and effective drugs, consumer education, and the concept of informed consent, the need for therapeutic mysticism of an illegible prescription written in a foreign language (e.g., medical Latin) no longer exists. Similarity between the names of some highly active and potentially toxic drugs makes illegibility all the more indefensible.

Prescription pads should also be kept secured in a locked drawer or under similar cover when not in use to avoid loss or theft. Inventories of prescription pads and drug stocks

should be performed regularly to detect theft and diversion of prescription forms and drugs. Sequentially numbered prescription blanks make detection of diversion easier. If theft of a prescription pad is suspected, such loss should be reported to the local pharmacies or state board or drug control agency. In addition, for good dental practice and for medicolegal reasons, a duplicate of each prescription or a record thereof should be kept in the patient's chart or record.

Blank printed prescription pads should not have the name of a pharmacy or pharmaceutical company imprinted anywhere on the form because such an implicit endorsement may direct the patient to a particular pharmacy or manufacturer's product. Similarly, phone, fax, or electronic prescriptions should be sent to the pharmacy of the patient's choice, not the practitioner's.

The U.S. Troop Readiness, Veterans' Care, Katrina Recovery, and Iraq Accountability Appropriations Act of 2007 now requires the use of tamper-resistant prescription forms for prescriptions for Medicaid patients. To be considered tamper-resistant, a prescription pad must contain industry-recognized features designed to prevent (1) unauthorized copying, (2) erasure or modification, and (3) counterfeiting of a completed or blank prescription form. The prescription should include a statement alerting the pharmacist of the tamper-resistant features and how the pharmacist can verify authenticity. The rule applies to all written and computer-generated prescriptions (OTC, Rx, and controlled) delivered to patients for which Medicaid reimbursement is expected.

Exceptions to the rules include (1) prescriptions phoned, faxed, or emailed from the prescriber to the pharmacy; (2) refills of written prescriptions presented to a pharmacy before the act was in force; (3) emergency fills on a noncompliant prescription form, for which a prescriber provides the pharmacy with a verbal, faxed, electronic, or compliant written prescription within 72 hours after the date on which the prescription was filled; and (4) prescriptions for certain specified institutions and clinical settings. The need for tamper-resistant prescription forms for non-Medicaid prescriptions varies on a state-by-state basis and needs to be determined for the dentist's the area of practice.

Figure 55-4 presents a typical preprinted prescription form used, with minor variations, by most practitioners. Because of state laws permitting or, in some instances, mandating the substitution of a generic preparation for a proprietary drug unless specifically prohibited by the prescriber, the prescription form may have a feature to allow the clinician to indicate whether a substitution is permitted. Because no physical prescription is written for telephone orders, the practitioner must indicate verbally to the pharmacist whether substitution is permitted. Some states also permit the transmission of prescriptions by electronic means (e.g., fax or computer network). In some hospitals, prescriptions are generated by the patient information system and sent directly to the pharmacy. Pharmacists occasionally note prescriptions that make no sense for a particular patient. On review, these prescriptions generally were for agents or doses on the computer medication screen that were adjacent to the desired drugs.

Figure 55-5 presents three sample prescriptions. The first, for antibiotic prophylaxis before dental therapy, is written by nonproprietary name; the second, for postoperative pain relief, is written by proprietary name for the sake of convenience. In the latter case, the dosage is implicit in the particular formulation selected (e.g., Tylenol with Codeine No. 3: acetaminophen [Tylenol] 325 mg and codeine 30 mg, with the notation 3 indicating the 30-mg strength of codeine). The third prescription, for fluoride supplementation in a child (2 years old) living in a low-fluoride area, is one of the few instances in which long-term drug use is appropriate in clinical dentistry.

Dosage Calculations (Posology)

The dosage of a prescribed drug may vary according to several factors: the degree or severity of the condition for which it is being prescribed; the age, weight, sex, or temperament of the patient; the route, frequency, or timing of administration; concurrent medication; patient suggestibility (placebo effect), habits, sensitivities, or previous medication history (hyperreaction or hyporeaction); and the systemic health of the patient. Important changes in clearance or volume of distribution can produce changes in expected half-lives of drugs. Because drug metabolism and elimination are primarily accomplished by the liver and kidneys, any significant change in the function of these organs may necessitate a change in dosing. For the fluoride prescription in Figure 55-5, the age

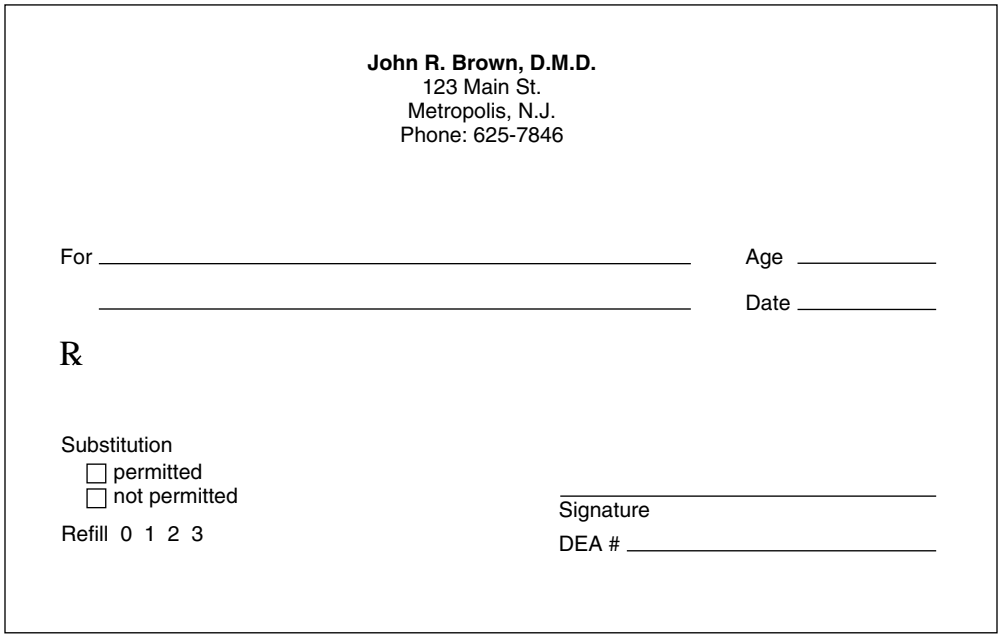

FIGURE **55-4** Typical prescription form.

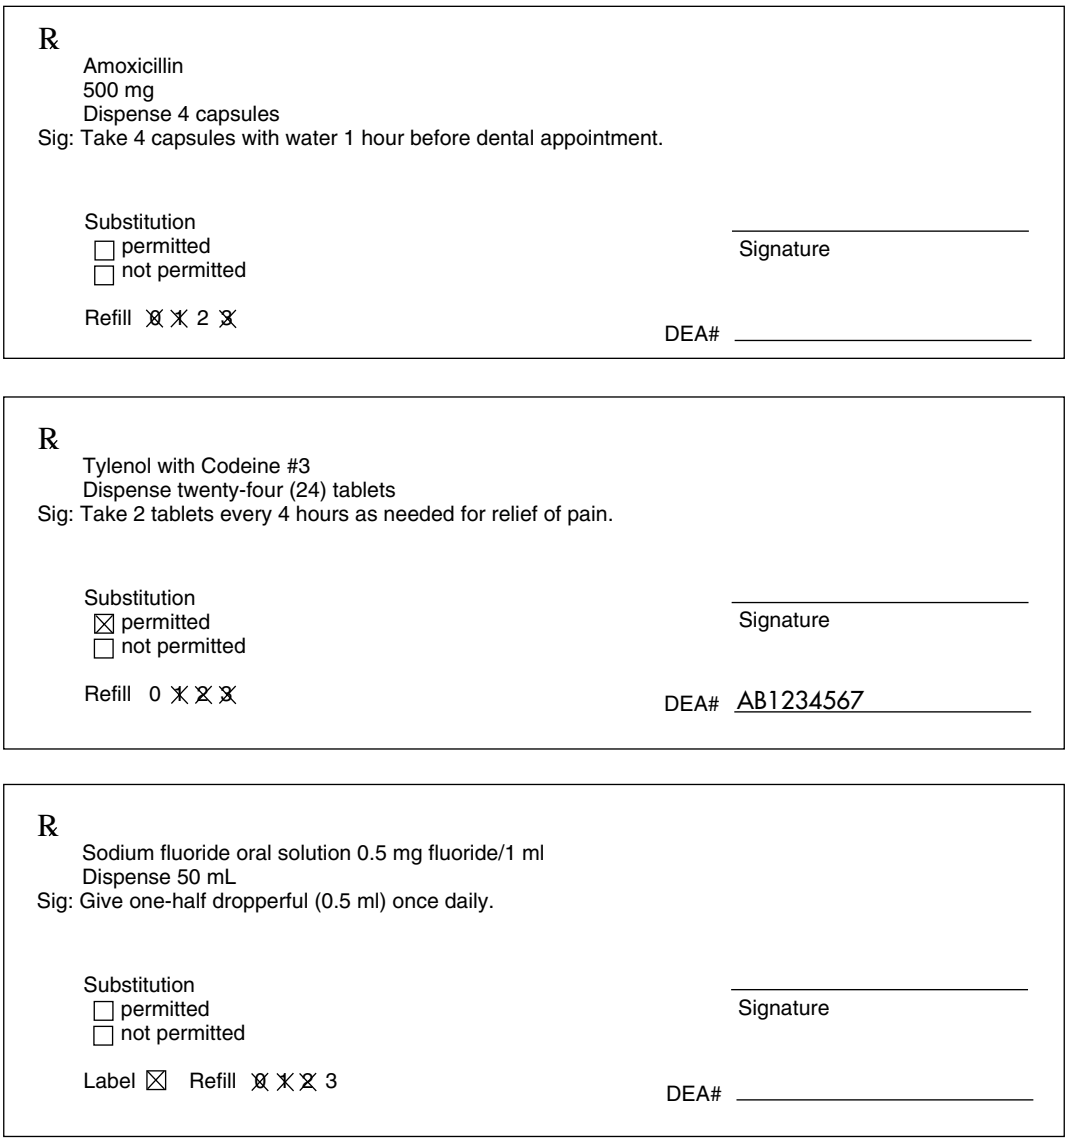

FIGURE **55-5** Sample prescriptions. The top and bottom prescriptions are by nonproprietary name. The middle prescription, for a combination product, is written by trade name for convenience (generic substitution is permitted).

of the patient and the amount of fluoride in the water supply are the primary determinants of the dosage.

The manufacturer's package insert, pharmacology texts, and the compendial sources mentioned earlier in this chapter and in Chapter 3 list the official, average, or usual 150-lb adult dose for a drug. A listed dose or dosage range is a guide for prescription purposes, and although it does not carry the weight of a regulation, it does have medicolegal implications if an adverse effect occurs. Practitioners are well advised to stay within the recommended dosage range unless they have a sound reason to vary from it (see later).

No uniform format is used in references to express dosing information. For most drugs, the dose is reported as the amount of drug to be given at a single dose, which is repeated at a stated interval each day. Alternatively, the manufacturer may indicate the total amount of drug to be administered "in divided doses" per day. The practitioner is expected to know what dosage forms are available and how often to give them on the basis of the pharmacokinetics of the drug and the nature of the patient (these can be found in an appropriate reference or drug database). For dosage determination, an "adult" is usually interpreted to mean an individual 18 years old or older and weighing approximately 70 kg (150 lb).

Children and many underweight, diseased, or elderly patients require a dosage of pharmacologically active agent that is lower than that suggested for a normal adult. Very large or obese patients may require dosage adjustment,[7] but this adjustment can depend on the characteristics of each drug; with some drugs (e.g., gentamicin), the increased dosage can increase the risk of toxicity.[17] Patient pharmacogenomics can also be a factor, such as a patient who is a CYP2D6 poor or ultra metabolizer.

Several rules have been proposed for computing the dosage of a drug for children, as follows:

1. Clark's rule,

$$\frac{\text{child's weight (lb [or kg])}}{\text{150 lb (or 70 kg)}} \times \text{adult dose} = \text{child's dose}$$

determines the dose suitable for a child based on the typical adult weight of 150 lb (or 70 kg).

2. Young's rule,

$$\frac{\text{child's age (yr)}}{\text{child's age} + 12\text{ (yr)}} \times \text{adult dose} = \text{child's dose}$$

calculates the dose for the child based on age, with a 12-year-old receiving half the adult dose.

3. Surface area, extrapolated from the patient's height and weight, is divided by the average adult surface area to determine the fraction of the adult dose. This method is seldom used in dentistry. Dosage tables or graphs (Figure 55-6) are available, which obviates time-consuming and error-prone calculations.

Of all these methods, Clark's rule is the most widely used, and Young's rule is the most subject to error. Because physiologic functions dealing with drug disposition are generally proportional to body surface area, the surface area method is probably the most accurate of the three. This distinction is dubious, however, because drug responses in children, especially very young children, are modified by factors other than body size (see Chapter 3). When dosage information is unavailable, and one of these methods has to be used to estimate the child dose, it is important to monitor the patient carefully to ensure that therapeutic effects are obtained, and toxic reactions are minimized.

Weights and Measures

Two systems of designating weights and measures of drugs and preparations are the apothecary and the metric systems. Although the older apothecary measures may still used by some clinicians for some drugs, the metric system is now standard. Roman numerals are generally used with the apothecary system, and Arabic numbers are used with the metric system. The grain is the unit of weight, and the minim is the unit of liquid measure (volume) in the apothecary system. There are 480 grains in 1 ounce and 480 minims in a fluid ounce. In the metric system, the gram is the unit of mass, and the liter is the unit of volume. Approximate equivalents between the two systems are given in Table 55-3. Apothecary measures are not equivalent to measures used for commercial purposes in the United States, which use the avoirdupois system. Although the grain is the same in avoirdupois, the ounce is 437.5 grains, and there are 16 ounces to the pound in avoirdupois.

Household measures are commonly encountered when liquid preparations are prescribed. If the directions call for the patient to take a certain volume of drug solution, the phar-

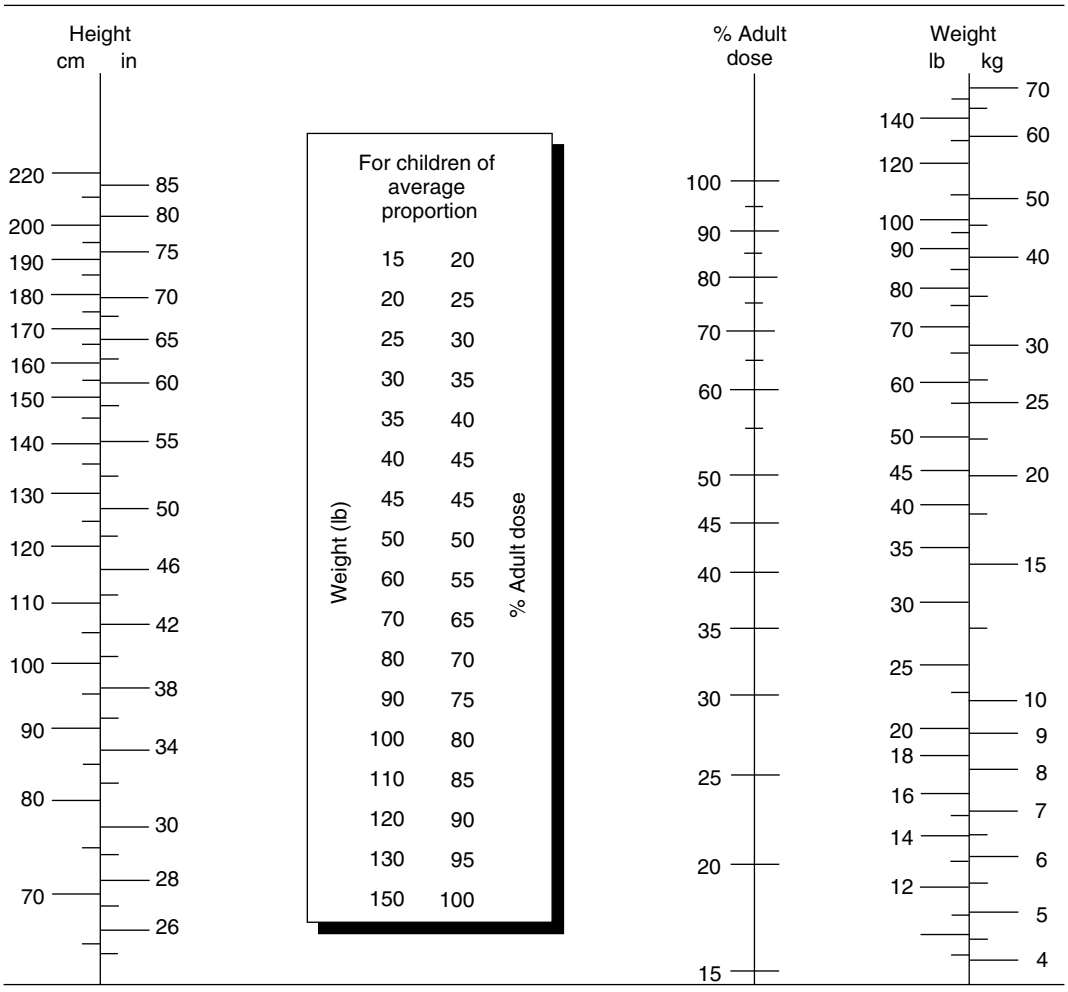

FIGURE **55-6** Nomogram for estimating dose based on surface area. A value of 1.73 m^2 is used as the adult surface area standard. The intersection of a *straight line* connecting the patient's height and weight with the dosage column indicates the correct percentage of the adult dose. A simplified table for children of normal height and weight is also provided.

TABLE **55-3**

Approximate Apothecary and Metric Equivalents

APOTHECARY	METRIC
Weight	
1/65 grain	1 mg
1 grain	65 mg
15 grains	1 g
1 dram	4 g
1 ounce	30 g
Volume	
1 minim	0.06 mL
16 minims	1 mL
1 fluid dram	4 mL
1 fluid ounce	30 mL
1 pint	480 mL

TABLE **55-4**

Metric Equivalents of Common Household Measures

HOUSEHOLD MEASURE	METRIC VOLUME
1 USP drop	0.05 mL
1 teaspoon	5 mL
1 tablespoon	15 mL
1 teacup	120 mL
1 glass	240 mL
1 pint	480 mL

macist converts the metric value given into its household equivalent, as indicated in Table 55-4. Utensils likely to be used by patients may yield different volumes of medicine than were initially intended. To circumvent this problem, many commercial products are provided with calibrated measuring devices; patients should be encouraged to use these when taking their medications.

Calculating the appropriate patient dose, calculating the amount of drug product needed to achieve this dose, expressing the dose in a household measure, and calculating the total amount of the drug to be dispensed by the pharmacist are common calculations performed in the practice of dentistry. Such calculations are required when prescribing an antibiotic suspension for a child. Although the mathematics is simple, teaching experience indicates that 40% of students are unable to perform calculations correctly on examination. The 1999 Institute of Medicine report on medical error noted that dosing errors are frequently made in children's dosing.[18] Students should practice performing such calculations, and any time drug doses are calculated for a patient they should be double-checked for accuracy.

DRUG LAWS

Various federal, state, and local laws have been enacted to control the manufacture, sale, and dispensing of drugs. To comply with these regulations, the clinician should be aware that the most stringent of these laws takes precedence, whether it is federal, state, or local. A summary of federal laws that affect dental prescribing is provided in Table 55-1.

Historical Development of Drug Legislation

A major concern of nations has always been the establishment of criteria for drug identity and purity; to this end, the development of pharmacopeias has proved invaluable. A pharmacopeia is a written description of the source, identification, and preparation of medicinal agents. The first pharmacopeia to gain legal status was one adopted by the city-state of Nuremberg in the early sixteenth century.

The first USP was published in 1820 by a group of physicians, pharmacists, and chemists. This first United States Pharmacopeial Convention established certain policies—notably that only drugs of proven merit would be included in the USP and that regular revisions of the document would be issued. The USP published in 2009 is the thirty-second edition. Because most multiple drug entities and various commonly prescribed remedies were excluded from the USP, the need remained for a compendium for standardization of these medicinals. In 1888, the American Pharmaceutical Association began to publish the *National Formulary of Unofficial Preparations*. In 1975, the National Formulary was merged into the USP, and it is in its twenty-seventh edition.

Around the turn of the twentieth century, a growing public clamor over the quality, purity, and safety of food and drug products led to the passage of the Federal Food and Drugs Act of 1906, also known as the Pure Food and Drug Act.[26] In this legislation, the USP and National Formulary were given legal status regarding defining the purity and quality of drugs. Standards were also established for the labeling of medicinal products. In the years that followed, these standards were extended by court decisions and congressional actions to cover promotional materials in addition to the products themselves.

Before 1937, the testing of drugs and ingredients used in the preparation of medications was unnecessary before marketing. In 1937, a relatively new solvent, diethylene glycol, was used in an "elixir of sulfonamide." This agent caused the death of many children and was responsible for the swift passage of the Federal Food, Drug and Cosmetic Act of 1938.[27] This act required manufacturers to provide the FDA with evidence of drug safety in the form of an NDA before distributing the agent. The Act of 1938 also introduced the principle of separating drugs into prescription and nonprescription categories by requiring companies selling OTC drugs to furnish purchasers with the information necessary for their safe and effective use. Questions concerning which drugs could be sold OTC and which had to be reserved for prescription use were not resolved, however, until passage of the Durham-Humphrey Amendment in 1951 (discussed subsequently).

In response to the thalidomide tragedy in Europe, Congress passed the Kefauver-Harris Amendments of 1962. These amendments to the 1938 Act required manufacturers of new drugs to follow set standards of animal and human pharmacologic and toxicologic testing, with the data from each step to be reviewed by the FDA. Requirements for evaluating safety and studying chronic and fetal toxicity and efficacy (omissions of the 1938 Act) were included in this legislation.

Two federal laws controlling prescription drugs are the Durham-Humphrey Amendment (Section 503B) of 1951 to the Food, Drug and Cosmetic Act of 1938 and the Comprehensive Drug Abuse Prevention and Control Act (Controlled Substances Act) of 1970. The Durham-Humphrey law prohibited the dispensing of certain kinds of drugs (e.g., systemic antibiotics and corticosteroids and other agents whose unsupervised use may be unsafe) except on the prescription order of a licensed practitioner. Under this law, a prescription for these drugs may not be refilled unless authorized by the prescriber.

The FDA has the responsibility for determining how a drug may be dispensed. The FDA is also responsible for reviewing the labeling and advertising of the use of prescription and OTC drugs. This review, based on documented clinical studies, limits the labeled indications and uses of the product, but it does not limit the right of practitioners to use the drug only in these situations because such action would represent interference with the practice of medicine, which the 1938 Act enjoined the FDA from ever doing. The practitioner can be liable, however, under civil law for mishaps that occur with "off-label" uses of a drug. Several drug sources, including the American Hospital Formulary Service Drug Information, provides prescribing information for off-label uses generally recognized as valid indications.

In 2006, the FDA incorporated new conventions in the formatting of the drug labeling for the "package insert" information.[22] The labeling now includes a half page summary of major points at the beginning of the labeling. The new labeling also makes provisions for electronic hot links between the summary and full discussion in the label. "Black box" warnings indicate adverse effects with particularly serious consequences that are featured prominently at the top of the drug labeling. The new labels are being phased in between 2006 and 2111.

In the 1980s, the high cost of drugs became the subject of congressional legislation. Substantive changes in drug substitution laws, simplified approval of generic drugs, and Medicaid drug reimbursement controls were introduced in attempts to curtail explosive drug costs. One component of the increased cost stems from the development of new drug entities. Because of the complexity of the approval process, much of the patent protection for a drug can expire before a drug is ever marketed. To recover their investments, manufacturers charge high prices for new drugs, contributing to the upsurge in medical costs. To blunt this trend, the Drug Price Competition and Patent Term Restoration Act of 1984 (Waxman-Hatch Act) was passed. It extended marketing protection for innovator drugs. An innovator product is an original, newly developed drug that requires an approved NDA for marketing; a synonym is New Molecular Entity (NME).

Under the Waxman-Hatch Act, innovator drugs may be given extensions on their patent protection. The law also simplified the process of obtaining an Abbreviated NDA for approval to market generic drugs to help reduce overall drug costs of known agents. In conjunction with the Orphan Drug Amendment of 1983, this law also made provisions for the development of "orphan drugs"—drugs used for rare diseases. In general, it is not economically feasible to produce these drugs for the small groups of patients (often <200,000) who need them. Exclusive rights can be granted under this law for production and marketing of a drug or for specific labeling to permit the use of a drug in a rare disease. No price restrictions are placed on drugs developed under the Orphan Drug Act, and these treatments can be expensive.

Drug companies have taken an interest in "discovering" new uses of known drugs in small population groups. The drug thalidomide, which was withdrawn from the market when it produced the severe birth defect phocomelia, has been rereleased for use in treating leprosy and aphthous ulcers seen in human immunodeficiency virus and Behçet's disease based on data indicating that it inhibits tumor necrosis factor-α production. Because of advances in understanding of the human genome and the development of diagnostic gene chips, more populations of disorders are expected to fit within the Orphan Drug Act. For the years 2004-2007, the FDA averaged 12 New Molecular Entity NDAs, two Biological License Applications, six orphan drug NDAs, and 103 labeling updates per year.[24] Although relatively few novel new drugs are approved, there are numerous changes in the labeling for existing entities (changes include new indications, dosage forms, or new warnings).

The 1984 Waxman-Hatch Act led to a surge of Abbreviated NDAs by generic manufacturers, and FDA personnel became overloaded with work. In an attempt to speed up the processing of their applications, several generic drug manufacturers bribed FDA officials for quick approval, and others submitted samples of the innovator drug as examples of their own product.[11] Other problems that have occurred include the selling of counterfeit drugs and physician drug samples to pharmacists at below-market prices. Their use may lead to therapeutic failure. To discourage these practices, the Generic Drug Debarment Act of 1991 and the Food, Drug, Cosmetic and Device Enforcement Amendment of 1991 were passed to increase substantially the penalties for such activities.

The 1990s represented a revolutionary period for drug regulation. Lawsuits and legal challenges of FDA actions led to substantial changes in the regulation of dietary supplements, natural product drugs, and complementary and alternative medications. In 1994, Congress passed the Dietary Supplements and Health Education Act, which allows numerous agents with pharmaceutical activity to be identified as dietary supplements. In addition, international trade agreements such as NAFTA and GATT necessitated the development of harmonization agreements between member countries by the International Conference on Harmonization. Harmonization seeks to unify pharmacopeias and laws related to the international pharmaceutical trade. Outside these agreements, there are additional trade agreements, such as those associated with normalization of the United States' relations with China.

These changes have led to increased availability of natural products from domestic and foreign sources. Natural products can have therapeutic potential, but also can complicate therapy by inducing unexpected toxic effects and drug interactions. One example is St. John's wort, which has been found to produce an antidepressant effect. It can also induce hepatic drug metabolism, however, and decrease blood concentrations of other drugs, such as antiviral protease inhibitors. In addition, imported natural products are occasionally found to be adulterated with conventional drugs such as phenylbutazone or chlordiazepoxide. These findings underscore the need for complete patient medical histories, including questions on prescription drugs, OTC drugs, dietary supplements, alternative medicines, and drugs of abuse.

The 1992 Prescription Drug User Fee Act (PDUFA)[31] authorized the FDA to charge pharmaceutical companies who are having their NDAs evaluated by the agency. This financial resource has enabled the FDA to double the rate of approval of new drug entities. An increased number of postmarketing withdrawals of new drugs has also occurred. The 1997 FDA Modernization Act has modified the role of the FDA further. For dentists, a key provision allows manufacturers to disseminate information about nonlabeled or unapproved uses of drugs and medical devices. This provision may increase drug company interest in promoting off-label dental uses of medical drugs and promoting dosing of agents that were not studied in the original application.

Evidence-based medicine is a movement that seeks to base clinical practice on scientifically validated treatments. This trend has many benefits, but also some unintended consequences. Most controlled clinical drug trials are funded by drug manufacturers, who can influence clinical decision making by providing published clinical data. The experimental design and statistical analysis of the results of these comparisons can be influenced or performed by the drug developers,[8] even though the actual studies are performed in universities or apparently independent laboratories. By a narrow selection of the study conditions and doses—and omis-

sion of other comparisons—biases can result. A review of treatments for hypertension provides a striking example. Although the manufacturers have shown that Ca^{++} channel blockers, angiotensin-converting enzyme inhibitors, and α_1-adrenergic blockers are effective compared with placebo medication, the ALLHAT study, a long-term, multicenter trial supported by the National Heart, Lung, and Blood Institute (NHLBI),[10] approached the question of drug activity by comparing different classes of drugs used to initiate treatment for high blood pressure against each other. The ALLHAT study found that the older and less expensive diuretic treatment was as or more effective than the newer drugs in lowering blood pressure and preventing some forms of heart disease.[14] Most published articles contain disclosure statements that reveal the role of various influences on the article; these should not be ignored.

A second source of bias can come from selective publication of drug trial results. The FDA has determined that studies of antidepressants with positive results were 12 times more likely to be published than studies of the same medications where the outcomes suggested questionable or no benefit.[19] Because of this bias in publication, the drugs seem to be more effective than they would be if all of the available results were published. The ratio of manufacturer-sponsored trials to independent investigator studies may be 100:1, which makes it a challenge to find the independent studies. Knowledge of these practices should make practitioners wary of manufacturer claims and look for unbiased sources of evidence.

Although pharmaceutical companies are crucial for development of new therapeutic entities, they have sought to prolong the sales life of many legacy drugs through reformulation, including the marketing of congeners with minor chemical modification ("me too drugs"), prodrugs, active drug metabolites, isolated enantiomers, and specialized dosage forms (e.g., extended release, layered, combination). Although these adaptations can provide valuable therapeutic alternatives, they sometimes support only higher profit margins. Zolpidem was initially marketed as an agent that produced little next-day hangover. It has been reformulated as a controlled-release product for prolonged action, however, reducing the significance of the original claims.

Another area of more recent concern involves health care practitioners accepting gifts from drug manufacturers, such as sample drugs, food (including breakfasts and luncheons at drug company–sponsored seminars), and trips to meetings. These marketing efforts have been found to bias prescribing habits, usually to the disadvantage of patients. Even trivial gifts that include drug name logos have the potential to alter prescriber practice. These influences are pervasive in many universities and have stimulated efforts to develop appropriate behavioral guidelines for students, faculty, and residents.[1]

Modern prescribing therapy is complicated by the relationships among the patient, physician, pharmacist, manufacturer, third-party payer, and government. Today, patients may rely on nontraditional payments for drug purchases. Group purchase plans may require copayments, the use of specific formularies, mail-order pharmacy services, and drug-use reviews. The practitioner who is informed about these processes is better able to elicit patient compliance and accomplish the therapeutic goal.

HIPAA also affects dental prescribers (see Table 55-1). This legislation is concerned with standardizing the process of third-party payment for medical treatment (requiring each practitioner to obtain an individual NPI number for use in insurance forms), but it has also substantially tightened the standards for confidentiality and privacy of patient information maintained in medical databases. As an unintended outcome, it has occasionally become more difficult for dentists to obtain medical information necessary to evaluate their patients for prescribing purposes. The fines for violating these new rules can be substantial.

Although the federal government has set no standards concerning which prescription drugs a dentist may use clinically, many state laws regulating the practice of dentistry restrict drugs used to those associated with dental treatment. A typical law of this kind states that dentists can "diagnose, treat, operate, or prescribe for any disease, pain, injury, deficiency, deformity, or physical condition of the human teeth, alveolar process, gums, or jaws."

The dispensing of drugs by physicians and dentists is a more recent development in the United States. The Federal Trade Commission has agreed to allow the sale of drugs by practitioners to their patients, and almost all states have recognized physician/dentist dispensing under strict regulatory requirements regarding storage, labeling, and record keeping. The ethical implications of this practice have been questioned on numerous grounds, including conflict of interest, lack of training and facilities for appropriate drug handling, and loss of the traditional practitioner-pharmacist double-checking of prescriptions.

Controlled Substance Laws

In addition to laws regulating drugs in general, special legislation has been enacted pertaining to drugs of abuse. A historical perspective of this legislation is given in Chapter 51. Control of the distribution of commonly abused drugs (e.g., opioids, barbiturates, and amphetamines) by the DEA is regulated by the Controlled Substances Act. This act divides drugs of abuse into five schedules based on the drugs' potential for abuse, their medical usefulness, and the degree to which they may lead to physical or psychological dependence. The criteria for inclusion within the five schedules are presented in Table 55-5.

To prescribe controlled substances, the licensed practitioner must register with the DEA. Many of these regulations are administered by the DEA Office of Diversion Control.[21] The registration must be renewed periodically, and the certificate of registration must be retained and displayed by the practitioner. When registered, the practitioner assumes several responsibilities, including keeping records of all controlled substances obtained, administered, dispensed, prescribed, lost, destroyed (DEA Form 106), or surrendered to the DEA (DEA form 41) and the secure storage of the drugs and prescription pads. To purchase Schedule II drugs, the practitioner must use the DEA 222C order form. Although Schedules III, IV, and V drugs may be obtained without special forms, a biennial inventory of all controlled substances on hand must be performed. This inventory must be kept for inspection and copying by officers for at least 2 years.

Schedule I drugs may not be prescribed. Schedule II drug prescriptions may not be refilled. Emergency, partially filled prescriptions must be completely filled within 72 hours. For patients in long-term care facilities or for patients with terminal illnesses, partial filling of Schedule II drugs may be permitted for 60 days after the date on the prescription. Multiple sequentially dated prescriptions for Schedule II drugs can be written for legitimate medical purposes to extend treatment to 90 days from the initial prescription's inception.[4] In many states, special prescription forms or restrictions are applied to Schedule II drugs. Controlled substances in Schedules III, IV, and V can be refilled five times within 6 months, assuming that the prescriber authorizes these refills. After the final permitted refill, a new prescription for the product must be obtained. Drugs in Schedule V, which consist of preparations containing limited quantities of certain opioid agents, may be sold without a prescription (if permitted by the state), assuming that the drug is dispensed by a pharmacist to a purchaser who is at least 18

TABLE **55-5**

Classification of Controlled Substances

SCHEDULE	CRITERIA FOR INCLUSION	EXAMPLES OF DRUGS
I	High abuse potential, no currently accepted medical use, may lead to severe dependence	Research use only: heroin, lysergic acid diethylamide, marijuana, mescaline, methaqualone, peyote, psilocybin
II	High abuse potential, accepted medical use, may lead to severe dependence	Amphetamines, cocaine, codeine, dronabinol, meperidine, methadone, methylphenidate, morphine, oxycodone, pentobarbital, secobarbital
III	Abuse potential less than drugs in Schedules I or II, accepted medical use, moderate to low physical dependence liability, possibly high psychological dependence	Benzphetamine, butabarbital, methyprylon, mixtures of codeine or hydrocodone with aspirin or acetaminophen, stanozolol
IV	Abuse potential less than drugs in Schedule III, accepted medical use, low dependence liability	Chloral hydrate, diazepam, meprobamate, phenobarbital, propoxyphene, triazolam
V	Abuse potential less than drugs in Schedule IV, accepted medical use, limited dependence liability	Cough preparations containing codeine or similar opioid derivatives

years old and that a record of the transaction is kept by the pharmacist.

A pharmacist is permitted to fill oral prescriptions for any prescription drug except Schedule II products, provided that they are subsequently committed to writing and filed by the pharmacist. The law allows for the dispensing of verbal prescriptions for opioid and other Schedule II drugs in emergency situations, but the quantity must be limited to the amount needed for the emergency, the prescription must be put in writing by the pharmacist, and the prescriber must furnish the pharmacist with a signed, written prescription within 72 hours. Labeling of prescriptions for all controlled substances must contain the warning "Caution: Federal law prohibits the transfer of this drug to any person other than the patient for whom it was prescribed."

Small amounts of controlled substances in Schedules II through V may be imported or exported by U.S. citizens for their personal use if the following conditions are met: (1) the controlled substance is in its original container dispensed to the individual, and (2) the prescription is declared to the Customs Service stating that (a) the controlled substance is for his or her personal use or for an animal traveling with him or her, and (b) the trade name and schedule symbol are on the label or the name and address of the dispenser and the prescription number are on the label. In addition, the total of controlled substance dosage units cannot exceed 50.

Information and applications for registration may be obtained from the DEA, Office of Diversion Control, Registration Unit, PO Box 28083, Central Station, Washington, DC 20005; online at http://www.deadiversion.usdoj.gov/online_forms.htm; or from the DEA Regional Office in the area in which the applicant practices. The DEA has created a website[21] that provides current information on registration and contacts and laws dealing with controlled substances. It is now possible to submit registration documents electronically to this website or to print out forms that can be mailed to the DEA for registration.

The DEA offers the following suggestions for writing prescriptions for controlled substances:

1. Keep prescription blanks in a safe place where they cannot be stolen easily. Minimize the number of prescription pads in use.
2. Write prescription orders for Schedule II drugs in ink or indelible pencil, or use a typewriter. They must be signed by the clinician. Prescribing controlled substances by telephone is discouraged unless the patient is familiar or the validity of the request can be substantiated.
3. Write out the actual amount prescribed, in addition to giving an Arabic number or roman numeral, to discourage the alteration of prescription orders.
4. Avoid writing prescription orders for large quantities of medications, especially controlled drugs, unless such quantities are necessary.
5. Maintain only a minimum stock of controlled drugs in the office.
6. Keep all controlled drugs under lock.
7. Be cautious when a patient says that another clinician has been prescribing a specific controlled drug product or claims that only one product works for him or her. Consult the clinician or the hospital records, or examine the patient thoroughly and decide independently whether the drug product should be prescribed.
8. Prescription blanks should be used only for writing prescription orders, not for notes or memos. A drug abuser could easily erase the message and use the blank to forge a prescription order.
9. Never sign prescription blanks in advance.
10. Maintain an accurate record of controlled drug products that have been dispensed or administered, as required by the Controlled Substances Act of 1970 and its regulations.
11. Assist the pharmacist who telephones in verifying information about a prescription order. A corresponding responsibility rests with the pharmacist who dispenses the prescribed medication.
12. Telephone the nearest office of the DEA to obtain or furnish information. Calls are held in the strictest confidence.

CHAPTER 56

Use of Herbs and Herbal Dietary Supplements in Dentistry

RICHARD P. COHAN AND MARK BLUMENTHAL

Alternative (integrative, complementary, natural, holistic) medicine is composed of a broad range of treatments that are often preventive in nature and commonly directed at treating the whole person rather than a specific disease. Substances used in alternative therapies are most often derived from natural sources. Many of these—particularly herbal medicines—have been used for more than 2000 years and are relied on by approximately 80% of the world's population in developing countries. Most people who use alternative care modalities do so because they are following traditions handed down from one generation to the next. What Western culture calls *alternative treatments* are in most cultures often the only available options for health care. Most such treatments have lacked rigorous scientific evidence of efficacy; however, there is a growing body of clinical research documenting the activity and utility of some of these regimens. The National Institutes of Health have designated such therapies as *complementary and alternative medicine (CAM)*. In contrast, Western medicine (sometimes referred to as *allopathic*) includes a diverse array of scientific, mostly evidence-based pharmacologic and surgical technologies, which, although described as "mainstream," "conventional," "orthodox," or "traditional," have been practiced for little more than a century. These treatments focus almost exclusively on eliminating disease.

The term *alternative medicine* is used in this chapter to indicate "interventions neither taught widely in medical schools nor generally available in hospitals."[10] This selection is not meant to exclude other terms. The increasingly popular term *integrative medicine* may be preferable because it stresses that these treatment protocols often can be effectively integrated with conventional medicine to optimize the health of the patient.

For decades in the United States and in some European countries, alternative medicine—and alternative (or holistic) dentistry—has implied care at the "fringe" of accepted medical (or dental) practice. There is an increasing trend now to incorporate many of these forms of care into the mainstream and include them as covered benefits in health insurance plans. Alternative medical therapies, depending on how they are defined (e.g., whether prayer is included as a CAM therapy) are used by an estimated 25% to 42% of the U.S. population.[4,10,18] About 20% use natural products, including vitamins, minerals, herbs, and other dietary supplements. Table 56-1 lists the reasons why patients pursue CAM therapies. Visits to alternative care practitioners exceed visits to allopathic primary care physicians by more than 200 million annually, and Americans spend an estimated $30 billion a year on these services plus $18.8 billion on dietary supplements; most of these expenses are not reimbursed.[10] In response to these trends, most medical and some dental schools in the United States now provide at least introductory coursework in CAM.

A survey of 46,000 subscribers to *Consumer Reports* magazine found that 60% of individuals who used alternative therapies told their physicians they were doing so, and most physicians approved of (55%) or were neutral to (40%) their actions.[16] One in four patients tried alternative therapies at the recommendation of a physician or nurse. Another national survey concluded that individuals who use alternative therapies are better educated but often less healthy than individuals who do not use them.[3] These individuals are not dissatisfied with conventional medicine, but they find alternative therapies "more congruent with their own values, beliefs, and philosophical orientations toward health and life."[3] Although most people using herbal medicines do so in a manner consistent with evidence-based medicine, there is concern that "evidence-based information is not reaching the consumer" and that "health care professionals should proactively educate consumers."[5] This conclusion presumes that health care professionals themselves are first educated on the scientifically established benefits of botanicals. The health benefits of an increasing number of CAM treatments are being supported by published peer-reviewed research. One such study documented that healthy individuals who regularly consume one or more dietary supplements (e.g., vitamin C) may have superior health, increased longevity, or both compared with their peers.[20] Chiropractic and acupuncture for certain chronic and acute conditions have been accepted by the American Medical Association (AMA), which often is reserved in accepting new or unconventional treatment modalities. Most CAM therapies are not so endorsed because the AMA considers scientific evidence regarding their efficacy lacking or insufficient. The AMA does not endorse the sale of dietary supplements from physicians' offices based on concerns that the inventorying and sale of such products may inappropriately affect physicians' clinical judgments.

Although some authors claim that alternative medicine differs from allopathic medicine by virtue of treating the patient as a whole person rather than for the specific disease or collection of diseases, alternative therapies do offer disease-specific methods of care. CAM treatment modalities also constitute a more self-determined form of health care, especially because they are frequently integrated with nutritional and lifestyle modifications. This chapter focuses on natural pharmacologic and therapeutic agents—principally botanical (herbal) remedies—that constitute one of the alternative or integrative means of health maintenance and disease treatment.

TABLE **56-1**

Reasons for Using Complementary and Alternative Medicine Therapies*

Thought CAM combined with conventional medicine would help	54.9%
Thought CAM would be interesting to try	50.1%
Thought conventional medicine would not help	27.7%
Conventional medicine professional suggested CAM	25.8%
Conventional medicine too expensive	13.2%

From Reference 4.
*Based on survey of 31,044 adults ≥18 years old from the U.S. civilian noninstitutionalized population.
CAM, Complementary and alternative medicine.

REGULATIONS AND QUALITY CONTROL

The growth of alternative therapies in the United States was spurred by the passage of the Dietary Supplement Health and Education Act (DSHEA) of 1994. This act greatly boosted the market for dietary supplements, including vitamins, minerals, and botanical remedies. Under DSHEA (Box 56-1), manufacturers could promote herbal products for the maintenance of health by using "structure/function" claims, such as the product "enhances the immune system" and "improves memory." It also permits, but does not require, manufacturers to list product safety precautions. Clarification of DSHEA in 1998 allowed herbal product manufacturers and distributors to make some additional claims, primarily to suggest their use for modifying natural life events, including menopause, pregnancy, and aging.

Under DSHEA, dietary supplements, including herbal products, are legally classified as foods. They are exempted from the normal review process the U.S. Food and Drug Administration (FDA) requires for drugs. New drugs require extensive documentation of purity, safety, and efficacy before FDA approval is given. Dietary supplements require no prior approval, however, of the manufacturer's claims. Nevertheless, the FDA can rely on third-party research to remove products from the market deemed to be unsafe. The FDA's 2004 ban on the sale of ephedra (*Ephedra sinica*, ma-huang) was the first successful action taken by the FDA since DSHEA to remove a potentially dangerous herbal product from the marketplace.

DSHEA also requires that manufacturers must be able to substantiate, when challenged, all claims made either on the container or in the literature that accompanies the dietary supplement product. Such challenges can come from the FDA or from self-regulatory mechanisms, such as the industry-funded program of the National Advertising Division of the Better Business Bureau, wherein ad claims are being reviewed for accuracy, resulting in the revision of such claims where evidence may be lacking or, if the manufacturer does not comply, referral to the Federal Trade Commission for possible action. DSHEA also authorized the FDA to establish Good Manufacturing Practices (GMP) for dietary supplements. The final rule by the FDA regarding current good manufacturing practice for dietary supplements was published in June 2007, and companies are required to comply with all provisions in 1, 2, or 3 years, depending on whether the companies are large-sized, medium-sized, or small-sized. Standard testing remains an ongoing major challenge, however, in the herb and dietary supplement industries and in the analytic laboratory industry.

BOX **56-1**

Important Components of the Dietary Supplement Health and Education Act

Definition of Dietary Supplement
1. A product (other than tobacco) that
   a. Contains one or more vitamins, minerals, herbs, amino acids
   b. Is formulated in capsules, tablets, liquids, powders, soft gels
   c. Is not a conventional food or sole item of a meal or diet
   d. Is labeled as a dietary supplement

Safety of Dietary Supplements
1. FDA has burden of proof that the supplement is dangerous or constitutes a risk to public health
2. New dietary ingredients introduced into the market after October 15, 1994, must have safety data submitted to FDA for premarket acceptance

Supplement Claims and Labeling
1. Manufacturers can make nutrient content claims and claims on how dietary supplement affects structure or function of body
2. Manufacturer must have reasonable evidence/research supporting claims, but is normally not required to disclose it
3. FDA has burden of proof that claim is inadequately substantiated

Statement of Nutritional Support (on Label or in Advertising)
1. Permitted if a classic nutrient-deficiency benefit is claimed
2. Permitted if role of supplement is to affect structure or function of body
3. Can include documented mechanism of action
4. Can describe general well-being from consuming the ingredients
5. Must prominently display disclaimer that statements have not been evaluated by FDA and that product is not intended to treat, mitigate, cure, or prevent a disease

Supplement Ingredient Labeling and Nutrition Information
1. Must include the following (or would be considered misbranded and removed)
   a. Commonly accepted name of each ingredient
   b. Quantity of each ingredient
   c. Total weight of ingredients
   d. Part(s) of the plant from which ingredients is (are) derived
   e. Term *dietary supplement*

Adapted from Israelsen LD: *Summary of the Dietary Supplement Health and Education Act of 1994. Quarterly review of natural medicine,* Seattle, WA, Spring 1995, Natural Product Research Consultants.

Because credibility is an increasingly important factor with consumers, some manufacturing companies of natural products, eager to gain and retain the public's trust, voluntarily established relatively stringent GMP in advance of the final GMP rule published by the FDA for dietary supplements. The botanical product industry is represented by the American Herbal Products Association, the leading organization that works exclusively with herbal product manufacturers to enhance their quality and credibility. Several other trade associations also work with herbal manufacturers (e.g., Council for Responsible Nutrition, Natural Products Associa-

tion, and United Natural Products Alliance). These organizations work with their respective industry members and with the FDA to help promote quality manufacturing standards for herbal and other dietary supplements in cases in which such quality has been shown to be lacking.

For professionals and the lay public, ConsumerLab publishes results of random tests of CAM products on its website (www.consumerlab.com). Products approved by ConsumerLab are eligible to receive its "CL" seal of approval if the manufacturer wishes to pay for the privilege. Currently, approximately 7% of these approved products carry this seal, and the number of such products is expected to increase. The United States Pharmacopeia is also conducting GMP and product quality audits and is offering a seal in its Dietary Supplement Verification Program. Another nonprofit group, NSF International (the world's largest certifier of the purity of drinking water and water filters), also has a program to monitor supplement manufacturers' GMP adherence and product identity and quality.

In addition to a growing trend within the industry to improve quality control, efforts are being made to document the efficacy of natural products for disease prevention and therapy. U.S. investigators face special challenges regarding herbal and other natural products. Much of the existing scientific evidence is reported in languages other than English. The problems of product purity, standardization, and quality control that have plagued this sector are potential research confounders in the United States.

Herbal supplement claims allowed under DSHEA are sometimes based on limited scientific data and may contain no detailed information concerning the types and concentrations of known active ingredients in the preparations.[31] Nevertheless, credible information is accumulating for certain herbal remedies. *Ginkgo biloba* does have antiplatelet effects and may have antioxidant properties; however, its suggested benefit in treating dementia and depression has yet to be reliably shown.[6] Saw palmetto (*Serenoa repens*) has been documented to decrease symptoms associated with benign prostatic hyperplasia.[7,12,30]

In industrialized nations, the German Commission E has been generally acknowledged as the leading regulatory model regarding the therapeutic actions of herbs. The German Commission E published 380 monographs in 1983-1995 based on extensive research. Its work has promoted product standardization, high manufacturing quality, and the acceptance and prescribing of herbal medicines (phytomedicines) by physicians in Germany, although the work of the Commission is now largely that of an advisory role to the German government,[7] as the role of evaluating and approving herbal medicines is now being conducted on a pan-European basis by the European Medicines Evaluation Agency. In the United States, the National Center for Complementary and Alternative Medicine (NCCAM, a division of the National Institutes of Health) is charged with developing evidence-based research information on the full range of alternative therapies, including the use of herbal supplements, by funding a large battery of randomized controlled trials and basic research at more than a dozen research centers documenting the mechanisms of actions of these complex natural substances.

TYPES OF HERBAL DIETARY SUPPLEMENTS AND RELATED BOTANICAL PRODUCTS

Natural products of plants are marketed in unmodified forms, such as the whole leaf, bark, berry, or root; as powders in capsules and tablets; as herbal teas; and in various extracts and other derivatives. The recorded use of natural preparations for their pharmacologic effects dates from at least 2735 BC, when a Chinese emperor recommended the use of ephedra (*Ephedra sinica*, which contains ephedrine and at least five other sympathomimetic agents) for a respiratory condition. Approximately 25% to 30% of prescription medications commonly used to treat diseases today are derived from natural sources. Examples include digoxin from the foxglove plant (*Digitalis purpurea* and *Digitalis lanata*, used to treat congestive heart failure) and quinidine from the cinchona plant (*Cinchona* species, used as an antiarrhythmic drug). Table 56-2 summarizes some common herbal remedies; their possible uses and indications; and their potential liabilities, including potential adverse drug interactions.

Most therapeutic products used as alternative therapies are the natural herb material or extracts of the herb. Water-based extracts include infusions (teas) and decoctions, whereas alcohol extracts are usually marketed as tinctures or other forms of extracts. An increasing number of products are combinations of herbs or mixtures of herbs and so-called nutraceuticals. *Nutraceuticals* are nutritional compounds—usually food extracts or their derivatives (e.g., the carotenoid lycopene derived from tomato)—promoted for use in a therapeutic way to treat or prevent specific problems or diseases. There is also an increasing trend to incorporate herbal derivatives into conventional products ranging from vitamin waters to shampoos to toothpastes (which have long relied on herbal essential oils, such as mint, for flavoring). A potential problem is the surreptitious adulteration of imported herbal products by the inclusion of conventional drugs. A few products have been identified, including the sale of so-called herbal supplements promoted for erectile dysfunction that contain pharmaceutical drug ingredients. Such products are not representative of most herbal dietary supplements sold by reputable manufacturers in the United States and are usually traced to foreign (usually Asian) sources.

Alternative therapies, especially herbs from which pharmacologic or therapeutic agents are derived, may be targeted toward the treatment of specific diseases, although the current regulatory system under DSHEA does not permit such claims for dietary supplements. There is usually some consensus regarding the specific disease for which a preparation is most appropriate. At the same time, there is a wide range of alternative practitioners, and many natural preparations have multiple uses, so when a patient reveals the use of a particular herbal product, the disease or condition being treated cannot always be predicted.

As previously mentioned, a prominent aspect of alternative therapy is the maintenance of health. The trend toward self-help encourages the use of many alternative preparations, which are considered safer than prescription drugs by the public because they are natural and usually less concentrated than conventional drugs. This assumption is often correct, but some substitute preparations (including the aforementioned adulterated product) may be just as or more harmful than the prescription drug, and injudicious use (especially combining the alternative product and the similar drug) can lead to untoward effects.

INTEGRATED HEALTH CARE AND DENTISTRY

Patient Evaluation

With all dental patients, it is essential to take a thorough health history. Various signs and symptoms may be revealed and diagnoses of specific diseases that may influence dental care. An important part of the health history is the solicitation of the patient's medication usage. All health history forms should specifically include questions regarding the patient's

TABLE **56-2**

Pharmacologic Profiles of Common Herbal Products

HERBAL PRODUCT*	USES/EFFECTS	PRECAUTIONS/ADVERSE EFFECTS	DRUG INTERACTIONS
Aloe vera—*Aloe vera* (and related species); aloe, zanzibar	Topical anesthetic (gel). Soothes wounds and burns; accelerates wound healing. Latex form is a laxative	Topical use to abraded skin may cause burning sensation. Ingestion of latex derivative causes powerful catharsis by irritating the large intestine; may cause GI cramps and congenital malformation	Cathartic effect of latex form often hastens passage of oral medications, often inhibiting their absorption, and may potentiate anticoagulant therapy by reducing intestinal absorption of vitamin K
Asian ginseng—*Panax ginseng*; Chinese ginseng	Adaptogen and immunomodulator. Fights fatigue; improves concentration and performance; enhances healing; generally increases ability to tolerate stress and recuperate. Principal male adaptogen in Chinese medicine	Inhibited blood clotting from effects on platelet adhesion and blood coagulation. May reduce blood glucose concentrations. A "ginseng abuse syndrome," with diarrhea, hypertension, and nervousness, has been described, which may be linked to concomitant intake of caffeine and large doses of unknown "ginseng" preparations	May increase effect of hypoglycemic drugs, but promote diuretic resistance when combined with loop diuretics. May potentiate headache, tremors, and mania with MAO inhibitors and increase responses to caffeine. May potentiate bleeding with antiplatelet agents and anticoagulants (but may decrease effect of warfarin)
Astragalus—*Astragalus membranaceus*; milk vetch, huang chi	Adaptogen and immunostimulant. Speeds metabolism	Subject to bacterial degradation when used as a component of denture adhesive. Mutagenic by the Ames test	May decrease effectiveness of immunosuppressants
Bilberry fruit—*Vaccinium myrtillus*; huckleberry, European blueberry	Mild anti-inflammatory of mucous membranes. Slows cataracts, diabetic retinopathy; leaf used as a tea to treat diarrhea	Mild antiplatelet effects. May cause diarrhea in some individuals and should be discontinued if it persists for >3 days. Bilberry leaf is toxic and can cause hypoglycemia	Potentiation of antiplatelet and anticoagulant drugs. Effects may be inhibited by phenobarbital. Leaf may increase effect of hypoglycemic drugs
Cascara sagrada—*Rhamnus purshiana*; buckthorn, sacred bark	Laxative/cathartic	K^+ may be lost, causing weakness and coagulation deficits	Cathartic-induced hypokalemia may potentiate or increase toxicity of muscle relaxants, antiarrhythmics, cardiac glycosides, and K^+-depleting diuretics
Dong quai—*Angelica sinensis*; Chinese angelica	Manage pain from injury, arthritis; improve circulation, treat allergic reactions. Principal female remedy in Chinese medicine for overcoming fatigue and treating gynecologic/menopausal symptoms	Excessive doses may cause hypotension and interfere with platelet activity	Increased hypotensive effects with antihypertensives and opioids. Potentiation of antiplatelet and anticoagulant drugs
Echinacea—*Echinacea purpurea* (and related species); purple cone flower	Immunomodulator. Boost immunity and treat symptoms of upper respiratory infections	Possible allergic reactions in individuals with ragweed and related allergies. Potential aggravation of autoimmune illness (e.g., lupus) and progressive diseases (HIV, tuberculosis)	Anti-inflammatory activity of herb can be inhibited by phenobarbital and other microsomal enzyme inducers. Potential adverse interactions with immunosuppressants (e.g., corticosteroids, cyclosporine)
Feverfew—*Tanacetum parthenium*	Antipyretic anti-inflammatory. Used for prophylaxis of migraine headache and to treat arthritis, premenstrual and menstrual discomfort, and fevers	Chewing fresh leaves or seeds may cause mouth irritation (swelling, ulcers), dysgeusia, nausea, vomiting, insomnia, and diarrhea. Discontinuation may cause postfeverfew syndrome of nervousness, tension headaches, insomnia, and joint discomfort. May cause abortion during pregnancy and interfere with platelet aggregation	Possible increased bleeding with concurrent use of antiplatelet and anticoagulant drugs

Garlic—*Allium sativum*; allium, stinking rose	Used as digestive aid and to treat hypertension and as broad-spectrum topical antibiotic. May decrease LDL cholesterol and triglycerides and increase HDL cholesterol	Possible bleeding from inhibition of platelet aggregation and antithrombotic effects. Allergic reactions possible. Ingestion of large dose may cause burning sensation in mouth and throat. Theoretic risk of increased autoimmune reactions and organ transplant rejection	Possible increased bleeding with concurrent use of antiplatelet and anticoagulant drugs. Possible increased hypoglycemia in patients taking insulin
Ginger—*Zingiber officinale*; black ginger, zingiberis rhizoma	Antibiotic, antioxidant, anti-inflammatory, and antiemetic. Used principally for prophylaxis of motion sickness and to treat digestive disorders, nausea, and vomiting (via local action on stomach receptors)	Possible bleeding from inhibition of platelet aggregation	Possible increased bleeding with concurrent use of antiplatelet and anticoagulant drugs
Ginkgo—*Ginkgo biloba*; maidenhair tree	Leaf extract is used to improve cerebral and peripheral circulation, for enhanced concentration, memory, and hearing; amelioration of dementia; and relief of peripheral vascular disease	Possible bleeding from inhibition of platelet aggregation. Mild GI upset and headache, occasional nausea and vomiting	Possible increased bleeding with concurrent use of antiplatelet and anticoagulant drugs
Goldenseal—*Hydrastis canadensis*; yellow root, orange root, Indian turmeric	Anti-inflammatory and broad-spectrum antimicrobial. Treats digestive and respiratory infections; promotes wound healing	Fresh plant or high doses may cause irritation to oral mucosa and GI distress	None documented
Kava-kava—*Piper methysticum*; kava-kava	Anxiolytic, sedative-hypnotic. Used to treat anxiety, insomnia, and muscle tension	Local anesthetic action causes temporary mouth numbness. May rarely cause hepatotoxicity and liver failure. High doses may cause inebriation, with incoordination, ataxia, and drowsiness. Long-term use may cause reversible scaly skin rash	Summation of effects with benzodiazepines and other CNS depressants. High doses may increase dystonic reactions with antipsychotics and levodopa
Red yeast rice—*Monascus purpureus*; ZhiTai	Antihypercholesterolemic. Blocks cholesterol synthesis and decreases total plasma cholesterol, LDL cholesterol, and triglycerides	Rarely causes hepatic and skeletal muscle damage. Allergic reactions in individuals sensitive to yeast or rice	Inhibitors of CYP3A4 (e.g., erythromycin, ketoconazole) potentiate hepatic and skeletal muscle toxicity. Risk is also increased with coadministration of other lipid-lowering drugs (statins, fibrates, gemfibrozil, niacin). Oral anticoagulant effects are potentiated
Saw palmetto—*Serenoa repens*; sabal	Treats benign prostatic hypertrophy. May inhibit dihydrotestosterone; may have antiestrogenic effects	May occasionally cause GI disturbances	Possible interaction with sex steroids
St. John's wort—*Hypericum perforatum*; Klamath weed	Treats mild-moderate depression and anxiety. Anti-inflammatory in GI and respiratory tracts; eases menstrual cramps. Antiviral in large doses against enveloped viruses in vitro. Topical use as an antibacterial and anti-inflammatory analgesic for minor wounds and infections	Photosensitivity in rare cases, such as with high doses, prolonged treatment, and excessive sun exposure. Induces CYP3A4, CYP1A2, and several CYP2 enzymes in liver and GI tract. May cause drowsiness	Increased phototoxic/photoallergic reactions with tetracyclines, sulfonamides, and proton pump inhibitors. Summation effects with benzodiazepines, opioids, and other CNS depressants. Serotonergic crisis possible with meperidine, MAO inhibitors, and other antidepressants. Decreases plasma concentrations of protease inhibitors, cyclosporine, digoxin, and warfarin
Valerian—*Valeriana officinalis*	Sedative-hypnotic. Used to reduce anxiety, alleviate motor activity and muscle spasms, and promote sleep	Drowsiness	Summation of effects with benzodiazepines, sedative-hypnotics, and other CNS depressants

*Listed in order are the principal **common name**, *scientific name*, and other common names. Some of the uses described in this table have not been validated by well-controlled clinical studies; likewise, many of the adverse effects and drug interactions listed are either speculative or of potential concern but not proved to be clinically significant.
CNS, Central nervous system; *GI,* gastrointestinal; *HDL,* high-density lipoprotein; *HIV,* human immunodeficiency virus; *LDL,* low-density lipoprotein; *MAO,* monoamine oxidase.

use of alternative or natural therapeutic agents. Although some patients provide this information unsolicited under the "medication" question usually asked in health questionnaires, other patients do not for various reasons. One reason is that they may not believe or understand that their alternative therapy products are considered medications. They also may not feel comfortable telling a conventional health care provider that they are using alternative therapies for fear of disapproval. In either case, there is a much greater probability that they would provide the information if it is specifically solicited, such as by a question requesting the patient to list "natural remedies" being taken.

If a dental patient is taking any alternative product, the dentist should inquire about its identity and doses and whether the product is being used preventively or to treat specific problems. Various natural products potentially may influence dental therapy, but most commonly the dose is low enough, the patient is healthy enough, and the dental procedure is sufficiently minor that specific interactions between alternative medicines and dental procedures do not occur. Still, it is important to be aware of the potential interactions and, if necessary, to acquire reliable information to advise the patient whether consultation with the health care provider is necessary to determine if modification of the patient's use of the alternative therapy during prescription drug therapy is appropriate. Another aspect of obtaining an accurate alternative medicine health history is that the product and the patient's reason for taking it provide information concerning the patient's overall health. If a patient is taking coenzyme Q_{10} (CoQ_{10}), it provides an opportunity to ask questions regarding the patient's general health and whether signs or symptoms suggestive of cardiac or other problems have been experienced.

Modifications of Dental Treatment

Sometimes the use of alternative medicines by a dental patient requires modification of the treatment plan. Most commonly, before surgical procedures, modification involves stopping herbal remedies that inhibit hemostasis. As listed in Tables 56-2 and 56-3, numerous alternative products may potentially exert antiplatelet or anticoagulant activity, but chief among them are garlic and ginger. The practitioner should be aware that the food form of the herb may be just as potent as the supplement. Bleeding can pose a significant problem after major oral and maxillofacial surgery and be a nuisance during the performance of minor surgical procedures.[2] Hospitals and surgeons are increasingly requiring patients to stop taking specific herbal products for 2 weeks before surgery. Although

TABLE **56-3**

Potential Herbal and Other Dietary Supplement Drug Interactions in Dentistry*

DENTAL DRUG	HERBAL/NUTRACEUTICAL PRODUCT	EFFECT	RECOMMENDATION
NSAIDs	Bilberry fruit, bromelain, cat's claw, coleus, cordyceps, devil's claw, evening primrose, feverfew, fish oils, garlic, ginger, ginkgo, ginseng, grape seed, green tea, guggul, horse chestnut, licorice, prickly ash, red clover, reishi, S-adenosylmethionine, turmeric, vitamin E	Antihemostatic effects (primarily antiplatelet actions) may result in increased bleeding after surgical procedures for which NSAIDs are prescribed	Avoid aspirin; use other NSAIDs cautiously after procedures likely to cause postoperative bleeding
	Deglycyrrhizinated licorice	May reduce or prevent GI bleeding	Dissolve deglycyrrhizinated licorice sublingually 20-30 min before consuming NSAID†
Meperidine, tramadol	5-hydroxytryptophan, L-tryptophan, S-adenosylmethionine, St. John's wort	Theoretic concern of serotonin syndrome	Avoid combined use
Benzodiazepines, barbiturates, opioids, other CNS depressants	Kava, melatonin, St. John's wort, valerian	Increased CNS depression	Avoid combined use
	Astragalus, coleus, hawthorn, dong quai, garlic, parsley, sage	Postural hypotension more likely	Protect patient against postural hypotension: change position slowly; avoid dehydration
Penicillin VK	Guar gum	Penicillin absorption inhibited	Avoid concurrent administration
Sulfamethoxazole-trimethoprim	p-Aminobenzoic acid	Competitive inhibition of antimicrobial effect	Avoid combination
Sulfamethoxazole-trimethoprim, tetracyclines	Dong quai (related species), St. John's wort	Phototoxic/photoallergic reactions more likely	Avoid combination
Tetracyclines	Calcium, iron, magnesium, zinc salts	Decreased tetracycline absorption	Avoid concurrent administration
Antibiotics	Probiotic supplements‡	Possible decreased GI adverse effects	Administer probiotic 20-30 min before or 2-3 hr after antibiotic

*Many of the interactions noted in this table are speculative and theoretic and are lacking adequate clinical evidence in humans. For an evidence-based assessment of hundreds of herbs and their potential or actual interactions with conventional pharmaceutical medications, see Brinker F: *Herb contraindications and drug interactions,* ed 3, Sandy, OR, 2001, Eclectic Medical Publications. Electronic updates with new information not included in the book are available at: http://www.eclecticherb.com/emp. Accessed January 8, 2010.

†Some of the proposed interactions noted in this table are beneficial (e.g., the effect of sublingual licorice on reducing potential gastric irritation caused by oral administration of NSAIDs).

‡Preparations of normal gut flora used to help restore the normal microbial ecology disrupted by the antibiotic.

CNS, Central nervous system; *GI,* gastrointestinal; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

this policy is undoubtedly excessive in most cases, the pervasive lack of knowledge concerning the identity, concentration, and pharmacokinetics of the active principles in most herbal products suggests that a restrictive policy is justified because of the risks and benefits involved. A second consideration regarding these herbal medicines is the possibility of postoperative bleeding if the dentist prescribes a nonsteroidal anti-inflammatory drug for postoperative pain relief (see Table 56-3). There is a potential for added risk of bleeding if a nonsteroidal anti-inflammatory drug, especially aspirin, is administered to a patient taking supplemental garlic or ginkgo.[11] The use of acetaminophen, opioids, or the cyclooxygenase-2–selective analgesic celecoxib may avoid this potential drug interaction.

Orthostatic hypotension may be more likely to occur in patients taking herbal products capable of decreasing arterial blood pressure. Such products include astragalus, dong quai, and sage. Patients taking these remedies—especially elderly patients, patients with cardiovascular disease, and patients fasting for sedation or anesthesia—should be monitored for hypotension. In addition, changes in body position (as in moving from the supine to the standing position) should be made slowly and with careful patient observation.

Several herbal agents, including kava and valerian, can cause sedation.[22] Their combination with standard doses of prescribed anxiolytics and sedative-hypnotics may result in severe central nervous system depression. Conversely, long-term use of these agents may decrease responsiveness to benzodiazepines and related drugs. Meperidine and tramadol probably should be avoided in patients taking St. John's wort because of the agents' shared potential for increasing 5-hydroxytryptamine activity in the brain, possibly resulting in a serotonergic syndrome of restlessness, motor hyperactivity, and coma.

St. John's wort may interact with a diverse array of medications because of its ability to stimulate microsomal enzyme activity.[15,17] Although increased drug metabolism is less of a problem in dentistry than it is in medicine, the increased first-pass metabolism of triazolam and related benzodiazepines may decrease benzodiazepine effectiveness when given by the oral route. Conversely, fresh garlic may significantly inhibit the first-pass effect, resulting in exaggerated triazolam effects.[13]

Herbal Therapies for Oral Conditions

An important area of interest for dentists, hygienists, and patients is the use of alternative remedies to manage dental and other oral problems. Agents listed in Table 56-2 that have antimicrobial, immunostimulant, and anti-inflammatory actions may be used systemically for various oral conditions. In addition, there is a growing range of natural and herbal products formulated for topical oral use, including numerous mouth rinses, toothpastes, and irrigating solutions. Herbal dental products typically include agents that may be classified as astringents, antimicrobials, anti-inflammatories, immunostimulants, circulation enhancers, tissue healers and soothers, and breath fresheners. Some of these natural agents are listed in Table 56-4.

Because of the importance of antiplaque/antigingivitis effects on gingival health and because of evidence suggesting antimicrobial effectiveness, numerous natural products for this use are now marketed. Most of these products contain essential oils and other herbal derivatives. Essential oils distilled from plants have been used for centuries as antimicrobials. Specifically, eugenol, thymol, carvacrol, and oil of cloves have a 200-year history of use in dental products. Essential oils are extracted from the glands, veins, sacs, and glandular hairs of aromatic plants. The essential oils are said to penetrate the oral mucosa between cells and through lipids and salivary ducts, allowing for enhanced adherence and a longer lasting effect.[25]

Few of the natural antigingivitis/antiplaque mouth rinses currently available have been scientifically evaluated. As previously mentioned, the quality of herbal extracts can vary greatly from one product to another. In addition, manufacturers may use a wide range of extraction processes,[28] which creates variability among products that are formulated with the same ingredients and for a similar purpose. Nevertheless, some herbal products contain antimicrobial substances similar in efficacy to chlorhexidine (the "gold standard" of periodontal maintenance therapy) without causing the tooth staining that commonly occurs with chlorhexidine.

Tinctures of chamomile and myrrh have an inhibitory effect in vitro on certain anaerobic microorganisms comparable to that of chlorhexidine.[21] Derivatives from plants such as goldenseal, rhatany, and sage are also reported to exert anti-inflammatory, astringent, and antiseptic actions.[27,29] Echinacea, gotu kola, and calendula are included in oral rinses to provide anti-inflammatory and tissue-regenerative properties. Goldenseal extracts contain variable quantities of berberine, hydrastine, canadine, and canadaline, one or more of which may be active against herpes labialis, mucositis, and gingivitis. These anti-inflammatory and antimicrobial benefits have been shown in cell culture and animal studies.[1,23]

Currently, the Council on Scientific Affairs of the American Dental Association (ADA) has four categories of dental therapeutic agents (antiplaque/antigingivitis drugs, anticaries agents, antihypersensitivity agents, and tooth-whitening products), each with specific criteria for evaluating the safety and efficacy of over-the-counter dental products. The potential exists for natural or herbal ingredients to be incorporated in multiple products for use in all these areas. One example is xylitol (an anticaries agent), found in toothpastes, mints, and gum and adhesive products, among others. Another is an herbal-related product, Listerine, which has the ADA Seal of Acceptance for antiplaque/antigingivitis activity. Listerine contains the essential oils menthol, thymol, eucalyptol, and methyl salicylate (although these oils are no longer naturally derived). Numerous herbal dentifrices with antimicrobial effects have been marketed. Most have effects against one or more oral pathogens; however, in one study, most did not show consistent antimicrobial activity against all four of the oral microorganisms tested: *Streptococcus mutans, Streptococcus sanguis, Actinomyces viscosus,* and *Candida albicans*.[24]

Kaim and coworkers[19] compared, in vitro, the antimicrobial activities of Listerine, 0.12% chlorhexidine gluconate, and a mouth rinse (Herbal Mouth and Gum Therapy) containing *Echinacea*, goldenseal, and other natural ingredients. All three oral rinses were found to exhibit significant antimicrobial activity against the microorganisms tested. In a separate examiner-blinded, parallel-group clinical trial, the herbal mouth rinse was shown to reduce gingival bleeding compared with a control mouth rinse.[26] For patients who prefer natural remedies, products such as this mouth rinse may offer motivational, psychological, and self-care benefits along with some specific antiplaque/antigingivitis efficacy.

The potential for interactions between herbal supplements and conventional medications used in dentistry has been an increasing concern among practitioners as more consumers use more herbal products along with conventional medications. A *Prevention* magazine survey found adult consumers use herbal supplements with prescription drugs (31%) and with over-the-counter drugs (48%), suggesting an increased potential for herb-drug interactions (HDIs).[18] Although there is a documented growth in the use of the herbal products with conventional medications, there has not

TABLE **56-4**

Herbal Ingredients in Oral Health Care Products

HERBAL INGREDIENT	PRODUCTS	POSSIBLE USES AND EFFECTS
Aloe vera (*Aloe vera*)	Mouth rinse, toothpaste, lubricating gel, antiseptic gel	Anti-inflammatory, antiseptic, promotes healing of canker sores and wounds
Anise (*Pimpinella anisum*)	Mouth rinse, toothpaste	Breath freshener; may increase bleeding
Bloodroot (*Sanguinaria canadensis*)	Mouth rinse, toothpaste	Inhibits oral bacteria, used for gingivitis/periodontitis; may cause leukoplakia
Calendula (*Calendula officinalis*)	Mouth rinse, toothpaste	Anti-inflammatory, promotes wound healing
Carrageenan (from red seaweed)	Toothpaste, tooth gel	Stabilizer, thickener
Cinnamon (*Cinnamomum verum* and related species)	Mouth rinse, toothpaste	Breath freshener
Clove (*Eugenia caryophyllata*)*	Toothache balm, mouth rinse, toothpaste, temporary filling material	Anti-inflammatory, analgesic, antifungal; may cause increased bleeding
Eucalyptus (*Eucalyptus globulus*)	Mouth rinse, toothpaste	Antiseptic
Ginkgo (*Ginkgo biloba*)	Toothpaste	No use reported
Goldenseal (*Hydrastis canadensis*)	Mouth rinse, toothpaste, antiseptic gel, tooth gel	Immunostimulant, antibiotic, used for cold sores
Green tea (*Camellia sinensis*)	Toothpaste	Antiviral, cariostatic, antineoplastic, used for gingivitis/periodontitis; if swallowed may decrease absorption of basic drugs
Lemon balm (*Melissa officinalis*)	Antiseptic gel, lip balm	Antiherpetic; used to treat cold sores, nerve pain; may increase intraocular pressure
Licorice (*Glycyrrhiza glabra*)	Toothpaste, topical gel	Flavoring, antiherpetic, used to treat cold sores, canker sores
Myrrh (*Commiphora molmol*)	Mouth rinse, floss, tincture	Anti-inflammatory, anticandidal, breath freshener, astringent; used to promote healing and for gingivitis
Neem (*Azadirachta indica*)	Toothpaste	Antimicrobial, mild abrasive, plaque inhibitor
Peelu (*Salvadora persica*)	Toothpaste, natural toothbrush	Mild abrasive, antibacterial, hemostatic, breath freshener
Peppermint (*Mentha piperita*)†	Mouth rinse, oral gel, dental gum, breath freshener, antiseptic gel, temporary filling material	Antibacterial, breath freshener, used for gingivitis/periodontitis and externally for myalgia and neuralgia; peppermint oil can cause burning sensation; possible tongue spasm; respiratory arrest contraindicates use in young children
Prickly ash (*Zanthoxylum americanum*)	Mouth rinse	None reported (analgesic and promotes healing?)
Propolis (propolis balsam)	Toothpaste, flossing ribbon, in lysine gel	Analgesic, antibacterial, antifungal, mild anti-inflammatory, promotes healing
Spearmint (*Mentha spicata*)‡	Toothpaste	Breath freshener
Stevia (*Stevia rebaudiana*)	Dental gel, mouth rinse	Cariostatic sweetener, weak antimicrobial
Tea tree oil (*Melaleuca alternifolia*)	Mouth rinse, breath freshener, antiseptic (in lozenges, toothpicks)	Antibacterial, antifungal, antiviral; may cause irritation in sensitive individuals
Thyme (*Thymus vulgaris*)	Mouth rinse	Antiseptic, breath freshener
Vegetable glycerin (glycerol)	Toothpaste, antiseptic gel	Lubricant, soother, sweetener
Witch hazel (*Hamamelis virginiana*)	Mouth rinse (alcoholic extract)	Anti-inflammatory, soothing astringent (from alcoholic content), promotes wound healing; may cause stomach irritation if accidentally ingested
Xylitol (from birch tree bark)	Toothpaste, chewing gum	Cariostatic sweetener§

*Derivatives used in dentistry: eugenol, clove oil.
†Derivatives used in dentistry: menthol, peppermint oil.
‡Distillate used in dentistry: spearmint oil.
§Bacteria cannot metabolize xylitol, which is converted to glucose in the liver.

been a significant increase in reports of adverse HDIs associated with the growing herb use. Several more recent published reports support this lack of adverse HDIs.

In one 2007 report, researchers concluded that numerous potential adverse HDIs were detected and a few mild adverse interactions were observed, primarily in diabetics taking nopal (prickly pear cactus, *Opuntia* species) with oral hypoglycemic drugs. Screening for herbal medicine usage in 804 patients did not uncover any serious adverse interactions with prescription medications.[8] A Canadian study of 7652 cognitively functional elderly individuals found only 1.3% using combinations of prescription medicines and herbal products that are considered potentially dangerous. In this study, the low incidence of potentially dangerous interactions was credited by researchers to greater awareness of potential risks among consumers and physicians.[9] About two thirds of adults consuming herbs (*Echinacea* was excluded) did not take the herbs according to evidence-based indications,

however.[5] This finding points out the need for greater education of the public by health care professionals. A 2001 review concluded that many of the HDI reports found in the clinical literature up to that time were inadequately documented, preventing an appropriate evaluation of the clinical significance of many of these reports.[14]

In a 2008 survey of 1818 patients, 1795 responded, and 710 (40%) of respondents reported use of dietary supplements. A total of 107 interactions with potential clinical significance were identified. The five most common natural products with a potential for interaction (garlic, valerian, kava, ginkgo, and St John's wort) accounted for 68% of the potential clinically significant interactions. The four most common classes of prescription medications with a potential for interaction (antithrombotic medications, sedatives, antidepressants, and antidiabetic agents) accounted for 94% of the potential clinically significant interactions. No patient was seriously harmed from any interaction. The researchers concluded that a few prescription medications and dietary supplements accounted for most of the interactions. The actual potential for harm was deemed to be low.[27]

SOURCES OF RELIABLE INFORMATION

As noted, the field of alternative medicine has grown quickly since 1994. This growth is expected to continue. Because the demand for information is coming from health professionals and laypersons, numerous resources have been developed for each audience. Textbooks such as this can present a brief overview of alternative medicine, but cannot provide in-depth information or remain current in such a rapidly developing discipline. Some published sources of information pertaining to herbal products are listed as general references. Table 56-5 contains a list of websites that provide access, often for a fee, to current, detailed information on alternative therapies, particularly herbs and dietary supplements. A dental professional wishing to keep abreast of this area may wish to subscribe to one of these sites. One website sponsored by NCCAM can be consulted free of charge for the latest information on research projects that the center is sponsoring.

APPENDIX 1

*Drug Interactions in Clinical Dentistry**

Numerous studies have documented that drugs are rarely taken in isolation. For example, adults in contemporary society may take an average of four to five drugs daily, and hospitalized patients may receive from 9 to 13 different agents every 24 hours, depending on the institution, the patient's status, and the intercommunication among attending physicians. As the number of administered drugs increases arithmetically, the risk of an adverse drug reaction increases geometrically. Although some of this increase undoubtedly reflects a greater severity of disease and reduced physiologic reserve in patients requiring multidrug therapy, it also underscores the fact that drugs may interact with each other in producing toxicologic effects. Drug interactions, in fact, account for 5% to 10% of all adverse reactions to drugs and may be responsible for extending the hospital stay of approximately 15% of admitted patients. However, not all drug interactions are clinically significant or undesired, and some are actively sought in pharmacotherapeutics to increase drug effectiveness, decrease toxicity, or both. This section reviews the basic principles and general mechanisms of drug interactions and illustrates these interactions with selected examples. Some interactions are not included here, for example, medication interference with laboratory tests and metabolic interactions with environmental chemicals, such as pesticides that alter in vivo enzyme activity. Interactions involving herbal products are described in Chapter 56. Finally, it is generally assumed for the sake of simplicity that only two agents are interacting concurrently.

The sources of drugs that may be involved in drug interactions are varied. They may be prescribed or administered by a single physician or dentist or by several practitioners. Patients may also medicate themselves with over-the-counter preparations, with drugs provided by relatives or friends, or with medication remaining from a previous prescription. Finally, certain substances in foods and in cigarette smoke may interact with administered drugs. Potential interactions between concurrently administered drugs are both dose and duration dependent; nevertheless, the degree or severity of an adverse interaction is seldom predictable. In the discussion that follows, drug interactions are reviewed according to type and mechanism, and examples of each are included for illustration.

Classification of Drug Interactions

Drug interactions are expressed in a bewildering diversity of altered responses. Quantitative changes in reactions to one or more drugs can occur, and complex systems of nomenclature and mathematic description have been developed to characterize the combined effects of drugs. Although such approaches are of theoretic and experimental value, they are less useful in the clinical setting and fail to take into account some qualitative changes in drug effect that can occur.

The simplest clinical classification scheme recognizes three basic types of drug interactions: *antagonism*, *potentiation*, and *unexpected drug effect*. Implicit in this classification is a primary or "object" drug whose effects are modified (i.e., reduced, increased, or transformed) and an interacting or "precipitant" drug responsible for altering the effects of the object drug. Omitted, however, are drugs that produce identical or similar actions, yielding a *summation* of drug effects when the drugs are administered together. Inasmuch as summation is commonly exploited in therapeutics and is often responsible for adverse drug reactions, it is included here. A last category, *synergism*, is used to identify agonist combinations that yield a magnitude of effect beyond that obtainable with a single agonist regardless of dose.

Antagonism

Antagonism indicates that the biologic or clinical response to a drug is reduced by administering a second agent. In some cases, the action of one or both of the drugs might be diminished or completely lost. An example of this type of interaction is occasionally seen in antibiotic therapy, where the combined use of a drug that acts by inhibiting the synthesis of bacterial cell walls, such as penicillin, and one that acts by inhibiting bacterial protein synthesis, such as tetracycline,

*This appendix lists important interactions that may occur between drugs a patient is taking for nondental conditions and common antimicrobial, analgesic, local anesthetic, and antianxiety-sedative preparations prescribed or used in clinical practice. It is assumed that all prescriptions are for short-term therapy (i.e., ≤1 week) and that all drugs are in conventional dosages. Antimicrobial drugs include oral forms of penicillins (e.g., penicillin V, amoxicillin), cephalosporins (e.g., cephalexin, cefaclor), macrolides (including the various salt forms of erythromycin), tetracyclines (e.g., tetracycline, doxycycline), clindamycin, metronidazole, and parenteral ampicillin. Analgesics covered consist of peripherally acting NSAIDs, acetaminophen and opioid analgesics, opioid agonist-antagonists, and their combinations. Local anesthetics include all formulations currently available for dental use in the United States. Antianxiety-sedative drugs include short-acting and ultrashort-acting barbiturates, propofol, benzodiazepines, chloral hydrate, and hydroxyzine. The term *use cautiously* indicates that the interaction is rare or not usually dangerous (or both), and that careful administration within recommended dosage limits and increased surveillance of drug effects should suffice to avoid serious toxicity.

results in less antimicrobial activity than might have been obtained by adequate doses of either antibiotic used alone.

Antagonism can directly occur when an antagonist produces a physical or chemical change in the agonist, reducing or abolishing its activity. An example of this is the chelation of divalent cations in antacids by tetracycline, reducing the absorption and therefore the therapeutic effectiveness of that antibiotic. A second form of antagonism may develop when one drug modifies the disposition of a second agent. An antagonism of this nature is caused by a compound that stimulates drug metabolism and shortens the biologic half-life of the agonist. Third, competition can develop between drugs for the same receptor site, diminishing or even abolishing the effectiveness of the active drug. Such pharmacologic antagonisms frequently occur with drugs that act on the autonomic nervous system, such as the blockade of sympathomimetic amines by α- and β-adrenergic antagonists. Fourth, antagonism of receptor activation may be of a noncompetitive nature, such as when one drug allosterically modifies the affinity of a receptor for a second agent. Finally, drugs having opposing actions at different receptor sites may partially or completely antagonize the effects of either or both drugs. Examples of this type of antagonism are the opposing effects of simultaneous administration of central nervous system (CNS) stimulants and depressants or the physiologic antagonism of glucocorticoids and insulin.

Potentiation

Potentiation is said to occur when a combination of two drugs that do not share similar pharmacologic activities results in an effect of one of the drugs that is greater than expected. Although not active in producing the effect by itself, the precipitant or potentiating drug sensitizes the person to the active object drug. Often, this form of interaction occurs when the precipitant drug elevates the free concentration of the active drug by increasing its absorption, altering its distribution, or inhibiting its elimination. A typical example of potentiation is the increased neuromuscular blocking activity of succinylcholine occurring in patients receiving a pseudocholinesterase inhibitor, such as neostigmine, which inhibits the inactivation of succinylcholine.

Unexpected drug effect

On occasion, the combination of two or more drugs can result in a response typically not observed when any of the drugs is given singly, even in overdose. One possible way in which such a novel drug effect may occur involves perturbation of the metabolism of one drug by another, leading to the formation of a highly active metabolite. For instance, disulfiram inhibits the intermediary metabolism of alcohol, resulting in the accumulation of acetaldehyde if alcohol is ingested by the patient. The symptoms of acetaldehyde intoxication—throbbing headache, blurred vision, pronounced hypotension, chest pain, dysphoria, and mental confusion—constitute a syndrome that does not normally occur with either drug administered alone.

Summation

Summation refers to the combined activities of two or more drugs that elicit identical or related pharmacologic effects. If the drugs act at the same site and produce simple arithmetic summation of effects, they are said to be *additive*. In this case, the drugs are interchangeable when the dose of each drug is expressed as a percentage of that drug's median effective dose. *Infraadditive* and *supraadditive effects* indicate, respectively, interactions that yield less than or more than an expected additive response. In all these situations, however, the maximum effect that can be obtained is no greater than what can be achieved by sufficient doses of a single drug. Examples of drugs that summate by acting at identical and at different sites include the opioid analgesics morphine and meperidine and the general anesthetics midazolam and sevoflurane.

Synergism

Occasionally, the combination of two or more agonists produces an effect that is greater quantitatively than what can be achieved by maximally effective doses of any one drug given alone. Common examples of *synergism* used therapeutically include the combination of chemotherapeutic agents to treat certain infections (e.g., tuberculosis) and neoplastic diseases. In these situations, the emergence of drug resistance is reduced and the cure rate is enhanced. The combination of alcohol and carbon tetrachloride provides an example of synergism leading to acute toxicity. Here, hepatotoxicity is much greater than what is typically associated with either drug given alone.

Mechanisms of Drug Interactions

Drug interactions can occur at any point along the pharmacologic pathway of the agonist, from even before the drug is administered to a patient, to the period when it is in contact with its site of action, to the point at which it is eliminated. The various mechanisms involved in drug interactions can be grouped taxonomically into three broad categories: pharmaceutical, pharmacokinetic, and pharmacodynamic interactions.

Pharmaceutical interactions

Pharmaceutical interactions represent drug incompatibilities of a physical or chemical nature. In general, pharmaceutical interactions can be anticipated between organic acids and bases, resulting in precipitation of one or both drugs. Chemical reactions between drugs may also occur, but these are less common. Most pharmaceutical interactions of importance to dentistry involve drugs that are given parenterally for intravenous sedation. As a general rule, drugs should not be mixed within the same syringe.

Pharmacokinetic interactions

Pharmacokinetic interactions derive from the influence of one drug on the absorption, distribution, biotransformation, or excretion of another drug.

Absorption. Many times an interaction affects the rate or extent of effective absorption of a drug into the systemic circulation, causing a decrease or increase in that drug's effect. Factors influencing absorption include the pH of lumen fluids, enzyme activity, and intestinal motility. Familiar examples of interactions that decrease drug absorption include the previously mentioned chelation by tetracycline of multivalent cations (Ca, Mg, Fe, and Al) in dairy products, antacids, or ferrous salts and the hydrolysis of penicillin G by fruit juice acids, resulting in a decrease in the amount of antibiotic available for absorption and therefore a decrease in the therapeutic effect. Dentists are familiar with combining vasoconstrictors with local anesthetics to retard absorption of the anesthetic from the site of administration.

A well-known example of an interaction that facilitates or increases absorption occurs in patients taking monoamine oxidase (MAO) inhibitors. Tyramine in beer, ripened cheese, red wine, and many other fermented foods is normally not absorbed because it is enzymatically inactivated by MAOs in the intestinal mucosa and liver. When MAO inhibitors suppress these enzymes, tyramine, a sympathomimetic amine, is absorbed in excessive amounts, releasing norepinephrine from sympathetic nerve endings. The effect frequently results in drug toxicity, including severe headache and, occasionally, hypertensive crisis and death.

Distribution. After a drug is absorbed, an interaction may modify its distribution or the rate of transfer of the drug from one location to another. Drugs may be free in the bloodstream or become reversibly bound to plasma or tissue components. Plasma proteins, primarily albumin and α_1-acid glycoprotein, act as acceptor or storage sites for many drugs. Protein-bound drugs are inactive, being unavailable for active combination with a receptor site, for biotransformation, or for glomerular filtration. Because a bound drug is in equilibrium with the free drug in plasma and tissue fluids, an interacting drug that displaces an agonist from its protein-binding sites raises the plasma concentration of the pharmacologically active, unbound agonist. This potentially increases its pharmacologic activity; it may also increase the amount available for metabolism and excretion, thus shortening its duration of action. Warfarin, which is highly protein bound, is displaced from its plasma protein binding sites by chloral hydrate (specifically, the trichloroethanol metabolite), transiently potentiating the anticoagulant effect and increasing the possibility of spontaneous hemorrhage. Of course, this interaction is more likely to become clinically evident in patients with a variant CYP2C9 phenotype.

Distribution across cellular membranes can be influenced by drugs that compete for or otherwise block active transport mechanisms such as the P-glycoprotein transporter, alter pH gradients, or disrupt membrane diffusion barriers. Inhibition of the active uptake of adrenergic vasoconstrictors into sympathetic nerve terminals by tricyclic antidepressants increases the concentration of the adrenergic drugs in the synaptic cleft. Drugs that cause acute respiratory acidosis tend to shift the distribution of opioid analgesics from intracellular locations to the extracellular space. Because the opioid receptors are located on the external surface of the plasma membrane, increased opioid effects result. The intra-arterial administration of osmotic agents to shrink the endothelial cells forming the bulk of the blood-brain barrier increases the entry of anticancer drugs into the CNS.

Metabolism. The degree and duration of activity of a drug are often functions of its metabolism; therefore an interacting drug can modify the effect of an agonist by altering its rate of biotransformation. Most drugs used therapeutically are metabolized in the liver by the microsomal enzyme system. As discussed in Chapter 2, the CYP family of enzymes is commonly involved in these reactions. Inhibition of CYP isozymes provides a rich source of drug interactions. Erythromycin, for instance, irreversibly inhibits CYP3A4; its nitrosoalkane metabolite forms complexes with the CYP3A4 iron, blocking the metabolism of other drugs dependent on the same CYP. These agents include the opioid agonist alfentanyl, the hypnotic agent triazolam, the immunosuppressant cyclosporine, and a host of other pharmacologically unrelated compounds. Additional agents that are capable of inhibiting the metabolism of multiple drugs include amiodarone, cimetidine, fluvoxamine, disulfiram, and the MAO inhibitors. In the latter two cases, nonmicrosomal enzymes are the targets of inhibition (alcohol dehydrogenase and MAO, respectively).

The anticonvulsants phenobarbital, phenytoin, and carbamazepine are known to induce the production of hepatic microsomal enzymes that are responsible for their own biotransformation. These same microsomal enzymes, however, also metabolize other drugs, such as oral anticoagulants, resulting in an increase in the rate of biotransformation of the anticoagulant and a consequent decrease in the active free form, with a resultant loss of therapeutic effectiveness. Because the effect of the enzyme-inducing agent is not permanent, care must be taken to reassess the anticoagulant dosage when the inducer is withdrawn, because effective doses of the anticoagulant in the presence of enzyme induction may lead to spontaneous hemorrhage after the induction is lost. The antibiotic rifampin also causes enzyme induction, resulting, for instance, in a decreased efficiency of hydrocortisone used in the treatment of acute asthma.

The hepatic biotransformation of some drugs may be indirectly affected by other agents that influence hepatic blood flow. Part of the inhibition of lidocaine clearance by the liver in patients receiving propranolol, for example, is believed to result from the fact that propranolol reduces cardiac output, hepatic blood flow, and therefore the transport of lidocaine to the liver, its primary site of elimination.

Excretion. Increasing or decreasing the rate of excretion, or renal or biliary clearance, of a drug also alters its elimination rate constant and therefore the amount of drug available in the circulating plasma, thus affecting the duration and the degree of activity of the drug. Renal excretion is influenced by urinary pH and tubular reabsorption, as well as inhibition of active transport. For example, weak acids such as aspirin are more rapidly excreted in an alkaline urine produced by sodium bicarbonate, whereas weak bases such as amphetamine are more readily excreted in a urine acidified by ammonium chloride. Tubular secretion of an object drug might also be decreased by an interacting agent. A common example is that of probenecid, which, by competing for the same renal transport system as the penicillins, increases the serum concentration and the duration of action of the penicillins.

Pharmacodynamic interactions

Pharmacodynamic interactions represent modifications in the pharmacologic effects of a drug independent of any change in the quantitative disposition of that drug. Such interactions may increase, diminish, or qualitatively alter the therapeutic effect.

Many interactions take place at or near receptor sites. The mechanisms involved can include competition for the receptor or alterations of either the receptor or its natural ligand. This type of interaction is especially common among autonomic drugs. For instance, phentolamine and propranolol are specific competitive antagonists for epinephrine at α- and β-adrenergic receptors. A drug such as guanethidine affects the synthesis, storage, release, and reuptake of norepinephrine, resulting in depletion of norepinephrine in the neuronal vesicles. Subsequent administration of an agent that acts by evoking the release of norepinephrine (e.g., ephedrine or amphetamine) is less effective. An example of the opposite effect is that of MAO inhibitors, such as pargyline, which permit the accumulation of norepinephrine by forming complexes with the enzyme that metabolizes the neuromediator within the nerve terminals. In this instance, ephedrine or amphetamine produces markedly exaggerated effects.

Interacting drugs may also exert their effects at sites of action in different locations. A previously cited example of this phenomenon is the physiologic antagonism of CNS stimulants, such as caffeine or amphetamine, by CNS depressants, such as the benzodiazepines or anticonvulsants. When the agents are administered simultaneously, these drug groups produce opposing actions. Probably the most common interactions involve drugs that evoke similar pharmacologic effects. Combinations of alcohol, barbiturates, benzodiazepines, phenothiazines, antihistamines, bromides, or other drugs capable of producing CNS depression are sometimes unwittingly consumed by people, resulting in somnolence, unconsciousness, or even death.

Factors Influencing Drug Interactions

Several variables can affect the occurrence and intensity of potential drug interactions. Prime among these are variations in the handling of and reaction to administered drugs,

including the genetic-based differences described in Chapter 4. Drug interactions and drug effects are both dose dependent and duration dependent; thus an interaction may not be clinically discernible each time interacting drugs are administered. The higher the dosage and the longer the administration, the greater the chance that an interaction may occur. Previous exposure affecting drug transport, metabolism, or responsiveness may alter the potential for interaction. In addition, many drugs have a long biologic half-life, and effective concentrations may be present in the blood or tissue for many days after the cessation of therapy; interactions may occur, therefore, days and occasionally weeks after discontinuation of therapy with one of the interacting drugs.

Drug Interactions Used in Pharmacotherapeutics

Combinations of drugs are used in therapy to provide enhanced effects and to prevent adverse reactions. Purposeful drug interactions are especially common in the treatment of certain diseases, such as essential hypertension, tuberculosis, and cancer, in which the concurrent administration of two or more drugs is routine. Drugs may also be given sequentially so the second agent abruptly terminates the action of the first. Thus edrophonium, a cholinesterase inhibitor, is administered to reverse the neuromuscular blockade of vecuronium, and leucovorin (folinic acid) is administered to "rescue" patients given potentially lethal doses of methotrexate, a folic acid analogue used in cancer chemotherapy. Agents useful as specific antidotes in accidental drug overdosage include protamine for heparin, naloxone for opioid analgesics, and atropine for anticholinesterases.

Particular mention should be made of fixed-dose combination products. Such preparations make up a significant fraction of all drugs sold in the United States, from over-the-counter remedies to prescription items to agents administered by practitioners. The fixed combination of a local anesthetic with epinephrine to provide more effective and more prolonged anesthesia is a notable example. In general, drug mixtures include a principal ingredient for the main therapeutic effect; adjuvants that summate with, potentiate, or otherwise complement the first drug; and correctives that antagonize or minimize undesired side effects.

The major criticisms of fixed-dose combinations are (1) the inability to adjust the dosages of the individual ingredients to the needs of a particular patient; (2) discrepancies in half-lives of individual agents, leading to the accumulation of some, but not other, constituents during repeated administration; (3) the likelihood of taking unnecessary drugs; (4) the possibility of increased toxicity or allergenicity without correspondingly increased therapeutic efficacy; and (5) the possibility of a higher cost from the manufacturer. However, fixed-dose combinations have certain potential advantages. Certain mixtures offer therapeutic gains in effectiveness or safety (e.g., acetaminophen with hydrocodone combinations, local anesthetic-vasoconstrictor solutions, and hydrochlorothiazide with triamterene). In addition, drug combinations may improve patient compliance by reducing the number of medications the patient must take. Finally, the reduced number of individual prescriptions can be less expensive to the patient. Although certain fixed-dose combinations are useful, such preparations should be avoided as a general rule, and only those mixtures that have been demonstrated to be therapeutically advantageous to the patient should be used.

DRUG	INTERACTING DRUG	EFFECT AND RECOMMENDATION
Antibiotics		
Penicillins, cephalosporins	Bacteriostatic antibiotics (e.g., macrolides, tetracyclines, clindamycin)	Bacteriostatic antibiotics (second group) may interfere with the action of bactericidal antibiotics (first group). Consult with other practioners for optimal therapy
Penicillins, cephalosporins, tetracyclines, ciprofloxacin	Oral contraceptives	There is a low risk that these antibiotics may stimulate estrogen elimination and may decrease effectiveness of contraceptive agent. Advise patient accordingly
Penicillins, cephalosporins	Probenecid	Urinary excretion of antibiotic is retarded. Consult with physician for appropriate dosage schedule
Penicillins	Enoxaparin, heparin	High-dose penicillins can increase bleeding time. Use cautiously
	Methotrexate	Urinary excretion of methotrexate may be inhibited. Use cautiously
Ampicillin	Allopurinol	High incidence of skin rash has been reported. Substitute amoxicillin for ampicillin
	Atenolol	Atenolol concentrations may be reduced. Use cautiously
Cephalosporins	Drugs that cause nephrotoxicity or ototoxicity (e.g., aminoglycosides, aspirin, amphotericin B, cisplatin, cephalosporins, colistimethate)	Additive toxicity may occur. Cephalexin and cefoxitin are apparently safe
Clindamycin, macrolides, tetracyclines	Bactericidal antibiotics (e.g., penicillins, cephalosporins)	Action of bactericidal antibiotics may be inhibited. Avoid concurrent use, or consult with other practitioners
Clindamycin	Erythromycin, clarithromycin, azithromycin	Antagonism can occur between these drugs. Avoid concurrent use. Do not use one agent for prophylaxis of endocarditis after recent use of other agent
	Kaolin	Absorption of clindamycin is delayed. Avoid concurrent use of clindamycin
Macrolides	Chloramphenicol, clindamycin, lincomycin	Erythromycin and other macrolides may interfere with the antibacterial effects of the other agents. Avoid concurrent use. Do not give clarithromycin or azithromycin for prophylaxis of endocarditis after recent use of one of these drugs

DRUG	INTERACTING DRUG	EFFECT AND RECOMMENDATION
Macrolides, tetracyclines	Digoxin	Absorption of digoxin preparations may be increased. Advise patient accordingly
Erythromycin, clarithromycin	Alfentanil, bromocriptine, caffeine, carbamazepine, corticosteroids, cyclosporine, disopyramide, ergot drugs, felodipine, midazolam, theophylline drugs, triazolam, valproic acid, warfarin	Erythromycin and clarithromycin may interfere with metabolism of these drugs. Use intravenous agents cautiously. Administration of clarithromycin prophylaxis of endocarditis is probably of little consequence, but a full course of macrolide therapy requires consultation with physician, especially regarding carbamazepine, cyclosporine, and warfarin
	HMG-CoA reductase inhibitors (statins)	Erythromycin and clarithromycin interfere with metabolism of these agents, possibly causing rhabdomyolysis. Avoid concurrent use.
Erythromycin	Drugs that cause ototoxicity or especially hepatotoxicity (e.g., furosemide, fluorouracil)	Use of erythromycin for prophylaxis of endocarditis is probably not a problem. Increased risk of ototoxicity or hepatotoxicity may warrant consultation with physician
Tetracyclines	Antacids, bismuth, Ca^{++}, iron, Mg^{++}, or zinc salts, H_2 antihistamines, colestipol	Absorption of tetracycline is impaired. Space administration schedules to avoid simultaneous ingestion. Occasionally, increased dosage necessary
	Li^+ salts	Plasma Li^+ concentrations may be increased. Advise patient accordingly
	Anisindione, warfarin	In patients with poor dietary vitamin K, tetracyclines may increase effect of oral anticoagulants. Use cautiously
Doxycycline	Barbiturates, alcohol (chronic use), carbamazepine, phenytoin	Hepatic clearance of doxycycline is increased. Adjust dosage upward, or use alternative tetracycline
Oxytetracycline	Insulin	Hypoglycemic action of oxytetracycline reduces insulin requirements. Substitute with another antibiotic
Metronidazole	Alcohol	Alcohol metabolism is altered, leading to buildup of acetaldehyde. Avoid concurrent use
	Cimetidine	Hepatic clearance of metronidazole is decreased. Use cautiously
	Chloroquine, disulfiram	Psychotomimetic reactions possible. Avoid concurrent use
	Barbiturates, phenytoin	Hepatic clearance of metronidazole is increased. Consider increasing dose if therapy proves to be suboptimal. Metronidazole may decrease phenytoin, however, which may warrant consultation with physician
	Li^+ salts	Renal toxicity of Li^+ may occur. Avoid concurrent use
	Warfarin	Hepatic clearance of warfarin is decreased. Full course of therapy requires consultation with physician
Analgesics		
Aspirin and other NSAIDs	NSAIDs	Ulcerogenic and platelet-inhibiting effects of these agents are increased, but not the analgesia. Aspirin may decrease effectiveness of some NSAIDs. Avoid concurrent use, but ensure optimal NSAID therapy
	Drugs that cause nephrotoxicity and ototoxicity (e.g., aminoglycosides, cyclosporine, furosemide, vancomycin)	Short courses for pain relief are probably of little concern, but avoid or minimize concurrent use
	Antidiabetic sulfonylurea drugs	Hypoglycemic effects are enhanced. Substitute with acetaminophen
	Baclofen, methotrexate, Li^+ salts, phenytoin, Ca^{++} channel blockers	Plasma concentrations of these agents are increased by aspirin-like drugs. Substitute with acetaminophen
	Probenecid, sulfinpyrazone	Probenecid interferes with renal and biliary excretion of NSAIDs. Aspirin may block uricosuric effects of probenecid and sulfinpyrazone. Substitute with acetaminophen
	Alcohol, corticosteroids	Combination may result in gastrointestinal ulceration and bleeding. Corticosteroid may also increase salicylate clearance. Avoid concurrent use
	ACE inhibitors, β blockers, diuretics	Hypotensive effect of ACE inhibitors, β blockers, and diuretics may be reduced. Advise patient accordingly
Aspirin, other NSAIDs, and acetaminophen	Anticoagulants and thrombolytics, broad-spectrum β-lactam antibiotics (e.g., ticarcillin)	Combination may result in increased bleeding, especially with aspirin. Cautious use of acetaminophen acceptable (<2 g/day)
Aspirin	Valproic acid	Increased plasma concentrations of valproic acid and additive antiplatelet effects may increase bleeding tendencies. Use cautiously

Continued

DRUG	INTERACTING DRUG	EFFECT AND RECOMMENDATION
	Carbonic anhydrase inhibitors	Increased central nervous system (CNS) toxicity from aspirin or carbonic anhydrase inhibitor may result. Use cautiously
	Antacids, griseofulvin	Salicylate concentrations reduced. Use alternative NSAID
Ibuprofen	Digoxin	Ibuprofen decreases clearance of digoxin. Substitute acetaminophen to avoid possibility of increased toxicity
Acetaminophen	Alcohol	Acetaminophen hepatotoxicity is more likely in chronic alcoholics. Use cautiously
	Cholestyramine	Concurrent ingestion inhibits acetaminophen absorption. Administer acetaminophen at least 1 hr before cholestyramine
	β Blockers, barbiturates, isoniazid, phenytoin, sulfinpyrazone	Alteration of acetaminophen metabolism may increase risk of hepatotoxicity. Use cautiously
Opioid analgesics and agonist-antagonists	Alcohol, CNS depressants, local anesthetics, antidepressants, antipsychotics, centrally acting antihypertensives, antihistamines, cimetidine, $MgSO_4$ (parenteral)	Increased CNS and respiratory depression may occur. Use cautiously, perhaps in reduced dosage
	Antimuscarinics, antidiarrheals, antihypertensives	Opioids increase effects of these drugs. Use cautiously
	Naltrexone, opioid agonist-antagonists	These drugs block the analgesic effects of opioids. Substitute with ibuprofen or similar NSAID for pain relief
	Monoamine oxidase inhibitors, furazolidone, procarbazine	Meperidine results in marked toxicity and is absolutely contraindicated. Use other opioids cautiously
	Aprepitant, diltiazem, ketoconazole, HIV protease inhibitors, verapamil	These drugs may increase the plasma concentrations and effects of the opioids. Avoid concurrent use if possible.
Codeine, hydrocodone, oxycodone	Fluoxetine, paroxetine, quinidine, ritonavir, sertraline	Conversion to analgesic metabolites may be impaired. Avoid use of codeine; may need increased doses of hydrocodone or oxycodone
Alfentanil	Erythromycin	Erythromycin may interfere with metabolism of alfentanil. Use cautiously
Propoxyphene	Alprazolam, carbamazepine, doxepin, warfarin	Propoxyphene inhibits metabolism of these agents. Substitute with another analgesic
Opioid agonist/antagonist	Opioid analgesics	Antagonism of opioid analgesic effect may lead to withdrawal symptoms in dependent patients. Avoid concurrent use
Local Anesthetic Preparations		
Local anesthetics	Alcohol, CNS depressants, opioids, antidepressants, antipsychotics, centrally acting antihypertensives, antihistamines, $MgSO_4$ (parenteral)	Increased CNS and respiratory depression may occur. Use cautiously
	Antiarrhythmic drugs	Increased cardiac depression may occur. Use cautiously
	Anticholinesterases	Local anesthetics may antagonize effects of anticholinesterases on muscle contractility. Treat myasthenic patients in consultation with physician
Amides	Amiodarone, β blockers, cimetidine	Metabolism of amides in liver is reduced. Use cautiously
Esters	Anticholinesterases	Metabolism of esters is reduced. Use cautiously
	Sulfonamides	Inhibition of sulfonamide action may occur. Avoid concurrent use
Adrenergic vasoconstrictors	Inhalation anesthetics	Increased possibility of cardiac arrhythmias exists with some agents. Consult with anesthesiologist
	Methyldopa, tricyclic antidepressants	Sympathomimetic effects may be enhanced. Use epinephrine cautiously. Avoid levonordefrin and norepinephrine
	β Blockers, adrenergic neuron blockers, entacapone, tolcapone	Hypertensive and cardiac reactions are more likely. Use cautiously
	Antipsychotics	Vasoconstrictor action is inhibited, which may lead to hypotensive responses. Use cautiously
Antianxiety-Sedative Agents		
Barbiturates, benzodiazepines, chloral hydrate, hydroxyzine, propofol	Alcohol, CNS depressants, opioids, local anesthetics, antidepressants, antipsychotics, centrally acting antihypertensives, antihistamines, $MgSO_4$ (parenteral)	Increased CNS and respiratory depression may occur. Use cautiously, perhaps in reduced dosage
Barbiturates, benzodiazepines, propofol	Antihypertensives, antipsychotics, intravenous opioids, Li^+ salts	Intravenous administration in patients receiving these medications can lead to hypotension. Use cautiously

DRUG	INTERACTING DRUG	EFFECT AND RECOMMENDATION
Barbiturates	Acetaminophen, anticoagulants (oral), β blockers (except renally excreted congeners), carbamazepine, chloramphenicol, cimetidine, corticosteroids, corticotropin, cyclophosphamide, cyclosporine, dacarbazine, digoxin, disopyramide, doxorubicin, doxycycline, estrogen and estrogen-containing contraceptives, fenoprofen, griseofulvin, guanfacine, haloperidol, hydantoin anticonvulsants, levothyroxine, methadone, metronidazole, mexiletine, phenothiazines, quinidine, theophylline-containing preparations, tricyclic antidepressants, valproic acid, verapamil	Barbiturates stimulate metabolism of many drugs. Avoid multidose use. Single administration of short-acting drug (e.g., pentobarbital) is not known to be a problem
	Antipsychotics	Increased tendency for hypothermia. Evaluate temperature as needed
	Chloramphenicol, methylphenidate, valproic acid	Metabolism of barbiturate decreased. Avoid multidose use. Advise patient of possibility of postsedation drowsiness
	Methsuximide	Metabolism of the barbiturate is decreased. Avoid multidose use. Advise patient of possibility of postsedation drowsiness
Thiopental, methohexital	Probenecid, sulfonamides	Decreased binding of barbiturate to plasma proteins can potentiate anesthetic effect. Use cautiously
Benzodiazepines	H_2 antihistamines	Delayed absorption of benzodiazepine. Advise patient accordingly
	Carbamazepine	Increased metabolism of both agents. Avoid multidose use
	Cimetidine, disulfiram, fluoxetine, ketoconazole, isoniazid, itraconazole, metoprolol, omeprazole, oral contraceptives, propranolol, probenecid, valproic acid	Metabolism of benzodiazepine may be decreased. Lorazepam and oxazepam least likely to be affected; avoid multidose use of other agents. Advise patient of possibility of postsedation drowsiness
	Levodopa	Decreased therapeutic effect of levodopa. Advise patient accordingly
	Amiodarone	Increased cardiovascular toxicity. Avoid concurrent use
	Digoxin	Digoxin elimination rate may be decreased. Substitute with short-acting benzodiazepine (e.g., triazolam), and avoid multidose use
Lorazepam	Alcohol, scopolamine	Increased anxiety with alcohol and irrational behavior with scopolamine. Avoid concurrent use
Midazolam, triazolam	Diltiazem, cimetidine, erythromycin, fluoxetine, fluvoxamine, ketoconazole, itraconazole, quinupristin/dalfopristin, nefazodone, verapamil	Metabolism of midazolam and triazolam impaired. Avoid concurrent oral use; otherwise use cautiously
	Clozapine, HIV protease inhibitors	Serious CNS adverse effects may occur. Avoid concurrent use
Chloral hydrate	Anisindione, warfarin	Oral anticoagulants are displaced from protein binding sites, which may lead to bleeding. Avoid concurrent use
	Alcohol	Combination causes increased cardiovascular toxicity and CNS depression. Avoid concurrent use

Common examples of drug groups listed in Appendix 1.

α Blockers: doxazosin, phenoxybenzamine, phentolamine, prazosin, terazosin

ACE inhibitors (angiotensin-converting enzyme inhibitors): benazepril, captopril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, trandolapril

Adrenergic neuron blockers: alseroxylon, deserpidine, guanadrel, guanethidine, rauwolfia, rescinnamine, reserpine

Adrenergic vasoconstrictors: epinephrine, levonordefrin, norepinephrine

Aminoglycosides: amikacin, gentamicin, kanamycin, neomycin, netilmicin, streptomycin, tobramycin

Angiotensin II receptor blockers: candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, valsartan

Antacids: aluminum hydroxide, aluminum carbonate, magnesium oxide, magaldrate, calcium carbonate, sodium bicarbonate

Antiarrhythmic drugs: amiodarone, β blockers, diltiazem, disopyramide, dofetilide, flecainide, ibutilide, mexiletine, procainamide, propafenone, quinidine, verapamil

Anticholinesterases: ambenonium, donepezil, echothiophate, edrophonium, galantamine, isoflurophate, neostigmine, physostigmine, pyridostigmine, rivastigmine, tacrine

Anticoagulants and thrombolytics: anticoagulants: anisindione, enoxaparin, heparin, warfarin; thrombolytics: alteplase, anistreplase, streptokinase, urokinase

Antidepressants: bupropion, fluoxetine, MAO inhibitors, paroxetine, sertraline, trazodone, tricyclic antidepressants, venlafaxine

Antidiarrheals: bismuth subsalicylate, difenoxin, diphenoxylate, loperamide

Antihistamines: H_1 antihistamines: brompheniramine, chlorpheniramine, diphenhydramine, promethazine, pyrilamine, tripelennamine, triprolidine; H_2 antihistamines: cimetidine, famotidine, nizatidine, ranitidine

Antihypertensives: ACE inhibitors, alikiren, angiotensin II receptor blockers, adrenergic neuron blockers, α blockers, β blockers, Ca^{++} channel blockers, centrally acting antihypertensives, diuretics, hydralazine, mecamylamine, metyrosine, minoxidil

Antimuscarinics: atropine, benztropine, clidinium, darifenacin, dicyclomine, flavoxate, glycopyrrolate, methantheline, oxybutynin, propantheline, solifenacin, tolterodine, trihexyphenidyl

Antipsychotics: aripiprazole, chlorpromazine, chlorprothixene, clozapine, haloperidol, olanzapine, perphenazine, prochlorperazine, quetiapine, risperidone, thioridazine

Barbiturates: amobarbital, butabarbital, mephobarbital, methohexital, pentobarbital, phenobarbital, secobarbital, thiamylal, thiopental

β Blockers: acebutolol, atenolol, betaxolol, bisoprolol, carteolol, carvedilol, labetalol,* metoprolol, nadolol, pindolol, propranolol, sotalol, timolol

Benzodiazepines: alprazolam, chlordiazepoxide, clonazepam, clorazepate, diazepam, estazolam, flurazepam, halazepam, lorazepam, midazolam, oxazepam, prazepam, quazepam, temazepam, triazolam

Ca^{++} channel blockers: amlodipine, diltiazem, felodipine, isradipine, nicardipine, nifedipine, verapamil

Carbonic anhydrase inhibitors: acetazolamide, dichlorphenamide, methazolamide

Centrally acting antihypertensives: clonidine, guanabenz, guanfacine, methyldopa

Centrally acting muscle relaxants: carisoprodol, chlorphenesin, chlorzoxazone, cyclobenzaprine, methocarbamol, orphenadrine, baclofen

Cephalosporins: cefaclor, cefixime, cefotaxime, cefoxitin, ceftazidime, ceftriaxone, cephalexin, cephalothin

CNS depressants: acetylcarbromal, barbiturates, benzodiazepines, centrally acting muscle relaxants, chloral hydrate, ethchlorvynol, eszopiclone, ethinamate, etomidate, glutethimide, inhalation anesthetics, ketamine, meprobamate, methyprylon, nitrous oxide, paraldehyde, propofol, propiomazine, zaleplon, zolpidem

Corticosteroids: cortisone, dexamethasone, hydrocortisone, methylprednisolone, prednisolone, prednisone, triamcinolone

Diuretics: amiloride, bumetanide, chlorothiazide, chlorthalidone, ethacrynic acid, furosemide, hydrochlorothiazide, spironolactone, torsemide, triamterene

Ergot drugs: dihydroergotamine, ergotamine, ergoloid mesylates, methysergide

HIV protease inhibitors: atazanavir, darunavir, fosamprenavir, indinavir, lopinavir/ritonavir, nelfinavir, ritonavir, saquinavir, tipranavir

HMG-CoA reductase inhibitors: atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, simvastatin

Inhalation anesthetics: desflurane, enflurane, halothane, isoflurane, sevoflurane

Local anesthetics: amides: bupivacaine, etidocaine, lidocaine, mepivacaine, prilocaine, ropivacaine; esters: benzocaine, chloroprocaine, cocaine, procaine, propoxycaine, tetracaine; combination: articaine

Macrolides: azithromycin, clarithromycin, dirithromycin, erythromycin, troleandomycin

MAO inhibitors: isocarboxazid, phenelzine, tranylcypromine

NSAIDs (nonsteroidal anti-inflammatory drugs): aspirin, diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, ibuprofen, indomethacin, ketoprofen, ketorolac, meclofenamate, mefenamic acid, nabumetone, naproxen, oxaprozin, piroxicam, sulindac, tolmetin

Opioid agonist-antagonists: buprenorphine, butorphanol, dezocine, nalbuphine, pentazocine

Opioid analgesics: alfentanil, codeine, dihydrocodeine, fentanyl, hydrocodone, hydromorphone, levorphanol, meperidine, methadone, morphine, oxycodone, oxymorphone, remifentanil, sufentanil

Oral sulfonylurea antidiabetic agents: chlorpropamide, glimepiride, glipizide, glyburide, tolazamide, tolbutamide

Penicillins: amoxicillin, ampicillin, carbenicillin, dicloxacillin, methicillin, mezlocillin, oxacillin, penicillin G, penicillin V, ticarcillin

Sulfonamides: sulfacytine, sulfadiazine, sulfamethizole, sulfamethoxazole, sulfasalazine, sulfisoxazole

Tetracyclines: demeclocycline, doxycycline, minocycline, oxytetracycline, tetracycline

Tricyclic antidepressants: amitriptyline, amoxapine, clomipramine, desipramine, doxepin, imipramine, nortriptyline, trimipramine

*Also α_1 blockers.

APPENDIX 2

*Glossary of Abbreviations**

–	negative
←	increase/upper
#	number
@	at
Δ	change
$\bar{c}$	with
$\bar{p}$	after
$\bar{s}$	without (sans)
$\bar{x}$	except
↓	decrease/lower
+	positive
<	less than
=	equal
>	greater than
≈	approximately
→	leading to
♀	female
♂	male
1,25[OH]D	1,25-dihydroxycholecalciferol, calcitriol
2°	secondary to
25[OH]D	calcifediol
5-FdUTP	5-fluorodeoxyuridine triphosphate
5-FU	fluorouracil
5-FUdR	floxuridine
5-HIAA	5-hydroxyindoleacetic acid
5-HT	5-hydroxytryptamine (serotonin)
5-HTT	5-hydroxytryptamine transporter
6-APA	6-β-aminopenicillanic acid
6-MNA	6-methoxy-2-naphthylacetic acid
$\bar{a}$	before
Å	angstrom
A + P	auscultation and percussion
A&O × 3	alert and oriented to person, place, time
A&W	alive and well
a.c.	before meals (*ante cebum*)
A/G ratio	albumin/globulin ratio
A:	assessment
A_1, A_2, A_3	adenosine receptors
A_2	aortic second sound
AA	aortic aneurysm
AAOS	American Academy of Orthopaedic Surgeons
Ab	abortion
ABC	ATP-binding cassette
ABCD	airway, breathing, circulation, defibrillation
abd	abdomen
ABG	arterial blood gas
ABO	antigenic determinants
ABVD	Adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine (regimen)
ABX	antibiotics
AC	adenylate cyclase
AC	anterior chamber
ACE	angiotensin-converting enzyme
ACh	acetylcholine
AChE	acetylcholinesterase
AChR	acetylcholine receptor
ACLS	advanced cardiac life support
ACTH	adrenocorticotropic hormone
ACVD	acute cardiovascular disease
AD	right ear
ad lib	as much as desired
ADA	adenosine deaminase
ADA	American Dental Association
ADH	antidiuretic hormone
ADHD	attention-deficit/hyperactivity disorder
ADL	activities of daily living
adm	admission
ADP	adenosine 5′-diphosphate
ADT	*Accepted Dental Therapeutics*
AED	automatic external defibrillator
AF (A. fib)	atrial fibrillation
AFB	acid-fast bacillus
AFHS DI	American Hospital Formulary Service Drug Information
AGA	appropriate gestational age
AGN	acute glomerulonephritis
$AgNO_3$	silver nitrate
AHA	American Heart Association
AHPA	American Herbal Products Association
AI	aortic insufficiency
AICD	automatic implanted cardiac defibrillator
AIDS	acquired immunodeficiency syndrome
AIMs	abnormal involuntary movements
AIP	acute intermittent porphyria
AKA	above-knee amputation
Al^{+++}	aluminum ion
ALA	δ-aminolevulinic acid
A-Line	arterial line
ALL	acute lymphocytic leukemia
ALS	amyotrophic lateral sclerosis
ALS	antilymphocytic serum

*This list includes abbreviations commonly used in medicine in addition to those used in the book.

ALT	alanine aminotransferase (formerly SGPT)
AMA	against medical advice
AMA	American Medical Association
amb	ambulatory
AMI	acute myocardial infarction
AMI	anterior wall myocardial infarction
AML	acute monocytic leukemia
AMP	adenosine 5′-monophosphate
amp	ampule
AMPA	α-amino-3-hydroxy-5-methyl-4-isoxazole propionate
AMPT	α-methylparatyrosine
amt	amount
ANA	antinuclear antibody
ANS	autonomic nervous system
ANUG	acute necrotizing ulcerative gingivitis
AOB	alcohol on breath
AODM	adult-onset diabetes mellitus
AP	anteroposterior, apical pulse, abdominoperitoneal, antepartum
AP	antiplasmin
AP-1	activating protein-1
AP5	2-amino-5-phosphonovaleric acid
AP7	2-amino-7-phosphonoheptanoic acid
APAP	acetaminophen
APC	aspirin-phenacetin-caffeine
aPC	activated protein C
APD	action potential duration
APF	acidulated phosphate fluoride
approx	approximately
APSAC	anisoylated plasminogen—SK activator complex
aPTT	activated partial thromboplastin time
AR	adrenergic receptor
AR	aortic regurgitation
Ara-A	vidarabine, adenosine arabinoside
ARA-C	cytosine arabinoside (cytarabine)
ara-g	analogue-9-beta-D-arabinofuranosylguanine
ARAS	ascending reticular activating system
ARC	AIDS-related complex
ARDS	acute respiratory distress syndrome
ARF	acute respiratory failure
AROM	artificial rupture of membranes
AS	aortic stenosis
AS	left ear
as tol	as tolerated
ASA	American Society of Anesthesiologists
ASA	aspirin
ASAP	as soon as possible
ASD	atrial septal defect
ASHD	atherosclerotic heart disease
AST	aspartate aminotransferase (formerly SGOT)
ATIII	antithrombin III
ATM	atmosphere
ATN	acute tubular necrosis
ATP	adenosine 5′-triphosphate
ATPase	adenosine triphosphatase
AU	both ears
AV	atrioventricular/arteriovenous
AVM	arteriovenous malformation
AVR	aortic valve replacement
AZT	zidovudine (azidothymidine)
Ba	barium
BA	brain abscesses
BAC	blood alcohol concentration
BaE	barium enema
BBB	blood-brain barrier
BBB	bundle branch block
BCG	bacillus Calmette-Guérin
BCL-ABL	breakpoint cluster region-Abelson
BCNU	carmustine
BCP	birth control pills
BCR	β-cell antigen receptor
bcr	breakpoint cluster region
BDP	beclomethasone dipropionate
β-arr	β-arrestin
BE	bacterial endocarditis
bFGF	basic fibroblastic growth factor
BG	blood glucose
BGTI	basal-ganglia thalamic inhibitor
BHK	baby hamster kidney
BHR	bronchial hyperreactivity
bid	twice a day (*bis in die*)
Bis-GMA	bisphenol A glycidylmethacylate
BKA	below-knee amputation
BLS	basic life support
BM	bowel movement
BMD	beclomethasone dipropionate
BMP	beclomethasone monopriopionate
BMR	basal metabolic rate
BMT	bone marrow transplant
BOLD	blood oxygen(ation) level dependent
BOM	bilateral otitis media
BoNT-A	Botulinum toxin type A
BoNT-B	Botulinum toxin type B
BP	blood pressure
BPA	bisphenol A
BPD	bronchopulmonary dysplasia
BPH	benign prostatic hypertrophy
BR	bathroom
BR	bed rest
BRP	bathroom privileges
BS	breath sound/bowel sounds
BSA	body surface area
BSAC	British Society for Antimicrobial Chemotherapy
BSO	bilateral salpingo-oophorectomy
BTL	bilateral tubal ligation
BuChE	butyrocholinesterase
BUN	blood urea nitrogen
BVH	bilateral ventricular hypertrophy
Bx	biopsy
BZ_1, BZ_2	benzodiazepine receptors
C	centigrade
C&S	culture and sensitivity
c/o	complains of
c/w	consistent with
C_1, C_2, ...	first cervical vertebra, second cervical vertebra, ...
C6	hexamethonium
CA	cancer/carcinoma
Ca^{++}, Ca^{2+}	calcium ion
CABG	coronary artery bypass graft
CAD	coronary artery disease
CAM	Complementary and alternative medicine
cAMP	cyclic adenosine 3′,5′-monophosphate
Cap	capsule
CAPD	continuous ambulatory peritoneal dialysis
CAT	computerized axial tomography
cath	catheter/catheterization/catheterize
CBC	complete blood count
CBD	common bile duct
CC	chief complaint
cc	cubic centimeter
CCB	calcium channel blocker

CCMS	clean-catch midstream
CCNU	lomustine
CCR5	cysteine-cysteine chemokine receptor 5
CCU	cardiac care unit
CD	cluster of differentiation
CD40L	CD40 ligand
CDAC	*Clostridium difficile*—associated colitis
CDAD	*Clostridium difficile*—associated diarrhea
CDC	Centers for Disease Control and Prevention
CDE	common duct exploration
CDH	congenital dislocation of hip
CDK	cyclin-dependent kinase
Cdk5	cyclin-dependent kinase 5
cDNA	complementary DNA
CDR	complementarity-defining region
CE	cardiac enlargement
CE	cataract extraction
CETP	cholesteryl ester transfer protein
CF	cystic fibrosis
CG	chorionic gonadotropin
cGMP	cyclic guanosine 3′,5′-monophosphate
CGN	chronic glomerulonephritis
CGRP	calcitonin gene—related peptide
ChAc	choline acetylase
CHD	congenital or coronary heart disease
CHF	congestive heart failure
CHG	chlorhexidine gluconate
CHI	closed head injury
CHO	Chinese hamster ovary
CI	color index/cardiac index
CIWA	Clinical Institute Withdrawal Assessment (alcohol/drug toxicology screen tool)
CL	clearance
CL	ConsumerLab
Cl^-	chloride ion
cl liq	clear liquid
CLL	chronic lymphatic/lymphocytic leukemia
cm	centimeter
CMI	cell-mediated immunity
CML	chronic myelogenous/myelocytic leukemia
CMV	cytomegalovirus
CNS	central nervous system
CO	cardiac output
CO	carbon monixide
CO_2	carbon dioxide
CoA	coenzyme A
CO-Hb	carboxyhemoglobin
COMT	catechol-O-methyltransferase
CoNS	coagulase-negative staphylococci
COPD	chronic obstructive pulmonary disease
cor	heart
COX	cyclooxygenase
CP	cerebral palsy
CPAP	continuous positive airway pressure
CPC	clinical pathologic conference
CPK	creatine phosphokinase
CPR	cardiopulmonary resuscitation
CRF	chronic renal failure
CRH	corticotropin-releasing hormone
CRP	C-reactive protein
CS or C/S	cesarean section
CSF	cerebrospinal fluid
CSW	clinical social worker
CT	computed tomography
CTLA-4	cytotoxic T-lymphocyte—associated antigen-4
C-Tube	chest tube
CTZ	chemoreceptor trigger zone
CV	cardiovascular
CVA	cerebrovascular accident
CVA	costovertebral angle
CVC	central venous catheter
CVP	central venous pressure
CXCR4	β-chemokine receptor 4
CXR	chest x-ray
CYP	cytochrome P450
Cys	cysteinyl
cysLTs	cysteinyl leukotrienes
D	dopamine (receptor)
d	dalton
DAT	dopamine tranporter
DATA	Drug Addiction Treatment Act
D&C	dilation and curettage
D/C	discharge/discontinue
D/Dx	differential diagnosis
D_5LR	dextrose 5% in lactated Ringer's
D_5W	dextrose 5% in water
DAG	diacylglycerol
DATATOP	deprenyl and tocopherol antioxidant therapy of parkinsonism
DCC	daycare center
DDAVP	desmopressin
DDT	dichlorodiphenyltrichloraethane
DEA	Drug Enforcement Administration
DES	diethylstilbestrol
DFP	isoflurophate (formerly diisopropylfluorophosphate)
DHFR	dihydrofolate reductase
DHT	dihydrotachysterol
DIC	disseminated intravascular coagulation/coagulopathy
dist H_2O	distilled water
DIT	diiodotyrosine
DIV	divorced
div	divide
DJD	degenerative joint disease
DKA	diabetic ketoacidosis
DL	direct laryngoscopy
DM	diabetes mellitus
DMARD	disease-modifying antirheumatic drug
DMFT	decayed, missing, and filled teeth
DMPP	dimethylphenylpiperazinium
DMSO	dimethyl sulfoxide
DMT	dimethyltryptamine
DNA	deoxyribonucleic acid
DNR	do not resuscitate
DOA	dead on arrival
DOB	date of birth
DOE	dyspnea on exertion
Dopa (DOPA)	dihydroxyphenylalanine
DPP-4	dipeptidyl peptidase 4
DPT	diphtheria, pertussis, tetanus vaccine
DR	delivery room
DR	diabetic retinopathy
DRG	diagnosis-related groups
dsg	dressing/dosage
DSHEA	Dietary Supplement Health and Education Act of 1994
DSM-IV-R	*Diagnostic and Statistical Manual of Mental Disorders,* ed 4
DSV	Dietary Supplement Verification Program
DT	delirium tremens
DTI	diffusion tensor imaging
DTH	dihydrotachysterol
DTIC	dacarbazine
DTR	deep tendon reflex

DU	dermal ulcer
DU	duodenal ulcer
DUB	dysfunctional uterine bleeding
DVD	dissociated vertical divergence
DVT	deep vein thrombosis
Dx	diagnosis
E	epinephrine
e.g.	for example
ea	each
EACA	ε-aminocaproic acid
EATT	excitatory amino acid transporter
EBL	estimated blood loss
EBV	Epstein-Barr virus
EC_{50}	concentration that yields a half-maximal response
ECCE	extracapsular cataract extraction
ECG	electrocardiogram
ECHO	echocardiogram
ECL	enterochromaffin-like cell
ECMO	extracorporeal membrane oxygenation
ECT	electroconvulsive therapy
ED	emergency department
ED_{50}	median effective dose
ED_{99}	dose effective in 99% of the population
EDRF	endothelium-derived relaxing factor
EDTA	ethylenediamine tetraacetic acid
EEG	electroencephalogram/ electroencephalography
EENT	eye, ear, nose, and throat
EGA	estimated gestational age
EGFR	epidermal growth factor receptor
EGFR-TK	epidermal growth factor receptor—tyrosine kinase
eIF-2	eukaryotic initiation factor
EKG	electrocardiogram
elix	elixir
EMG	electromyogram
EMLA	eutectic mixture of local anesthetics
ENG	electronystagmograph
ENT	ear, nose, and throat
EOM	extraocular movements
EOMI	extraocular muscles intact
EPA	Environmental Protection Agency
EPO	erythropoietin
EPP	end plate potential
EPSP	excitatory postsynaptic potential
ER	emergency room
ER/PR	estrogen receptor/progesterone receptor
ERCP	endoscopic retrograde cholangiopancreatography
erm	erythromycin-resistant methylase
ERP	effective refractory period
ESBL	extended-spectrum β-lactamase
ESR	erythrocyte sedimentation rate
ESRD	end-stage renal disease
ESWL	extracorporeal shock wave lithotripsy
ET	ejection time
ET, ETT	endotracheal tube
ETOH	ethyl alcohol
ETS	endotracheal suction
EUA	examination under anesthesia
Ex	examination
ext	external
ext	extract
ext	extremity
ext fl	fluid extract
F	factor
F^-	fluoride ion
F/U	follow-up
FAS	fetal alcohol syndrome
FBG	fasting blood glucose
FBS	fasting blood sugar
Fc	crystallizable fragment (region)
FD	fetal demise
FDA	U.S. Food and Drug Administration
Fe^{++}	ferrous ion
Fe^{+++}	ferric ion
FEV_1	forced expiratory volume in 1 second
FFP	fresh frozen plasma
FH/FHx	family history
FHR	fetal heart rate
FHT	fetal heart tones
fib	fibrillation
FIFRA	Federal Insecticide, Fungicide, and Rodenticide Act
FKBP	tacrolimus-binding protein
fl	fluid
FMG	fine mesh gauze
FMO	flavine monooxygenase
FNA	fine needle aspiration
FRAP	FKBP-rapamycin—associated protein
FROM	full range of motion
FSE	fetal scalp electrode
FSH	follicle-stimulating hormone
FSS	fetal scalp sampling
FTA-Abs	fluorescent treponemal antibody, absorbed
FTNB	full-term newborn
FTSG	full-thickness skin graft
FTT	failure to thrive
FUO	fever of unknown origin
FUTP	fluoridine 5′-triphosphate
FVC	forced vital capacity
Fx	fracture
G	gravida
G protein	guanine nucleotide—binding regulatory protein
ga	gestational age
GA	gastric analysis/general anesthesia
GABA	γ-aminobutyric acid
GAT	GAMA transporter
GB	gallbladder
GC	gonococcus
G-CSF	granulocyte colony-stimulating factor (filgrastim)
GDP	guanosine diphosphate
GERD	gastroesophageal reflux disease
GH	growth hormone
GHBA	good health before admission
GHD	growth hormone deficiency
GHRF	growth hormone—releasing factor
GI	gastrointestinal
GILZ	glucocorticoid-induced leucine zipper protein
GINA	Global Initiative for Asthma
GIP	glucose-dependent insulinotropic polypeptide
Gla	amino-terminal γ-carboxyglutamic acid
GLP-1	glucagon-like peptide 1
GLSA	glycopeptide *Staphylococcus aureus*
Glut 4	glucose transporter 4
GlyT	glycine transporter
gm	gram
GM-CSF	granulocyte-macrophage colony-stimulating factor (sargramostim)
GMP	Good Manufacturing Practices
GNB	gram-negative bacilli
GNR	gram-negative rods

GnRH	gonadotropin-releasing hormone
GOAL	Gaining Optimal Asthma control study
GOLD	Global Initiative for Chronic Obstructive Lung Disease
GP	glycoprotein
GPCR	G protein—coupled receptor
gr	grain
Grav. I	primigravida/one pregnancy
GRE	glucocorticoid response element
GRIP-1	glucocorticoid receptor interacting protein-1
GRK	G protein—coupled receptor kinase
GSK-3β	glycogen synthase kinase-3β
GSW	gunshot wound
GTP	guanosine 5′-triphosphate
GTT	glucose tolerance test
G-tube	gastrostomy tube
GU	genitourinary
GVHD	graft-versus-host disease
GYN/Gyn	gynecology
H&P	history and physical
H/O	history of
H^+	hydrogen ion
H_1, H_2, H_3	histamine receptor
H_2O	water
H_2O_2	hydrogen peroxide
HA	headache
HAA	hepatitis-associated antigen
HAART	highly active antiretroviral therapy
HACEK (group)	*Haemophilus influenzae, Aggregatibacter actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, Kingella kingae*
HAV	hepatitis A virus
Hb, Hgb	hemoglobin
HbA_{1c}	hemoglobin A_{1c}
HBO, HBO_2	hyperbaric oxygen therapy
HBP	high blood pressure
HBV	hepatitis B virus
HCG	human chorionic gonadotropin
Hcl	hydrochloric acid
HCP	home care partners
HCT	hematopoietic cell transplantation
Hct	hematocrit
HCV	hepatitis C virus
HCVD	hypertensive cardiovascular disease
hd	high dose
HDAC	histone deacetylase
HDI	herb-drug interactions
HDL	high-density lipoprotein
HEENT	head, eyes, ears, nose, throat
HETE	hydroxyeicosatetraenoic acid
Hg^+	mercurous
Hg^{++}	mercuric
Hg^0	elemental mercury (dental amalgam)
Hgb	hemoglobin
HGT	horizontal gene transfer
HHN	handheld nebulizer
HIO	hypoiodous acid
HIPAA	Health Insurance Portability and Accountability Act (of 1996)
HIT	heparin-induced thrombocytopenia
HIV	human immunodeficiency virus
HLA	human leukocyte antigen
HM	hand motion
HMG-CoA	3-hydroxy-3-methylglutaryl coenzyme A
HMWK	high-molecular-weight kininogen
HNP	herniated nucleus pulposus
HO	house officer
HOB	head of bed
HPF	high-power field
HPI	history of present illness
HPV	human papillomavirus
hr	hour
HR	heart rate
hs	at bedtime (*hora somni*)
HSCT	hematopoietic stem cell transplant
HSV	herpes simplex virus
Ht	height
HTN	hypertension
HVD	hypertensive vascular disease
Hx	history
Hz	hertz
HZV	herpes zoster virus
I^-	iodide ion
I&D	incision and drainage
I&O	intake and output
i.e.	that is
IADHS	inappropriate antidiuretic hormone syndrome
IAP	inhibitor of apoptosis protein
IBS	irritable bowel syndrome
ICCE	intracapsular cataract extraction
ICD	implanted cardiac defibrillator
ICS	intercostal space
ICU	intensive care unit
ID	infectious disease
IDDM	insulin-dependent diabetes mellitus
IDL	intermediate-density lipoprotein
IDM	infant of diabetic mother
IE	infective endocarditis
IFIS	inoperable floppy iris syndrome
IFN	interferon
IFN-γ	interferon-γ
Ig	immunoglobulin
IgA	gamma A immunoglobulin
IgD	gamma D immunoglobulin
IgE	gamma E immunoglobulin
IGF, IGF-I	insulin-like growth factor I
IgG	gamma G immunoglobulin
IgM	gamma M immunoglobulin
IHD	ischemic heart disease
IHSS	idiopathic hypertrophic subaortic stenosis
IL	interleukin
IL-1	interleukin-1
IL-1R	interleukin-1 receptor
IL-1RA	interleukin-1 receptor antagonist
IL-2	interleukin-2
IL-3	interleukin-3
ILAE	International League Against Epilepsy
IM	intramuscular
IMF	intermaxillary fixation
IND	Notice of Claimed Investigational Exemption for a New Drug
INH	isonicotinic hydrazide
iNOS	inducible nitric oxide synthetase (or synthase)
INR	International Normalized Ratio
int	internal
IOL	intraocular lens
IOP	intraocular pressure
IP	inositol phosphate
IP	*International Pharmacopoeia*
IP_2	inositol bisphosphate
IP_3	inositol 1,4,5-triphosphate
IPG	inositol phosphoglycan
IPPB	intermittent positive pressure breathing
IPPF	immediate postsurgical prosthetic fitting

IPSP	inhibitory postsynaptic potential
IQ	intelligence quotient
IR	delayed outwardly rectifying current
irreg	irregular
irrig	irrigation
irrig/deb	irrigation/debridement
IS	incentive spirometer
ISA	intrinsic sympathomimetic activity
ITP	idiopathic thrombocytopenia purpura
IU	international unit
IUC	intrauterine catheter
IUD	intrauterine device
IUFD	intrauterine fetal demise
IUFT	intrauterine fetal transmission
IUGR	intrauterine growth retardation
IUP	intrauterine pregnancy
IV	intravenous
IV Cath	intravenous catheter
IV Push	intravenous push
IVC	inferior vena cava
IVC	intravenous cholangiogram
IVDA	intravenous drug abuse
IVF	in vitro fertilization
IVP	intravenous pyelogram
IVPB	intravenous piggyback
IVVC	intravenous venacavogram
JODM	juvenile-onset diabetes mellitus
JRA	juvenile rheumatoid arthritis
J-tube	jejunostomy tube
JVD	jugular vein distention
K^+	potassium ion
K_D	dissociation constant
kDa	kilodaltons
Kg, kg	kilogram
KGD	lysine-glycine-aspartic acid sequence
KO	keep open
KUB	kidney, ureter, bladder
L	large
L	left
L	liter
L	long-lasting current
L_1, L_2, ...	first lumbar vertebrae, second lumbar vertebrae, ...
LA	left atrium
LAD	left anterior descending (coronary artery)
LAE	left atrial enlargement
LAK	lymphokine-activated killer (cell)
LAO	left anterior oblique
LAP	laparotomy
LAP	left atrial pressure
LAP	leucine amino peptidase
LAP	leukocyte alkaline phosphatase
LASH	left interior superior hemiblock
lat	lateral
LAV	lymphadenopathy-associated virus
lb	pound
LBBB	left bundle branch block
LC	locus coeruleus
LCS	low constant suction
LD	lattice degeneration
LD	light difference
LD_{50}	median lethal dose
LDH	lactic dehydrogenase
LDL	low-density lipoprotein
L-dopa	levodopa
LE	lower extremity
LEEP	loop electrosurgical excision procedure
LFA-1	leukocyte function antigen-1
LFT	liver function test
LGA	large for gestational age
LGV	lymphogranuloma venereum
LH	luteinizing hormone
LHRH	luteinizing hormone—releasing hormone
Li^+	lithium ion
liq	aqueous solution
LIS	low intermittent suction
LJP	localized juvenile periodontitis
LLL	left lower lobe
LLQ	left lower quadrant
LMP	last menstrual period
LMWH	low-molecular-weight heparin
LNAT	large neutral amino acid transporter
LND	lymph node dissection
LOA	left occipital anterior
LOC	level/loss of consciousness
LOP	left occipital posterior
LP	lumbar puncture
LPH	lipotropic pituitary hormone
LPO	left posterior oblique
LPr	light perception
LR	lactated Ringer's solution
LRRK2	leucine-rich repeat kinase 2
L-S	lumbosacral
LSD	lysergic acid diethylamide
LSK	liver, spleen, kidney
LT	leukotriene
LTB4	leukotriene B4
LTCF	long-term care facility
LTOT	long-term low-flow oxygen therapy
LUL	left upper lobe
LUQ	left upper quadrant
LV	left ventricle
LVAD	left ventricular assist device
LVH	left ventricular hypertrophy
LVN	licensed vocational nurse
LVRS	lung volume reduction surgery
M	married
M	million
M	muscarinic receptor (protein)
m, ⓜ	murmur/meter
MA	mental age
Mab	monoclonal antibody
MAC	medical ambulatory care
MAC	minimum alveolar concentration
MAC	monitored anesthesia care
MAO	monoamine oxidase
MAOI	monoamine oxidase inhibitor
MAP	mean arterial blood pressure
MASCC/ISOO	Multinational Association for Supportive Care in Cancer and the International Society of Oral Oncology
MAT	multifocal atrial tachycardia
mcg, µg	microgram
MCH	mean corpuscular hemoglobin
MCHC	mean corpuscular hemoglobin concentration
mChR	muscarinic cholinergic receptor
MCL	midclavicular line
MCP	mean corpuscular volume
MCP	metacarpophalangeal
MCP-1	monocyte chemoattractive protein-1
m-CPP	*m*-chlorophenylpiperazine
M-CSF	monocyte/macrophage colony-stimulating factor
MCV	mean corpuscular volume
MD	muscular dystrophy
MDD	major depressive disorder
MDMA	3,4-methylenedioxymethamphetamine

MDP	maximum diastolic potential
MDR	multidrug resistant protein
MDR-1	multidrug resistance protein-1
MDS	myelodysplastic syndrome
MEA	multiple endocrine adenoma syndrome
meds	medications/medicine
MEOS	microsomal enzyme oxidation system
MEPP	miniature end plate potential
mEq	milliequivalent
mets	metastatic
MFP	sodium monofluorophosphate
MG	myasthenia gravis
mg	milligram
Mg^{++}	magnesium ion
MGluR	metabotropic glutamate receptor
MH	malignant hyperthermia
MHC	major histocompatibility gene complex
MHPG	3-methoxy-4-hydroxyphenylglycol
MI	mitral insufficiency
MI	myocardial infarction
MIC	minimum inhibitory concentration
MICU	medical intensive care unit
MIT	monoiodotyrosine
MKP-1	mitogen-activated protein kinase phosphatase-1
μL	microliter
mL	milliliter
MLC	minimum lethal concentration
MLCK	myosin light-chain kinase
MLKS (resistance)	macrolide, lincosamide, ketolide, streptogramin
MLS_B	macrolide-lincosamide-strepogramin B (aggregate gene)
mm	millimeter
MM	mucous membrane
MMAD	mass median aerodynamic diameter
MMPI	matrix metalloprotease inhibitor
MN	midnight
Mod	moderate
MOM	milk of magnesia
MOPP	mechlorethamine, Oncovin (vincristine), procarbazine, prednisone (regimen)
MPHG	3-methyl-4-phenyl-pyridinium
MPP^+	1-methyl-4-phenylpyridinium
MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MR	may repeat
MR	mental retardation
MR	mitral regurgitation
MRCoNS	methicillin-resistant coagulase-negative staphylococci
MRI	magnetic resonance imaging
MRP	multidrug resistance-associated protein
MRSA	methicillin-resistant *Staphylococcus aureus*
MS	mitral stenosis
MS	morphine sulfate
MS	multiple sclerosis
MSKL	musculoskeletal
MSL	midsternal line
MSSA	methicillin-sensitive *Staphylococcus aureus*
MTIC	monomethyl 5-triazinoimidazole carboxamide
MUGA	multigated acquisition (a nuclear echocardiogram)
MVA	motor vehicle accident
MVI	multivitamins
MVP	mitral valve prolapse
MVR	mitral valve replacement/regurgitation
MW	molecular weight
N	nicotinic
N&V	nausea and vomiting
N/A	not applicable
N_2O	nitrous oxide
Na^+	sodium ion
Na^+,K^+-ATPase	Na^+,K^+-activated adenosine triphosphatase
NAD	no acute distress
NAD (NADH)	nicotinamide adenine dinucleotide
NADPH	nicotinamide adenine dinucleotide phosphate
NAM	N-acetylmuramic acid
NAPA	N-acetylprocainamide
NAPQI	N-acetyl-*p*-benzoquinoneimine
NB	newborn
NBD	nucleotide-binding domain
NC	noncontributory
NC/AT	normocephalic/atraumatic
NCCAM	National Center for Complementary and Alternative Medicine
NCCLS	National Committee for Clinical Laboratory Standards
NCEP	National Cholesterol Education Program
NDA	New Drug Application
NE	norepinephrine
NEC	necrotizing enterocolitis
NED	normal equivalent deviation units
neg	negative
NET	nasoendotracheal
NET	norepinephrine transporter
NF	*National Formulary*
NF-ATc	cytoplasmic component of nuclear factor of activated T cells
NF-ATn	nuclear component of nuclear factor of activated T cells
NF-κB	nuclear factor (κB)
Ng	nicotinic receptor, ganglia
NG	nasogastric
NGB	neurogenic bladder
NGT	nasogastric tube
NGTD	no growth to date (bacterial cultures)
NHANES	National Health and Nutrition Examination Survey
NHL	non-Hodgkin's lymphoma
NHLBI	National Heart, Lung, and Blood Institute
NI	nosocomial infection
NICE	National Institute of Health and Clinical Excellence
NICU	neonatal intensive care unit
NIDDM	non—insulin-dependent diabetes mellitus
NK	natural killer (cell)
NKA	no known allergies
NKDA	no known drug allergies
NLD	nasolacrimal duct
NLP	no light perception
N_M	nictonic (receptor), muscle type
Nm	nicotinic receptor on neuromuscular junction
NMDA	N-methyl-D-aspartate
NME	new molecular entity
NMR	nuclear magnetic resonance
NMS	neuroleptic malignant syndrome
N_N	nicotinic (receptor), nerve type
Nn	nicotinic receptor on postganglionic cells
NNT	number needed to treat
NO	nitric oxide
noc	night

NOS	nitric acid synthetase (or synthase)
NPH (insulin)	neutral protamine Hagedorn
NPI	National Provider Identifier
NPN	nonprotein nitrogen
NPO	nothing by mouth
NPT-1	Na^+/phosphate transporter-1
NPY	neuropeptide Y
NRM	nucleus raphe magnus
NS	normal saline/neurosurgery
NSAID	nonsteroidal anti-inflammatory drug
NSCLC	non—small cell lung cancer
NSILA	nonsuppressible insulin-like activity
NSPH	nonspecific plaque hypothesis
NSR	normal sinus rhythm
NSVD	normal spontaneous vaginal delivery
NTG	nitroglycerin
NTS	nucleus tractus solitarius
NTT	nasotracheal tube
NVDC	nausea, vomiting, diarrhea, constipation
NYHA	New York Heart Association
O&P	ova and parasites
O:	objective
O_2	oxygen
O_3	ozone
OA	occiput anterior
OA	osteoarthritis
OAT	organic anion transporter
OATP	organic anion—transporting polypeptide
OB	obstetrics
ob	occult blood
OBRA	Omnibus Budget Reconciliation Act
OBS	organic brain syndrome
OCT	organic cation transporter
OD	right eye (oculus dexter)
OD	overdose
oint	ointment
OM	otitis media
OMPA	octamethyl pyrophosphamide
OmpF	outer membrane protein F
ONJ	osteonecrosis of the jaw
OP	occiput posterior
OP, op	operation
OPC	outpatient clinic
OPD	outpatient department
ophth	ophthalmic
OPP	Office of Pesticide Programs
OPS	outpatient surgery
OR	operating room
ORIF	open reduction internal fixation
ORL	opioid receptor—like
ORN	osteoradionecrosis
Ortho	orthopedics
OS	left eye (oculus sinister)
OSHA	Occupational Safety and Health Administration
OT	occupational therapy
OTC	over-the-counter
Oto	otology
OU	both eyes (oculus uterque)
p	para
P	peptidergic receptor
P	pulse
P	purine receptor
P:	plan
P&A	percussion and auscultation
PA	posteroanterior
PABA	*p*-aminobenzoic acid
PAC	premature atrial contraction
$PaCO_2$	partial pressure of carbon dioxide in arterial blood
PACU	postanesthesia care unit
PAE	postantibiotic effect
PAF	platelet-activating factor
PAG	periaqueductal gray matter
PAI-1	plasminogen activator inhibitor type 1
PALC	postantibiotic leukocyte effect
PALS	pediatric advance life support
PaO_2	partial pressure of oxygen in arterial blood
PAP	pulmonary artery pressure
Pap S	Papanicolaou smear
PAR	postanesthesia recovery
PAR	protease-activated receptor
Para I	primipara/one live birth
PAS	p-aminosalicylic acid
PAT	paroxysmal atrial tachycardia (now usually said SVT)
Path	pathology
PAWP	pulmonary artery wedge pressure
PBI	protein-bound iodine
PBP	penicillin-binding protein
PBSCT	peripheral blood stem cell transplants
PC	1-phenyl-1-cyclohexene
PC	posterior chamber
pc	after meals (post cebum)
PCA	patient-controlled analgesia
PCMX	parachlorometaxylenol
PCN	penicillin
PCP	phencyclidine
PCP	*Pneumocystis carinii* pneumonia
PCP	primary care physician
PCTA	percutaneous coronary transluminal angioplasty
PDA	patent ductus arteriosus
PDC	potential-dependent channel
PDGF	platelet-derived growth factor
PDR	*Physicians' Desk Reference*
PDUFA	Prescription Drug User Fee Act
PE	physical examination
PE	pulmonary edema
PE	pulmonary emboli
PEEP	positive end-expiratory pressure
PEG	percutaneous enterogastric tube
PEG	pneumoencephalogram
PEG	polyethylene glycol
PEG-MGDF	pegylated megakaryocyte growth and development factor
per	by/through
PERRLA	pupils equal, round, reactive to light and accommodation
PET	positron emission tomography
P-F	phosphofluoride linkage
PF-3	platelet factor 3
PFC	perfluorocarbon
PFTs	pulmonary function tests
PG	prostaglandin
PGG_2, PGH_2	prostaglandin endoperoxides
PGI_2	prostacyclin
pH	acidity index
PHPV	primary hyperplastic vitreous
PHx	past history
PI	peripheral iridectomy
PI	present illness
PI	principal investigator
PICC	peripherally inserted central catheter
PID	pelvic inflammatory disease

pIgR	polymeric immunoglobulin receptor
PIP	proximal interphalangeal
PIP_2	phosphatidylinositol 4-5-bisphosphate
PJC	premature junctional contraction
PJI	prosthetic joint infection
pK_a	negative log of the dissociation constant
PKP	penetrating keratoplasty
PKU	phenylketonuria
PLC	phospholipase C
PLO	pleuronic lecithin organogel
plt	platelet
pm	postmeridian
PMB	postmenopausal bleeding
PMC	pseudomembranous colitis
PMD	private medical doctor
PMH/PMHx	past medical history
PMI	point of maximum impulse
PMN	polymorphonuclear (leukocyte)
PMP	previous menstrual period
PND	paroxysmal nocturnal dyspnea
PND	postnasal drip
PNMT	phenylethanolamine-N-methyltransferase
PNP	pediatric nurse practitioner
po	by mouth (per os)
PO	postoperative
POC	products of conception
PO/IM	oral/intramuscular potency ratio
PP	postpartum
PP	postprandial
PPARα	peroxisomal proliferators—activated receptor α
PPBS	postprandial blood sugar
PPD	purified protein derivative
PPH	postpartum hemorrhage
PPI	protein pump inhibitor
ppm	parts per million
PPP	postpartum psychosis
pr	per rectum
PRBC	packed red blood cells
pre-op	preoperative
PRH	prolactin-releasing hormone
prn	*pro re nata* (as needed)
PROM	premature rupture of membranes
PRON	postradiation osteonecrosis
PRSTN	postradiation soft tissue necrosis
PS	pulmonary stenosis
PSI, psi	pounds per square inch
PSS	progressive systemic sclerosis
Psy	psychiatry/psychology
PT	prothrombin time
PT	physical therapy
pt	patient
PTA	prior to admission/plasma thromboplastin antecedent
PTCA	percutaneous transluminal coronary angioplasty
PTH	parathyroid hormone
PTT	partial thromboplastin time
PUD	peptic ulcer disease
PUFA	polyunsaturated fatty acids
pulv	powder
PUVA	psoralen plus ultraviolet A
pv	per vagina
PVC	premature ventricular contraction
PVR	postvoid residual
q	every (*quaque*)
q.a.m./q.p.m.	every morning/every evening
q.d.	every day, daily
q.h.	every hour, hourly
q.h.s.	every night at bedtime
q.i.d.	four times daily (quarter in die)
q.n.s.	quantity not sufficient
q.o.d.	every other day
q.o.h.	every other hour
q.s.	quantity sufficient
q2 (3, 4, ...) d.	every 2 (3, 4, ...) days
q2 (3, 4, ...) h.	every 2 (3, 4, ...) hours
q2 (3, 4, ...) n.	every 2 (3, 4, ...) nights
R	resistance factor
R	respiration
R	right
R/O	rule out
RA	rheumatoid arthritis
RA	right atrium
RAE	right atrial enlargement
RAI	radioactive iodine
RANKL	RANK ligand
RAO	right anterior oblique
RAR	retinoid acid receptor
RBBB	right bundle branch block
RBC	red blood count
RD	Raynaud's disease
RD	retinal detachment
RDS	respiratory distress syndrome
reg	regular
Rehab	rehabilitation
REM	rapid eye movement (sleep)
RF	rheumatic fever
RGD	arginine-glycine—aspartic acid sequence
RH	releasing hormone
Rh	Rhesus factor
RHD	rheumatic heart disease
RLL	right lower lobe
RLQ	right lower quadrant
RML	right middle lobe
RN	Registered Nurse
RNA	ribonucleic acid
RND	radical neck dissection
RNP	ribonucleoprotein
ROA	right occipital anterior
ROC	receptor-operated channel
ROM	range of motion
ROM	right otitis media
ROM	rupture of membranes
ROP	right occipital posterior
ROS	reactive oxygen species
ROS	review of systems
RPO	right posterior oblique
RPT	Registered Physical Therapist
RR	respiratory rate
RRR	regular rate and rhythm
RSR	regular sinus rhythm
RSV	respiratory syncytial virus
RT	respiratory therapy
RT/RAD Rh	radiation therapy
RTC	return to clinic
RTF	resistance transfer factor
RUA	routine urinalysis
RUL	right upper lobe
RUQ	right upper quadrant
RV	right ventricle
RVH	right ventricular hypertrophy
RVM	rostroventral medulla
R_x	prescription
RXR	retinoid X receptor
S	Svedberg unit

S/P	status post
S/S	signs/symptoms
S:	subjective
S_1, S_2, S_3	first, second, and third sacral vertebrae
S_1, S_2, S_3, S_4	systolic heart sounds
SA	sinoatrial (node)
Sab	spontaneous abortion
SAD	seasonal affective disorder
SaO_2	saturation of oxygen in arterial blood
SAR	structure-activity relationship
SB	stillbirth
SBA	standby assistance
SBE	subacute bacterial endocarditis
SBFA	single baby for adoption
SBO	small bowel obstruction
SBP	spontaneous bacterial peritonitis
SC	subcutaneous
SCF	stem cell factor
SD	standard deviation
SDA	same-day admission
SEM	standard error of the mean/scanning electron microscope
SEM	systolic ejection murmur
Sep	separated
SERM	selective estrogen receptor modulator
SGA	small for gestational age
SGOT	serum glutamic-oxaloacetic transaminase (now AST)
SGPT	serum glutamic-pyruvic transaminase (now ALT)
SHV	sulfhydryl variable
SI	serious illnesses
SIADH	syndrome of inappropriate antidiuretic hormone secretion
SIF	small, intensely fluorescent (cell)
Sig	let it be labeled
Sig	significant
SK	streptokinase
SKB	single, keeping baby
SKF 525A	proadifen
SL	sublingual
SLC	solute carrier
SLE	systemic lupus erythematosus
SLUD	salivation, lacrimation, urination, defecation
SMA	sequential multiple analyzer
SMART	Salmeterol Multi-Center Asthma Research Trial
SMR	submucous reaction
SNARE (complex)	synaptobrevin, syntaxin, SNAP-25
SNC	substantia nigra pars compacta
SNP	single nucleotide polymorphism
SNS	sympathetic nervous system
SO_2	Sulfur dioxide
SOB	shortness of breath
sol	solution
SP	substance P
SP	suprapubic
sp gr	specific gravity
SPA	stimulation-produced analgesia
SPECT	single-photon emitted computed tomography
SPH	specific plaque hypothesis
SQ	subcutaneous
SR	sarcoplasmic reticulum
SRC-1	steroid receptor coactivator-1
SROM	spontaneous rupture of membranes
SRS	slow-reacting substance (leukotrienes)
SRS-A	slow-reacting substance of anaphylaxis (leukotrienes)
SSRI	selective serotonin reuptake inhibitor
SSS	sick sinus syndrome
STAT	signal transducers and activators of transcription
STAT	immediately (*statum*)/at once
STD	sexually transmitted disease
STD	skin test dose
STD	standard
STS	serology test for syphilis
STSG	split-thickness skin graft
subcut	subcutaneous
supp	suppository
SV2	synpatic plasma membrane protein
SVT	supraventricular tachycardia
Sx	symptom(s)
syr	syrup
T	temperature
T	tension
T&A	tonsillectomy and adenoidectomy
T_1, $T_{2,..}$	thoracic vertebrae first, second, ...
$T_{½}$	half-life, half-time
T_3	triiodothyronine, liothyronine
T_4	tetraiodothyronine/thyroxine/levothyroxine
tab	tablet
TAB	therapeutic abortion
TAH	total abdominal hysterectomy
TALH	thick ascending limb of the loop of Henle
TAT	tetanus antitoxin
TAT	toxin-antitoxin
TB	tuberculosis
TBG	thyroxine-binding globulin
TBI	total body irradiation
TBI	traumatic brain injury
tbsp	tablespoon
TCA	tricyclic antidepressant
TCC	transitional cell carcinoma
TCDB	turn, cough, deep breath
TCDD	dioxin
TCR	T-cell antigen receptor
TD_{50}	median therapeutic dose
TEA	tetraethylammonium
TEF	tracheoesophageal fistula
TF	tissue factor
TF	tube feeding
TFPI	tissue factor pathway inhibitor
TGF-γ	transforming growth factor-γ
TGV	transposition of great vessels
THC	tetrahydrocannabinol
THC	transhepatic cholangiogram
THO	activated T cells that have yet to differentiate
THR	total hip replacement
TI	therapeutic index
TIA	transient ischemic attack
TIBC	total iron-binding capacity
tid	three times a day
TIPS	transjugular intrahepatic portosystemic shunt
TKO	to keep open
TKR	total knee replacement
TLC	total lung capacity
TM	transmembrane helice
TM	tympanic membrane
TM1	transmembrane helix 1
TMD	temporomandibular disorder

TMD	transmembrane domain
TMJ	temporomandibular joint
TMN	tumor, metastases, nodes
TNF	tumor necrosis factor
TNF-α	tumor necrosis factor-α
TNFR	tumor necrosis/nerve growth factor receptor
TO	telephone order
TOA	tubo-ovarian abscess
TOF	tetralogy of Fallot
t-PA	tissue-type plasminogen activator
TPMT	thiopurine S-methyltransferase
TPN	total parenteral nutrition
TPO	thrombopoietin
TPR	total peripheral resistance
TPR	temperature, pulse, and respiration
tr	tincture
TRH	thyrotropin-releasing hormone
TRP	transient receptor potential (channels)
TRPV1	transient receptor potential vanilloid receptor 1
tRNA	transfer RNA
trt	treatment
TS	thoracic surgery
TSH	thyroid-stimulating hormone; thyrotropin
tsp	teaspoon
TT	thrombin time
TTA	transtracheal aspiration
TTN	transient tachypnea of newborn
TURB	transurethral resection of the bladder
TURP	transurethral resection of the prostate
TV	tidal volume
TVH	total vaginal hysterectomy
Tx	treatment, therapy
TXA_2	thromboxane A_2
U	uptake
UA	umbilical artery
UA	urinalysis
UC	uterine contraction
UCHD, UCD	usual childhood diseases
UE	upper extremity
UGI	upper gastrointestinal
UGT	uridine diphosphate glucuronosyltransferase
UNPIC	Prior Informed Consent (procedure)
UOP	urinary output
u-PA	urokinase plasminogen activator
UPDRS	Unified Parkinson's Disease Rating Scale
UPP	urethral pressure profile
URI	upper respiratory infection
USAN	United States Adopted Name
USANC	United States Adopted Name Council
USN	ultrasonic nebulizer
USP	*United States Pharmacopeia*
USPDI	*United States Pharmacopeia Dispensing Information*
UTI	urinary tract infection
UTZ	ultrasound
UV	ultraviolet
V Fib	ventricular fibrillation
VA	visual acuity
VC	vital capacity
VCUG	voiding cystourethrogram
V_d	volume of distribution
VD	venereal disease
VDRL	Venereal Disease Research Laboratory (test for syphilis)
V_DV_T	physiologic dead space in percent of tidal volume
VE	vacuum extraction
VEGF	vascular endothelial growth factor
VF	ventricular fibrillation
VGS	viridans group streptococci
VIP	vasoactive intestinal peptide
VIPPS	Verified Internet Pharmacy Practices Site
VISA	vancomycin-intermediate—resistant *Staphylococcus aureus*
viz	namely
VKOR	vitamin K epoxide reductase
VLDL	very-low-density lipoprotein
VMA	vanillylmandelic acid
VO	verbal order
vol	volume
VRE	vancomycin-resistant enterococci
VRG	vessel-rich group
vs	versus
VS	vital signs
VSD	ventricular septal defect
VSS	vital signs stable
VT	ventricular fibrillation
vWD	von Willebrand's disease
vWf	von Willebrand factor
VZV	varicella-zoster virus
w/c	wheelchair
w/d	wet to dry
w/o	without
w/u	workup
w/w	wet to wet
W-3 PUFA	W-3 polyunsaturated fatty acid
WB	whole blood
WBC	white blood cell, leukocyte count
wd	wound
WDWN	well-developed, well-nourished
WF, BF	white female, black female
WHO	World Health Organization
WM, BM	white male, black male
WNL	within normal limits
wt	weight
x	times
y/o, yo, yrs	years old
