The treatment of aspirin overdose is primarily palliative and supportive. Chronic toxicity usually is treated simply by withholding the drug temporarily and then reinstituting therapy at lower doses. Acute toxicity often requires respiratory support, gastric lavage, maintenance of electrolyte balance (e.g., K^+ replacement if necessary), maintenance of plasma pH, and alkalinization of the urine with intravenous bicarbonate. Alkalinization of the urine increases the percentage of ionized salicylate in the glomerular filtrate. Salicylate reabsorption is reduced, and renal clearance is increased up to fourfold. The carbonic anhydrase inhibitor acetazolamide may also be used to promote urinary alkalinization.

Allergic reactions to aspirin can also occur. Many patients confuse side effects such as nausea or tinnitus with true allergic responses manifested by skin rashes, hives, angioedema, or anaphylaxis. Patients with a history of skin eruptions caused by aspirin ingestion should be cautioned to avoid all proprietary compounds containing aspirin or any salicylate to avoid more serious anaphylactic reactions.

Intolerance to salicylates can occur, with symptoms ranging from rhinitis to severe asthma. This reaction does not seem to be immune mediated even though it resembles drug allergy in clinical presentation. Aspirin intolerance is more common in patients with preexisting asthma or nasal polyps. The incidence of this reaction in asthmatic patients has been reported as high as 20%. Patients with a history of asthma, allergic disorders, or nasal polyps should be questioned to ensure that they can tolerate aspirin and other NSAIDs. The bronchoconstriction may be caused by a shift in the arachidonic acid cascade when the COX enzyme is blocked. This inhibition prevents arachidonate metabolism from producing bronchodilating PGs, primarily PGE_2.[160] The lipoxygenase pathway predominates and produces leukotrienes that constrict bronchioles in sensitive individuals, mimicking the asthmatic attack.[22,39] Other manifestations of aspirin intolerance include urticaria (hives) and angioedema. Switching from aspirin to another salicylate or even another NSAID does not prevent the reaction; acetaminophen is the only antipyretic analgesic that may be used safely in patients with aspirin intolerance. The clinician should be aware that, although relatively rare, there are reports of aspirin-intolerant asthmatic patients also displaying severe respiratory symptoms when ingesting therapeutic doses of acetaminophen.[7]

Contraindications and precautions

Aspirin is contraindicated or at least must be used with caution in numerous medical conditions (Table 21-4). Serious internal bleeding can result from the ingestion of aspirin by a patient with an ulcer. Patients with compromised liver function should use aspirin cautiously because, when used on a long-term basis, aspirin increases the prothrombin time, which could aggravate bleeding problems. Low doses of aspirin can increase plasma urate concentrations and exacerbate gouty arthritis as a result of competition between salicylate and uric acid at the active secretion sites in the proximal tubule of the kidney or by an increase in uric acid reabsorption. High doses of aspirin may increase or decrease plasma glucose concentrations by stimulating epinephrine and glucocorticoid release or by depleting liver glycogen. Salicylates may also increase insulin secretion because PGE_2 inhibits insulin secretion.[66]

Asthma patients, patients with nasal polyps, and patients with chronic allergic disorders (e.g., urticaria) should use aspirin cautiously because, as previously mentioned, up to 20% of these patients have reported intolerance to aspirin, other salicylate drugs, and other NSAIDs. Aspirin (and other NSAIDs) is contraindicated in patients with aspirin intolerance. True allergy, mediated by IgE, usually involves allergy to only one class of NSAID (i.e., salicylates or propionic acids but not both). From a clinical perspective, it is often difficult to distinguish aspirin intolerance from a true aspirin allergy based on the patient's description of the event, whereas in the case of true aspirin allergy, a nonsalicylate NSAID could theoretically be used safely.

TABLE 21-4

Contraindications to the Use of Aspirin and Other Salicylates

DISEASE STATE	POSSIBLE ADVERSE EFFECT OF ASPIRIN
Ulcer	Internal bleeding, possible hemorrhaging
Asthma	Asthmatic attack resembling an allergic reaction
Diabetes	High doses may cause hyperglycemia or hypoglycemia
Gout	Low doses increase plasma urate; high doses decrease plasma urate
Influenza	Reye's syndrome in children
Hypocoagulation states	Excessive bleeding

Aspirin is not absolutely contraindicated in pregnancy, but it should be used with caution. In the third trimester, aspirin tends to prolong labor by inhibiting the synthesis of PGs involved in initiating uterine contractions. Aspirin has also been reported to increase blood loss at the time of delivery and may cause premature closure of the ductus arteriosus in the fetus. Some evidence also suggests that, in very high doses, aspirin can have teratogenic effects.

A number of drug interactions may involve aspirin (Table 21-5). Because of its effects on blood glucose, aspirin can interact adversely with insulin or oral hypoglycemic agents, causing unpredictable changes in blood glucose concentrations. Aspirin and other salicylates compete with oral hypoglycemic drugs for binding sites on plasma proteins. This interaction theoretically leads to higher amounts of unbound oral hypoglycemic in the plasma and an enhanced hypoglycemic effect. Internal bleeding may occur if aspirin, which causes GI irritation and inhibition of platelet aggregation, is used in conjunction with anticoagulants such as warfarin and heparin. In addition, warfarin can be displaced from plasma proteins by aspirin. As with oral hypoglycemic drugs, this competition for binding is more of a theoretic concern than a practical issue (as discussed in Chapter 2). Another potentially dangerous drug combination is aspirin and alcohol because alcohol sensitizes the gastric mucosa to aspirin. Aspirin and other NSAIDs also increase the toxicity of methotrexate and valproic acid and can decrease the effect of certain antihypertensive drugs (e.g., β-adrenoreceptor blockers, diuretics, and ACE inhibitors). Long-term low doses of aspirin used for antiplatelet therapy do not seem to interact with antihypertensive drugs.[124]

Diflunisal

Diflunisal is a difluorophenyl derivative of salicylic acid (see Figure 21-5) with anti-inflammatory, analgesic, and antipyretic activity. Although structurally related to salicylates, diflunisal is not hydrolyzed in vivo to salicylate and is unique among the salicylates. Similar to other salicylates, diflunisal blocks the synthesis of PGs by inhibiting COX. Diflunisal is approximately 10-fold more potent than aspirin in suppressing PG formation in rats.

TABLE **21-5**

Drug Interactions Involving Aspirin

DRUG	POSSIBLE INTERACTION WITH ASPIRIN
Warfarin	Internal bleeding, possible hemorrhaging
Heparin	Internal bleeding, possible hemorrhaging
Insulin	Aspirin may cause hyperglycemia or enhancement of hypoglycemic effect
Sulfonylureas (oral hypoglycemic agents)	Enhancement of hypoglycemic effect
Phenytoin, valproicacid	Increased free plasma concentration of phenytoin, valproic acid
Methotrexate	Increased free plasma concentration of methotrexate
Ethanol	Internal bleeding, possible hemorrhaging
Probenecid, sulfinpyrazone	Decreased uricosuric effect, reappearance of gout
ACE inhibitors, β-adrenergic blockers, diuretics	Loss of antihypertensive effect

ACE, Angiotensin-converting enzyme.

The drug is well absorbed after oral administration, with peak blood concentrations occurring in 2 to 3 hours. It is highly bound to plasma protein. Diflunisal has a long plasma half-life (8 to 12 hours versus 2.5 hours for salicylate), which permits dosing intervals of 12 hours. The drug is excreted in the urine, with two soluble glucuronide conjugates accounting for approximately 90% of the administered dose.

Diflunisal is indicated for the treatment of mild-moderate pain and for osteoarthritis and rheumatoid arthritis. In postoperative dental pain, 500 to 1000 mg of diflunisal produces greater analgesia than aspirin or acetaminophen (both 650 mg), and peak effects are comparable to those obtainable with fixed combinations containing optimal doses of opioids.[57,59] Because diflunisal has an extended duration of action and a relatively slow onset of action in acute pain models, the recommended dosage regimen is a 1000-mg loading dose followed by 500 mg every 8 to 12 hours. The effectiveness of diflunisal in osteoarthritis seems to be comparable to that of aspirin.

In terms of adverse effects, diflunisal qualitatively resembles aspirin. Effects on the GI tract range from nausea and epigastric pain to peptic ulcer and GI bleeding. Diflunisal is less problematic in this respect than aspirin, however. Platelet function and bleeding time are affected in a dose-related fashion but to a lesser degree than with aspirin because diflunisal is a competitive, reversible inhibitor of COX. Similar to aspirin, diflunisal prolongs the prothrombin time in patients receiving oral anticoagulants, perhaps by competitive displacement of coumarins from protein binding sites. Diflunisal does not penetrate the blood-brain barrier as well as aspirin does, and diflunisal causes fewer CNS effects, including tinnitus. For this same reason, it is not used as an antipyretic.

Other NSAIDs

Many NSAIDs chemically unrelated to the salicylates are now available. They all inhibit COX, but they vary in their relative potencies against COX-1 and COX-2.[128,172] Some NSAIDs may have other anti-inflammatory actions in addition to inhibiting COX.[120] Many of these NSAIDs have been evaluated in postoperative dental pain and have been found to be superior to optimal doses of either aspirin or acetaminophen in terms of peak analgesic effect and duration of effect. For more long-term use, as in the treatment of rheumatoid arthritis, the choice of an NSAID for therapy is largely empiric and often based on what drug is best tolerated and best relieves symptoms in the individual patient. Most of these drugs are arylalkanoic or heteroarylalkanoic acid derivatives and are discussed according to their chemical classification. The more recently developed highly selective COX-2 inhibitors are discussed separately.

Propionic acid derivatives

Among NSAIDs, the substituted phenylpropionic acid derivatives constitute the largest group of aspirin alternatives (Figure 21-9). In addition to their anti-inflammatory indications in treating the symptoms of rheumatoid arthritis, osteoarthritis, and degenerative joint disease, ibuprofen, naproxen, ketoprofen, and fenoprofen are also approved as analgesic agents. The short-term use of ibuprofen, naproxen, and ketoprofen is available without a prescription for relief of headache, fever, dysmenorrhea, and mild-moderate musculoskeletal and postoperative pain. In patients with rheumatoid arthritis and osteoarthritis, the propionic acid derivatives and other NSAIDs reduce joint swelling, pain, and morning stiffness, and they improve mobility as measured by an increase in walking time. When used in patients treated with corticosteroids, these agents may permit reduction of the steroid dose.

Similar to aspirin and other NSAIDs, these drugs inhibit PG synthesis by nonselective inhibition of COX. Their ability to inhibit COX and prevent the effect of PGs on uterine smooth muscle makes them useful in the treatment of dysmenorrhea. Although they share a common pharmacologic profile, some unique characteristics exist among individual drugs. Naproxen seems to be especially effective in reducing leukocyte activity in inflammation, and ketoprofen seems to prevent lysosomal enzyme release by stabilizing the membranes of lysosomes.

Because propionic acid derivatives as a group are less likely than analgesic and anti-inflammatory doses of aspirin to cause GI or bleeding disturbances, they have increasingly been used in place of aspirin. Although the highly selective COX-2 inhibitors challenged the preeminence of ibuprofen and naproxen for several years in antiarthritic therapy because of an even lower risk of serious GI events, their cardiotoxic potential in selected patients has greatly diminished their use. Propionic acid NSAIDs are almost completely absorbed from the GI tract. The rate of absorption is generally rapid but can be altered for some drugs by the presence of food in the stomach. Peak blood concentrations are reached in 1 to 4 hours. All these agents are highly bound (>90%) to plasma proteins; they are theoretically capable of interfering with the binding of other drugs such as phenytoin or sulfonamides. The drugs are variably metabolized and conjugated, and they are largely excreted in the urine.

Ibuprofen, fenoprofen, and ketoprofen have short plasma half-lives (1 to 4 hours), whereas naproxen has a plasma half-life of approximately 15 hours, which allows less frequent dosing. Flurbiprofen has an intermediate half-life of approximately 6 hours; the half-life of oxaprozin is approximately 50 hours. A brief overview of some of the individual drugs follows, with an emphasis on the analgesic use of these drugs in patients with postsurgical dental pain.

Ibuprofen. Ibuprofen was the first single-entity oral analgesic to be approved by the FDA that showed a greater peak anal-

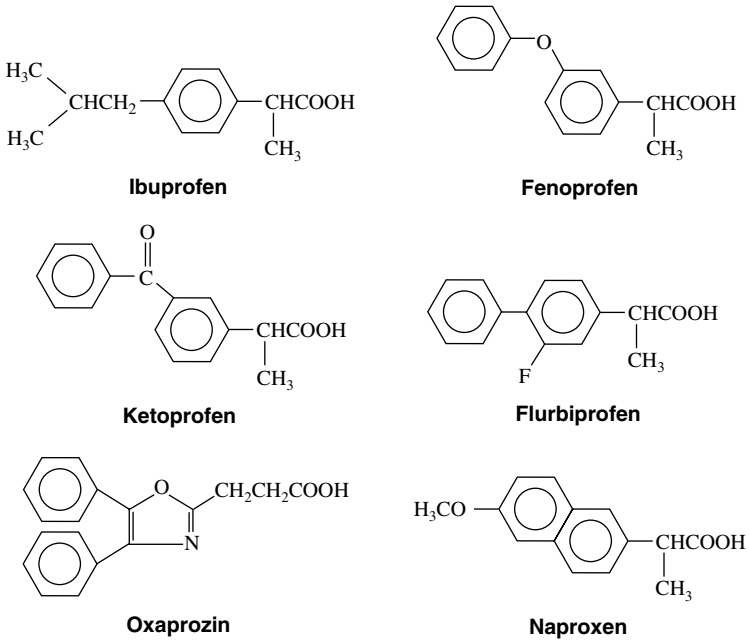

FIGURE **21-9** Structural formulas of some propionic acid derivatives.

gesic effect than 650 mg of aspirin.[26,34] It is also available as a nonprescription drug. The recommended prescription analgesic dose of ibuprofen is 400 to 600 mg every 4 to 6 hours with a maximum daily dose of 2400 mg. When used OTC without a health professional's guidance, the maximum daily dose should not exceed 1200 mg. In one study, a 400-mg dose of ibuprofen was more effective than a combination of 650 mg of aspirin with 60 mg of codeine when evaluated over 4 hours (Figure 21-10).[31] In another study, an ibuprofen liquigel formulation containing 200 mg of solubilized potassium ibuprofen displayed greater peak analgesic effects and a longer duration of action than 1000 mg of acetaminophen.[80] Doses of ibuprofen larger than 400 mg have not consistently shown enhanced analgesic efficacy in nonrheumatic pain, although a meta-analysis of various analgesic interventions in postsurgical dental pain studies reported a modest increase in pain relief (at least with the first dose of drug) with 600 mg of ibuprofen compared with 400 mg of ibuprofen.[10]

Ibuprofen administered preoperatively or immediately postoperatively can delay the onset and lessen the severity of postoperative pain.[46,166,170] Such treatment may be particularly useful when there is a high likelihood of moderate-severe postoperative discomfort. For rheumatic pain and inflammation, doses of ibuprofen can range from 1200 to 3600 mg daily. Ibuprofen is widely used as an antipyretic and is second to acetaminophen as the most used antipyretic in pediatric patients. Dosages for antipyresis are based on the child's age and body weight.

Ibuprofen is a weak organic acid and is highly (approximately 99%) bound to plasma albumin. It is extensively metabolized and then excreted as the metabolites or their conjugates in the urine, with an elimination half-life of approximately 2 hours.

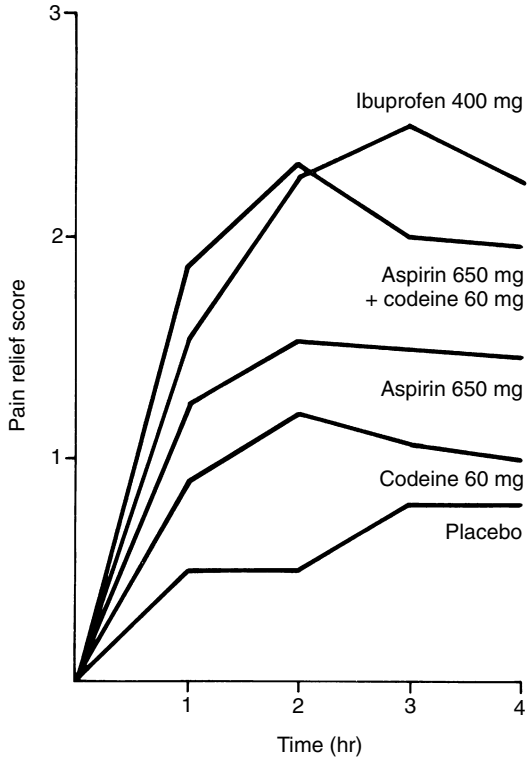

FIGURE **21-10** Time-effect curves for placebo, codeine, aspirin, aspirin plus codeine, and ibuprofen. Mean pain relief scores are plotted against time in hours. (Adapted from Cooper SA, Engel L, Ladov M, et al: Analgesic efficacy of an ibuprofen-codeine combination, *Pharmacotherapy* 2:162-167, 1982.)

Naproxen. Naproxen is approved for various inflammatory conditions and for the relief of pain. It is the only NSAID manufactured as the pure active S-enantiomer. It is available as the free acid and as the sodium salt, the latter of which is more rapidly absorbed from the GI tract and is the preferred form for analgesic use. The sodium salt of naproxen at a 220-mg dose is available OTC with a maximum recommended daily dose of 660 mg (440 mg if the individual is older than 65 years). Naproxen sodium by prescription can be taken at a dose of 1375 mg/day. In one study of postsurgical dental pain, a 220-mg dose of naproxen sodium was equivalent in analgesic efficacy and duration to 200 mg of ibuprofen.[91] In two other studies, 440 mg of naproxen

sodium was superior to 1000 mg of acetaminophen in peak analgesia and duration and equivalent in efficacy to 400 mg of ibuprofen.[62,90] At doses of 440 to 550 mg, naproxen sodium displays a duration of action of 8 to 12 hours, which is the recommended dosing interval. This extended duration of action is explained by its long half-life of approximately 15 hours.

Naproxen is more irritating to the GI tract than ibuprofen, possibly because of its greater selectivity for blocking COX-1.[81] The drug is partially metabolized, and its clearance is almost entirely renal. Similar to ibuprofen, naproxen is highly bound to plasma albumin.

Fenoprofen. Fenoprofen is marketed with analgesic and anti-inflammatory indications. The recommended dose of 200 mg every 4 to 6 hours is likely to be superior to 650 mg of aspirin. Similar to the other propionic acid derivatives, fenoprofen is extensively (approximately 99%) and reversibly protein bound. It has a mean plasma half-life of approximately 2.5 hours in healthy adults. Most of the drug is excreted by the kidney as hydroxylated and conjugated metabolites.[69]

Ketoprofen. Ketoprofen is FDA-approved as an analgesic and is effective for the symptomatic management of rheumatoid arthritis, osteoarthritis, and dysmenorrhea. Similar to the other propionic acid derivatives, it inhibits PG synthesis. Ketoprofen has also been shown to inhibit leukotriene synthesis in at least two in vitro cell culture systems. In addition, ketoprofen stabilizes lysosomal membranes and has an antibradykinin effect. It is more potent than ibuprofen, with 25 to 50 mg of ketoprofen about equally effective for mild-moderate pain as 400 mg of ibuprofen. In one dental pain study, 100 mg of ketoprofen was significantly more effective than 400 mg of ibuprofen, although this represents an unapproved supratherapeutic analgesic dose of ketoprofen (Figure 21-11).[28]

Although a 12.5-mg dose is approved for OTC use, ketoprofen has been reported to be more irritating to the GI tract than aspirin.[81] Ketoprofen is extensively bound to plasma proteins (approximately 99%), and it has an elimination half-life of 2 to 4 hours in young and middle-aged adults. It is conjugated with glucuronic acid in the liver and is excreted by the kidney. For nonarthritic pain, doses of 25 to 50 mg three or four times daily are usually sufficient. For arthritic pain, daily doses may approach 300 mg.

Flurbiprofen. Flurbiprofen has no unique advantages over ibuprofen. It is much more potent, however, with 50 to 100 mg of flurbiprofen being equal in effectiveness to 400 mg of ibuprofen.[109] Although approved by the FDA as an antiarthritic drug, flurbiprofen does not possess an analgesic indication. Of particular interest to periodontists is that flurbiprofen (in addition to some other NSAIDs) taken on a long-term basis has been shown to slow the progression of alveolar bone resorption in different experimental models of periodontal disease.[86,175,176]

Oxaprozin. Oxaprozin is currently approved for rheumatoid arthritis and osteoarthritis only. With a half-life of approximately 50 hours, it is typically dosed once a day. In contrast to other members of the propionic acid class, oxaprozin produces a significant incidence of photosensitivity, manifested as vesicular eruptions on sun-exposed skin. Similar to other NSAIDs, oxaprozin is associated with a prolongation of bleeding time, which may persist for more than 8 days after the last dose because of its long half-life.

Adverse effects. Although the incidence with some propionic acid derivatives may be less than with aspirin, various GI disturbances (epigastric pain, nausea, vomiting, gastric bleeding, and constipation or diarrhea) can occur, and these drugs should be used with caution in patients with a history of peptic or duodenal ulcer. Long-term, high-dose administration for arthritic conditions is far more likely to produce serious adverse events than short-term administration for acute pain. Meta-analyses of OTC doses of ibuprofen (800 to 1200 mg/day) or naproxen sodium (440 to 880 mg/day) taken for 10 days or less have revealed a side-effect profile no worse than placebo.[9,89] Propionic acid derivatives can injure the gastric mucosa, however, by suppressing COX-1 activity and decrease the cytoprotection afforded by PGI_2 and PGE_2.

CNS effects may include headache, dizziness, drowsiness, vertigo, and visual and auditory disturbances including tinnitus. Skin rashes are common, and immediate allergic reactions have been reported. All NSAIDs can lead to anaphylactoid reactions in aspirin-intolerant patients (i.e., patients susceptible to aspirin-induced asthma). These agents decrease platelet aggregation and adhesiveness and increase bleeding time, although to a lesser degree than aspirin; they should be avoided in patients with bleeding disorders and used with caution in patients receiving anticoagulants. These drugs may promote Na^+ retention, and their use may lead to the formation of edema in susceptible individuals. They can interfere with the antihypertensive effects of β-adrenergic blockers, ACE inhibitors, and diuretics if they are administered for more than 1 week.[88] In elderly patients, especially during long-term therapy, the dosage of the propionic acid NSAIDs may have to be reduced by 50%.

More recent epidemiologic reports indicate an increased risk of GI bleeding when these drugs and other NSAIDs are taken concomitantly with antidepressants of the selective serotonin reuptake inhibitor (SSRI) class, such as fluoxetine

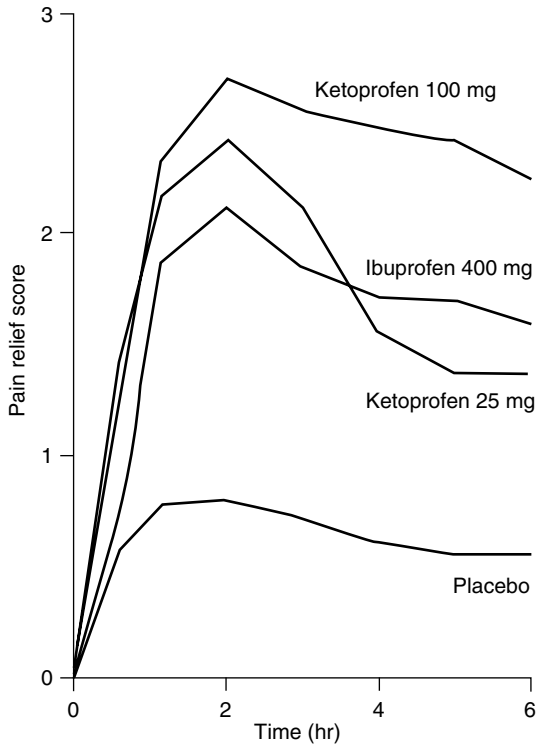

FIGURE **21-11** Time-effect curves for placebo, ketoprofen, and ibuprofen. The mean pain relief scores are plotted against time in hours. (Adapted from Cooper SA, Berrie R, Cohn P: Analgesic efficacy of ketoprofen 25 and 100 mg compared to ibuprofen 400 mg, *Clin Pharmacol Ther* 39:187, 1986.)

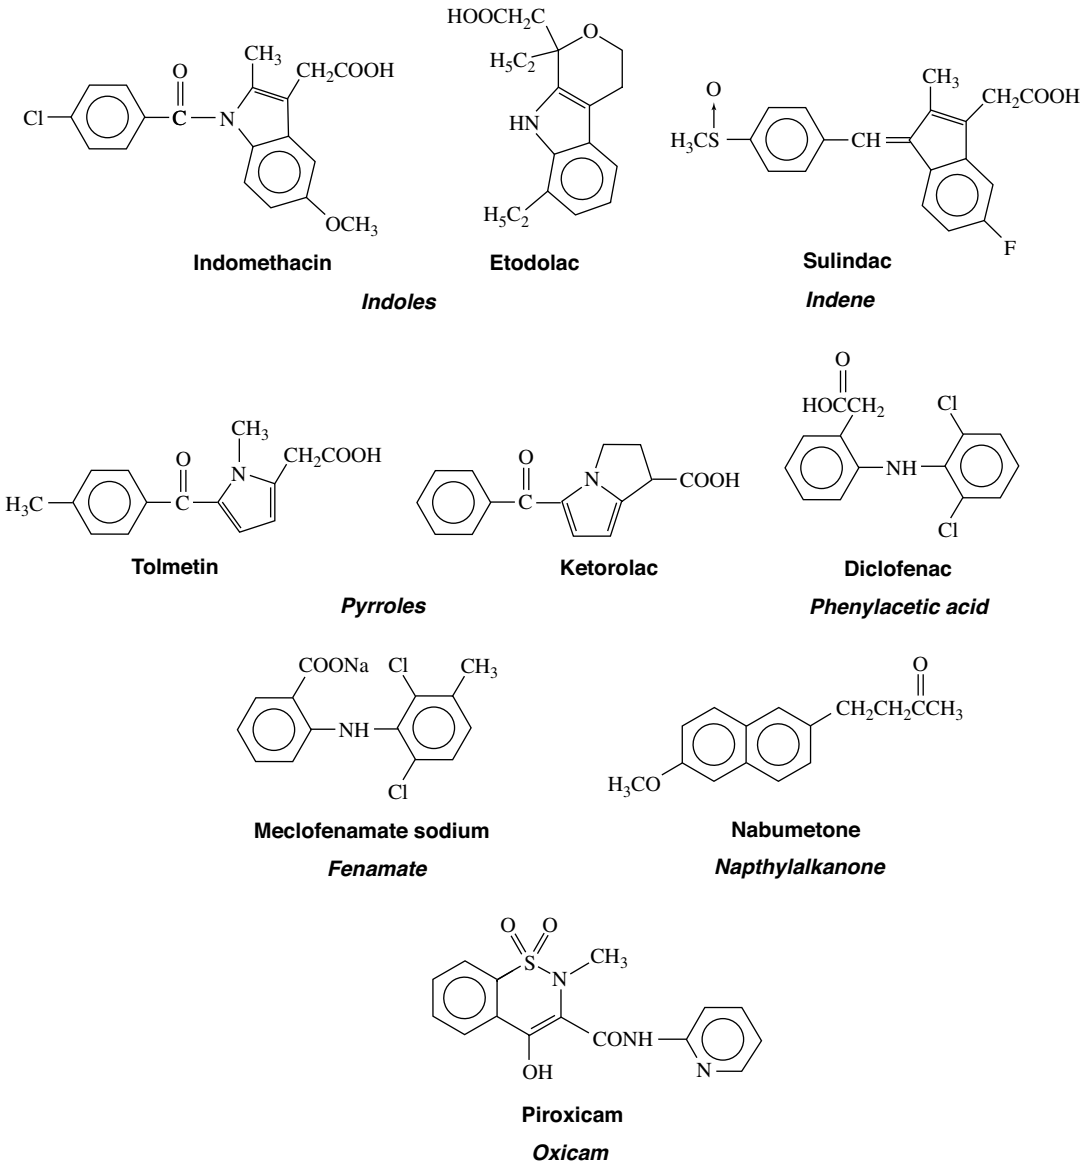

FIGURE **21-12** Structural formulas of various arylalkanoic and heteroarylalkanoic acid derivatives. The chemical categories are noted.

(Prozac) and paroxetine (Paxil).[82] SSRIs seem to block the reuptake of serotonin in the platelet as they do in neurons in the CNS[140]; this reduces the ability of platelets to store serotonin. Similar to the COX-1 arachidonic acid product thromboxane A_2, serotonin stimulates platelet aggregation. The combined intake of SSRIs and NSAIDs can result in an additive or supra-additive antiplatelet effect.

Another more recent concern has been the reported ability of NSAIDs such as ibuprofen to inhibit the antiplatelet and cardioprotective effects of low-dose aspirin.[23] Because ibuprofen and other NSAIDs are reversible inhibitors of COX and aspirin is rapidly metabolized to salicylate, which is also a reversible COX inhibitor, the competition of NSAIDs with aspirin for the COX-1 binding site could inhibit the antiplatelet effects of aspirin under certain conditions. In an experimental paradigm that resembled the typical cardioprotective use of aspirin (i.e., a patient already taking low-dose aspirin and then having ibuprofen, 400 mg, introduced three times daily for ≤1 week), there was no diminution of aspirin's antiplatelet activity, indicating that short-term use of ibuprofen was acceptable in these patients.[37]

Indole and indene derivatives

The indole and closely related indene derivatives include several drugs useful in the treatment of acute and chronic inflammatory diseases.

Indomethacin. Indomethacin is a methylated indole acetic acid with powerful anti-inflammatory properties. Its chemical structure is shown in Figure 21-12. Indomethacin is a potent inhibitor of COX (see Table 21-2) and a more potent anti-inflammatory drug in vivo than aspirin. Similar to the salicylates, it influences numerous biochemical and cellular events that may be involved in the inflammatory process; some of these events may or may not be mediated by PGs.

Clinically, indomethacin produces antipyretic and analgesic effects, the latter being most notable when the pain is associated with an inflammatory condition. Because of its toxic potential, however, indomethacin should not be used as an antipyretic or simple analgesic. An exception is its use as an antipyretic in Hodgkin's disease. Indomethacin is reserved for cases of rheumatoid arthritis, ankylosing spondylitis, and osteoarthritis in which less dangerous drugs are ineffective or

are not tolerated. Indomethacin has also been used as a short-term anti-inflammatory agent in the treatment of bursitis, tendinitis, and acute attacks of gouty arthritis. The drug is occasionally administered as a tocolytic (to halt premature labor) and to promote the closure of a patent ductus arteriosus. The mechanism in both cases is inhibition of PG production. There are no indications for indomethacin in dentistry.

Indomethacin is well absorbed from the GI tract, and peak plasma concentrations are reached in 1 to 2 hours. The drug is largely bound to plasma proteins. After a single dose, most of the drug is eliminated in the urine as various metabolites during the next 24 hours. Its plasma half-life is approximately 2.5 hours.

Adverse effects are common with indomethacin therapy. GI disturbances such as epigastric pain, nausea, and diarrhea, occur frequently. The drug may also cause perforation of the esophagus, stomach, and duodenum, and the resultant hemorrhage can be fatal. The drug is contraindicated in patients with active GI lesions or a history of such lesions. CNS effects, including severe headache and confusion, also occur. Psychosis is possible. In addition to dermatologic and allergic reactions, leukopenia, aplastic anemia, thrombocytopenia, and hepatitis have been reported; some of these reactions have also proved fatal. Indomethacin has the potential to interact with many drugs. Simultaneous administration of indomethacin and oral anticoagulants may be hazardous.

Etodolac. The NSAID etodolac (see Figure 21-12) is approved in the United States for the treatment of acute pain and for managing the signs and symptoms of rheumatoid arthritis and osteoarthritis. Although it is classified as a nonselective NSAID, etodolac apparently is approximately threefold more selective for the inducible COX-2 isoenzyme than for the constitutive COX-1 isoenzyme (see Figure 21-6).[67,128,172] This relative activity is thought to explain the lower incidence of GI side effects and ulceration seen with long-term dosing compared with other nonselective NSAIDs.[118]

Peak plasma concentrations are reached in 1 to 2 hours after oral administration. Etodolac has a plasma half-life of approximately 7 hours, and 200 to 400 mg is taken every 6 to 8 hours for the relief of pain. The daily dose should not exceed 1200 mg. Etodolac has been studied in postsurgical dental pain. Onset of analgesia occurs approximately 30 minutes after oral administration, and its duration is 4 to 6 hours.[64,79] In patients with postimpaction dental pain, 200 mg of etodolac provides peak analgesia comparable to 650 mg of aspirin but longer in duration. In half of patients, doses of 400 mg generally provide relief for 5 to 6 hours before remedication is required. An extended-release formulation of etodolac, which can be administered once a day, is available for the treatment of arthritic conditions. Its onset of action is too slow, however, to be used in the treatment of acute postsurgical pain.[79]

Sulindac. Sulindac, an indene derivative, is also a sulfoxide (see Figure 21-12). Sulindac is a prodrug that must be reduced to the sulfide before it becomes active as an NSAID. Peak plasma concentrations are reached in approximately 2 hours. Sulindac sulfide has a half-life of approximately 15 hours. Its long half-life probably results from the fact that the drug undergoes enterohepatic circulation. Extensive metabolism yields a sulfone and several conjugates. Sulindac is used to treat rheumatoid arthritis and other inflammatory diseases and is occasionally prescribed as a tocolytic and for treatment of acute gout.

Pyrrole derivatives

The pyrrole acetic acids include tolmetin and ketorolac. Although tolmetin is not used in clinical dentistry, ketorolac is used because of its parenteral dosage form.

Tolmetin. Tolmetin, whose structure is shown in Figure 21-12, has anti-inflammatory, antipyretic, and analgesic properties. It is used to treat various inflammatory diseases. Tolmetin has pharmacokinetic properties similar to those of other NSAIDs (well absorbed from the GI tract, highly bound to plasma proteins, and highly metabolized). Peak plasma concentrations are reached approximately 20 minutes to 1 hour after oral dosing. It has a half-life of about 5 hours.

Ketorolac. Ketorolac (see Figure 21-12) was the first injectable NSAID approved in the United States. It is also available in tablet form for oral use, but only after initial intramuscular or intravenous injection. It is recommended that the total course of therapy with ketorolac not exceed 5 days. These limitations follow the drug's high incidence of GI ulceration and bleeding complications compared with other NSAIDs. The more than 400-fold selectivity for inhibiting COX-1 over COX-2 (see Figure 21-6) probably accounts for ketorolac's enhanced toxicity. Although ketorolac is marketed as a racemic mixture, only the S-enantiomer is an active analgesic.

Injectable ketorolac has an important application in postoperative pain management in patients who are unable to consume oral analgesics or when the pain is severe and injectable opioids are contraindicated. Clinical trials have shown that, in some circumstances, parenteral ketorolac is as effective as standard doses of intramuscular morphine or meperidine, is longer lasting, and has fewer adverse effects.[178] In patients with moderate-severe postoperative pain, 30 mg of intramuscular ketorolac is comparable to 12 mg of morphine and equal or superior to 100 mg of meperidine.[63,122,179]

The oral and the intramuscular forms are well absorbed. Similar to other NSAIDs, ketorolac is highly bound (approximately 99%) to plasma proteins. Plasma concentrations of 0.3 μg/mL are estimated to be required for effective analgesia; when plasma concentrations exceed 5 μg/mL, side effects are frequent. Onset of analgesia after parenteral ketorolac is similar to that after injectable opioids. The S- and R-isomers have half-lives of about 2.5 and 5 hours and are metabolized largely to oxidized and conjugated products.

Initial intramuscular doses of 30 to 60 mg of ketorolac are recommended, followed by 15 to 30 mg every 6 hours with a maximum daily dose not to exceed 120 mg. The initial intravenous dose is 15 to 30 mg. Oral doses are recommended at 4- to 6-hour intervals. Oral ketorolac (10 mg) has also been evaluated in postoperative dental pain and found to be superior to 650 mg of aspirin, 600 mg of acetaminophen, and combinations of 600 mg acetaminophen/60 mg codeine or 1000 mg acetaminophen/10 mg hydrocodone; it is at least as effective as 400 mg of ibuprofen.[58,61]

Clinical studies have shown that ketorolac does not produce several of the common adverse effects associated with opioid analgesics. It does not depress respiration or cardiovascular function and causes less constipation and drowsiness than equivalent doses of opioids. As with other NSAIDs, physical dependence and tolerance do not develop. The most common adverse effects after ketorolac are drowsiness, dyspepsia, GI pain, and nausea. Peptic ulcers and GI bleeding have occurred after ingestion of oral ketorolac. Renal toxicity has also been associated with ketorolac. The drug is contraindicated before surgery because its intense antiplatelet effect is likely to result in increased intraoperative bleeding, which reflects its potent COX-1–blocking activity. In ophthalmologic conditions, ketorolac is instilled as a topical preparation to treat ocular itching associated with seasonal allergic conjunctivitis.

Diclofenac. Diclofenac is a phenylacetic acid derivative (see Figure 21-12). It has pharmacokinetic properties and a mech-

anism of action similar to other NSAIDs. Although similar to etodolac, it is approximately twofold to threefold more selective for COX-2 than COX-1, probably explaining its relative inability to inhibit platelet aggregation. It undergoes significant first-pass metabolism in the liver and, in addition to inhibiting COX, may reduce the concentration of arachidonic acid in some inflammatory cells.[21] Diclofenac reaches peak plasma concentrations in 2 to 3 hours after oral administration and has a half-life of 1 to 2 hours. The drug is used to treat inflammatory conditions, pain, and dysmenorrhea. At 50 to 100 mg, it has proved effective in the relief of pain after third molar extraction.[20,74] A solubilized potassium formulation of the drug is also under investigation for treating various painful conditions.[78] Diclofenac is also available in topical gel and patch formulations to treat localized joint and muscle pain and as eye drops to treat ocular inflammation.

The adverse effects are similar to other NSAIDs; however, elevation of hepatic enzymes in the plasma is more common and indicates a higher likelihood of producing hepatotoxic effects. In an effort to reduce the ulcerogenic potential of long-term diclofenac therapy, a formulation combining diclofenac with the PG analogue misoprostol has been developed. A 6-month study of long-term NSAID use indicated that misoprostol reduced the incidence of serious drug-induced GI complications by 40%.[144] Misoprostol is an abortifacient and must be used with extreme care in women of childbearing potential. The reader is referred to Chapter 33 for a more complete discussion of misoprostol and other GI drugs.

Fenamates

The fenamates are a group of aspirin-like drugs derived from N-phenylanthranilic acid. The structure of meclofenamate sodium is shown in Figure 21-12. Mefenamic acid is another member of this group approved in the United States. Mefenamic acid is indicated for the relief of moderate pain (therapy not to exceed 1 week) and for relief of primary dysmenorrhea, and meclofenamate is indicated for mild-moderate pain, dysmenorrhea, and arthritis. The plasma half-lives range from 2 to 4 hours. Meclofenamate has one active metabolite whose elimination half-life is 15 hours.

Mefenamic acid inhibits the synthesis and activity of PGs. In doses of 250 to 500 mg, its analgesic properties are comparable to those of aspirin. It is superior to aspirin, however, for the treatment of severe dysmenorrhea. The potential for serious blood dyscrasias and GI side effects (dyspepsia, diarrhea) limits the use of mefenamic acid to short-term, intermittent administration.

Meclofenamate has been extensively studied as an oral analgesic in the short-term management of acute postsurgical dental pain. In three independent dental studies, 100 mg of meclofenamate seemed to be more effective than 650 mg of aspirin and 600 mg of acetaminophen combined with 60 mg of codeine and as effective as 400 mg of ibuprofen.[32,45,76] Even the short-term clinical use of meclofenamate and mefenamic acid may be limited, however, by a high (25%) incidence of GI disturbances ranging from gastric pain to diarrhea. The ability of these drugs to produce stomach cramping and diarrhea after 1 week or less of dosing has been shown in two dental pain studies.[33,76] In addition, fenamates have adverse effects typical of other NSAIDs (tinnitus, gastric bleeding, and impairment of platelet function). More serious toxicities in the form of abnormal renal and hepatic function, hemolytic anemia, and bowel inflammation have been documented.

Oxicams

Piroxicam (see Figure 21-12), the first member of the relatively new class of NSAIDs known as oxicams to be marketed in the United States, is approved for the treatment of rheumatoid arthritis and osteoarthritis. Although it has also been used to treat pain and dysmenorrhea, its onset of analgesic action is too slow for piroxicam to be routinely used for the treatment of dental postoperative pain. Similar to other NSAIDs, piroxicam inhibits platelet aggregation and promotes GI bleeding. All these effects are attributed to the inhibition of COX-1.

Piroxicam is at least as effective as aspirin for the treatment of rheumatoid arthritis and seems to be better tolerated. Its major advantage is pharmacokinetic in nature. Piroxicam is well absorbed, with peak plasma concentrations occurring 3 to 5 hours after administration. The drug is highly bound to plasma protein, undergoes considerable enterohepatic recycling, and is eventually eliminated in the urine after being extensively metabolized. The average plasma half-life for piroxicam is 50 hours. This slow elimination rate permits administration of a single daily dose, an advantage for any drug that must be taken on a long-term basis. It also requires 2 weeks for full therapeutic concentrations to be achieved after the initiation of therapy.

The side effects of piroxicam are similar to those of other NSAIDs. In addition to GI upset and the possibility of ulceration and hemorrhage, peripheral edema and renal damage may occur. Similar to other NSAIDs, this drug should not be administered to a patient susceptible to aspirin-induced bronchospasm.

Meloxicam, a congener of piroxicam, is the newest oxicam derivative to be approved in the United States. Similar to etodolac, meloxicam is a weakly preferential blocker of COX-2,[52] displaying approximately twofold selectivity over COX-1 in whole blood assay systems (see Figure 21-6).[128] It is currently approved by the FDA for the treatment of osteoarthritis but has too slow an onset to be used for acute postsurgical dental pain. In clinical studies of osteoarthritis and rheumatoid arthritis, 7.5 to 15 mg/day of meloxicam has displayed equivalent anti-inflammatory efficacy to 100 mg/day of diclofenac, 750 mg/day of naproxen, or 20 mg/day of piroxicam. In addition, meloxicam seems to produce a lower incidence of serious GI toxicity than most other NSAIDs, probably as a result of its relative sparing of COX-1 activity.[72] GI ulceration and bleeding can still occur, however.

Meloxicam has an elimination half-life of 15 to 20 hours, which enables once-a-day dosing. The major path of metabolism is through hepatic CYP2C9 enzymes; there is a theoretic possibility that inhibitors of this enzyme system, such as metronidazole or fluconazole, could cause meloxicam to accumulate in the blood.

Nabumetone

Nabumetone (see Figure 21-12) is a prodrug that is converted to the active naphthylalkanone metabolite 6-methoxy-2-naphthylacetic acid (6MNA) in vivo. The half-life of the active metabolite is approximately 24 hours. Because clinical reports originally suggested that nabumetone produced less GI toxicity than anti-inflammatory doses of aspirin, naproxen, or indomethacin, it was thought to be a selective COX-2 inhibitor. More recent research has revealed, however, that 6MNA is actually a threefold to fivefold more potent blocker of COX-1 than COX-2.[128,172] At therapeutic doses of nabumetone, COX-1–blocking effects, including GI ulceration and platelet inhibition, can occur. The drug is indicated to treat the signs and symptoms of osteoarthritis and rheumatoid arthritis.

Pyrazolones

Phenylbutazone is a congener of the pyrazolones antipyrine, aminopyrine, and dipyrone. The latter agents were used historically as analgesics, antipyretics, and anti-inflammatory

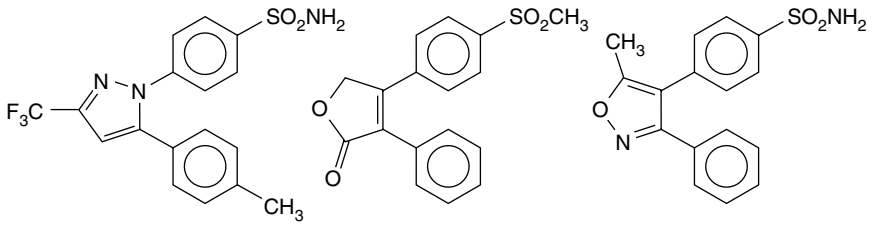

FIGURE **21-13** Structural formulas of cyclooxygenase-2-selective inhibitors.

drugs, but their toxicity and the introduction of phenylbutazone in 1948 led to their abandonment (except for the use of antipyrine as a topical analgesic for earache). More recently, phenylbutazone has also been withdrawn voluntarily by its manufacturer because of its well-documented, serious, and sometimes fatal adverse reactions and the availability of alternative NSAIDs. The most serious of these side effects is bone marrow depression, leading to agranulocytosis, thrombocytopenia, leukopenia, or aplastic anemia. Blood dyscrasias occur most frequently during high-dose therapy and may be manifested initially by fever, stomatitis, and sore throat. GI disturbances associated with COX-1 inhibition are common and range from mucosal irritation to frank ulceration and hemorrhage.

Other adverse reactions include skin rashes, hepatitis, jaundice, purpura, and hematuria. Phenylbutazone causes Na^+ retention by the kidney; the resultant edema may be significant in patients with congestive heart failure or hypertension. Phenylbutazone is a good candidate for drug interactions because of its tendency to promote bleeding and GI disturbances. Phenylbutazone is also known to inhibit hepatic microsomal enzymes. It is still widely used as an anti-inflammatory agent in veterinary medicine.

Selective Cyclooxygenase-2 Inhibitors

The introduction into the U.S. marketplace of the drugs celecoxib, rofecoxib, and valdecoxib was initially thought to be a major advance in NSAID therapy because these drugs are highly selective for inhibiting the inducible COX-2 isoform while sparing the constitutive COX-1 isoform. In contrast to preferential or semiselective COX-2 inhibitors, such as etodolac, diclofenac, and meloxicam, whose COX-2 selectivity does not exceed twofold to threefold, celecoxib, valdecoxib, and rofecoxib display COX-2 selectivity in the range of 8-fold to 35-fold in whole blood assay systems (see Figure 21-6).[77,128] Two other members of this drug class, which were never approved in the United States, etoricoxib and lumiracoxib, have reported COX-2 selectivity in the 100-fold to 200-fold range.[77]

The selectivity of these so-called coxibs led to roughly a 50% to 60% reduction in serious GI complications—including symptomatic ulcers and GI bleeds, perforations, and obstructions—compared with standard NSAIDs (e.g., ibuprofen, naproxen, diclofenac) in long-term safety studies in arthritic patients.[16,137,143] This reduction represented a major potential health cost savings because clinically important gastroduodenal ulceration has been reported to occur in 6% of patients on long-term NSAID therapy and result in more than 100,000 hospitalizations and 16,000 deaths annually.[146] Short-term NSAID use for treating acute postsurgical dental pain is typically measured in a few days,[33,76,81] however, and is rarely associated with serious GI side effects, and the safety advantage of highly selective COX-2 inhibitors in this patient population would be dubious at best. The widely publicized increase in cardiovascular risk (MI and stroke) in patients with long-term use (18 months) of rofecoxib and in the most "fragile" patients who underwent CABG surgery with only 10 days use of valdecoxib led to the removal of both these drugs from the worldwide marketplace.[19,119]

Celecoxib

With the removal of rofecoxib and valdecoxib from the market, celecoxib currently is the only FDA-approved highly selective COX-2 inhibitor available for use in the United States. Celecoxib (Figure 21-13) is a novel diaryl substituted pyrazole that possesses a sulfonamide group. Its COX-2 selectivity in whole-blood assays is almost eightfold. It is highly protein bound (approximately 97%) and has a plasma elimination half-life of 10 to 12 hours. Its metabolism is mediated primarily by CYP2C9, yielding three inactive metabolites: a primary alcohol, the corresponding carboxylic acid, and its glucuronide metabolite. In randomized trials in patients with rheumatoid arthritis and osteoarthritis, the therapeutic responses seen with celecoxib are equal to the responses seen with nonselective and COX-2 preferential NSAIDs, including naproxen, ibuprofen, and diclofenac.[50,136,145]

The recommended dose of celecoxib for arthritic conditions is 100 to 200 mg/day. In contrast to the results of arthritis studies, 200 mg of celecoxib was inferior to 400 mg of ibuprofen in terms of analgesic onset and peak effects in patients with acute postsurgical dental pain.[108] An initial loading dose of 400 mg (followed by 200 mg every 12 hours) provides a quicker onset and greater peak effects and is considered the recommended dosing regimen for acute postsurgical pain.[24] At 400 mg, celecoxib's duration of action is longer than that of an equal dose of ibuprofen, but its analgesic onset is still slower.

An additional FDA indication for celecoxib is to reduce the number of adenomatous colorectal polyps in patients with familial adenomatous polyposis. This is a genetic condition in which more than 90% of affected individuals develop colorectal cancer. Celecoxib at 400 mg twice per day, which is the recommended dose for this indication, reduced the number of polyps by roughly 25% after 6 months of therapy.[154] COX-2 is known to be overexpressed in human colorectal adenomas and adenocarcinomas,[48] and the ability of celecoxib to inhibit COX-2 probably explains its usefulness in this condition. In a large trial of subjects who were high polyp formers, with an average age of 60 years and almost half with cardiovascular disease or related risk factors (angina, previous MI, hypertension, or poor lipid profile), celecoxib at 200 mg and 400 mg taken twice per day increased the risk of a serious cardiovascular event (MI, stroke, or heart failure) by 2.5-fold and 3.4-fold compared with placebo after 36 months of treatment.[151]

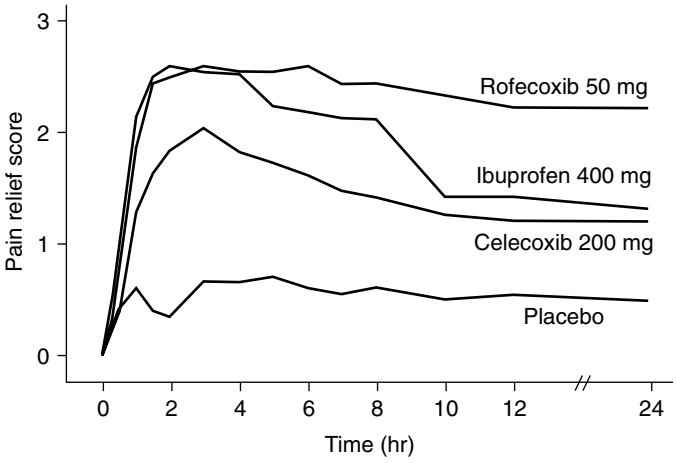

FIGURE **21-14** Time-effect curves for placebo, celecoxib, ibuprofen, and rofecoxib. The mean pain relief scores are plotted against time in hours. (Adapted from Malmstrom K, Daniels S, Kotey P, et al: Comparison of rofecoxib and celecoxib, two cyclooxygenase-2 inhibitors, in postoperative dental pain: a randomized, placebo- and active-comparator-controlled clinical trial, *Clin Ther* 21:1653-1663, 1999.)

The enhanced GI safety of celecoxib with long-term administration must be balanced with the increased cardiovascular risk that has also been shown with long-term, high-dose use. In a major celecoxib study, 400 mg of celecoxib twice a day, which is two times the maximum approved antiarthritic dose, resulted in a reduction of GI ulceration, perforations, and bleeds after 6 months by half compared with large therapeutic doses of ibuprofen or diclofenac.[143] Because celecoxib is a selective COX-2 inhibitor, it has less effect on COX-1 and does not inhibit platelet aggregation or increase bleeding time, which may enhance its GI safety further with long-term dosing.[99] Many patients with arthritis also require cardioprotective dosages of aspirin, however. These patients must be reminded that they must take their low-dose aspirin therapy in addition to their antiarthritic dosages of the COX-2 inhibitor. Concomitant low-dose aspirin seems to diminish greatly, if not abolish, the GI-sparing effect of celecoxib and other highly selective COX-2 inhibitors.[137,143]

Despite celecoxib's COX-2 selectivity, patients still must be warned of the potential for the drug to cause serious GI toxicity. Because COX-2 plays a normal constitutive role in the kidney (see Figure 21-3), celecoxib and other COX-2 inhibitors can cause renal toxicity, including Na^+ and water retention, hypertension, and acute renal failure. Similar to other NSAIDs, celecoxib may interfere with the antihypertensive effects of ACE inhibitors, diuretics, and β-adrenergic blockers. In patients with aspirin intolerance, the use of COX-2 inhibitors may precipitate potentially life-threatening asthmatic or allergic-type reactions. Because celecoxib is a sulfonamide, patients with documented allergies to other sulfonamides (including the thiazide diuretics) should avoid celecoxib. Drug interactions involving celecoxib resemble interactions of aspirin and other NSAIDs. As with other NSAIDs, reports of significant bleeding episodes have occurred in patients taking warfarin who subsequently received celecoxib.[11] Drugs that are inhibitors of CYP2C9, such as fluconazole and metronidazole, may significantly increase celecoxib blood concentrations.

Rofecoxib

Rofecoxib is a diaryl substituted furanone (see Figure 21-13) with COX-2 selectivity of approximately 35-fold in whole blood assays and was the first highly selective COX-2 inhibitor FDA-approved for the treatment of acute pain in addition to more long-term use for treatment of arthritis.[128,172] Its pharmacokinetic properties, including an elimination half-life of 17 hours, made it suitable for once-daily oral administration. Although rofecoxib contained a sulfur atom in its structure, it was not a sulfonamide and could be given safely to patients with documented sulfonamide allergies. Similar to celecoxib, it did not inhibit platelet aggregation or interfere with the antiplatelet effect of aspirin.[68]

Rofecoxib was indicated for the treatment of osteoarthritis and for the management of acute pain, including primary dysmenorrhea. The recommended anti-inflammatory dose of rofecoxib was 12.5 to 25 mg once a day, whereas the analgesic dose was 50 mg once per day. In large-scale studies of osteoarthritis of the hip or knee, rofecoxib displayed therapeutic equivalency to diclofenac and to ibuprofen.[43,136]

In acute postsurgical dental pain, 50 mg of rofecoxib was equivalent to 400 mg of ibuprofen in analgesic onset and peak analgesic effect but had a much longer duration of action (24 hours for rofecoxib versus 8 hours for ibuprofen).[49,108,116] Rofecoxib was also more efficacious than 200 mg of celecoxib in analgesic onset, duration, and peak effects (Figure 21-14).[108]

The major GI safety advantages of rofecoxib were related to its ability to block COX-2 selectively. In a major study involving more than 8000 patients with rheumatoid arthritis, the administration of rofecoxib at twice the maximum antiarthritic dose for up to 1 year resulted in an approximate 60% reduction in GI ulcerations, perforations, obstructions, and bleeds compared with a standard dose of naproxen of 500 mg twice a day.[16] The possibility of increased cardiovascular risk of long-term rofecoxib, 50 mg, compared with naproxen arose in this study. Considering that rheumatoid arthritis patients are at higher risk of MI than the general public, that the mean age of patients in this study was almost 60 years, and that patients on cardioprotective doses of aspirin were not allowed to enter the study, the overall incidence of this event was considered low. Although it occurred in 0.1% of subjects taking naproxen and 0.4% of subjects taking rofecoxib, it was thought that the increased incidence of this event in the rofecoxib group really reflected a cardioprotective effect of naproxen and not a cardiotoxic effect of rofecoxib.

Naproxen, being at least 10-fold selective in blocking COX-1 and having a relatively long half-life, has been shown to possess profound but reversible antiplatelet activity.[93] The cardiovascular risk of rofecoxib was clearly identified when a placebo-controlled polyp reduction trial of rofecoxib, 25 mg, was performed in patients with a mean age of 59 years, 28% of them judged to be at high cardiovascular risk.[19] For the first 18 months of use, the incidence of MI and other ischemic events was similar between groups. After 18 months, more events occurred in the rofecoxib group with a cumulative incidence at

36 months of approximately 4.5% in the rofecoxib group and only 2% in the placebo group. When these results became known, the manufacturer of rofecoxib voluntarily withdrew the drug from the worldwide marketplace in September 2004.

Valdecoxib and parecoxib

Valdecoxib (see Figure 21-13) was approved by the FDA in 2002 as an oral anti-inflammatory agent and had shown promise as an analgesic agent, including the treatment of postsurgical dental pain.[41] It possessed approximately 30-fold selectivity for the COX-2 isoform.[128] The results of a short-term postsurgical pain study involving valdecoxib and its intravenous prodrug parecoxib in patients who had undergone CABG procedures revealed that only 10 days of therapy with valdecoxib or a combination of 3 days of therapy with parecoxib followed by 7 days of therapy with valdecoxib significantly increased the incidence of serious postsurgical cardiovascular events compared with a third group of CABG surgery patients not taking either drug for postsurgical pain control.[119] These results, plus an unusually high incidence of serious skin reactions including Stevens-Johnson syndrome reported in patients on valdecoxib therapy, led to the removal of valdecoxib from the marketplace in April 2005. Parecoxib was never approved by the FDA.

Other COX-2 inhibitors

Two other COX-2 inhibitors have been developed more recently. The first member of this group, etoricoxib, possesses 106-fold COX-2 selectivity.[128] It is available in Europe but was denied approval by the FDA in the United States on April 12, 2007, because it seemed to offer no significant benefit with regards to cardiovascular risk compared with other highly selective COX-2 inhibitors that had been removed from the market.

Lumiracoxib with more than 200-fold COX-2 selectivity,[77] although approved in Europe, was denied FDA approval because of concerns regarding cardiovascular risk. In addition, Canada and Australia removed the drug from their marketplace because of many reports of serious liver toxicity, including a few reports of liver failure requiring transplants.

Implications for Dentistry

The major use of aspirin and other NSAIDs in dentistry is to relieve pain associated with pathologic processes (e.g., pulpitis, dentoalveolar abscesses) or after surgical procedures. In both situations, the anti-inflammatory actions of the NSAID may contribute significantly to the therapeutic effect sought. Aspirin at doses of 650 to 1000 mg is an acceptable drug for mild-moderate dental pain. For more traumatic surgical procedures, such as the removal of impacted third molars, the newer NSAIDs at dosages that approach their analgesic ceiling are more efficacious and sometimes better tolerated than aspirin. Postsurgical dental pain studies that have used ceiling analgesic doses of NSAIDs, such as ibuprofen at 400 mg and naproxen sodium at 550 mg, have displayed efficacy at least equal to that obtained with opioid combination drugs. In addition, NSAIDs produce far fewer side effects of drowsiness, dizziness, nausea, and vomiting than opioid-containing analgesics. The recommended dosing schedules of NSAIDs for acute pain of dental origin are shown in Table 21-6.

There are few instances in which the use of the highly selective COX-2 inhibitor celecoxib can be recommended. In most instances, traditional NSAIDs such as ibuprofen or naproxen are used only for a few days in the dental setting, which mitigates any GI benefit associated with the long-term use of celecoxib. In addition, these traditional NSAIDs are probably more efficacious and cost-effective. One possible exception would be in the treatment of temporomandibular joint (TMJ) pain, in which the duration of NSAID therapy is measured in weeks and significant GI toxicity of NSAIDs becomes a greater concern.[114] Still, it would behoove the clinician not to prescribe celecoxib to patients with cardiovascular risk factors, including previous MI or stroke, unstable angina, or poorly controlled hypertension on the basis of concern about increased cardiovascular risk of highly selective COX-2 inhibitors as a whole. In addition, although naproxen has shown efficacy in TMJ pain, celecoxib has not.[161] The TMJ may be involved in systemic inflammatory diseases that would be treated with NSAIDs. The TMJ can also be singly affected by an acute or chronic inflammatory process, the cause of which may be known (e.g., trauma, immobilization, malocclusion) or unknown (e.g., nonspecific osteoarthritis). In these cases, an NSAID may be used in conjunction with other therapies such as heat, exercise, bite splints, and joint surgery.

Contraindications to NSAIDs must be heeded. Salicylates must be avoided in children or teenagers with viral infections or suspected viral infections. The antiplatelet effect of NSAIDs, especially aspirin and ketorolac, must be considered if the patient is at risk from a bleeding abnormality or anticoagulant therapy. Many NSAIDs antagonize the effect of probenecid and sulfinpyrazone. Hypersensitivity to aspirin may indicate a risk of NSAIDs in general, including COX-2 inhibitors. The elimination of methotrexate and lithium is reduced with NSAIDs[82]; other drug interactions may occur because of the ability of NSAIDs to displace drugs from plasma albumin and otherwise alter their pharmacokinetic properties. The common adverse effects for NSAIDs on the GI tract and CNS should be considered, especially when the patient is taking drugs with overlapping toxicity. NSAIDs can block the therapeutic effects of several antihypertensive drugs. Drugs potentially antagonized by NSAIDs include β-adrenoreceptor blockers, ACE inhibitors, and diuretics.

ACETAMINOPHEN

Acetaminophen (N-acetyl-*p*-aminophenol) is the only aniline derivative currently in clinical use. It is widely promoted as the antipyretic analgesic of choice when aspirin cannot be used because of gastric problems or other contraindications. For many years, phenacetin (an acetaminophen analogue) was a common constituent of analgesic preparations, including numerous aspirin-phenacetin-caffeine combinations. Phenacetin has disappeared from use in the United States because of several studies linking long-term administration of such combinations with renal damage. Phenacetin is also capable of producing CNS disturbances (e.g., sedation), hemolytic anemia, and methemoglobinemia.

Chemistry and Classification

The history of acetaminophen dates back to the late 1800s, when the antipyretic activity of aniline derivatives was discovered and several congeners, including acetaminophen, were synthesized. Two other aniline derivatives, acetanilid and phenacetin, became popular, and acetaminophen was put aside. Chemists eventually realized that acetaminophen was an active metabolite of both of these drugs (Figure 21-15), but it was not until the mid-1900s that acetaminophen became commercially successful.

Mechanism of Action

Acetaminophen has analgesic and antipyretic activity that is essentially equivalent to that of aspirin. The drug's mechanism of action also seems to stem from an inhibition of PG synthesis, although there may be some differences in the spectrum of COX enzymes that are inhibited.[157] It has been suggested

TABLE **21-6**

Nonopioid Analgesics Approved for Acute Pain

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	ANALGESIC DOSAGE*	MAXIMUM DAILY DOSE*
Aspirin	ASA, others	650-1000 mg q4-6h	4000 mg
Diflunisal	Dolobid	1000 mg to start, then 500 mg q8-12h	1500 mg
Acetaminophen	Tylenol, others	650-1000 mg q4-6h	4000 mg
Ibuprofen	Motrin, Rufen, others	400 mg q4-6h	2400 mg
Ibuprofen (OTC)	Advil, Nuprin, others	200-400 mg q4-6h	1200 mg
Naproxen	Naprosyn	500 mg to start, then 250 mg q6-8h	1250 mg
Naproxen sodium	Anaprox	550 mg to start, then 275 mg q6-8h	1375 mg
Naproxen sodium (OTC)	Aleve	220-440 mg q8h	660 mg
Fenoprofen	Nalfon	200 mg q4-6h	1200 mg
Ketoprofen	Orudis	25-75 mg q6h	300 mg
Ketoprofen (OTC)	Orudis KT, Actron	12.5-25 mg q4-6h	75 mg
Diclofenac	Cataflam	50 mg q8h	150 mg
Meclofenamate	Meclomen	50-100 mg q6h	400 mg
Mefenamic acid	Ponstel	500 mg to start, then 250 mg q6h	1250 mg
Etodolac	Lodine	200-400 mg q6-8h	1200 mg
Ketorolac	Toradol	15-30 mg IV or 30-60 mg IM to start, then 15-30 mg IV or IM q6h; 20 mg orally 6 hr after last parenteral dose, then 10 mg q4-6h†	60-120 mg IM or IV; 40 mg orally
Celecoxib	Celebrex	400 mg to start, then 200 q12h	600 mg

*Doses are for acute pain only. Higher doses are sometimes used for control of inflammatory disorders.
†Therapy limited to 5 days.
IM, Intramuscularly; *IV,* intravenously; *OTC,* over-the-counter.

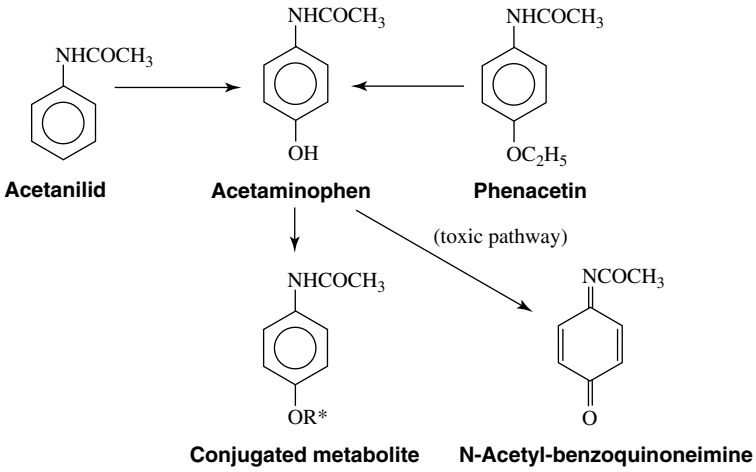

FIGURE **21-15** Structures and major metabolic pathways of acetaminophen, phenacetin, and acetanilid. *R**, Glucuronide (major) and sulfate (minor) conjugates. N-acetyl-benzoquinoneimine, produced in high amounts in acetaminophen overdose, forms a conjugate with glutathione that results in depletion of glutathione.

that acetaminophen may be more active than aspirin as an inhibitor of CNS COX and less active in the periphery, although more recent reports of a newly characterized CNS isoform in humans termed COX-3[173] have not been supported by additional research.[77] This CNS selectivity of acetaminophen is based largely on the differences in the therapeutic and toxic effects of aspirin and acetaminophen, rather than on direct experimental evidence.

Acetaminophen has very weak anti-inflammatory effects compared with aspirin. Acetaminophen may be a more selective inhibitor of neuronal PG synthesis than aspirin. More recent evidence suggests that a peripheral mechanism of acetaminophen may be partially responsible for its analgesic effects.[115] The presence of peroxides from leukocytes in inflamed tissues leads to inhibition of acetaminophen, however, caused by the peroxides combining with acetaminophen. This inhibition may severely limit any effect of acetaminophen on inflammation. Other proposed mechanisms of action for acetaminophen do not involve PGs and include the activation of spinal serotonergic pathways and the inhibition of nitric oxide synthase.[15,164]

Pharmacologic Effects

Compared with aspirin, acetaminophen exerts few important effects on specific organs or systems. The potency and efficacy of acetaminophen as an antipyretic are similar to those of aspirin. At therapeutic doses, acetaminophen has little if any effect on the cardiovascular or respiratory systems. Acetaminophen does not inhibit platelet aggregation, cause occult bleeding or gastric irritation, affect uric acid excretion, or have

as many drug interactions as aspirin. In overdose, the organ most affected is the liver. Acute renal toxicity may also occur. With long-term use, analgesic nephropathy is possible, but the risk is low.

Absorption, Fate, and Excretion

Acetaminophen is well absorbed in the small intestine after oral administration. The drug is evenly distributed throughout the body fluids and tissues, and it freely crosses the placenta. The half-life is approximately 2 to 4 hours, and the primary site of biotransformation (by glucuronide conjugation) is the liver (see Figure 21-15). Other minor metabolites include a conjugate with sulfate and various hydroxylated metabolites. A highly reactive and hepatotoxic metabolite, N-acetyl-*p*-benzoquinoneimine (NAPQI), is usually of little significance. In the case of acetaminophen overdose, the accumulation of this metabolite can be disastrous, however. The binding of acetaminophen to plasma proteins is variable but rarely exceeds 40% of the total drug. Elimination is through the kidneys by glomerular filtration and active proximal tubular secretion. There is no competition for secretion with organic acids such as uric acid and aspirin.

General Therapeutic Uses

Although acetaminophen is approximately equipotent to aspirin as an analgesic and an antipyretic, it is not a true anti-inflammatory drug, and aspirin and other NSAIDs are far superior for conditions such as rheumatoid arthritis. For patients in whom aspirin and other NSAIDs are contraindicated, acetaminophen is usually the drug of choice. Tables 21-4 and 21-5 list some of the disease states and potentials for drug interactions that make acetaminophen a more acceptable antipyretic analgesic than aspirin or related NSAIDs. Although acetaminophen is not used to reduce inflammation, it can be effective in treating pain resulting from inflammation. Because of its low toxicity at therapeutic dosages (≤4 g/day), acetaminophen is still considered first-line therapy for osteoarthritis, despite the fact that NSAIDs are generally more efficacious.[2,136] Acetaminophen remains the antipyretic of choice in children and teenagers because, in contrast to aspirin, it is not associated with the development of Reye's syndrome.

Therapeutic Uses in Dentistry

The wide publicity given to the adverse effects of aspirin has caused increasing numbers of dentists to substitute acetaminophen for aspirin in the treatment of postoperative dental pain, even though the anti-inflammatory effects of acetaminophen are minor. In clinical studies, aspirin and acetaminophen are similar in their effectiveness in relieving pain after the extraction of third molars (Figure 21-16).[29,30]

Acetaminophen has a positive dose-effect curve for analgesia up to 1000 mg. On the basis of this finding, some clinicians are recommending the use of 1000 mg of acetaminophen rather than the customary 650-mg dose. In contrast, concerns about liver toxicity have led others to recommend restrictions against the larger dose. For postsurgical dental pain, acetaminophen is most often used in combination with an opioid analgesic agent (see later). In contrast to NSAIDs, acetaminophen has not proved useful as a preemptive analgesic agent, presumably because it does not block sensitization of pain pathways owing to tissue damage.

Adverse Effects

The potential for adverse effects from acetaminophen seems to be confined to situations in which there is an acute or chronic overdose with the drug. At therapeutic doses, acetaminophen does not cause nausea, inhibit platelet aggregation, prolong prothrombin time, or produce the other side affects associated with the use of aspirin or NSAIDs. Allergy to acetaminophen is rare and is generally manifested as skin eruptions. Acetaminophen rarely has been associated with neutropenia, thrombocytopenia, and pancytopenia. In contrast to phenacetin, acetaminophen rarely produces methemoglobinemia.

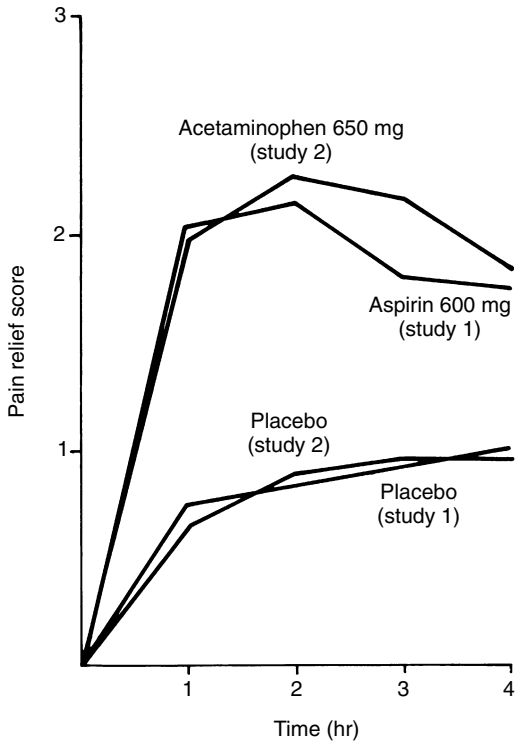

FIGURE **21-16** Time-effect curves for placebo, aspirin, and acetaminophen. The mean pain relief scores are plotted against time in hours. (Adapted from Cooper SA, Breen JF, Giuliani RL: Replicate studies comparing the relative efficacies of aspirin and indoprofen in oral surgery outpatients, *J Clin Pharmacol* 19:151-159, 1979; Cooper SA, Breen JF, Giuliani RL: The relative efficacy of indoprofen compared with opioid-analgesic combinations, *J Oral Surg* 39:21-25, 1981.)

Acute overdose from acetaminophen has become a problem because of the extent of its use.[158] In 1992, acetaminophen-containing products accounted for more than 40% of all OTC analgesic drugs sold in the United States, and they remain popular today.[82] Acetaminophen is frequently used in suicide attempts because of its availability in sizable quantities. The therapeutic index for acetaminophen is high; it is estimated that 6 g or more must be ingested within a relatively short time for hepatotoxicity to occur. In children younger than 10 years, a therapeutic overdose, which typically involves multiple dose miscalculations on the part of the parent administering the drug, has also led to severe hepatotoxicity. The degree of liver damage is directly related to the amount of drug ingested, and individuals with preexisting liver disease are most susceptible.

Hepatotoxicity seems to result from the formation of the highly reactive metabolite NAPQI, which normally reacts rapidly with glutathione and, as a result, is largely neutralized (see Figure 21-15). In acetaminophen overdose, this metabolite depletes glutathione and accumulates, resulting in the alkylation of liver proteins and cellular injury. When enough liver cells are damaged, clinical signs of toxicity, such as nausea and jaundice, appear.[158] Clinicians should also be aware that in patients who have consumed supratherapeutic doses of acetaminophen alone or combined with an opioid for

many days, as sometimes happens with untreated toothache pain, an early sign of liver injury may be intraoral bleeding because the blood coagulation factors are synthesized in the liver. In contrast to the rapid onset of toxic signs seen after an overdose with aspirin or related NSAIDs, clinical manifestations of acetaminophen poisoning may not appear until several days after ingestion of the drug, making diagnosis and treatment much more difficult than with aspirin overdose.

Severe hepatotoxicity after acetaminophen overdose is life-threatening. There is a satisfactory treatment for acetaminophen overdose if initiated in sufficient time. Gastric lavage may be beneficial if started within a few hours of drug ingestion, even before clinical signs of toxicity appear. N-acetyl cysteine is an effective treatment in many cases of toxicity. It enables the formation of new glutathione and dramatically reduces mortality rates. To be effective, N-acetyl cysteine must be administered as soon as possible, but usually not more than 36 hours after ingestion. A better response is obtained if N-acetyl cysteine is given within 10 hours. N-acetyl cysteine is administered orally or intravenously. At present, acetaminophen overdose is a more dangerous and difficult management problem than aspirin overdose. The clinician should not be lured into a false sense of security because of acetaminophen's relative lack of adverse effects at therapeutic doses. To some extent, the dramatic increase in reported cases of acetaminophen toxicity results from a reluctance of the health professions to realize the potential hazards of this drug and to warn their patients of the consequences of misuse.

Warning labels appear on all acetaminophen products concerning the potential adverse drug interaction between it and alcohol.[81] As with acetaminophen overdosage, chronic alcohol use is associated with hepatotoxicity. The theoretic basis of the interaction is that in patients who consume alcohol, CYP2E1 is highly induced. More CYP2E1 would be available to promote the conversion of acetaminophen to NAPQI (see Figure 21-15).[147] In addition, hepatic glutathione, usually available to bind and inactivate NAPQI, tends to be depleted in alcoholics. Counterbalancing this is the fact, however, that when patients are actively consuming alcohol, CYP2E1 is preferentially occupied by alcohol and not acetaminophen, which may limit the production of NAPQI.

This protective effect of alcohol has been shown in suicidal patients showing little hepatotoxicity after ingesting acute overdoses of acetaminophen in combination with large quantities of alcohol.[81] Theoretically, patients may be at greatest risk of hepatotoxicity when, after acute alcohol consumption (which may be as little as a few drinks every day), they stop drinking and begin taking acetaminophen for fever, pain, or a hangover.[58,82] In this scenario, CYP2E1 is induced, alcohol is no longer present, and the enzyme is free to convert a large portion of the acetaminophen to NAPQI. Studies in normal volunteers who received alcohol infusions to increase their blood alcohol levels to 0.1% (greater than legally intoxicated in most states) showed that the administration of 1000 mg of acetaminophen 8 hours after this infusion (when most of the alcohol would be cleared but CYP2E1 would still be upregulated) produced an amount of NAPQI equivalent to ingesting 1200 mg of acetaminophen, far less than the 6 g needed for hepatotoxicity.[163]

Whether more chronic alcohol consumption (≥3 drinks per day for an extended period) followed by a period of abstinence and the ingestion of high therapeutic doses of acetaminophen challenge could produce toxic levels of NAPQI is open to debate. Patients who are alcoholics are likely to exhibit reduced glutathione stores, preexisting liver damage, and malnutrition, which may predispose the alcoholic further to acetaminophen-induced hepatotoxicity, although cases of acetaminophen toxicity in alcoholics invariably involve an overdose of the analgesic.[131]

COMBINATION ANALGESICS

Nonopioids

Aspirin and acetaminophen are sometimes combined in proprietary compounds (Table 21-7). There is little evidence, however, that either analgesia or antipyresis is enhanced by this combination. A ceiling effect still occurs when the total amount of aspirin and acetaminophen approaches 1 g. The rationale for combining an NSAID with acetaminophen, although still debated, seems to have some justification based on the fact that acetaminophen has some actions that are distinct from the actions of NSAIDs. In pain following impacted third molar surgery, the combination of 100 mg of enteric-coated diclofenac with 1000 mg of acetaminophen provides a superior analgesic effect than either drug alone, or a combination of 1000 mg of acetaminophen plus 60 mg of codeine.[20] The formulation of diclofenac used in this study, however, was less effective than typically observed in clinical trials.

Many of these combinations also contain caffeine. Caffeine is considered to be an analgesic adjuvant.[97] Caffeine does not seem to have analgesic effects when used alone. When 65 to 100 mg of caffeine is combined with traditional analgesics (aspirin, acetaminophen, or ibuprofen), however, it improves their analgesic efficacy.[56,97] The mechanism for this adjuvant effect is unknown but may include the ability of caffeine to block adenosine receptors at free nerve endings or in mast cells, to enhance central catecholamine effects, or to increase the absorption of weak acids such as aspirin.[134] The central vasoconstrictive effects of caffeine probably help alleviate certain types of headache.

Opioid and Nonopioid Analgesics

There is a sound scientific basis for combining NSAIDs or acetaminophen with opioids. The former drugs combat pain principally by interfering with production of biochemical mediators that cause sensitization of nerve endings at the site of injury or spinal cord, whereas the opioids alter CNS perception and reaction to pain. These complementary actions support the use of the drugs in combination.[167] In addition to the fact that these combinations seem reasonable, abundant clinical data exist to support the validity of their combined use.[12,112,113] There is a common misconception, however, that such combinations produce a synergistic phenomenon—that is, a total effect greater than the sum of individual effects expected from both drugs. No evidence currently supports this belief, and, at best, there is a purely additive effect when drugs from these two classes of analgesics are combined. If any synergism does exist, it probably involves toxic effects rather than analgesia.

Another misconception is that the opioid component in an oral analgesic combination is the major contributor to the preparation's overall effectiveness. Clinical studies indicate the opposite, showing that the nonopioid component is an equal or, more often, greater contributor to the overall efficacy of the combination for most types of pain. When comparisons are limited to studies evaluating dental pain, there is no question that the aspirin-like drugs provide most of the pain relief.[27,31] The opioids are, however, most often the cause of side effects.[12,35]

The clinical significance of the opioids is that they provide additional analgesia beyond the ceiling effect of the NSAID or acetaminophen alone, and they contribute a centrally mediated sedative effect. The most effective combinations are

TABLE **21-7**

Analgesic Combinations Used in Dentistry

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	CONTAINS (mg)			AVERAGE ADULT DOSE	SCHEDULE
		ASA	APAP	OTHER INGREDIENTS		
ASA, caffeine	Anacin	400	—	Caffeine, 32	2 q4h	OTC
ASA, APAP, caffeine	Excedrin	250	250	Caffeine, 65	1-2 q4h	OTC
ASA, codeine	Empirin with codeine					
	#2	325	—	Codeine, 15	2 q4h	Rx III
	#3	325	—	Codeine, 30	1-2 q4h	Rx III
	#4	325	—	Codeine, 60	1 q4h	Rx III
APAP, codeine	Tylenol with codeine					
	#2	—	300	Codeine, 15	2 q4h	Rx III
	#3	—	300	Codeine, 30	1-2 q4h	Rx III
	#4	—	300	Codeine, 60	1 q4h	Rx III
APAP, hydrocodone	Lortab 5/500, Vicodin	—	500	Hydrocodone, 5	1-2 q4-6h	Rx III
	Lorcet Plus	—	650	Hydrocodone, 7.5	1 q4-6h	Rx III
	Lorcet 10/650	—	650	Hydrocodone, 10	1 q4-6h	Rx III
	Vicodin HS	—	660	Hydrocodone, 10	1 q4-6h	Rx III
	Vicodin ES	—	750	Hydrocodone, 7.5	1 q4-6h	Rx III
	Maxidone	—	750	Hydrocodone, 10	1 q4-6h	Rx III
ASA, oxycodone	Percodan-demi	325	—	Oxycodone, 2.44*	1-2 q6h	Rx II
	Percodan	325	—	Oxycodone, 4.88*	1 q6h	Rx II
APAP, oxycodone	Percocet 5/325	—	325	Oxycodone, 5	1-2 q4-6h	Rx II
	Tylox	—	500	Oxycodone, 5	1-2 q4-6h	Rx II
	Percocet 7.5/500	—	500	Oxycodone, 7.5	1-2 q4-6h	Rx II
	Percocet 10/650	—	650	Oxycodone, 10	1 q4-6h	Rx II
ASA, pentazocine	Talwin Compound	325	—	Pentazocine, 12.5	2 q4-6h	Rx IV
APAP, pentazocine	Talacen	—	650	Pentazocine, 25	1 q4-6h	Rx IV
APAP, propoxyphene N	Darvocet N 100	—	650	Propoxyphene N, 100	1 q4h	Rx IV
APAP, tramadol	Ultracet	—	325	Tramadol, 37.5	2 q4-6h	Rx
ASA, caffeine, butalbital	Fiorinal	325	—	Caffeine, 40 Butalbital, 50	1-2 q4h	Rx III
APAP, caffeine, butalbital	Fioricet	—	325	Caffeine, 40 Butalbital, 50	1-2 q4h	Rx III
ASA, caffeine, butalbital, codeine	Fiorinal with codeine	325	—	Same as Fiorinal, plus codeine, 30	1-2 q4h	Rx III
ASA, caffeine, dihydrocodeine	Synalgos-DC	356.4	—	Caffeine, 30 Dihydrocodeine, 16	1-2 q4h	Rx III
ASA, caffeine, propoxyphene HCl	Darvon Compound	389	—	Caffeine, 32.4	1-2 q4h	Rx IV
ASA, meprobamate	Equagesic	325	—	Meprobamate, 200	1-2 q4h	Rx IV
Ibuprofen, hydrocodone	Vicoprofin	—	—	Ibuprofen, 200 Hydrocodone, 7.5	1 q4-6h	Rx III
Ibuprofen, oxycodone	Combunox	—	—	Ibuprofen, 400 Oxycodone, 5	1 q6h	Rx II

Note: No attempt has been made to present a complete listing of drug combinations or proprietary preparations (which are available in a variety of dosage forms). Such listings can be found in various sources, including *Facts and Comparisons* and *Physicians' Desk Reference*. Many of the combinations provide suboptimal amounts of aspirin or acetaminophen. In such cases, taking two tablets instead of one would remedy this problem. With some drug preparations such as Empirin or Tylenol with codeine #4, however, taking two tablets would result in administration of an excessive amount of the opioid analgesic, and unwanted side effects could occur.

*Formulation contains a mixture of two different oxycodone salts.

APAP, Acetaminophen; *ASA,* aspirin; *HCl,* hydrochloride; *OTC,* over-the-counter; *Rx,* prescription.

those that use the optimal amount of an aspirin-like drug combined with the appropriate dose of an opioid analgesic.

Analgesic Combinations That Include a Sedative

Some proprietary compounds combine peripherally acting analgesics with either a sedative or a sedative and an opioid analgesic. The rationale is that patients with pain usually have anxiety, which a sedative drug may help alleviate. Such fixed-dose combined drugs provide a convenient method to administer an analgesic and sedative with one prescription. The use of fixed-dose combinations, however, makes it difficult to adjust the dosage of the various constituents to the individual needs of a patient. Another good argument against fixed-dose combined drugs is that they increase the potential for adverse drug interactions. This problem is compounded further if the patient receives psychoactive drugs (intravenous sedatives) during treatment that could have effects that carry over into the postoperative period.

Sedatives found in fixed-dose combined drugs are butalbital, meprobamate, and the antihistamines phenyltoloxamine and pyrilamine. There is little published evidence that sedative drugs either adversely affect the pain threshold or in any way contribute to the analgesic efficacy of the combination. They are capable, however, of blunting behavioral responses, which sometimes may be mistaken for an increase in the pain threshold.

Oral Analgesic Combinations Used in Dentistry

Although the pharmacologic features of opioids are discussed thoroughly in Chapter 20, it is appropriate to mention here some of the combinations of opioids and peripherally acting analgesics that are widely used in dentistry. Many opioid analgesics have poor oral/intramuscular (PO/IM) potency ratios because of low oral bioavailability. After oral administration, several opioids are rapidly absorbed into the portal system and mostly transformed to inactive metabolites on their first pass through the liver. To equal the effect of 10 mg of morphine administered intramuscularly, about 60 mg of oral morphine would have to be given, in accord with the drug's PO/IM potency ratio of 0.16. A low PO/IM potency ratio also means that unpredictable and sometimes dangerous effects may occur because individuals show great variability in their metabolic efficiencies. The highest PO/IM potency ratio for any of the commonly used centrally acting analgesics is about 0.5 for drugs such as codeine, hydrocodone, oxycodone, and propoxyphene.

Another general problem with opioid analgesics is their relatively high incidence of undesirable side effects. They all cause nausea and CNS depression, which become more intense as the dosage is increased. Mild CNS depression manifested as sedation may sometimes be useful, but ambulatory dental patients generally want to be able to function normally after they leave the dental office.

Codeine is a commonly used opioid in combination analgesics. Its effective oral dose range is 30 to 90 mg, 30 mg providing only minimal analgesia, 60 mg providing a little more analgesia with considerably more nausea and sedation, and 90 mg approaching the dose at which intolerable side effects occur. Codeine is available in combination with aspirin or acetaminophen. For most patients, 600 to 650 mg of either drug combined with 60 mg of codeine should provide adequate pain relief for most acute dental pain situations.[12,31,32]

Hydrocodone and oxycodone are close but more potent analogues of codeine.[13] Hydrocodone/acetaminophen combinations (see Table 21-7) are now the most widely prescribed analgesics in the United States. A formulation combining 200 mg of ibuprofen with 7.5 mg of hydrocodone is also being marketed, but the 200-mg ibuprofen dose is suboptimal. In patients with severe pain, 10 mg of oxycodone combined with either aspirin or acetaminophen is an effective oral analgesic combination, although side effects such as nausea, dizziness, and sedation should be expected. A more recently introduced preparation of 400 mg of ibuprofen with 5 mg of oxycodone possesses optimal concentrations of both components. Typical opioid side effects should be expected. In addition, as with other analgesic preparations containing oxycodone, this combination is considered a Schedule II narcotic by the U.S. Drug Enforcement Administration (see Table 21-7).

Propoxyphene (hydrochloride or napsylate) is also popular in analgesic combinations. Its therapeutic efficacy is questionable, however. Some investigators have found that propoxyphene is slightly less potent than codeine, whereas others claim it is no more effective than a placebo. Propoxyphene combinations with aspirin or acetaminophen are listed in Table 21-7. It is usually assumed that 65 mg of propoxyphene hydrochloride is needed to achieve significant analgesia over and above the effect of aspirin or acetaminophen with which it is combined.

Pentazocine, an opioid with mixed agonist-antagonist activity, is available in combination with aspirin and with acetaminophen. It offers no therapeutic advantages over codeine. At the recommended dose of 50 mg, pentazocine is about as effective as 60 mg of codeine. Most combinations provide only for a maximum of 25 mg of pentazocine per tablet, however. The drug can produce a withdrawal syndrome in opioid-dependent patients.

Other opioid or opioid-like drugs may be used in combination, but most drug combinations on the market include codeine, hydrocodone, oxycodone, propoxyphene, or pentazocine combined with either aspirin or acetaminophen (see Table 21-7). Opioids such as morphine, meperidine, and oxymorphone have such low PO/IM potency ratios that they are of little use in routine oral analgesic therapy. In general, single-entity opioid analgesics are not the drugs of choice for the management of acute dental pain in ambulatory patients.

Implications for Dentistry

Abundant evidence suggests that dental pain is most amenable to treatment by NSAID analgesics and acetaminophen, and these drugs have become the mainstay for management of acute dental pain. Their use is associated, however, with some risks that are readily reduced by understanding the pharmacologic characteristics of these drugs, including the contraindications and precautions to be followed in selected populations. Opioid combination drugs are most useful in patients with a strong emotional component to their pain, in whom the mood-altering and sedative effects of the opioid are most desirable. Side effects of drowsiness, impaired psychomotor function, and nausea are common with these drugs and should be expected. In addition, the practicing dentist must be aware of drug-seeking patients, who often request a prescription including a specific opioid, most often oxycodone. Chapter 47 presents a more detailed approach for selecting an appropriate analgesic for particular dental indications.

MISCELLANEOUS AGENTS FOR RHEUMATOID ARTHRITIS

Several groups of compounds unrelated to NSAIDs and to adrenal corticosteroids considered in Chapter 35 are useful in suppressing the signs and symptoms of rheumatoid arthritis. Although these drugs are relatively toxic, it is now known that structural damage to joints and extra-articular manifestations of the disease, including lymphadenopathy, vasculitis, splenomegaly, and conjunctivitis, can occur early in the disease process. Although they provide symptomatic relief, NSAIDs alone do not slow or arrest the progression of the disease. These additional drugs as a whole are often referred to as *disease-modifying antirheumatic drugs* because they can alter the progression of the disease.[111] Of these, methotrexate in particular is now considered a first-line drug in the treatment of rheumatoid arthritis.

Gold Compounds

Medicinal preparations containing gold historically have been used to treat certain inflammatory conditions. Because of their toxicity, their use is now restricted to rheumatoid arthritis, and the use of gold in this condition has also greatly declined. Gold compounds are generally indicated in active cases where the arthritis steadily progresses despite an adequate regimen of NSAIDs, other DMARDs, rest, and exercise therapy. In such cases, chrysotherapy (therapy with aurothioglucose or auranofin) usually induces a partial or complete remission of the disease and not merely a palliation of symptoms. Parenteral gold has been shown to reduce the number of bony erosions in joint tissue.[142] The duration of these remissions is highly variable, however.

The exact mechanism by which gold formulations suppress inflammation is unknown. Gold compounds inhibit PG synthesis, suppress cellular immune reactions, inhibit lysosomal hydrolases, inactivate the classic and alternative com-

plement pathways, and, in particular, diminish the phagocytic activity of mononuclear cells. The relationship of these diverse actions to the observed clinical effects is unclear. In contrast to the NSAIDs, gold salts have no antipyretic or analgesic properties in nonrheumatic conditions.

Because conventional gold salts such as aurothioglucose are not well absorbed by the GI tract, the dosage is given by intramuscular injection. The distribution of gold is complex and depends on the dose and dosing interval. The plasma half-life increases with each subsequent dose because of tissue binding, and months may be required for mean blood concentrations to reach a plateau. After some period of constant weekly injections, gold accumulates in various tissues to such an extent that it may be continuously excreted for many months after administration has ceased. More than half of an administered dose is eventually eliminated in the urine, and the remainder is eliminated in the feces.

Parenteral chrysotherapy is complicated by numerous, occasionally serious adverse reactions. The toxicity of aurothioglucose may be manifested initially by mucocutaneous lesions, including pruritus, dermatitis (ranging from mild to severe), stomatitis (including glossitis), colitis, and vaginitis. Blood dyscrasias, including leukopenia, agranulocytosis, and aplastic anemia, have been reported. A nitritoid reaction, resembling the orthostatic hypotension, facial flushing, and nausea often seen with nitroglycerin administration, may occur shortly after the injection. Toxic effects involving the liver, kidney (proteinuria), and CNS can also occur. Taste disturbances caused by gold compounds may be a primary reason a patient with rheumatoid arthritis visits the dentist. These adverse effects seem to be dose-related and may develop at any time during chrysotherapy.

Auranofin is an orally effective form of gold. It seems to be less toxic than parenteral chrysotherapy; the major adverse effect is diarrhea, rather than skin rash and bone marrow depression. The latter problems can still occur, however. Auranofin also seems to be less effective than the injectable form of gold. The choice between auranofin and aurothioglucose is based on the seriousness of the illness, responsiveness to previous therapy, and desire to avoid injections.

Antimalarial Agents

Chloroquine and, more frequently, hydroxychloroquine have anti-inflammatory effects, including the impairment of neutrophil locomotion and eosinophils chemotaxis, that have been used in the treatment of rheumatoid arthritis and lupus erythematosus.[96] The drugs are generally administered in conjunction with other anti-inflammatory agents for the relief of mild early rheumatoid arthritis, or they may be used as alternatives to gold compounds or penicillamine (see later) in more severe cases. Clinical improvement is usually very slow, requiring 3 to 6 months. After this time, if there is no evidence of benefit, the drug is discontinued.

Serious ocular toxicity has been caused by these drugs; the retinopathy is dose-related and may progress even after therapy is discontinued. This effect has made antimalarial drugs controversial as antirheumatic agents and mandates regular ophthalmologic testing during therapy.[6] Other toxic effects include GI, dermatologic, and neuropsychiatric disturbances.

Penicillamine

Penicillamine, a degradation product of penicillin used as a chelating agent in the treatment of heavy metal poisoning (see Chapter 52), was first reported in 1970 to be effective in rheumatoid arthritis. Because of its toxicity, use of penicillamine in rheumatoid arthritis has greatly declined. Its mode of action is unknown; penicillamine has immunosuppressive and immunostimulant properties but is devoid of antibacterial activity. Penicillamine, similar to gold compounds, is indicated in cases of rheumatoid arthritis that are refractory to other compounds. As with chrysotherapy, penicillamine must be administered for several months before clinical improvement is noted. Side effects are frequent, usually occurring early in therapy. Skin rash similar to that caused by ampicillin is common, as are GI reactions, stomatitis, and taste disturbances. Nephropathy and thrombocytopenia also occur to a lesser extent. The drug must be withdrawn from approximately one third of patients because of adverse reactions.[83]

Sulfasalazine

Sulfasalazine is a sulfonamide derivative that has been used for the treatment of ulcerative colitis and, in a delayed-release form, for the management of rheumatoid arthritis. In Europe, it is often the initial DMARD that is used after rheumatoid arthritis is diagnosed. The agent has anti-inflammatory and immunomodulatory effects. After oral administration, sulfasalazine is hydrolyzed by enteric bacteria to yield the sulfonamide sulfapyridine and 5-aminosalicylate. Although 5-aminosalicylate is the active moiety against ulcerative colitis, there is no consensus regarding the drug's mechanism of action in rheumatoid arthritis. GI disturbances are the most frequently observed side effects; blood dyscrasias occurring early in therapy are among the most serious. Stevens-Johnson syndrome, hepatitis, and peripheral neuropathy have also occurred with use of sulfasalazine. Patients who have a history of allergy to sulfonamides or salicylates should not receive sulfasalazine.

Immunosuppressants and Antineoplastics

The immunosuppressants azathioprine and cyclosporine (see Chapter 41) and the antineoplastics cyclophosphamide and methotrexate (see Chapter 42) are effective in relieving the symptoms and slowing the disease progression of rheumatoid arthritis.[8] Methotrexate (combined with NSAIDs to treat pain and inflammation) has become the initial DMARD of choice in rheumatoid arthritis patients. Compared with gold, antimalarials, and penicillamine, methotrexate's onset of action is more rapid, and it tends to have better efficacy than these compounds or the immunosuppressants azathioprine or cyclosporine.[25,87,174] Symptomatic improvement from methotrexate therapy administered once weekly can be seen in 3 weeks. As with other DMARDs, NSAIDs can be used in conjunction with methotrexate as a bridge to provide symptomatic relief in the first few weeks of treatment. Because methotrexate, cyclophosphamide, azathioprine, and cyclosporine are general systemic immunosuppressants and affect many components in the inflammatory response, the exact mechanism by which such drugs ameliorate rheumatoid arthritis is unknown.

In the treatment of rheumatoid arthritis, the dosages of these drugs are less than those used in antineoplastic therapy or organ rejection therapy, so the incidence of serious adverse effects is also less. These drugs can still cause serious toxicity in these patients, however, such as promoting infections, blood dyscrasias, nephrotoxicity, and neoplastic transformation. In the oral cavity, cyclosporine can induce gingival hyperplasia, whereas methotrexate and cyclophosphamide can induce stomatitis and mucositis. Because one action of methotrexate is to reduce folic acid synthesis in highly proliferating tissues, its side effects can be minimized by the concomitant administration of folic acid or leucovorin.

The concomitant use of NSAIDs can displace methotrexate from plasma proteins and increase free methotrexate blood concentrations and toxicity. This pharmacokinetic interaction seems most important with high-dose methotrexate therapy used in cancer and not low-dose methotrexate therapy used in the treatment of rheumatoid arthritis.[70] In

addition, because cyclosporine is metabolized by the CYP3A4 isoenzyme, inhibitors of this enzyme, such as erythromycin, clarithromycin, and the azole antifungal drugs, can dramatically increase cyclosporine blood concentrations and associated toxicities, including irreversible nephrotoxicity.[75]

Leflunomide is an immunomodulatory drug that inhibits dihydroorotate dehydrogenase, an enzyme involved in pyrimidine synthesis. The resulting antiproliferative and anti-inflammatory activity is useful in the treatment of active rheumatoid arthritis and produces similar benefits to that of methotrexate. An active metabolite of leflunomide, termed *M1*, is responsible for essentially all of the drug's action. Because M1 has a half-life of approximately 2 weeks, a loading dose schedule must be used to achieve therapeutic concentrations in several days (rather than the 2 months normally required). Adverse effects attributed to leflunomide include alopecia, skin rash, myelosuppression, and elevated liver enzymes. The drug should not be taken with other hepatotoxic drugs; coadministration of rifampin can significantly elevate the concentration of M1. A pregnancy category X agent, leflunomide is fetotoxic and contraindicated in pregnant women.

Biologic Agents

Advances in biotechnology have led to the development of biologic agents that selectively target specific pathogenic components of the immune response without causing generalized immunosuppression. Two intravenously administered agents, infliximab and etanercept, and one subcutaneously administered agent, adalimumab, target TNF-α. Infliximab is a chimeric IgG1 monoclonal antibody composed of human constant and murine variable regions,[141] adalimumab is a fully human monoclonal anti-TNF-α,[165] whereas etanercept is a dimeric fusion protein consisting of the extracellular ligand-binding portion of the TNF receptor linked to the Fc portion of human IgG1.[177] All three drugs bind specifically to TNF-α and inhibit the binding of TNF-α to its receptor located on various inflammatory cell types. Through this action, the biologic activity of TNF-α is neutralized, including the ability of TNF-α to induce IL-1 and IL-6, enhance leukocyte migration, and activate neutrophils and eosinophils.

These drugs are typically used in patients with the most advanced forms of the disease and in whom methotrexate therapy has failed to alleviate the symptoms. Infliximab and adalimumab are generally given in combination with low-dose methotrexate therapy, whereas etanercept can be administered alone or in combination with low-dose methotrexate therapy. Infliximab is also approved for the treatment of the signs and symptoms of Crohn's disease; adalimumab is also approved for the treatment of psoriatic arthritis, ankylosing spondylitis, and Crohn's disease; and etanercept is also approved for the treatment of psoriatic arthritis, ankylosing spondylitis, and moderate-severe plaque psoriasis. Although these drugs are not generalized immunosuppressants, serious and sometimes fatal infections have been reported in patients receiving any of these agents. Many of these events have occurred in patients who were receiving concomitant immunosuppressive therapy with drugs such as methotrexate or azathioprine. Infusion reactions, such as chills, fever, and urticaria, have also been reported and are more likely to occur in patients who have antibodies develop to these drugs.

Other biologic agents with targets distinct from TNF-α have also been introduced to treat the signs and symptoms of rheumatoid arthritis. Abatacept was approved in 2006 for the treatment of moderate-severe rheumatoid arthritis in adults that is refractory to other treatments. It is given intravenously and cannot be given concomitantly with TNF-α inhibitors because of the increased risk of serious infections. The drug is a soluble fusion protein that consists of the extracellular domain of the human cytotoxic T-lymphocyte antigen 4 linked to the Fc portion of human IgG. It blocks T-cell activation, which seems to be a key component of the disease.[135] In one pivotal trial involving rheumatoid arthritis patients who had failed methotrexate, abatacept was equal in efficacy to infliximab but with less serious adverse events.[135]

Rituximab is approved to treat CD20 B-cell–positive non-Hodgkin's lymphoma and in combination with methotrexate to reduce signs and symptoms in adults with moderately to severely active rheumatoid arthritis who have had an inadequate response to one or more TNF-α antagonists. It is a genetically engineered chimeric murine/human monoclonal antibody directed against the CD20 antigen on B lymphocytes, which when given by intravenous infusion can result in a selective depletion of these cells for many months.[138] Severe infusion reactions manifested by hypoxia, pulmonary infiltrates, MI, and death have been reported. The development of severe mucocutaneous reactions and the activation of the JC virus leading to progressive multifocal leukoencephalopathy have also been reported after rituximab infusions.

Anakinra is indicated to reduce signs and symptoms and to slow the progression of structural damage in moderately to severely active rheumatoid arthritis, in patients ≥18 years old who have failed one or more DMARDs. The drug is given subcutaneously once daily and can be used alone or in combination with DMARDs other than TNF-α–blocking agents. It is an interleukin-1 receptor antagonist. Adverse effects include transient injection site reactions, the development of respiratory tract infections including pneumonia, and headache and nausea.[54]

Implications for Dentistry

Most rheumatoid arthritis patients presenting for dental care are receiving one or more DMARDs to slow the progression of their disease and invariably exhibit some degree of immunosuppression. Before any dental surgical procedure, consultation with the patient's rheumatologist is advised to discuss the need for a presurgical or postsurgical antibiotic course. In addition, patients with rheumatoid arthritis who have also had a prosthetic joint replacement may require a prophylactic antibiotic regimen that has been approved by the American Academy of Orthopedic Surgeons and the American Dental Association: either 2 g of amoxicillin, cephalexin, or cephradine or, in penicillin-allergic individuals, 600 mg of clindamycin 1 hour before the procedure (see Chapter 49).[3] All rheumatoid arthritis patients receiving DMARDs should maintain a high degree of oral hygiene to prevent the development of serious intraoral infections.

DRUGS USED TO TREAT GOUT

Gout is an inflammatory disease that stems from elevated concentrations of uric acid in blood and other body fluids. Such elevations may be the result of either increased production (metabolic gout) or decreased excretion (renal gout) of uric acid. Decreased excretion is usually the major contributing factor. Reduced elimination may be caused by an inability to excrete uric acid properly, resulting from renal disease or from certain drugs that reduce renal excretion of uric acid. Overproduction may be associated with a primary defect in purine metabolism, such as a deficiency in the enzyme phosphoribosyl transferase, or be caused by certain hematologic disorders, leukemias, cancer chemotherapy, or effects of ethanol.

Essentially all the clinical manifestations of gout derive from the precipitation of sodium urate from extracellular

fluids when and where it exceeds the limits of solubility. These manifestations can be divided into four categories: acute gouty arthritis, tophaceous deposits (sodium urate deposits in cartilage, bone, bursae, and subcutaneous tissue in and around joints), uric acid nephrolithiasis, and gouty kidney with various degrees of impairment of renal function. Of all these, gouty arthritis is most frequently the first clinical manifestation of the disease. Intensive study of the mechanism of gouty arthritis has shown it to be an inflammatory reaction to sodium urate microcrystals deposited in synovial fluid. Precisely how these crystals initiate inflammation is unknown. The generation of reactive oxygen species has been proposed.[65,162] The crystals can activate Hageman factor and in this way initiate the chain of events leading to bradykinin formation.

Numerous neutrophils accumulate in the synovium, possibly because of a chemotactic effect of uric acid. These neutrophils actively phagocytize urate crystals, leading to release of lysosomal enzymes and increased lactic acid production. Both these events tend to propagate the inflammatory response, the former by damaging tissue and the latter by lowering the local pH and fostering further urate deposition. A glycoprotein released by neutrophils after the ingestion of urate crystals has been shown to replicate the histopathologic characteristics of gout on injection into normal joints.

Although the overall pathogenesis of gouty arthritis is understood, many specific events are still obscure. It is known that acute gouty arthritis often follows a precipitating event. Surgery, injury, alcohol ingestion, dietary excess, emotional crisis, or even the minor stress of walking can elicit an acute attack, but it is unknown how these events are related to urate crystal deposition. Another unknown is the reason why less than 10% of gout occurs in women.

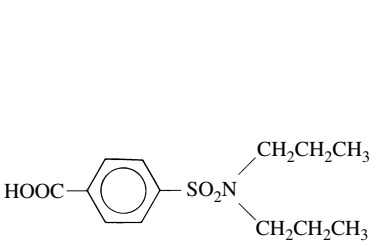
Acute gouty arthritis is clinically characterized by severe inflammation of the joint and periarticular tissues. One or several joints may be involved simultaneously, as shown by marked swelling, redness, heat, and intense pain. Lymphadenitis is occasionally present. There may also be systemic signs of inflammation, including fever, leukocytosis, and an increased erythrocyte sedimentation rate. Without treatment, the arthritis gradually subsides over 1 to 2 weeks. The rate of recurrence varies after an initial attack, but in most patients recurrence is common, usually within 1 year. With increasing age, the incidence of attacks increases, as does the severity, duration of inflammation, and number of joints affected. In time, the patient may rarely be free of gouty arthritis, and the pain, swelling, and stiffness can result in total and permanent disability.

The treatment of gout may involve multiple agents acting at different sites and having distinctly different objectives. Because the pathologic manifestations of the disease result from an elevated extracellular uric acid titer, a rational therapeutic maneuver is to reduce urate concentrations. Two approaches toward this end are currently available: the use of uricosuric drugs to increase renal urate clearance and the use of allopurinol to inhibit urate synthesis.

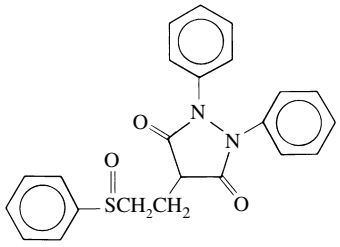
The uricosuric agents most often used are probenecid and sulfinpyrazone (Figure 21-17). Both of these anionic compounds can enhance urate retention by blocking its renal tubular secretion or by participating in an anion exchange reaction with urate. At higher doses, these agents block the quantitatively more important process of tubular reabsorption of urate, increasing the urinary excretion of uric acid and decreasing plasma urate concentrations. Uricosuric drugs are used primarily in chronic gout to prevent the formation of new tophi and slowly to mobilize urate deposits in old lesions. They are not useful in treating attacks of gouty arthritis because mobilization of previously deposited urates may initially increase the severity of the attack. The use of uricosuric drugs may lead to the formation of renal urate stones in the presence of a high plasma uric acid concentration.

Maintenance of an alkaline diuresis during therapy with uricosuric agents is important. The pK_a of uric acid is 5.6, and the solubility of the nonionized form is low. An alkaline environment minimizes intrarenal deposition. Probenecid and sulfinpyrazone are initially given in low doses, which are gradually increased until the desired serum urate concentration is obtained (usually 6 mg/dL); a maintenance dose is then established. Both drugs are generally well tolerated. The most common adverse effects are GI disturbances and allergic reactions ranging from dermatitis to anaphylaxis. Although the salicylates are uricosuric at high doses, they are no longer used for this purpose. Because salicylates at ordinary doses may decrease urate excretion (see Table 21-4), they should be used cautiously in patients with gout.

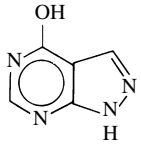
Allopurinol (see Figure 21-17) and its metabolite alloxanthine (oxypurinol) are inhibitors of the enzyme xanthine oxidase. Most of the effect on uric acid seems to be caused by alloxanthine because it has a considerably longer half-life



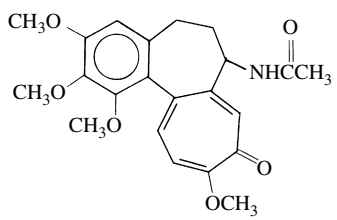
Probenecid



Sulfinpyrazone



Allopurinol



Colchicine

FIGURE **21-17** Drugs used in the prevention and treatment of gout.

than allopurinol. Also, although allopurinol is a competitive inhibitor, alloxanthine is a noncompetitive inhibitor of xanthine oxidase, with a higher potency than allopurinol. Xanthine oxidase catalyzes the oxidation of hypoxanthine to xanthine and then to uric acid. The action of allopurinol is to reduce the biosynthesis of uric acid and lower blood and urine concentrations. The uric acid precursors do not accumulate in body fluids because they are sufficiently cleared by the kidney.

Similar to the uricosuric agents, allopurinol is indicated for chronic rather than acute gout. It may be preferred in the more severe forms over the uricosuric agents. As with the uricosuric agents, allopurinol may initially increase the number of acute attacks of gouty arthritis, unless colchicine prophylaxis, as described subsequently, is used. The toxic effects of allopurinol include allergic reactions involving the skin (e.g., exfoliative, urticarial, and purpuric lesions) and blood (e.g., leukopenia, thrombocytopenia, agranulocytosis). There is a modest incidence of gastric irritation. Febuxostat, a new xanthine oxidase inhibitor, has been approved recently by the FDA. In one clinical trial comparing it with allopurinol, it was more effective in lowering serum urate concentrations than standard daily doses of allopurinol.[14] It was not compared to allopurinol used in doses adjusted to ensure optimal clinical effect. Because febuxostat is inactivated in the liver, it may be the preferred drug in patients with renal impairment.

In addition to efforts aimed at reducing the extracellular uric acid concentration, another aspect of therapy for gout is management of acute arthritis. This goal entails the short-term use of anti-inflammatory agents, some of which (indomethacin, naproxen, and sulindac) have already been described. Although these drugs have no specific actions in gouty arthritis, they can effectively relieve the pain, tenderness, and swelling in affected joints.

The most widely used drug to treat severe gouty arthritis is colchicine, a plant alkaloid with a long history of use in gout (see Figure 21-17). When given at the first indication of an attack, colchicine effects a striking reduction of the emerging signs and symptoms of arthritis. Pain begins to disappear within 4 to 12 hours after oral medication and is completely gone after 24 to 48 hours. Intravenous administration leads to a more rapid onset of action and is preferred for some patients. Colchicine is relatively specific for this condition; the drug has little effect on other inflammatory conditions, and it does not have inherent analgesic properties. Colchicine may also be given prophylactically to prevent recurrent attacks.

The anti-inflammatory effects of colchicine are believed to derive from its well-known antimitotic activity. It arrests mitosis in metaphase by binding to microtubular protein and preventing spindle formation. By a similar action, colchicine disrupts fibrillar microtubules in neutrophils and other motile cells. The involvement of the microtubular system in cell locomotion could explain colchicine's inhibition of neutrophil migration and phagocytic activity in inflamed joints.[5] This action is thought to inhibit the neutrophil's engulfment of uric acid crystals, preventing the subsequent release of destructive lysosomal enzymes into the extracellular environment.

Colchicine is rapidly absorbed from the GI tract. The drug is partially metabolized in the liver, and the metabolites and unchanged drug are excreted in the feces for 10 days after a single dose. This finding may explain why the GI tract is a frequent site of adverse reactions.

The most common untoward effects of colchicine are nausea, vomiting, and diarrhea. Diarrhea is an important sign because it may signal more serious toxic reactions, such as hemorrhagic gastroenteritis. The GI effects of colchicine may result from direct toxicity to intestinal mucosal cells. Long-term use of colchicine may lead to bone marrow depression, myopathy, and alopecia.

NSAIDS, ANALGESIC COMBINATIONS, AND ANTIRHEUMATIC AND ANTIGOUT DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Salicylates*	
Choline magnesium trisalicylate	Trilisate
Choline salicylate	Arthropan
Magnesium salicylate	Magan, Mobidin
Salsalate	Amigesic, Disalcid
Sodium salicylate	—
Sodium thiosalicylate	Asproject, Rexolate
Other NSAIDs*	
Celecoxib	Celebrex
Diclofenac	Voltaren
Flurbiprofen	Ansaid
Indomethacin	Indocin
Meloxicam	Mobic
Nabumetone	Relafen
Oxaprozin	Daypro
Phenylbutazone†	Butazolidin
Piroxicam	Feldene
Sulindac	Clinoril
Tolmetin	Tolectin
Analgesic combinations	
See Table 21-7	
Other antirheumatic drugs	
Abatacept	Orencia
Adalimumab	Humira
Anakinra	Kineret
Auranofin	Ridaura
Aurothioglucose	Solganal
Azathioprine	Imuran
Chloroquine	Aralen
Cyclophosphamide	Cytoxan
Cyclosporine	Sandimmune
Etanercept	Enbrel
Gold sodium thiomalate	Aurolate, Myochrysine
Hydroxychloroquine	Plaquenil
Infliximab	Remicade
Leflunomide	Arava
Methotrexate	Rheumatrex
Penicillamine	Cuprimine
Rituximab	Rituxan
Sulfasalazine	Azulfidine
Antigout drugs	
Allopurinol	Zyloprim
Colchicine	—
Probenecid	Benemid
Febuxostat	Uloric
Sulfinpyrazone	Anturane

CHAPTER 22

Histamine and Histamine Antagonists

CLARENCE L. TRUMMEL

HISTAMINE

Histamine, or β-aminoethylimidazole, is one of a heterogeneous group of biologically active, naturally occurring substances whose physiologic roles are becoming increasingly better understood. In addition to histamine, this group includes another amine (5-hydroxytryptamine), polypeptides (angiotensin, bradykinin, and kallidin), and lipid-derived substances (prostaglandins, leukotrienes, and platelet-activating factor). These compounds have been collectively termed *autacoids*. This designation, derived from the Greek *autos* ("self") and *akos* ("cure"), is sufficiently nonspecific yet still acknowledges the endogenous origin and biologic activities of these substances and their important role in the body's economy.

Histamine was the first autacoid to be discovered. After its synthesis in 1907, a series of studies by Dale and Laidlaw[10] of the pharmacologic properties of histamine suggested that this substance might be involved in inflammatory and anaphylactic reactions. Dale and Laidlaw[10] observed that the local application of histamine caused redness, swelling, and edema, mimicking a mild inflammatory reaction. They also determined that large doses of histamine given systemically produced profound vascular changes similar to those seen in shock of traumatic or anaphylactic origin. Although the presence of histamine in animal tissues had been suggested, it was not until 1927 that histamine was conclusively shown to be a natural constituent of mammalian tissues and not the result of bacterial action.[2] This finding provided important support for the work of Lewis and Grant,[23] who had shown earlier that a histamine-like substance ("H substance") was released in the skin after various injuries, including antigen-antibody reactions.

These early studies and the studies that followed established that histamine is involved in various pathophysiologic phenomena seen after injury to tissue. Since then, a large amount of detailed information regarding the synthesis, storage, release, and actions of histamine has been generated. Despite this knowledge base, our understanding of the role of histamine in the complex response of cells to injurious stimuli and the relation of this compound to other autacoids is meager. It is increasingly evident that this ubiquitous amine is involved in physiologic processes other than reaction to injury. These processes include gastric secretion,[8] neurotransmission in the central nervous system (CNS),[36,43] and local control of the microcirculation.[55]

Formation, Distribution, and Release

Histamine is widely distributed in nature and is found in plants, bacteria, and animals. Nearly all mammalian tissues contain histamine or have the ability to form it. The histamine content of different tissues varies greatly. In humans and most other mammals, the highest concentrations are found in lung, skin, and intestinal mucosa; organs such as the pancreas, spleen, liver, and kidney have a low histamine content (Table 22-1). The physiologic significance of this pattern of distribution is unknown. Although some tissue histamine may be derived from dietary sources or synthesized by bacteria in the gastrointestinal tract, most of it seems to be formed in situ.

Histamine is synthesized in mammalian tissues by the intracellular decarboxylation of the amino acid histidine (Figure 22-1). This conversion may be catalyzed either by aromatic L-amino acid decarboxylase or by histidine decarboxylase. Histidine decarboxylase is specific for L-histidine, requires pyridoxal phosphate, and seems to be primarily responsible for the synthesis of histamine in humans.

Histamine is found in most tissues in the mast cell and in blood in a related cell, the basophil.[39,44] These cells synthesize histamine and store it as a proteinaceous complex with heparin or chondroitin sulfate in membrane-bound secretory granules. Histamine in this form is physiologically inactive but can be discharged from the cell by a process called *exocytosis*, or *degranulation*. The first step in this process is activation of the cell by an appropriate stimulus. When the cell is activated, a complex series of events leading to degranulation occurs. These events require an increase in cytosolic Ca^{++} and metabolic energy and involve activation of Ca^{++}-dependent protein kinases (protein kinase C and Ca^{++}/calmodulin-dependent protein kinase), assembly of microtubules, and, finally, fusion of the perigranular membrane with the cell membrane. The granule contents are released into the extracellular environment and dissociate to yield histamine, heparin, several proteases, and chemoattractants such as tumor necrosis factor α. In addition to release of these preformed mediators, activation of mast cells activates phospholipase A in the cell membrane, which hydrolyzes phospholipid esters to yield arachidonic acid. The arachidonic acid is metabolized by the cyclooxygenase pathway to various prostaglandins and thromboxanes and by the lipoxygenase pathway to various leukotrienes.

A small amount of histamine not stored in mast cells or basophils is found in several sites. One of these sites is certain neurons in the hypothalamus. The function of these histaminergic neurons is unknown. Another site of non–mast cell histamine is the enterochromaffin-like cell in the gastric mucosa. These cells synthesize and release histamine, which subsequently stimulates gastric acid secretion by mucosal parietal cells (see Chapter 33). Certain neoplasms collectively known as *carcinoid* can also secrete various bioactive substances, including histamine.[9] These substances likely contribute to the so-called carcinoid syndrome, a prominent feature of which is cutaneous flushing and bronchoconstrictive attacks

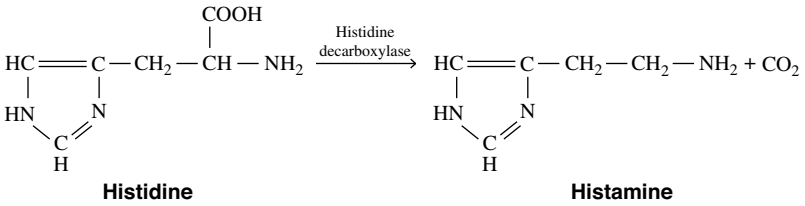

FIGURE **22-1** Conversion of histidine to histamine.

TABLE **22-1**

Distribution and Content of Histamine in Various Human Tissues and Cells

TISSUE OR CELL	HISTAMINE CONTENT*
Lung	33 ± 10
Mucosa (nasal)	15.6 (range 5-38.5)
Stomach	14 ± 4
Duodenum	14 ± 0.9
Skin (face)	30.4
Skin (abdomen)	6.6
Pancreas	4.8 ± 1.5
Spleen	3.4 ± 1
Bone marrow	3.3 ± 1.5
Kidney	2.5 ± 1.2
Liver	2.2 ± 0.8
Heart	1.6 ± 0.1
Thyroid	1 ± 0.1
Skeletal muscle	0.9 ± 0.1
Peripheral nerves	2-11
CNS tissue	0-0.2
Whole blood	16-89 μg/L
Plasma	2.6 μg/L (range 0-15)
Basophils	1080 $\mu g/10^9$ cells
Eosinophils	160 $\mu g/10^9$ cells
Neutrophils	3.0 $\mu g/10^9$ cells
Lymphocytes	0.6 $\mu g/10^9$ cells
Platelets	0.009 $\mu g/10^9$ platelets

From Van Arsdel PP Jr, Beall GN: The metabolism and functions of histamine, *Arch Intern Med* 106:714-733, 1960. Copyright 1960, American Medical Association.
*Means or means ± standard error expressed as μg/g unless otherwise indicated.
CNS, Central nervous system.

similar to that seen after the intravascular administration of histamine.

Various conditions (or stimuli) can trigger the release of histamine from mast cells and basophils. These can be grouped into three categories: tissue injury, allergic reactions, and drugs and other foreign compounds.

Tissue injury

Any physical or chemical agent that nonspecifically injures tissue, particularly skin or mucosa, causes the immediate release of histamine from mast cells in the affected area. Depending on the severity of injury, histamine continues to be released for several minutes and seems to be largely responsible for the initial sharp increase in vascular permeability that is characteristic of acute inflammation. This histamine-dependent change in permeability is transient (≤30 minutes) but is followed in 2 to 4 hours by a more prolonged increase in permeability lasting up to 4 hours. Although inhibitors of histamine release or inhibitors of the subsequent action of histamine can block the initial phase of vascular permeability after injury, they have little effect on the secondary or delayed phase, suggesting that autacoids or factors other than histamine mediate the secondary phase.[54] The mechanism by which a nonspecific injury triggers mast cell degranulation is unclear. It could depend on direct physical damage to mast cells, or alternatively it may involve the initial production of factors such as activated complement components or vasoactive polypeptides, which stimulate histamine release.[21,31]

Allergic reactions

Presentation of a specific antigen to a previously sensitized subject can trigger immediate allergic reactions, ranging in intensity from mild (localized edema, erythema, and itching) to severe (marked decrease in blood pressure and bronchospasm). The pathophysiologic manifestations of such reactions are caused largely by the release of histamine (Figure 22-2). This release occurs as a consequence of the binding of specific antigens to allergen-specific reaginic (IgE) antibodies attached to the plasma membranes of mast cells and basophils transmembrane high-affinity receptors termed *FcεRI*.[29] Binding of antigen and antibody may cause conformational changes in the membrane, leading to an increase in Ca^{++} permeability. In any case, this antigen-antibody interaction is an appropriate stimulus for the series of events leading to degranulation of these cells.

Drugs and other foreign compounds

Although drugs that are antigenic (e.g., penicillin) can cause histamine release, a large group of drugs and other chemicals can trigger histamine release directly without a requirement for previous sensitization through an immune response. For convenience, these agents can be classified as basic histamine releasers, macromolecular compounds, and enzymes.[21] The basic histamine releasers include aliphatic and arylalkyl amines, amides, amidines, diamidines, quaternary ammonium compounds, alkaloids, piperidine derivatives, pyridinium compounds, antimalarial drugs, dyes, and basic polypeptides. The prototypic histamine releaser compound 48/80 and numerous therapeutic agents of interest, such as tubocurarine and morphine, fall into this category.

Dextran is an example of a macromolecular compound that causes histamine release. Several enzymes, such as phospholipase A, have been shown to initiate mast cell degranulation, a fact that may explain the release of histamine caused by various insect and snake venoms. The mechanisms by which chemicals trigger histamine release vary. Some agents, typified by the Ca^{++} ionophore compound 48/80, act by stimulating an energy-dependent degranulation process with characteristics similar to anaphylactic histamine release. Other histamine releasers are effective in the absence of energy sources and seem to act by a detergent-like effect on cell membranes.

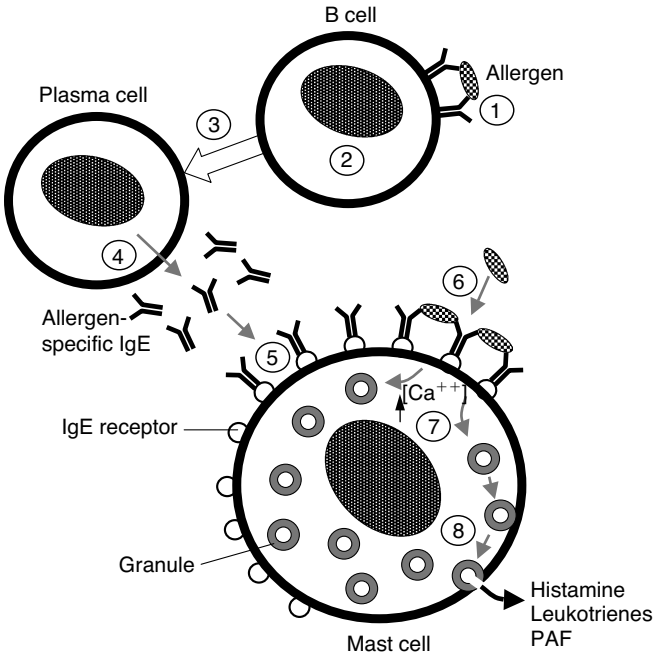

FIGURE **22-2** Schematic representation of mast cell degranulation and histamine release from mast cells after antigenic challenge. B cells bind allergen (*1*) via surface immunoglobulin and are induced (*2*) by TH2 cells (not shown) to proliferate and differentiate into plasma cells (*3*), which produce allergen-specific IgE (*4*). IgE binds through the Fc portion of the molecule to very-high–affinity receptors on mast cells (*5*). On subsequent exposure, the antigen binds to and cross-links IgE (*6*), leading to rapid influx of Ca^{++} and cell activation (*7*). Granules containing histamine fuse with the cell membrane and "degranulate" (*8*), releasing histamine, platelet-activating factor *(PAF)*, and leukotrienes extracellularly.

Metabolism

Histamine of either exogenous or endogenous origin is rapidly inactivated by two routes.[41] The more important of these is methylation of the imidazole ring by the enzyme histamine-N-methyltransferase, which is widely distributed throughout the body. The resultant product is converted to methylimidazole acetic acid by monoamine oxidase. The other route involves the oxidative deamination of histamine by diamine oxidase to produce imidazole acetic acid, much of which is subsequently conjugated with ribose. All these metabolites are inactive and, along with a small amount of free histamine, are excreted by the kidney.

Large oral doses of histamine have little effect because histamine is rapidly degraded by intestinal bacteria. Any free histamine that is absorbed is largely inactivated in the intestinal wall and in the liver.

Pharmacologic Effects

Most of the important effects of histamine can be attributed to its actions on smooth muscle and glands. In general, histamine causes relaxation of vascular smooth muscle in smaller blood vessels. It also causes the constriction of some larger blood vessels, the contraction of nonvascular smooth muscle, and the stimulation of secretion of exocrine glands, especially glands of the gastric mucosa. These actions are independent of innervation. Different species show considerable variation in the sensitivity of target tissues to histamine. The bronchial smooth muscle of the guinea pig is highly sensitive to histamine, and fatal bronchospasm occurs at concentrations that have minimal effects in other species, including humans. Within a single species, the actions of histamine are usually reproducible.

The existence of compounds that can selectively block the actions of histamine strongly supports the existence of four histamine receptors, H_1, H_2, H_3, and H_4.[16,18] Although the first two seem to be unique (i.e., have selective agonists and antagonists), the H_3 and H_4 receptors share a degree of homology and are more difficult to distinguish pharmacologically from one another.[47] All four histamine receptors are G protein–linked receptors. H_1 receptors are associated with $G_{q/11}$, and stimulation of these receptors leads to an increase in intracellular Ca^{++} and Ca^{++}-dependent protein kinase activity. H_2 receptors are linked to G_s, and stimulation of these receptors brings about an increase in intracellular cyclic adenosine 3′,5′-monophosphate (cAMP). H_3 and H_4 receptors seem to stimulate $G_{i/o}$ proteins, leading to reduced cAMP (see Chapters 1 and 5 for more details on the specifics of signal transduction involving G proteins).

H_1 receptors primarily mediate effects on smooth muscle, leading to vasodilation, increased vascular permeability, and contraction of nonvascular smooth muscle. These effects are blocked by the "classic" antihistamines, such as pyrilamine. H_2 receptors mediate the stimulation of gastric acid secretion. H_2 receptors may be involved in other effects, such as direct cardiac stimulation and vasodilation seen after high doses of histamine, based on studies showing that H_2-blocking agents specifically antagonize these effects.[5,6]

H_3 receptors have been identified in various cells, including presynaptic sites on histaminergic neurons in the CNS and prejunctional sites in gastric mucosa, cardiovascular system, and the enterochromaffin-like cells of the stomach. The function of H_3 receptors is not firmly established, but these receptors seem to antagonize stimulatory effects mediated by the activation of H_1 receptors. Their prejunctional location suggests a role as autoregulatory receptors in many tissues. Activation of H_3 receptors on adrenergic nerve terminals in the myocardium inhibits the release of norepinephrine.[19,22] The more recently identified H_4 histamine receptor is found primarily on cells of hematopoietic origin, particularly mast cells, basophils, and eosinophils. Activation of H_4 receptors on these cells induces changes in cell shape, chemotaxis, and upregulation of various cell-adhesion molecules.[17,24]

Cardiovascular system

The effects of histamine on the circulatory system are complex and vary markedly according to species. In most mammals, histamine causes some constriction of large arterial and venous vessels. Histamine also constricts arterioles and increases blood pressure in rats and rabbits. In contrast, the intravenous administration of histamine in humans and carnivores causes dilation of terminal arterioles, capillaries, and postcapillary venules and leads to a sharp decrease in peripheral resistance and a consequent decrease in blood pressure. The dilation of these vessels is caused by histamine stimulation of H_1 receptors on endothelial cells, resulting in the release of nitric oxide, which causes the relaxation of smooth muscle of the arterioles and precapillary sphincters. Stimulation of H_1 receptors also leads to activation of phospholipase A_2 and the generation in endothelial cells of prostacyclin, which contributes to the vasodilation.

Histamine also stimulates H_2 receptors on vascular smooth muscle cells, leading to relaxation of small blood vessels. The subsequent increase in arteriolar and capillary blood flow causes a passive dilation of postcapillary venules that is accompanied by an increase in their permeability. This increased permeability is initiated by distention or stretching of the venules and by a contractile response of the endothelial cells caused directly by histamine; both phenomena contribute to

"gaps" between the endothelial cells of the venules and exposure of the basement membrane. These gaps permit the movement of plasma protein and fluid through the basement membrane into the extravascular space, causing the formation of edema.

In addition to hypotension, arteriolar dilation induced by histamine leads to cutaneous flushing, especially over the face and upper trunk, and an increase in skin temperature. A short-lived but intense headache caused by dilation of cerebral vessels also occurs. This "histamine headache" is similar in quality and duration to the headache produced by other potent vasodilators, such as amyl nitrite.

The effect of histamine on the terminal vasculature can be illustrated by injection of 10 to 20 μg of the amine into the skin. At the site of the injection, there is first immediate reddening, reflecting vasodilation. This reddening is followed shortly by a zone of erythema, or "flare," extending as an irregular halo for 1 cm or more beyond the original red spot. The flare is presumed to be caused by reflex vasodilation of adjacent small vessels, resulting from the axon reflex, and is abolished by disruption of the peripheral sensory nerves. Finally, the central spot is replaced by a disk of localized edema, or wheal, resulting from increased capillary permeability, and is accompanied by pain and itching. These events constitute the classic triple response first described by Lewis and Grant.[23] A similar response is elicited by the intradermal injection of antigen in a sensitized individual.

Hypotension resulting from moderate doses of histamine is transient because reflex circulatory mechanisms come into play, and the drug is rapidly inactivated. When histamine is given in large doses, there is a progressive decrease in blood pressure that resembles traumatic or surgical shock. This decrease is a consequence of vasodilation and increased capillary permeability. The increased capillary permeability leads to loss of plasma from the vascular compartment and a decrease in the effective blood volume. Venous return to the heart is diminished, so cardiac output declines despite compensatory tachycardia. There may also be dyspnea caused by bronchoconstriction. In normal humans, circulatory depression is predominant. Without adequate treatment, death may ensue from histamine shock.

In an intact animal, histamine can cause cardiac stimulation, principally the result of reflex mechanisms triggered by the histamine-induced decrease in peripheral vascular resistance. Histamine also has some direct positive chronotropic and inotropic effects on the heart. The receptors responsible are largely H_2 receptors.[22]

Nonvascular smooth muscle

Histamine generally stimulates contraction of nonvascular smooth muscle to a variable degree depending on the species and tissue. In humans, the smooth muscle of the bronchioles and gastrointestinal tract is most sensitive to this action; the smooth muscle of other organs, such as the uterus and bladder, is affected to a much lesser extent. Individuals with asthma are highly susceptible to histamine and may have marked bronchial constriction from doses that would cause only minor increases in the airway resistance of normal subjects.

Exocrine glands

Histamine is a potent stimulator of gastric secretion in most species. Low doses of histamine that have minimal effects on blood pressure elicit near-maximal secretion of acid and pepsin by the gastric mucosa. On the basis of this sensitivity of gastric secretory cells to histamine, the presence of histamine in gastric mucosa and gastric fluid, and the presence of H_2 receptors on the acid-secreting parietal cells, it is accepted that histamine plays a major physiologic role in gastric secretion. This conclusion is strongly supported by the discovery of H_2 receptor antagonists (see later), which block histamine-stimulated gastric secretion and reduce basal secretion and secretion induced by some other physiologic agents, such as acetylcholine and gastrin.

The relationships among histamine and the potent gastric secretagogues acetylcholine and the polypeptide hormone gastrin are complex (see Figure 33-1). As previously noted, histamine is synthesized by the enterochromaffin-like cells in the gastric mucosa, and its release from these cells is triggered by either gastrin or acetylcholine. The fact that H_2 receptor antagonists inhibit stimulation of gastric secretion by histamine, gastrin, or acetylcholine lends support to the possibility that the latter two agents act by releasing histamine from enterochromaffin-like cells, which acts directly on the parietal cells through H_2 receptors.[33] Identification of specific receptors for gastrin and acetylcholine on the parietal cell, plus an ability of gastrin to augment (although moderately) histamine-induced secretion, indicates, however, that gastrin can also cause release of H^+ by acting directly on parietal cells and independently of histamine.

Histamine also stimulates the secretion of catecholamines by the chromaffin cells of the adrenal medulla. This action is of little significance in normal patients, but in patients with pheochromocytoma, release of a large amount of catecholamines occurs. Although histamine can enhance salivary and lacrimal gland secretion, this effect is minimal unless large doses are used.

General Therapeutic Uses

Currently, no valid therapeutic applications exist for histamine. It is of limited use as a diagnostic tool in the assessment of gastric acid production. In this test, histamine is given subcutaneously in a dose (usually 1 mg) that stimulates gastric secretion without causing major effects on blood vessels or smooth muscle. The gastric fluid is subsequently sampled, and its acid content is determined. An isomer of histamine, betazole, can also be used in this test. Betazole has less H_1 receptor activity than histamine and offers the advantage of causing a lesser degree of unwanted side effects for a given degree of gastric stimulation. Pentagastrin, a potent synthetic analogue of gastrin, has essentially supplanted histamine and betazole for the clinical evaluation of gastric secretion. Another use of histamine (in aerosol form) is in testing for nonallergic bronchial hyperreactivity in asthmatics.

Adverse Effects

The toxic effects of histamine are largely predictable on the basis of its pharmacologic actions. In normal individuals, these effects are dose-dependent. The more prominent manifestations of histamine toxicity are cutaneous flushing; hypotension; headache; visual disturbances; dyspnea; and gastrointestinal disturbances such as nausea, vomiting, and diarrhea. Massive doses may lead to shock and circulatory failure. Histamine, even in low doses, may have serious adverse consequences in elderly individuals or patients with cardiovascular disease, asthma, or recent gastrointestinal bleeding.

HISTAMINE ANTAGONISTS

Histamine antagonists, or antihistamines, encompass a large group of compounds with the characteristic ability to block the actions of histamine. These compounds do not alter the formation, release, or degradation of histamine but competitively antagonize it at receptor sites. As described earlier, four groups of antihistamines are now known by their ability to block selectively effects of histamine mediated by the various receptors. These groups of antihistamines are appropriately termed *H_1, H_2, H_3,* and *H_4 receptor antagonists*. The generic

term *antihistamine* is often used to refer to the "classic" antihistamines, or H_1 antagonists.

Early interest in histamine as a mediator of certain pathologic processes of an allergic nature spurred interest in agents that could block histamine. The first such compound, a derivative of phenoxyethylamine, was reported by Bovet and Staub in 1937.[5] Although this substance could adequately protect guinea pigs against injected histamine or anaphylactic shock, it was too toxic for human use. Other, less toxic compounds with antihistaminic activity were immediately sought. By 1946, numerous compounds with therapeutically useful properties had been found, including phenbenzamine, pyrilamine, diphenhydramine, and tripelennamine. During the following 20 years, hundreds of other compounds with antihistaminic properties were developed.

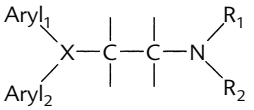
As the pharmacologic properties of antihistamines were studied, it became apparent that they had no effect on histamine-induced gastric acid secretion. In 1972, a potent antagonist of histamine-induced gastric secretion, burimamide, was discovered.[3] The subsequently developed congeners of burimamide—the H_2 receptor antagonists—quickly became an important new class of therapeutic agents and tools for further investigation of the role of histamine in health and disease.

Antagonists of H_3 and H_4 receptors have more recently been identified. In animal studies, specific H_3 receptor antagonists, such as thioperamide, have shown numerous CNS effects, such as increased alertness, improved attention and learning, and antiepileptic effects.[42] Although these pharmacologic effects may have obvious human applications, H_3 and H_4 antagonists have not yet been approved for clinical use in the United States. Specific antagonists of H_4 receptors exert anti-inflammatory effects in vitro and in animals, suggesting a potential use in the treatment of inflammatory disorders.[50,51]

H_1 Receptor Antagonists

Chemistry and classification

Most antihistamines with the ability to block H_1 receptors contain a side chain that resembles the ethylamino group in histamine. These H_1 receptor antagonists, or H_1 antihistamines, can be represented by the following general formula:



In this representation, *aryl* is a heterocyclic aromatic group that may or may not be separated from X by a methylene group. *X* is a carbon, oxygen, or nitrogen atom that connects the side chain to the aryl groups. R_1 and R_2 are usually, but not always, methyl groups. The ethylene group in the side chain may also be part of a heterocyclic system containing nitrogen, as in cyclizine. A general conclusion from examination of structure-activity relationships is that a basic nitrogen atom is essential, whether it exists in an aliphatic side chain, as in diphenhydramine, or in a ring structure, as in meclizine (Table 22-2).

By using the general formula just presented, most H_1 antihistamines can be grouped according to the substitution made at the X position. Six distinct classes are recognized: (1) alkylamines, in which X is carbon; (2) ethanolamines, in which X is oxygen; (3) ethylenediamines, in which X is nitrogen; (4) piperazines, in which X is carbon linked to a piperazine ring; (5) phenothiazines, in which X is nitrogen as part of a phenothiazine nucleus; and (6) piperidines, in which X is carbon linked to a piperidine ring. Levocabastine is a piperidine but does not fit the structural chemistry in the six above-listed categories. Azelastine, used only topically on the nasal mucosa, is a phthalazinone and is structurally unrelated to these other categories.

The chemical structures of representative compounds of each of the major classes of H_1 antihistamines are shown in Table 22-2. Despite their structural heterogeneity, the older antihistamines have only minor differences in pharmacologic properties, and these are mainly in potency, duration of action, and intensity of effects on other systems. In the last two decades, several H_1 antihistamines have been developed that differ from older antihistamines in that they are largely devoid of effects on the CNS.[1,48] Because of this difference, this group of agents, which are predominantly piperidine derivatives and include fexofenadine, levocabastine, and loratadine, are often termed *second-generation antihistamines* to distinguish them from the older, or first-generation, antihistamines. Other second-generation H_1 antihistamines include acrivastine (an alkylamine), cetirizine (a piperazine), and azelastine (a phthalazinone).

Pharmacologic effects

H_1 antihistamines exert various effects. Although the basis of some of these effects is obscure, many clearly result from histamine antagonism. These agents can inhibit the contraction of gastrointestinal and bronchial smooth muscle, the increase in capillary permeability, and the flare and itch components of the "triple response." Although H_1 antihistamines do not block histamine-induced gastric secretion, they do antagonize the increased secretions of the salivary and lacrimal glands and the increased release of epinephrine from the

TABLE **22-2**

Chemical Classification, Representative Structures, and Dosages of Major H_1 Antihistamines—cont'd

CLASS	REPRESENTATIVE COMPOUND* (PROPRIETARY NAME)	USUAL ADULT DOSE (ORAL)	DURATION OF ACTION	SOME OTHER COMPOUNDS IN THE SAME CLASS
Ethanolamines	 **Diphenhydramine hydrochloride (Benadryl, others)**	25-50 mg	6-8 hr	Carbinoxamine maleate (in Carbiset): 4-8 mg, 6-8 hr Clemastine fumarate (Tavist): 1.34-2.68 mg, 8-12 hr Dimehydrinate (Dramamine): 50-100 mg, 4-6 hr Doxylamine succinate (Unisom): 12.5-25 mg, 4-6 hr
Ethylenediamines	 **Tripelennamine citrate (PBZ, others)**	25-50 mg	4-6 hr	Pyrilamine maleate (Nisaval): 25-50 mg, 6-8 hr
Piperazines	 **Meclizine hydrochloride (Bonine, others)**	25-50 mg	24 hr	Buclizine hydrochloride (Bucladin-S): 50 mg, 4-12 hr Cetrizine hydrochloride (Zyrtec): 5-10 mg, 24 hr Cyclizine hydrochloride (Marezine): 50 mg, 4-6 hr Hydroxyzine hydrochloride (Atarax, others): 50-100 mg, 6-24 hr Hydroxyzine pamoate (Vistaril): 50-100 mg, 6-24 hr
Phenothiazines	 **Promethazine hydrochloride (Phenergan)**	12.5-25 mg	4-12 hr	Methdilazine hydrochloride (Tacaryl): 8 mg, 6-12 hr Trimeprazine tartrate (Temaril): 2.5 mg, 6 hr
Piperidines	 **Loratadine hydrochloride (Claritin)**	10 mg	24 hr	Azatadine maleate (Optimine): 1-2 mg, 8-12 hr Cyproheptadine hydrochloride (Periactin)†: 4 mg, 6-8 hr Fexofenadine hydrochloride (Allegra): 60 mg, 12 hr Levocabastine hydrochloride (Livostin): topical Phenindamine tartrate (Nolahist): 25 mg, 4-6 hr
Phthalazinones	 **Azelastine hydrochloride (Astelin)**	274 µg (topical nasal application; per nostril)	8-12 hr	

Second-generation H_1 antihistamines are acrivastine, azelastine, cetirizine, desloratidine, fexofenadine, levocabastine, levocetirizine, and loratadine.
H_1 histamine receptor blockers used in ophthalmology are emedastine, epinastine, ketotifen, and olopatadine.
*Each structural formula is of the free base form.
†Also a serotonin-receptor antagonist.

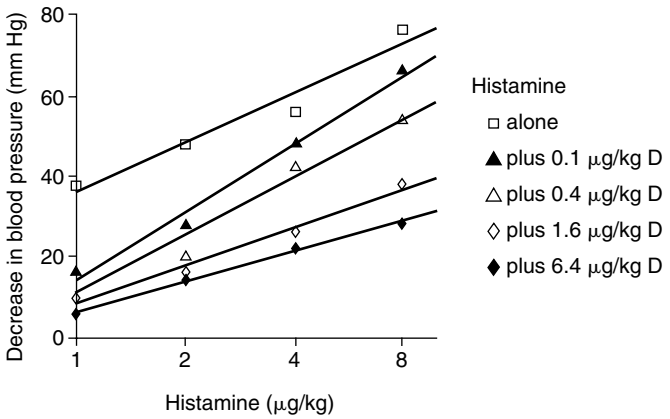

FIGURE **22-3** Log dose-response curves illustrating competitive antagonism of histamine by diphenhydramine (*D*). Decreases in blood pressure (*ordinate*) by graded intravenous doses of histamine (*abscissa*) were determined in anesthetized dogs. The animals received diphenhydramine (0.1 to 6.4 μg/mL) followed by the same graded doses of histamine. (Data from Chen G, Russell D: A quantitative study of blood pressure response to cardiovascular drugs and their antagonists. *J Pharmacol Exp Ther* 99:401-408, 1950.)

adrenal medulla stimulated by histamine. As with many other pharmacologic inhibitors, the basic mechanism of action can be explained in terms of a competitive blockade of receptors; that is, antihistamines seem to interact with the H_1 receptors on the target cell, resulting in a decreased availability of these receptors for histamine. This interaction is reversible, or competitive, because the inhibition produced by a given concentration of antihistamine can be overcome by increasing the concentration of histamine (Figure 22-3).

No evidence indicates that antihistamines interfere with the synthesis, release, or biotransformation of histamine. Cetirizine seems to be unique among antihistamines because it has been reported to have antieosinophilic activity, so it inhibits the late phase of inflammation in addition to the more immediate histaminic effects.[49,52]

The action of H_1 antihistamines in antagonizing histamine is specific; that is, H_1 antihistamines "reverse" the effects of histamine by inhibiting its further action, but they have no directly opposing actions of their own. In contrast, epinephrine nonspecifically antagonizes histamine by exerting its own distinct effects, such as vasoconstriction, bronchodilation, and decreased gastrointestinal motility. This type of antagonism is sometimes referred to as *physiologic*. The distinction is important in understanding why a physiologic antagonist such as epinephrine is a more effective agent than an antihistamine in treating systemic histamine toxicity.

As previously indicated, the bronchial smooth muscle of the guinea pig is exquisitely sensitive to histamine, and low doses can trigger lethal bronchospasm. The prior administration of an H_1 antihistamine such as pyrilamine can protect the respiratory smooth muscle of these animals, however, from a dose of histamine that is more than 100 times the lethal dose. These agents can similarly protect guinea pigs against the effects of released histamine during experimental anaphylaxis. A different situation prevails in humans. Although H_1 antihistamines can antagonize the histamine-induced contraction of human respiratory muscle in vitro, these agents are ineffective in relieving bronchospasm associated with asthma, anaphylaxis, and other allergic reactions. This ineffectiveness is caused partly by the involvement of autacoids other than histamine in mediating allergic bronchospasm in humans. These substances include leukotrienes and kinins, against which classic antihistamines show little antagonism.

In the human vascular system, H_1 antihistamines are effective in antagonizing the increased capillary permeability and consequent edema formation induced by histamine, but their effects on the vasodilation caused by histamine are more complex. H_1 antihistamines can prevent the vasodilation elicited by small doses of histamine; however, a combination of H_1 and H_2 antagonists is required to block large doses. This finding indicates that both receptor subtypes mediate the vascular effects of histamine, with the autacoid having a higher affinity for H_1 receptors.[35,47] The minor direct cardiac stimulation produced by histamine is little affected by H_1 antihistamines because this cardiac stimulation results largely from H_2 receptor stimulation.

Sedation is a common feature of therapeutic doses of all H_1 antihistamines except second-generation agents. It is usually manifested by drowsiness and may be accompanied by lassitude, fatigue, dizziness, and incoordination. Sedation is mediated by the inhibition of H_1 receptors in the brain.[38] The ability to cause sedation varies widely among the available first-generation H_1 antihistamines. The most active are the ethanolamines and phenothiazines, whereas the alkylamines have a low incidence of drowsiness.[46] Another clinically useful CNS effect of first-generation H_1 antihistamines is inhibition of nausea and vomiting, especially associated with motion sickness. These agents also possess mild anti-Parkinson activity. Large doses of first-generation H_1 antihistamines can cause CNS stimulation that may result in convulsions. Some degree of stimulation—restlessness or insomnia—may occasionally be encountered even at therapeutic doses.

The mechanism of the CNS effects of H_1 antihistamines is not fully known, although histamine is present in the brain and is thought to play a role as a neurotransmitter. H_1 receptor antagonists have been shown to block histamine-induced depolarizations in human cortical brain slices[38]; this could explain the sedative effects of antihistamines. Although some degree of tolerance to the sedative effects of H_1 antihistamines usually develops with long-term use, no concomitant decrease in their peripheral antihistaminic effects has been observed. It has been suggested that the anti–motion sickness and the anti-Parkinson activities of H_1 antihistamines are caused by a central cholinergic receptor–blocking action.

Antimuscarinic activity is a feature of most first-generation H_1 antihistamines. The decrease in salivary secretion associated with their use is largely related to this action. Second-generation H_1 antihistamines have little or no antimuscarinic activity. Most antihistamines have some degree of local anesthetic activity. This property is most notable in diphenhydramine, promethazine, pyrilamine, and tripelennamine and has been used clinically in dentistry.[29,53]

Absorption, fate, and excretion

As a group, older H_1 antihistamines are well absorbed after either oral or parenteral administration. The onset of action occurs 15 to 60 minutes after an oral dose. Effects are typically maximal in 1 to 2 hours, with a duration of 4 to 6 hours, although the duration is longer for some agents (see Table 22-2). In contrast, most second-generation H_1 antihistamines have a considerably longer duration of action. Loratadine is transformed to an active metabolite with an average elimination half-time of greater than 24 hours, which allows once-daily dosing.

After absorption, first-generation H_1 antihistamines are widely distributed in body fluids. Loratadine and other second-generation agents cross the blood-brain barrier poorly, however, and are barely detectable in brain tissue.[7] This failure to gain access to the CNS largely explains the nearly complete absence of sedation with these drugs. Levo-

cabastine is a second-generation H_1 antihistamine that is administered topically only.

Although the biotransformation of first-generation H_1 antihistamines has not been studied intensively, the activity of this group seems to be terminated by conversion to inactive metabolites through hydroxylation in the liver.[34] The second-generation antihistamine cetirizine is a metabolite of the first-generation agent hydroxyzine.

Second-generation antihistamines are extensively metabolized in the liver by the CYP3A4 microsomal enzyme (see Chapter 2). In some cases, such as with loratadine, these result in active metabolites.[45] Concurrent administration of other agents metabolized by this same enzyme can reduce the biotransformation of these particular antihistamines. Other second-generation H_1 antihistamines (e.g., acrivastine and cetirizine) are not metabolized to an active form and are largely excreted unchanged in the urine.

General therapeutic uses

The introduction of antihistamines into clinical medicine stimulated great interest in these agents and their application in pathologic states presumed to be caused by histamine release. The early enthusiasm for antihistamines often led to their irrational use in various clinical situations. Although subsequent experience has brought about a better appreciation of the therapeutic indications and limitations of antihistamines, they are still often used when their clinical efficacy is doubtful or when other agents might be more appropriate.

The most prominent use of H_1 antihistamines is in countering the manifestations of various allergic conditions—that is, reactions resulting from antigen-antibody combination in which histamine release occurs. The antihistamines have no effect on the interaction of antigens and antibodies or on the release of histamine that may be triggered by this interaction but act by competitively antagonizing the binding of liberated histamine to its receptor. This mechanism of action has several implications for the therapeutic use of antihistamines. It means that these agents cannot alter the allergic basis of a given disease but can provide relief only from some of the symptoms. It also means antihistamines are most effective when given before the release of histamine. After histamine release has occurred, an antihistamine can reduce only further undesirable effects, in contrast to physiologic antagonists, which can reverse them. Finally, the competitive nature of antihistamine action means that the effectiveness of these agents in a given situation depends on the relative concentrations of agonist and antagonist. When substantial amounts of histamine are released either locally or systemically, the adverse effects of the antihistamine may preclude attainment of a sufficient concentration of antagonist to be clinically effective.

The clinical applications of H_1 antihistamines can be summarized as follows:

1. H_1 antihistamines are generally useful in the treatment of nasal allergies of either a seasonal (e.g., hay fever) or perennial (nonseasonal) nature because they relieve rhinorrhea, sneezing, lacrimation, and itching of the eyes and nasal mucosa.[6] Azelastine is effective for 12 hours when applied topically to the nasal mucosa.[27] This route of administration minimizes unwanted systemic effects such as drowsiness. In chronic or vasomotor (nonallergic) rhinitis, H_1 antihistamines are less effective.[46] Antihistamines are often combined with decongestants such as pseudoephedrine for the management of allergic symptoms in the upper respiratory tract.
2. Numerous allergic dermatoses can be treated with H_1 antihistamines.[14,46] Acute and chronic urticaria responds favorably to these agents. Angioedema also responds to antihistamine therapy, although a severe attack involving the larynx almost certainly requires epinephrine for proper management of this serious complication. H_1 antihistamines may be useful in controlling the itching associated with eczematous pruritus, atopic or contact dermatitis, and insect bites. In some situations (e.g., atopic dermatitis), topical corticosteroids are usually more effective, however. Although antihistamines are topically effective in treating pruritus and urticaria, topical application can also cause an allergic dermatitis.
3. In systemic anaphylaxis, H_1 antihistamines have no primary therapeutic role because they cannot control either the marked hypotension or the bronchospasm associated with a severe anaphylactic reaction. Here the agent of choice is the physiologic antagonist epinephrine. Antihistamines and corticosteroids may be given parenterally as an adjunct to the physiologic antagonist, but only after life-threatening problems are controlled. Antihistamines are of some value in treating the itching and urticarial lesions of serum sickness, although other manifestations such as arthralgia are little affected.
4. H_1 antihistamines have little effect on the acute manifestations of bronchial asthma. The pathogenesis of bronchial asthma is complex, and, as indicated earlier and in Chapter 32, mediators of bronchial muscle constriction other than histamine are involved. β-Adrenergic receptor agonists and corticosteroids are the primary drugs used to alleviate an acute asthmatic episode. Antihistamines have been used in an attempt to decrease preasthmatic cough in children, although the efficacy of this therapy is not established.
5. H_1 antihistamines, particularly chlorpheniramine, combined with nasal decongestants and analgesics, are widely used for symptomatic relief of the common cold. There are dozens of such preparations on the market, which indicates the popularity of these nostrums. Unless the cold is superimposed on an allergic rhinitis, any relief obtained from this combination stems largely from the drying of the mucosa caused by the anticholinergic action of the antihistamine and the actions of the vasoconstrictor and analgesic. Antihistamines alone are of no proven value in either preventing or shortening the duration of the common cold.
6. A CNS action of first-generation H_1 antihistamines can be used to prevent or treat nausea and vomiting induced by motion. In general, these agents exert less anti–motion sickness activity than do anticholinergics such as scopolamine. The effectiveness of individual antihistamines varies widely; promethazine, diphenhydramine, dimenhydrinate, and cyclizine are probably the most effective of all. The more effective agents also tend to have greater sedative effects, however, a fact that must be considered in selecting an anti–motion sickness drug. H_1 antihistamines may also be useful in counteracting nausea and vomiting in vestibular disturbances such as Ménière's disease and other forms of vertigo. They are less effective than prochlorperazine or ondansetron for the control of nausea and vomiting after general anesthesia or associated with pregnancy, malignant diseases, radiation sickness, and various drugs.
7. Various over-the-counter (OTC) preparations sold as hypnotics include H_1 antihistamines because of their sedative effect. Because the amounts of antihistamine in such preparations are low, they are of limited value in inducing sleep. Even in higher doses the antihistamines are less effective sedatives, however, than benzodiazepines and other sedative-hypnotics. Promethazine is used as an adjunct to general anesthesia to produce drowsiness and to prevent or control nausea and vomiting induced by anesthetic agents and opioid analgesics.

8. Some miscellaneous uses of H_1 antihistamines include reduction of tremors and muscle rigidity in Parkinson's disease; treatment of headaches of unknown cause; and control of nonhemolytic, nonpyrogenic reactions to blood transfusion. They are also useful in relieving acute dystonias caused by phenothiazines and other neuroleptics.

Uses in dentistry

H_1 antihistamines are used in dentistry primarily for their CNS actions, rather than for their specific antihistaminic effects. Promethazine, hydroxyzine, and diphenhydramine may be used in minimal-moderate sedation procedures and as premedication for deep sedation and general anesthesia (see Chapters 18 and 48). The sedative effect is increased by the concomitant administration of an opioid analgesic; meperidine and fentanyl are commonly used for this purpose.[25] The preoperative administration of these agents may also cause some inhibition of salivary and bronchial secretions, although more effective anticholinergic drugs should be used if control of secretions is essential. A particular benefit of antihistamines is their ability to reduce postoperative nausea and vomiting in the outpatient setting.

Although H_1 antihistamines have some local anesthetic activity, and their feasibility as local anesthetic agents for dental procedures has been shown, they have not been used much for this purpose because far more effective agents (e.g., lidocaine) are available. The local anesthetic activity of antihistamines may be useful when a patient is allergic to conventional local anesthetics.

H_1 antihistamines can be used as secondary agents in the management of systemic anaphylactic reactions that may occur in the course of dental therapy. They can also be valuable in the treatment of allergic lesions of the oral mucosa and as adjuncts in treating angioneurotic edema of the orofacial region.

Adverse effects

At therapeutic doses, H_1 antihistamines are relatively free of serious adverse reactions. The most common side effects result from CNS depression, which is generally manifested as drowsiness, diminished alertness, lethargy, and decreased motor coordination. The incidence of sedation varies with individual agents, but in general the ethanolamines and the phenothiazines are the most sedating, the ethylenediamines are intermediate, and the alkylamines and piperazines are the least sedating. As previously mentioned, loratadine and other second-generation H_1 antihistamines are essentially devoid of sedative or other CNS effects. Sedation caused by antihistamines may be a serious liability in a patient whose daily activities require mental alertness and coordination. In such cases, a reduction of dosage or substitution of agents may be necessary. Gastrointestinal disturbances—nausea, vomiting, and epigastric distress—also occur but are uncommon. The anticholinergic properties of antihistamines occasionally cause insomnia, tremors, nervousness and irritability, palpitation, tachycardia, dry mouth, blurred vision, urinary retention, and constipation. The incidence of these effects is dose-related.

Serious disturbances of cardiac rhythm have occurred in patients receiving astemizole or terfenadine, second-generation H_1 antihistamines of the piperidine class.[55] These arrhythmias largely involve prolongation of the QT interval, resulting in polymorphic ventricular tachycardia (torsades de pointes) (see Chapter 24), the consequences of which can be fatal. Such cardiotoxic effects usually occur when plasma concentrations of the drugs are increased as a result of either excessive doses or altered hepatic metabolism. The latter can occur as a result of impaired liver function or the concurrent administration of certain drugs, especially the macrolide antibiotics (erythromycin and, to a lesser extent, clarithromycin) and azole antifungals (ketoconazole and itraconazole) that bind to the CYP3A4 enzyme and interfere with metabolism of antihistamines. Because of this uncommon but serious problem, terfenadine and astemizole were voluntarily withdrawn from the U.S. market in the past decade. Although loratadine is metabolized by CYP3A4, it does not seem to increase the QT interval alone or in the presence of drugs that interact with terfenadine and astemizole. Fexofenadine, cetirizine, and acrivastine have not been associated with these arrhythmias or drug interactions.

Large doses of antihistamines can cause marked stimulation of the CNS manifested by hallucinations, excitement, and motor disturbances such as tremors and convulsions. Deaths from overdosage almost invariably occur outside a therapeutic setting (e.g., accidental poisoning in the home).

Allergic reactions to H_1 antihistamines can occur; they are more frequent after topical application than after oral administration and can complicate the treatment of allergic lesions of the skin or oral mucosa. Allergic reactions can take the form of urticarial, eczematous, bullous, or petechial rashes; fixed drug eruptions; or, more rarely, anaphylaxis.

As with most drugs, various blood dyscrasias (hemolytic anemia, agranulocytosis, pancytopenia, and thrombocytopenia) have been reported after the use of antihistamines. Patients receiving long-term antihistamine therapy should be periodically monitored. Although certain piperazine H_1 antihistamines have been shown to be teratogenic in some laboratory animal models, there is no clinical evidence to indicate that antihistamines cause birth defects in humans. Use of these drugs should be avoided, however, during the first trimester of pregnancy. Doxylamine was suspected to cause birth defects when used as an antinausea drug during pregnancy. Several studies have shown no increase in birth defects with doxylamine, although it cannot be ruled out that the drug is weakly teratogenic.

Because of their sedative properties, H_1 antihistamines can potentiate the CNS depressant effects of other agents, such as barbiturates, opioid analgesics, general anesthetics, and alcohol. Although such an interaction may be deliberately sought, as in the preanesthetic use of promethazine, these combinations should otherwise be avoided or monitored closely. Because antihistamines have antimuscarinic properties, they can produce manifestations of excessive cholinergic blockade if given during therapy with other anticholinergic drugs. Such manifestations (e.g., dry mouth, constipation, blurred vision) are more likely to be troublesome than serious. Long-term use can have important consequences; if dry mouth persists, it can lead to a higher incidence of caries. Second-generation H_1 antihistamines do not have antimuscarinic effects.

Antihistamines are variably excreted in breast milk. Because infants, especially newborns and premature infants, are at higher risk of adverse effects, the use of antihistamines in nursing women should be avoided. Antihistamines, similar to other anticholinergic drugs, may inhibit lactation.

Preparations and doses of drugs used in dentistry

The therapeutic utility of H_1 antihistamines can be encompassed by relatively few agents. Because numerous preparations are available, the clinician has the task of selecting the most effective drug with the fewest side effects. Because there are few quantitative data on which to base this choice, the clinician should select one or two well-known representatives of each class and become familiar with their therapeutic indications and limitations. These selections can be modified when convincing evidence of an advantage offered by another agent becomes available. Because they lack sedative and anticholinergic effects, second-generation H_1 antihistamines seem to meet this criterion. These drugs are expensive, however, and are often best reserved for patients who are intolerant

of established first-generation drugs. In dentistry, the unique pharmacologic profile of second-generation agents precludes them from most applications because sedative and anticholinergic effects are usually desirable outcomes.

Oral doses of examples of each of the major classes of H_1 antihistamines are given in Table 22-2. For more prescribing information, the reader should consult a standard reference for this purpose.[30]

H_2 Receptor Antagonists

Chemistry and classification

H_2 receptor antagonists, or H_2 antihistamines, are basically structural analogues of histamine (Figure 22-4). Two changes in the histamine molecule are necessary to achieve H_2 receptor–blocking activity.[13] One is modification of the imidazole ring or its substitution by a furan or thiazole ring. A second modification is the presence of a flexible connecting chain linked to a polar substituent capable of hydrogen binding.

The first compound discovered to have the ability to block H_2 receptors was burimamide.[3] Its poor oral absorption and partial-agonist properties led to a search for active congeners. The first of these to be tested was metiamide.[4] Although metiamide is orally effective, it caused a reversible neutropenia during clinical trials. Because the thiourea moiety in the side chain of metiamide was believed to be responsible for this adverse effect, the thiourea group was replaced by a cyanoguanidine group. The resultant compound, cimetidine, became available for clinical use in 1977.[20] Shortly thereafter, ranitidine was approved. It differs from cimetidine and earlier H_2 antagonists in that it is not an imidazole derivative but instead contains a furan ring. Later, two other H_2 receptor antagonists, famotidine and nizatidine, were approved for use. In contrast to either cimetidine or ranitidine, famotidine and nizatidine are based on a thiazole ring structure (see Figure 22-4).

Several differences between H_1 and H_2 antihistamines are obvious. H_1 antihistamines have aryl or heteroaryl rings that are highly lipophilic and bear little resemblance to the imidazole ring of histamine. Their side chains usually have an ammonium group and are mostly positively charged at physiologic pH. In contrast, H_2 antihistamines have a modified imidazole or other heterocyclic ring and a polar but uncharged side chain. H_2 antihistamines are hydrophilic; this property may account for their weak CNS and local anesthetic properties.[13]

Pharmacologic effects

H_2 antihistamines are potent competitive antagonists of histamine. Because H_2 receptors are strongly implicated in the secretory function of the gastric mucosa, these compounds cause a marked reduction in H^+ output, pepsin activity, and the total volume of gastric secretion (Figure 22-5). Inhibition of secretion can be attained in the fasting state and after stimulation with food, histamine, betazole, pentagastrin, or caffeine.

Although H_2 receptors are found in many tissues, including vascular and bronchial smooth muscle, H_2 antihistamines have few important effects on physiologic function other than gastric secretion. In certain situations, such as antagonism of a histamine-induced hypotension, a combination of H_1 and H_2 antihistamines is more effective than either alone, which suggests that in such situations H_1 and H_2 receptors are involved.[35]

Absorption, fate, and excretion

Except for famotidine, H_2 antihistamines are rapidly and completely absorbed after oral administration. All undergo a variable degree of first-pass metabolic degradation in the liver, resulting in an oral bioavailability of approximately 50% for cimetidine, ranitidine, and famotidine and more than 90% for nizatidine. After absorption, H_2 antihistamines are generally distributed in the total body water. Therapeutic concentrations are reached in approximately 1 to 2 hours. The elimination half-life is 2 to 3.5 hours except for nizatidine, which has

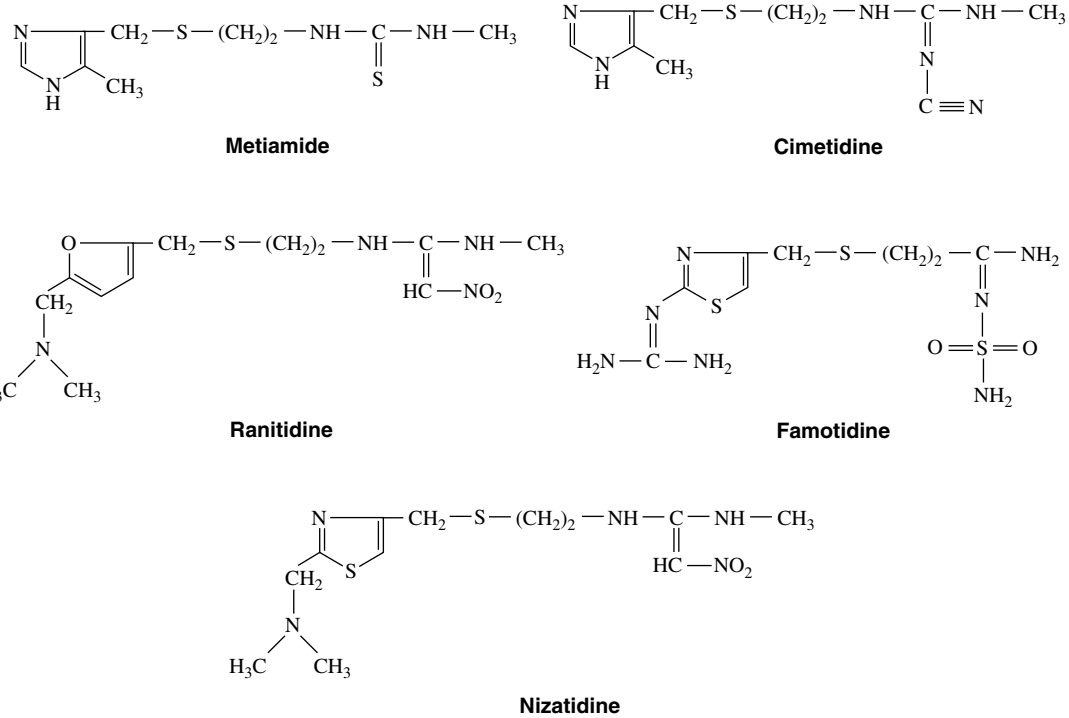

FIGURE **22-4** Structural formulas of some H_2 receptor antagonists.

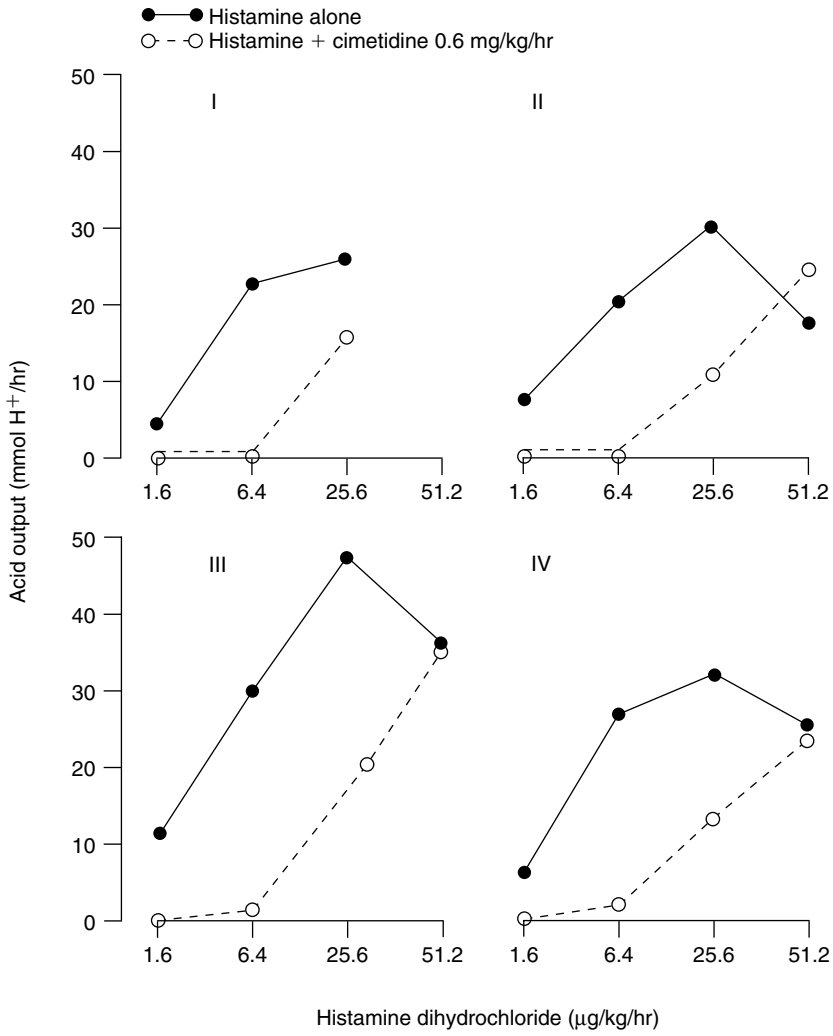

FIGURE **22-5** Inhibition of histamine-stimulated gastric acid production by cimetidine in humans. Histamine dihydrochloride in doses of 1.6 to 51.2 μg/kg/hr was infused intravenously with or without cimetidine at a dose of 0.6 mg/kg/hr for 105 minutes. When cimetidine was given, its administration was begun 15 minutes before the histamine infusion was started. Gastric juice was collected at 15-minute intervals and analyzed for acid concentration; the last four 15-minute intervals were used to establish the dose-response curves. Data shown are individual results from four normal adult subjects (*I-IV*). (From Aadland E, Berstad A: Inhibition of histamine- and pentagastrin-stimulated gastric secretion by cimetidine in man. In Creutzfeldt W, editor: *Cimetidine,* Amsterdam, 1978, Excerpta Medica Foundation.)

a half-life of 1 to 1.5 hours. Urinary excretion of the parent compound accounts for 60% to 70% of the injected dose of each drug. The remainder is oxidized, the sulfoxide being a major metabolite, and excreted in the urine and feces. Cimetidine (300 mg), the least potent agent, reduces basal gastric acid secretion by at least 80% for 4 to 5 hours, whereas famotidine (20 mg), the most potent, lasts for 10 to 12 hours. Because of the relative safety of these drugs, increased doses can be used to extend the duration of effect.

General therapeutic uses

It has now been shown that *Helicobacter pylori* plays a role in the pathogenesis of most peptic ulcer disease. This organism is a gram-negative rod that can colonize the mucosal surface of the stomach and evoke an inflammatory gastritis. Two lines of evidence implicate *H. pylori* in peptic ulcer disease. First, it is found in most cases (70% to 90%) of active gastric or duodenal ulcers. Second, eradication of the organism by appropriate antimicrobial therapy often leads to remission of symptoms, healing of ulcers, and prevention of recurrence. The fact that *H. pylori* may be found in healthy individuals suggests that other risk factors are involved also in the genesis of this disease. These observations have altered conventional therapy of peptic ulcer disease; anti-infective measures aimed at *H. pylori* are now frequently combined with control of gastric acid secretion by H_2 antihistamines. The reader is referred to a consensus review for a more detailed discussion of the association between peptic ulcer disease and *H. pylori* infection and the anti-infective strategies for elimination of this putative pathogen.[32] Chapter 33 also discusses antibiotic therapy for *H. pylori*.

H_2 antihistamines are used clinically for their marked ability to inhibit basal and stimulated secretion of gastric acid. They are approved for use in a wide variety of gastrointestinal disorders in which reduction of acid secretion may relieve symptoms, lead to healing, and prevent recurrence of previously resolved disease. Specifically approved indications include duodenal ulcer disease (active or in maintenance), active gastric ulcer disease, gastroesophageal reflux disease, and pathologic hypersecretory conditions (e.g., systemic mast cell disease and Zollinger-Ellison disease).[12,37] H_2 antihistamines are generally given orally, but parenteral forms (except for nizatidine) are also available for acute suppression of gastric acid secretion. Oral dosage may be divided into once-daily or twice-daily administration; if once daily, the dose is best given at bedtime to block nocturnal gastric acid secretion.

A major use of H_2 antihistamines is treatment of active benign gastric ulcers and prophylaxis and treatment of active duodenal ulcers. All the currently available agents (cimetidine, ranitidine, famotidine, and nizatidine) have been shown to be equally effective in appropriate doses in suppressing gastric acid secretion (by up to 90%) and accelerating the healing of duodenal and, to a lesser extent, gastric ulcers.[11] Healing of ulcers generally occurs within 2 to 4 months of therapy; if healing is not achieved in this period, further therapy is unlikely to be successful. Although cimetidine and

other H_2 antihistamines have been used to treat upper gastrointestinal bleeding caused by liver disease, such as cirrhosis, little evidence supports their effectiveness in these conditions. Finally, H_2 antihistamines may be used before general anesthesia, particularly in patients with gastrointestinal obstruction, to elevate gastric pH and reduce the danger of aseptic pneumonia if gastric contents are aspirated during induction.

After their introduction more than 20 years ago, H_2 receptor antagonists became one of the most widely prescribed groups of drugs in the world. Their use has declined considerably in recent years because of the introduction of proton pump inhibitors (see Chapter 33). The U.S. Food and Drug Administration now allows OTC marketing of all four currently available H_2 antihistamines for symptomatic relief of occasional heartburn, acid indigestion (hyperchlorhydria), or "sour" stomach. This decision reflected the extensive use of H_2 antihistamines previously dispensed by prescription for nonapproved conditions, while acknowledging the relative safety of these agents in unsupervised use. Such OTC use may risk delaying diagnosis of more serious disease, however, such as peptic ulcer or gastric cancer.

As noted earlier, the management of gastroesophageal reflux disease and gastroduodenal ulcers currently relies mostly on proton pump inhibitors because of their superiority in the more clinically significant forms of these disorders. Consequently, the prescription use of H_2 antihistamines has declined. Because of their more rapid onset of action and lower cost, H_2 antihistamines are still preferred for patient-based treatment of mild or infrequent symptoms of acid-peptic disorders.

Adverse effects

The initial impression that cimetidine was generally free of serious adverse effects has been validated by the passage of time and extensive clinical use. More recently introduced H_2 antihistamines seem to be similarly well tolerated by most patients. It has also become apparent that cimetidine and, to a lesser extent, other H_2 antihistamines can cause various toxic reactions and side effects.[26,40] Most untoward responses seem to have no obvious relation to blockade of H_2 receptors. This assumption may simply result from an incomplete understanding of the presence and function of H_2 receptors in tissues other than the gastric mucosa.

The most common adverse effects of cimetidine are manifested in the CNS. These are highly variable and range from minor symptoms (dizziness, lethargy, and fatigue) to more serious disturbances (mental confusion, delirium, focal twitching, hallucinations, and seizures). The CNS effects often seem to be dose-related and are most commonly seen in elderly patients or patients with impaired liver or kidney function.

Cimetidine exerts many effects on endocrine function that are generally minor and reversible on cessation of therapy. The most notable of these is gynecomastia; others are elevation of serum prolactin concentrations, galactorrhea, loss of libido, impotence, and reduction in sperm counts. Small but definite increases in serum creatinine concentrations occur in most patients treated with cimetidine. This effect is not associated with other changes in renal function and ceases when the drug is withdrawn. The depression of granulocytes associated with metiamide does not seem to be a problem with cimetidine, but transient leukopenia, granulocytopenia, and thrombocytopenia have been reported. It is difficult to implicate cimetidine as a direct bone marrow suppressant because the cases reported almost always involve the concomitant use of other drugs or the existence of other serious systemic diseases. Although cimetidine enhances cell-mediated immune reactions, no evidence suggests that this phenomenon is related to any of the observed clinical responses.

The occurrence of gastric cancer in patients treated with cimetidine has led to the suggestion that the agent may be carcinogenic. This possibility has not been proved, and present information is insufficient to label cimetidine as a carcinogen.

Although cimetidine initially seemed to have no significant drug interactions, subsequent clinical reports and laboratory studies indicate that this is not the case. Cimetidine has been shown to increase blood concentrations of numerous drugs, including anticoagulants of the warfarin type, tricyclic antidepressants, various benzodiazepines, phenobarbital, theophylline, propranolol and other β-adrenoceptor blockers, Ca^{++} channel blockers, lidocaine, estradiol, and phenytoin, creating a risk of toxicity. The basis of these interactions seems to be competitive inhibition by cimetidine of the hepatic mixed-function oxidase enzymes responsible for the metabolism of these drugs.[15] Also, a cimetidine-induced decrease in hepatic blood flow may depress the entry of drugs into the liver and slow metabolism. Patients receiving cimetidine together with any from a long list of drugs should be carefully monitored; if appropriate, reduction of dosages or use of alternative agents should be considered.

Ranitidine, famotidine, and nizatidine seem to have fewer adverse effects than cimetidine. These drugs do not exert significant antiandrogenic effects, and they do not influence serum prolactin concentrations. Impotence and gynecomastia do not occur with their use. Mental disturbances are less likely with these drugs, and they have not been reported to elevate serum creatinine concentrations. Because the binding of these agents to cytochrome P450 enzymes is much less firm than that of cimetidine, they do not significantly inhibit the microsomal metabolism of other drugs.

ANTIHISTAMINES

Nonproprietary (generic) name	*Proprietary (trade) name*
H_1 receptor antagonists—first-generation	
Alkylamines	
Brompheniramine	In Dimetane, Bromphen
Chlorpheniramine	Chlor-Trimeton, in Teldrin
Dexbrompheniramine	In Disobrom, in Drixoral
Dexchlorpheniramine	Polaramine
Pheniramine	In Dristan, in Triaminic
Triprolidine	Actidil, Tripohist
Ethanolamines	
Clemastine	Tavist
Dimenhydrinate*	Dramamine, Marmine
Diphenhydramine	Benadryl, Sominex
Doxylamine	Unisom
Carbinoxamine	Palgic, in Rondec
Phenyltoloxamine	In Comhist LA, in Phenylgesic
Ethylenediamines	
Pyrilamine	In Midol Complete
Tripelennamine	PBZ
Piperazines	
Buclizine	Bucladin-S
Cyclizine	Marezine
Hydroxyzine	Atarax, Vistaril
Meclizine	Antivert, Bonine

ANTIHISTAMINES—cont'd

Nonproprietary (generic) name	*Proprietary (trade) name*
Phenothiazines	
Methdilazine	Tacaryl
Promethazine	Phenergan
Piperidines	
Azatadine	Optimine
Cyproheptadine	Periactin
Ketotifen†	Zaditor
Phenindamine	Nolahist
Others	
Emedastine†	Emadine
Epinastine†	Elestat
Olopatadine†	Patanol
H_1 receptor antagonists—second-generation (nonsedating)	
Alkylamine	
Acrivastine	In Semprex-D
Piperazines	
Cetirizine	Zyrtec
Levocetirizine	Xyzal
Piperidines	
Desloratadine	Clarinex
Fexofenadine	Allegra
Levocabastine†	Livostin
Loratadine	Claritin
Phthalazinone	
Azelastine‡	Astelin, Azalex
H_2 receptor antagonists	
Cimetidine	Tagamet
Famotidine	Pepcid
Nizatidine	Axid
Ranitidine	Zantac

*The chlorotheophylline salt of diphenhydramine.
†For topical ophthalmic use.
‡For topical use.

CHAPTER 23

Drugs for Treating Orofacial Pain Syndromes

ROBERT L. MERRILL

PHARMACOLOGY AND CHRONIC PAIN

The management of chronic orofacial pain, as compared with acute pain, requires an in-depth knowledge of pharmacology and pharmacotherapy because chronic pain disorders are a heterogeneous group of conditions with various pathologic mechanisms and characteristics requiring diverse families of medications for treatment. Dentists do not generally use these medications because dentistry has traditionally focused on acute pain problems. The pharmacologic characteristics of opioids are discussed in Chapter 20, and the pharmacologic characteristics of acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs) are discussed in Chapter 21. Treatment of acute pain in dentistry is addressed in Chapter 47.

With more recent advances in understanding chronic pain disorders and recognition that these disorders affect the orofacial region, dentists are now being educated to manage chronic pain and use medications traditionally used only in a medical setting. This chapter reviews the medications used for chronic orofacial pain disorders and relates them to known or putative disorders and pain mechanisms.

When a patient is evaluated for chronic orofacial pain, the clinician must determine which of various potential conditions may be the source of the pain. In general, after eliminating intracranial and extracranial sources, the clinician has narrowed the differential diagnosis to musculoskeletal, neurovascular, and peripheral or central neuropathic pain, or combinations of these. These categories of pain have different pathophysiologic mechanisms and require different treatment modalities or strategies. Intertwined with the pain issues are psychological issues that have developed in conjunction with chronic pain. These issues must be dealt with to optimize treatment of pain and obtain a beneficial outcome.

Often medications used to treat one condition may be useful for another. Tricyclic antidepressants (TCAs), used to treat depression, are useful in prophylaxis of migraine and may be the most effective drugs for treating certain neuropathic or musculoskeletal pain disorders. In addition, medications may be used differently in each of the pain categories. To understand chronic orofacial pain, the clinician needs to understand the mechanisms behind the various conditions because this knowledge may be helpful in choosing the medications that would be most beneficial for the patient. This chapter reviews the medications used to treat these categories of chronic pain and elaborates on the general and specific mechanisms of action, if known, for each of the medications listed. This chapter does not discuss the use of opioids for chronic pain other than to indicate that in cases of intractable pain resulting from cancer or other conditions such as chronic neuropathy resulting from failed temporomandibular joint (TMJ) surgery, long-term use of opioids may be the only option for helping the patient, although this is rare because opioids are generally less effective in treating neuropathic pain than several other drugs.

SEROTONIN (5-HYDROXYTRYPTAMINE)

To understand chronic pain and its pharmacologic management, it is necessary to understand the 5-hydroxytryptamine (5-HT) system and its impact on pain modulation. Besides chronic pain, alteration in 5-HT function has been implicated in numerous other clinical conditions, including affective disorders, obsessive-compulsive disorders, schizophrenia, anxiety states, phobic disorders, eating disorders, migraine, and sleep disorders. Serotonin receptors are found on presynaptic and postsynaptic neurons. The two key presynaptic neurons are 5-HT_{1A} and 5-HT_{1D}. The postsynaptic 5-HT receptors include 5-HT_{1A}, 5-HT_{1D}, 5-HT_{2A}, 5-HT_{2C}, 5-HT_{3}, and 5-HT_{4}. Presynaptic receptors function as autoreceptors, controlling the release of serotonin and serotonergic action potentials. The 5-HT_{1A} receptor is a somatodendritic autoreceptor that slows action potentials. The presynaptic 5-HT_{1D} autoreceptor detects 5-HT being released into the synaptic cleft and inhibits further release; the 5-HT_{1D} receptor is also called a *terminal autoreceptor*.

A wide range of drugs affects 5-HT neurotransmission, including antidepressants (TCAs, selective serotonin reuptake inhibitors [SSRIs], and heterocyclic antidepressants), hallucinogens, anxiolytics, antiemetics, antimigraine agents, atypical antipsychotics, and appetite suppressants. Many other drugs not generally considered to affect the 5-HT system nevertheless have an assumed effect on 5-HT receptors because of the influence they have on conditions that are linked to 5-HT dysregulation, such as migraine.

Historical Aspects of Serotonin

Since 1868, serum *(sero-)* from blood clots was known to possess a substance that caused blood vessels to constrict, increasing their smooth muscle tone *(-tonin)*. Subsequent physiologic studies of this vasoconstrictive activity vacillated between some unknown substance and epinephrine as the cause. Eventually, the issue was clarified when it was observed that the serum constricted frog vascular and rabbit intestinal preparations, whereas epinephrine caused only relaxation of the gut. Because no evidence of epinephrine was found in the blood plasma, it was assumed that vasoconstriction was caused by a substance in the coagulated blood, and by the early 1900s the source of that substance was identified with platelets.

Janeway and associates[20] did a thorough investigation of the vasoconstrictive substance and noted that it was not present in uncoagulated or citrated blood, that it was definitely associated with platelets, that it was soluble in water more than ether or chloroform, and that the factor did not depend on the clot formation but on the disintegration of the platelets in the clot. The substance itself was eventually isolated and named *serotonin* by Rapport and colleagues in 1948.[36] Shortly after this, Rapport and colleagues identified the agent as 5-HT, and Hamlin and Fischer[18] reported synthesizing it in 1951.

Meanwhile, in Italy, in a separate series of studies, Erspamer and Asero[8] isolated a substance from the mucosa of rabbit stomach and found that it was abundant in the enterochromaffin cells of the gut, could be extracted with alcohol and acetone, was an amine that affected smooth muscle, and was deactivated by deamination. Erspamer and Asero named it *enteramine*. By 1952, serotonin and enteramine had been chemically identified as 5-HT, eventually leading to international wrangling over the naming of 5-HT. It was argued that "enteramine" was inaccurate because the substance was found in places other than the gut, and "serotonin" was equally inadequate from the points of origin and pharmacologic action. In 1986, when the International Serotonin Club was organized, American researchers prevailed over the European contingent in naming the substance *serotonin* by arguing that serotonin was the most widely accepted name, 5-hydroxytryptamine was too long, and 5-HT was only an abbreviation (but one used here).

5-HT and Pain

Stimulation of the periaqueductal gray (PAG) was shown to modulate nociception on a spinal level.[28] This effect is known as *stimulation-produced analgesia (SPA)*. Although a number of areas have been studied in animals, human studies of necessity have been limited. In humans, stimulation of the midbrain region of the PAG and areas slightly more rostral in the periventricular gray matter of the hypothalamus are known to produce SPA. Neurosurgeons were able to show SPA in humans by stimulating the equivalent human midbrain sites. Researchers had determined that electrical stimulation of brainstem PAG produced analgesia in animals. Although the exact boundaries of the responsive area were not clearly defined, the sites most responsive to SPA were: ventral to the midbrain cerebral aqueduct; in the PAG; sites lateral to this structure; the rostroventral medulla (RVM), including the midline nucleus raphe magnus (NRM) and reticular formations; the hypothalamus; the frontal lobe; and the spinal cord. Areas outside of the midbrain have not been systematically studied.

Most of the projections from the RVM/PAG are tryptaminergic. Injection of morphine in the PAG also has a similar antinociceptive effect and is thought to be mediated by activation of a raphe-spinal pathway. Other studies have implicated descending 5-HT fibers and other non–5-HT–containing fibers in this process. Increased production of 5-HT in the bulbospinal 5-HT neurons supports the role of 5-HT in modulation of pain in these pathways. Studies of the raphe pathways have confirmed that with such stimulation there is a concomitant increase in 5-hydroxyindoleacetic acid (5-HIAA), a major metabolite of 5-HT, in the dorsal horn, implicating activation and degradation of 5-HT in the process.

Anatomic Distribution

5-HT is a biogenic monoamine and is widely distributed throughout the plant and animal kingdom. In mammals, the highest concentrations are found in the enterochromaffin cells of the gastrointestinal mucosa, central nervous system (CNS), and blood platelets. The structure of 5-HT is shown in Figure 23-1. Its most notable features are the hydroxyl group on position 5 of the indole nucleus and the primary amine nitrogen that can accept a proton, making the compound hydrophilic and unable to pass the blood-brain barrier easily. Rapport and colleagues[36] found the substance in the brain, indicating that it must be synthesized and perform some unidentified function there. It was subsequently assumed that 5-HT was associated with psychiatric disorders such as depression and schizophrenia when it was shown that the psychedelic drug lysergic acid diethylamide (LSD) antagonized 5-HT function. 5-HT is now known to be involved in many behavioral and psychiatric disorders, such as schizophrenia, obsessive-compulsive disorder, depression, and anxiety, and drugs that have an effect on the 5-HT system have been beneficial in treating these disorders (see Chapter 12).

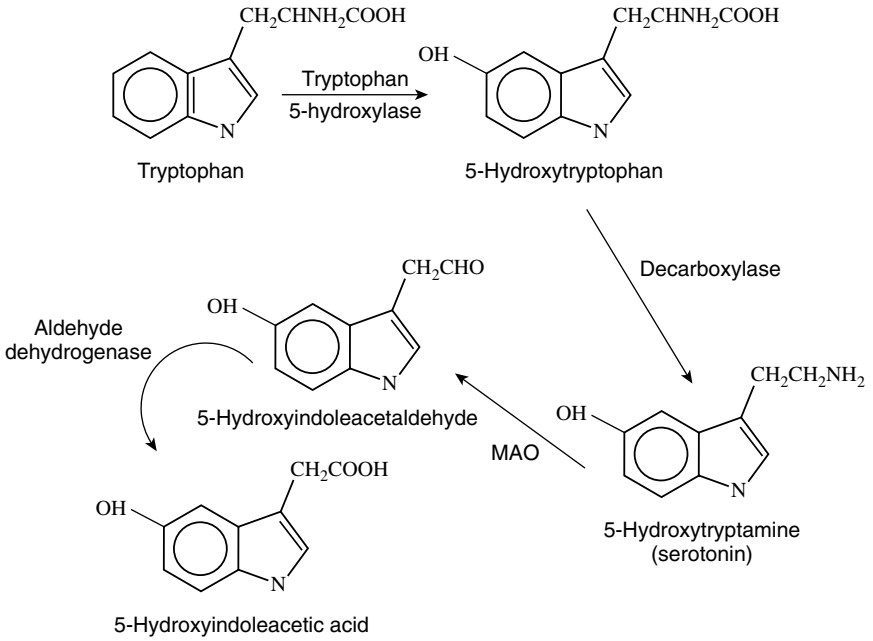

FIGURE **23-1** Biosynthesis and metabolism of serotonin. *MAO,* Monoamine oxidase.

Despite earlier suggestions that 5-HT was a neurotransmitter synthesized in the brain, the actual localization of 5-HT neurons was not determined for at least 10 more years. By using lesioning and fractionation techniques, 5-HT was grossly associated with specific neuronal elements, but it was impossible to observe the relationship directly until fluorescence histochemical techniques were developed. This process had inherent problems, however, that made identification a significant challenge. Dahlström and Fuxe,[7] using immunocytochemical techniques, localized 5-HT–associated neurons in nine discrete clusters of cells along the midline of the upper brainstem and pons. These 5-HT–containing cell bodies, designated *B1* to *B9*, corresponded for the most part to the dorsal raphe nuclei. Only approximately 40% to 50% of the dorsal raphe nuclei are serotonergic neurons, and some serotonergic nuclei are found outside the midline raphe nuclei area, although the major brain concentration is in the dorsal raphe nuclei.

Additional studies have shown that the lateral and dorsolateral pontine tegmentum, which contain many noradrenergic neurons, are also involved in nociceptive modulation when stimulated, and these sites send projections to the PAG, the RVM, and the spinal cord. The projections from the lateral and dorsolateral pons are noradrenergic and possess important α_2-adrenergic receptors. In animal studies, norepinephrine (NE) applied directly to the spinal cord blocks response to nociception through selective inhibition of the nociceptive dorsal horn neurons (see Chapter 20). Lesioning the white matter of the dorsolateral funiculus of the spinal cord blocks the inhibitory effect of SPA and confirms the existence of a descending modulatory pathway that travels through the dorsolateral funiculus. Further studies of the dorsolateral funiculus projections to the spinal cord have found that most of the brainstem projections arise in the RVM and dorsolateral pons, with few projections from the PAG. This finding implies that the PAG projections must be relayed through the RVM. This has been confirmed by studies showing that the major neuronal input to the RVM is from the PAG and adjacent structures, and lesioning or blocking RVM cells eliminates the analgesic effect obtained from PAG stimulation.

Anti–5-HT antibody labeling has identified 5-HT in all dorsal horn laminae, but the highest densities are found in laminae I, II, IV, V, and X. The RVM projections terminate mainly in laminae I, II, and V. These areas are important for pain because this is where the central terminals of afferent nociceptors and cell bodies of second-order neurons are found. This dorsal horn area is the major "switchboard" for pain, and stimulation of the PAG and RVM modulates nociceptive activity here (see Chapter 20).

Immunocytochemical studies have also found 5-HT reactive cells in the area postrema, the caudal locus coeruleus, and around the interpeduncular nucleus. Through lesioning studies, it has been observed that the caudal clusters project mainly to the medulla and spinal cord, the rostral clusters project to the telencephalon and diencephalon, and the more centrally located clusters project rostrally and inferiorly. In general, 5-HT cells send axons through virtually every part of the CNS, however, and more recent findings indicate a lack of pattern to this innervation.

Transmission of sensory and particularly nociceptive messages by afferent fibers entering the dorsal horn of the spinal cord is under control of pathways originating in the ventromedial medulla. It had been observed that neurons from the medullary raphe nuclei and particularly the NRM project predominantly to the dorsal horn, including the superficial laminae and the area around the central canal, and are involved in a descending inhibitory pathway for modulation of nociceptive input. Because the area was found to have an abundance of 5-HT–containing neurons, researchers postulated that 5-HT was a descending pain modulatory system neurotransmitter. 5-HT–containing neurons are located in the rostroventromedial medulla and caudal pons, and particularly in the NRM, the nucleus paragigantocellularis, and the ventral portion of the nucleus gigantocellularis. More recent studies have described other descending projections from the bulbomesencephalon to the spinal cord that do not contain 5-HT and are more numerous within the medulla and caudal pons, indicating that descending modulation is not limited to 5-HT fibers.[24]

Immunocytochemical studies of antibodies directed against 5-HT have shown that two distinct types of 5-HT neurons innervate the cerebral cortex of many mammals. The studies have found fine axons with small varicosities originating from the dorsal raphe nuclei and beaded axons with large spherical varicosities originating from the median raphe nuclei. Apparently the two types of axons have different regional and laminar distributions and exhibit different sensitivities to neurotoxic drugs such as 3,4-methylenedioxymethamphetamine, commonly referred to as "ecstasy." The fine axons seem to be more sensitive to the neurotoxic effects, with loss of functions that may be long-term or permanent. Cooper and associates[6] suggested that laboratory animal findings may relate to humans' use of the drug because the doses commonly used by recreational drug users are similar to what are used in animal studies. Ecstasy users have shown a 26% decrease in 5-HIAA, the 5-HT metabolite. The decrease in metabolite may indicate a decrease of 5-HT function in the brain related to loss of some 5-HT neurons. The functional distinction between these two types of neurons generally remains unclear, however.

Synthesis, Storage, and Fate

5-HT is synthesized from the amino acid L-tryptophan (see Figure 23-1). Although platelets contain large amounts of 5-HT, it only accumulates rather than being synthesized there. Synthesis in the CNS involves active transport of tryptophan through the blood-brain barrier. Tryptophan is derived primarily from the diet, and its elimination from the diet can profoundly decrease brain 5-HT. In addition, the active transport of tryptophan is affected by its concentration in the blood and the relative concentration of other amino acids that are transported by the same active transport mechanism. L-Tryptophan is converted in serotonergic neurons containing the enzyme tryptophan hydroxylase (L-tryptophan-5-monooxygenase).

The initial synthesis step is hydroxylation of tryptophan at the 5 position to form 5-hydroxytryptophan (see Figure 23-1). Tryptophan hydroxylase, the enzyme responsible for this reaction, occurs in low concentrations in most tissues, including the brain, and has proved to be difficult to isolate.

Tryptophan hydroxylase has a rate-limiting requirement for oxygen. In addition, mounting evidence suggests that the system adjusts to the amount of tryptophan available. It has been shown that drug treatments affecting the 5-HT system are soon counteracted by a built-in feedback mechanism involving regulation of the synthesis of 5-HT. Short-term treatment with lithium salts initially increases tryptophan uptake, resulting in increased amounts of tryptophan being converted to 5-HT; however, with long-term treatment, increased uptake is still measured, but the synthesis of 5-HT from the increased tryptophan returns to pretreatment levels.

5-Hydroxytryptophan is rapidly decarboxylated to form 5-HT by the aromatic enzyme L-amino acid decarboxylase, which is the same enzyme that catalyzes the decarboxylation of L-dopamine in catecholamine neurons (see Figure 23-1). Because the rate of the reaction is so rapid and requires less substrate than the initial reaction, the action of tryptophan hydroxylase in the first step is regarded as the rate-limiting

step in the synthesis of 5-HT, and drugs targeting the action of the decarboxylase have not been shown to be effective.

The synthesis of 5-HT is markedly increased with the electrical stimulation of serotonergic soma. This is the result of enhanced conversion of tryptophan to 5-HT and depends on extracellular Ca^{++}. Because, as discussed previously, the rate-limiting step is the action of tryptophan hydroxylase on tryptophan, it is likely that Ca^{++} affects the Ca^{++}-dependent phosphorylation of the enzyme, increasing its availability.

Storage and release

Similar to other monoamines, 5-HT is stored in vesicles within the cell. Drugs such as reserpine and tetrabenazine that inhibit the activity of the transporter mechanism within the vesicular membrane deplete the brain content of 5-HT. The storage of 5-HT in vesicles requires an active transport mechanism to transfer the molecule from the cytosol to the storage vesicle.

Metabolism

5-HT is also metabolized in the liver by the enzyme monoamine oxidase (MAO) (see Figure 23-1). The product of this reaction is 5-hydroxyindoleacetaldehyde, which is oxidized further by aldehyde dehydrogenase to form the final acid metabolite, 5-HIAA, which is excreted (see Figure 23-1). It had been suggested that increased levels of either of the metabolites of 5-HT or the concentration of 5-HT itself would affect its metabolism, but it has been noted that using MAO inhibitors to block metabolism does not affect the synthesis of 5-HT, and concentrations increase to three times greater than controls. If the elimination of 5-HIAA is blocked by the drug probenecid, the 5-HIAA levels continue to increase without apparent feedback inhibition. The implication of these findings is that the synthesis of 5-HT is not affected by changes in concentrations of its metabolites.

Reuptake and transport across body membranes

Presynaptic reuptake of 5-HT from the synaptic cleft is a major mechanism for controlling the synaptic concentration and action of 5-HT. The presynaptic terminals of serotonergic neurons contain high-affinity uptake sites that are involved in this process by using a plasma membrane transporter protein that can transport 5-HT in either direction depending on the concentration gradient. The transporter proteins involved in this process are composed of 12 membrane-spanning proteins that are Cl^- and Na^+ dependent. Although older TCAs inhibit the reuptake of 5-HT, they also have a variable capacity to inhibit NE reuptake and affect other systems and receptors (see Chapter 12). SSRIs that have shown great utility in moderating depression, anxiety, and obsessive-compulsive disorders also inhibit the 5-HT transporter proteins. These medications are more 5-HT selective with more limited effects on the NE transporter.

5-HT Receptors and Pain

In 1957, Gaddum and Picarelli[11] reported two separate 5-HT receptors in peripheral smooth muscle preparations studied in vitro. Since then, there has been an exponential development of information relating to 5-HT receptor types and functions, and numerous receptor subtypes have been identified and cloned more recently. Nevertheless, the complete picture of how 5-HT and its receptors modulate pain remains obscure. There are now seven main family groups of receptors, but current understanding attributes most of the 5-HT actions relative to pain to the families designated *5-HT$_1$*, *5-HT$_2$*, *5-HT$_3$*, *5-HT$_4$*, and *5-HT$_7$*. Each receptor family is operationally and structurally distinct, each having its own separate transducing system.

Although other more recently identified 5-HT receptors also show characteristics indicative of separate classes or families of 5-HT receptors, not all receptors for 5-HT are fully included in the classification system at this time because of a lack of needed characterization through cDNA cloning and amino acid sequencing of their proteins or data concerning their operational and transductional characteristics. This situation applies to the 5-HT$_{1E}$, 5-HT$_{1F}$, 5-HT$_5$, and 5-HT$_6$ receptors, which have been cloned and their amino acid sequence defined, although their operational and transductional characteristics are unclear, and the final nomenclature is unsettled. Fourteen different 5-HT receptor subtypes have been identified.

As mentioned, seven classes or families of 5-HT receptors have been identified and designated *5-HT$_1$*, *5-HT$_2$*, *5-HT$_3$*, *5-HT$_4$*, *5-HT$_5$*, *5-HT$_6$*, and *5-HT$_7$*. Each class has subtypes (with the exception of 5-HT$_3$), and all have been identified in the brain. Localization of the receptors in the CNS and spinal cord is variable, and not all 5-HT receptors are found in all locations. Within the spinal cord itself there is variability in the location of different receptors. Because 5-HT$_1$, 5-HT$_2$, and 5-HT$_3$ receptors have the highest distribution in the dorsal horn, it is assumed that they are involved in sensory processing. In general, the 5-HT$_1$ family is assumed to be inhibitory, and the other classes are thought to be excitatory; however, 5-HT$_2$ and 5-HT$_3$ receptors have been linked to an antinociceptive response as measured by some animal models. Much work is still to be done before the 5-HT–modulating system is fully understood.

The 5-HT$_{1D}$ receptor, also called the *terminal autoreceptor,* is found on the presynaptic button. It turns off the release of serotonin in response to the presence of serotonin in the synaptic cleft. The receptor is also found on postsynaptic neurons and has been implicated in migraine pathophysiology. The 5-HT$_{1A}$ receptor, also known as a *somatodendritic autoreceptor,* is found primarily on the dendrites and cell bodies of the serotonin neurons but performs a similar function in regulating the release of serotonin. When these receptors are activated or stimulated by serotonin or drugs that mimic serotonin action, the receptor causes a blockade of serotonin release. When the receptors are blocked by receptor blocking medications, the receptor is no longer able to inhibit serotonin release. Serotonin release is also modulated by an α_2-adrenergic heteroreceptor on the terminus of the serotonin neurons. This receptor is activated by NE resulting in the inhibition of serotonin release.

5-HT$_1$ receptors

The 5-HT$_1$ family of receptors (Table 23-1) produces its cellular action by inhibiting adenylyl cyclase and opening K^+ channels. Binding studies with autoradiographic ligands have shown binding sites throughout the spinal cord gray matter, raphe nuclei, and substantia gelatinosa, with the higher concentrations in laminae I and II of the dorsal horn and lower in lamina VII in the ventral horn. The hippocampus, the substantia nigra, and dorsal raphe contain the highest concentrations.

5-HT$_{1A}$ receptor. Taiwo and Levine[42] showed that 5-HT$_{1A}$ receptors are implicated in peripheral mechanical hyperalgesia. They reported that the hyperalgesia could be blocked by selective 5-HT$_{1A}$ antagonists injected locally. It was also shown in various pain models that the 5-HT$_{1-3}$ receptors all mediated pain. Powell and Dykstra[35] suggested that 5-HT$_{1A}$ receptor agonists may reduce the effects of morphine in an electrical shock model for pain. This same effect was not seen with agonists at 5-HT$_2$, 5-HT$_3$, or α_2-adrenergic receptors.

Autoradiographic studies have shown that half of the spinal cord binding sites involve the 5-HT$_{1A}$ receptor, with the greatest concentration in the superficial layers of the dorsal horn in the lumbar cord, rather than in the cervicotho-

TABLE **23-1**

5-Hydroxytryptamine (5-HT) Receptor Subtypes, Drugs, and Antimigraine Medications

5-HT RECEPTOR	DRUG	AGONIST/ ANTAGONIST	ACTION IN MIGRAINE
$5\text{-HT}_{1B/1D}$	Triptans, DHE	Agonists	Action on cranial neurovascular receptor to cause vasoconstriction or stimulation of inhibitory receptor to stop release of neuroinflammatory mediators; abort migraine
5-HT_{1F}	Triptans, DHE, ergotamine	Agonists	Blockade of neurogenic dural inflammation
5-HT_{2}	Methysergide, cyproheptadine, DHE	Antagonists	Migraine prophylaxis

DHE, Dihydroergotamine.

racic segments. The 5-HT_{1A} receptor has been implicated in anxiety, but may also be involved in migraine. Antianxiety drugs such as buspirone act as agonists on this receptor.

5-HT_{1B} receptor. 5-HT_{1B} is a postsynaptic vascular receptor found primarily on cerebral blood vessels and to a smaller extent on coronary arteries and trigeminal ganglia neurons. Stimulation of the 5-HT_{1B} receptor results in numerous smooth muscle contraction actions such as vasoconstriction, closing of atrioventricular shunts, and bronchoconstriction, and platelet aggregation. Although there are a few receptors on coronary arteries, 5-HT_{1B} agonists cause some degree of coronary artery constriction.

5-HT_{1D} receptor. As indicated previously, the 5-HT_{1D} receptor functions as a presynaptic autoreceptor on trigeminovascular sensory afferent fibers, modulating neurotransmitter release such as 5-HT, substance P (SP), acetylcholine, NE, and calcitonin gene–related peptide (CGRP). 5-HT_{1D} is the most widespread 5-HT receptor in the brain and is thought to be the main 5-HT receptor involved in migraine. As discussed previously, the 5-HT_{1} family of receptors is inhibitory through action of the G_i protein. Activation of the 5-HT_{1D} receptors on subdural blood vessels involved in migraine pathophysiology decreases or stops action potential formation, resulting in the aborting of migraine.

5-HT$_2$ receptors

5-HT_{2A} receptors are found in layers three and five of the cerebral cortex, the subcortical gray matter, the brainstem, and the spinal cord. These receptors, similar to the other non–5-HT_{1} family of receptors, are excitatory. Activation of 5-HT_{2} receptors results in closure of K^+ channels and activation of phospholipase C. The 5-HT_{2B} receptor has been associated with cerebrovascular endothelium, and it has been suggested that migraine is caused by sensitization of these receptors. 5-HT bioavailability increases during development of the migraine attack and is attended by production and release of nitric oxide (NO). Nitroglycerin, a donor of NO, is known to cause headache when used to control angina, and this effect is blocked by indomethacin, which antagonizes the effect of NO. Patients who have analgesic rebound headache have a greater density of postsynaptic 5-HT_{2} receptors on platelet membranes than migraine patients who do not have analgesic rebound headache. The implication is that chronic ingestion of analgesics may cause a depletion of 5-HT and concomitant upregulation of 5-HT_{2} receptors, leading to more headache.

Although the exact role of 5-HT neuronal modulation is still unclear in migraine, the medications that seem to give the most benefit have definite 5-HT activity. The role of 5-HT in platelets during the ictal phase of migraine is apparently important but remains to be defined. All aspects of the 5-HT system seem to come into play during a migraine attack and not only the 5-HT_{1} receptors, but also 5-HT_{2} receptors. It has been observed that some of the most commonly used compounds in migraine prophylaxis—propranolol, pizotifen, methysergide, cyproheptadine, amitriptyline, and chlorpromazine—have an antagonistic effect on specific subtypes of the 5-HT_{2} receptor family, now known as the 5-HT_{2B}/5-HT_{2C} (formerly 5-HT_{1C}) receptors. This hypothesis is supported by previous observations that the 5-HT_{2} receptor agonist m-chlorophenylpiperazine (m-CPP) triggers migraine in susceptible individuals when it is administered at doses high enough to activate $5\text{-HT}_{2B/2C}$ receptors.[21]

5-HT$_3$ receptor

The 5-HT_{3} receptor is found mainly in the lower brainstem and on the presynaptic terminals of small-diameter unmyelinated nociceptive afferents in substantia gelatinosa where they may be involved in pain processing. The 5-HT_{3} receptor is the only ion-gated cation channel receptor in the 5-HT receptor family. It causes increased conductance for Na^+, K^+, and Ca^{++} and depolarization of the involved cell membrane. It has been shown that 5-HT_{3} receptors participate in the nociceptive activity in the dorsal horn and are probably involved in the antinociceptive effect when 5-HT is administered intrathecally. This receptor has also been implicated in emesis associated with migraine. The "triptans," which have been developed for symptomatic treatment of migraine through their agonist action on the $5\text{-HT}_{1D/1B}$ receptors, also are antagonists of the 5-HT_{3} receptor, relieving nausea.

5-HT$_4$ receptors

In contrast to the inhibitory effects of the 5-HT_{1} receptors, the 5-HT_{4} family of receptors is positively coupled to adenylyl cyclase, provoking second messenger activation of cyclic adenosine 3′,5′-monophosphate (cAMP). This receptor has high concentration in the gut, and antagonists of the receptor prevent development of increased bowel activity that would be stimulated by 5-HT or 5-hydroxy-L-tryptophan sensitization. Ghelardini and colleagues[13] reported that 5-HT_{4} agonists had an antinociceptive effect, raising pain thresholds in mice and rats.

5-HT$_7$ receptors

The 5-HT_{7} receptor subtype activates adenylyl cyclase with consequent closure of K^+ channels. The 5-HT_{7} receptor was shown more recently to mediate cerebrovascular smooth muscle relaxation, independent of any mechanism in the endothelium. Because of its action on the regulation of vascular tone, it has been proposed to have a role in migraine. This role has been supported by observations that 5-HT_{7} receptor–linked relaxation has been observed in dog basilar

and middle cerebral arteries, together with other circumstantial evidence such as the high affinity of antimigraine drugs for the 5-HT_7 receptor and the high expression of 5-HT_7 transcripts in animal and human brain vessels. 5-HT_7 receptor mRNA and second messenger cAMP levels were elevated in cultured smooth muscle cells from human brain vessels, possibly indicating that this same mechanism is operating in the human brain. This mechanism would allow for 5-HT_7 receptor action affecting dilation of meningeal blood vessels without direct interaction with dural blood vessel endothelium and may indicate a role for 5-HT_7 receptors in human brain blood vessels during the migraine attack.

Signal transduction pathways

Researchers have identified two major 5-HT receptor–linked signal transduction pathways. One pathway regulates ion channels, and the other is a multistep enzyme-mediated pathway. The second pathway requires a G protein to link the receptor to the internal effector molecule. In the case of the 5-HT_1 family of receptors, the link is G_i protein because the response is inhibition of adenylyl cyclase.

As noted previously, the 5-HT_2 G protein–linked family of receptors is coupled to phospholipase C, leading to a variety of intracellular actions. The G protein–type linkage of the 5-HT_2 receptor to its second messenger system is G_q. Activation of adenylyl cyclase was the first signal transduction pathway to be linked to metabotropic 5-HT receptor activity, but the specific receptor linkages to 5-HT_4, 5-HT_6, and 5-HT_7 were not identified until more recently. The 5-HT_4 receptor has been found in the human atrium and guinea pig ileum; 5-HT_6 found in the cortex has been shown to have a high affinity for TCA drugs, and 5-HT_7 is found in the brain and heart.

As noted earlier, the 5-HT_3 receptor differs from the other 5-HT receptors because it does not have G protein linkage but is associated directly with a ligand-gated ion channel. The receptor has been found on peripheral sensory, autonomic, and enteric neurons and in the cortex, hippocampus, and area postrema, mediating excitation by inducing neurotransmitter release.

Physiologic Function and Drug Intervention

The 5-HT system modulates activity in diverse regions of the brain and spinal cord. It is suggested that the system coordinates various sensory and motor patterns associated with behavioral states. 5-HT activity is highest during waking and lowest during sleep. Descending neurons are involved in pain modulation in the dorsal horn and motor activity in the ventral horn. 5-HT activity is absent during rapid eye movement sleep when physical movement is limited, although the animal is in a state of heightened internal arousal. The increased 5-HT activity during waking periods aids in enhancing motor neuron excitability.

The raphe nuclei 5-HT neurons display spontaneous discharge activity of one to five spikes per second, releasing 5-HT into the presynaptic cleft. The neurons possess negative feedback autoreceptors that limit the amount of discharge and release of 5-HT. The autoreceptors seem to function only when the discharge and release of 5-HT reaches levels greater than the normal background activity inherent in the neurons. Dysfunction of the autoreceptor regulation has been associated with some forms of neuropathy, and the autoreceptor may provide a therapeutic target for medications. Although in some areas microelectrophoretically administered 5-HT can have an excitatory effect on the discharge rate, the most common response in 5-HT–containing neuron tracts is inhibition of the discharge rate.

5-HT released from neurons has presynaptic and postsynaptic receptor effects. There are many options for affecting the availability of 5-HT directly, either by inhibiting the processes that decrease its availability or by enhancing the processes that make it available (Figure 23-2). Figure 23-2 shows sites of interaction with known drugs that influence the 5-HT system. Of all the options, reuptake blockade of 5-HT by TCAs is the most common mechanism of 5-HT active medications prescribed for the treatment of depression and chronic

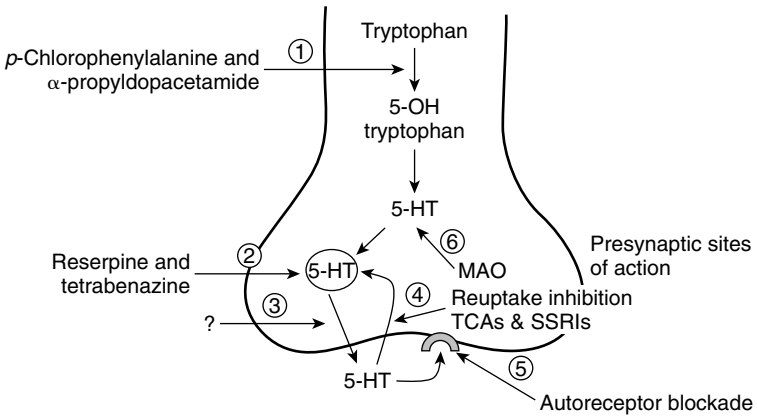

FIGURE **23-2** Possible drug sites for influencing 5-HT neurotransmission. The sites of potential drug action on the 5-hydroxytryptamine (*5-HT*) neuron are enumerated from 1 to 6. *Site 1* represents the modulation of enzymatic action forming the 5-HT precursor and ultimately 5-HT from tryptophan. *Site 2* is a potential target for drugs that affect the storage vesicles of 5-HT. Reserpine and tetrabenazine are known to interrupt the storage and cause release of 5-HT. *Site 3* targets the release mechanism itself; however, there are currently no known agents that act to interrupt or increase the action of the transporter proteins that carry the 5-HT molecule across the membrane. *Site 4* involves the reuptake mechanism that brings 5-HT back into the intracellular environment to be repackaged in the vesicles. Numerous drugs inhibit the reuptake of 5-HT (see Chapter 12). *Site 5* refers to the 5-HT autoreceptor. Blockade of this receptor site allows more presynaptic release of 5-HT. *Site 6* focuses on the action of monoamine oxidase that converts the free 5-HT to the metabolic product 5-HIAA. Monoamine oxidase (*MAO*) inhibitors such as phenelzine block this action. *SSRIs,* Selective serotonin reuptake inhibitors; *TCAs,* tricyclic antidepressants.

pain; however, the issue of availability of 5-HT to help modulate pain has yet to be settled.

DRUGS FOR ACUTE TREATMENT OF MIGRAINE

Sicuteri and associates[40] were the first to note a relationship between 5-HT and migraine in their report on the significant increase in 5-HIAA in the urine of migraine subjects during attacks. Subsequent data did not show a consistent increase in 5-HIAA in all patients with migraine. Nevertheless, the relationship between migraine and 5-HT became solidified at that time and has been elucidated further to the present. Further studies have noted increases in plasma 5-HT, decreases in 5-HT platelet content, and increases in 5-HIAA content in cerebrospinal fluid in migraine patients. These observations support the theory that migraine is caused by chronic 5-HT dysregulation. Further support for the role of 5-HT in migraine has come from clinical positron emission tomography scan studies in patients during migraine attacks showing increased blood flow in the highly serotonergic dorsal raphe nucleus area.

Ergot Derivatives

In the Middle Ages, epidemics of a gangrenous disorder known as "holy fire" or "St. Anthony's fire" were afflicting communities in Europe. The condition was so named because of the attendant burning experienced by the sufferer. The disorder soon became associated with the grain of rye that had been contaminated with the ergot fungus *Claviceps purpurea*. In 1918, the ergot alkaloid ergotamine was isolated from the fungus and was found to have sympatholytic activity (see Chapter 7). Shortly thereafter, it was proposed for use as a therapeutic agent for migraine.

Ergotamine has a complex mode of action involving a variety of receptor activities, not only with 5-HT receptors, but also with dopamine and NE receptors. The vasoconstrictive effect, the most notable characteristic of this medication, can become problematic with overuse, leading to claudication of extremities. The major vasoconstrictive activity is noted in the carotid circulation; the cephalic arteriovenous anastomoses; the pulmonary, cerebral, temporal, and coronary arteries; and the blood pressure. These effects are short-lived, although constriction of leg arteries can last 8 hours. Chronic overuse becomes a problem, and clinicians need to monitor users carefully.

Ergot derivatives are nonselective partial agonists and antagonists at 5-HT receptors, having high affinity for the 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1F}, and 5-HT_{2} receptors and low to moderate affinity for the 5-HT_{1C} and 5-HT_{3} receptors. It is currently believed that their primary mode of action in alleviating migraine attacks is through their action on the $5\text{-HT}_{1B/1D}$ receptors, inhibiting neurogenic inflammation and nociceptor activity. Table 23-1 lists some 5-HT receptors and related medications and some indications for the drugs.

Ergotamine

Ergotamine is a nonselective 5-HT partial agonist/antagonist and acts at multiple receptors accounting for therapeutic and adverse effects. For migraine, ergotamine acts primarily as a 5-HT_{1D} receptor agonist, inhibiting depolarization of the dural blood vessel–associated nociceptors. The beneficial effect of ergotamine in treating migraine likely occurs by blocking neurogenic inflammation possibly through prejunctional inhibition of neuropeptide release. Ergotamine is commonly available as Cafergot, a tablet or suppository that is a combination of ergotamine and caffeine. Patients should be instructed regarding the possibility of developing rebound headache if using ergotamine more than two times per week.

BOX **23-1**

Contraindications and Side Effects of Ergot Alkaloids

Contraindications
Pregnancy
Breastfeeding
Renal impairment
Liver impairment
Uncontrolled hypertension
Drug allergy
Peripheral vascular disease

Common Side Effects
Nausea
Vomiting
Restlessness
Irritability
Palpitation
Nervousness
Rebound headache
Claudication
Numbness of fingers and toes
Myalgia
Leg weakness

Other Precautions
Avoid concomitant use of triptans and β blockers

Ergotamine is used as an abortive drug at the onset of the migraine attack. Typically, abortive medications have to be taken early in the onset of the migraine because absorption and distribution are impaired as the gastric symptoms of migraine increase. The combination of caffeine with ergotamine speeds gastric absorption, getting the medication into the system more rapidly. In addition to the adverse effects listed in Box 23-1, ergotamine can cause gangrene and damage to blood vessels. The drug is given for short periods at carefully controlled doses.

Dihydroergotamine

Dihydroergotamine was introduced in 1945, approximately 10 years after ergotamine. Past and more recent studies have determined that the venoconstrictive effect is significantly greater than the arterial effect. It is a nonselective 5-HT receptor partial agonist/antagonist. In addition, it is a nonselective antagonist at dopaminergic receptors with partial agonist/antagonist activity at α adrenoceptors. The half-life of dihydroergotamine is approximately 10 hours, which is longer than ergotamine and all but one of the triptans. This longer half-life may explain the lower likelihood for rebound adverse effects in headache compared with ergotamine and the shorter acting triptans (see later). This longer half-life makes dihydroergotamine a useful medication for chronic migraine, which tends to return within hours of treatment with either ergotamine or the triptans with shorter half-life.

Dihydroergotamine comes in a parenteral form and as a nasal spray. The parenteral form can be used intravenously, intramuscularly, or subcutaneously. The nasal form has a bioavailability of less than 65%, which may significantly limit its ability to abort a headache in many patients. This medication has definite advantages over the triptans with short half-life and is associated with lower vasoconstrictive potential. Dihydroergotamine is useful in the hospital to treat protracted unresponsive migraine. Side effects and contraindications for

dihydroergotamine, ergotamine, and the other ergot alkaloids are listed in Box 23-1. Methylergonovine and methysergide, semisynthetic ergot alkaloids, are discussed subsequently.

Triptans

The new family of triptan antimigraine drugs represents the most dramatic advance in the understanding and treatment of migraine. They are classified as 5-$HT_{1B/1D}$ receptor agonists. Discovery of the first of these drugs, sumatriptan, came after the 5-$HT_{1B/1D}$ receptor was linked with migraine. When it became apparent that the receptor had an inhibitory G protein–linked action on the host vascular and nociceptor neurons, agonist agents were sought that could act with the receptor to stop the attack. Sumatriptan was originally thought to act primarily on nociceptor 5-HT_{1D} receptors, but action was also noted on dilated dural blood vessels. Sumatriptan-sensitive sites of action in the pain transmission pathway have been identified centrally and suggested as additional putative antimigraine targets for brain-penetrant triptan derivatives. Sumatriptan has selective affinity for 5-HT receptor subtypes, 5-HT_{1B} and 5-HT_{1D}. More recent development of 5-HT receptor subtype–specific compounds and antibodies has allowed a more precise identification of the vascular and neuronal sites of action, providing a basis for a more targeted therapeutic approach.

Moskowitz[29,30] developed the concept of neurovascular inflammation in the trigeminovascular system as a migraine mechanism. He observed that sumatriptan's action on peripheral neuronal 5-HT_{1D} receptors blocked subsequent release of neuropeptides such as SP and CGRP that were responsible for the development of neurovascular inflammation with concomitant swelling of the dural blood vessels. Moskowitz then proposed that the blood vessel dilation and plasma extravasation noted during the migraine attack was an epiphenomenon of the migraine and not the cause of the migraine, as had been proposed by Graham and Wolff.[17]

The 5-HT_{1B} receptor was discovered in humans after the discovery of the 5-HT_{1D} receptor. It is expressed on human brain blood vessels where it induces contraction of dural blood vessels. An untoward observation of the effect of sumatriptan is the induced contraction of human coronary arteries, which also is most likely mediated by the 5-HT_{1B} receptors. Although the cardiac effect is not severe, it is a concern and has led to some more recent efforts to find a compound that would not have an agonistic effect on the coronary 5-HT_{1B} contractile receptors.

Centrally located 5-HT receptor targets in the trigeminal nucleus caudalis have also become the focus of research as potential targets for intervention in acute treatment of migraine. 5-HT_{1B} and 5-HT_{1D} receptors have been identified in the nucleus caudalis. On the basis of protein and mRNA localization studies, presynaptic 5-$HT_{1B/1D}$ and postsynaptic 5-HT_{1F} receptors have been identified. These central 5-HT receptors may be potential sites of action for the new generation of brain-penetrant triptan derivatives (e.g., naratriptan, zolmitriptan, rizatriptan). Identification of the exact nature of these central receptors should be possible when selective receptor subtype compounds become available. Besides the effect on migraine, one of the great benefits for patients with migraine is the relief from nausea that is obtained with the use of triptans. This effect may be caused by additional 5-HT receptors in the nucleus tractus solitarius and area postrema, regions of the brain where the blood-brain barrier does not exist. These areas could be accessible even to non–brain-penetrating compounds such as sumatriptan, which could explain some of their antiemetic effects. In addition, as noted previously, the triptans act as 5-HT_3 receptor antagonists, which gives the drugs an antiemetic effect.

TABLE **23-2**

Triptans

TRIPTAN AND DOSAGE FORMS	T_{max} (hr)	HALF-LIFE (hr)
Almotriptan, 6.25, 12.5 mg	2.6	3-4
Eletriptan, 20, 40 mg	2.8	4
Frovatriptan, 2.5 mg	2-3	26
Naratriptan, 1, 2.5 mg	2-3	6
Rizatriptan, 5, 10 mg	1	2-3
Sumatriptan, 25, 50, 100 mg	2	2
Sumatriptan, 20 mg nasal	1-1.5	2
Sumatriptan, 6 mg injectable	5-20 min	2
Zolmitriptan, 2.5, 5 mg	1	3

T_{max}, Time to maximal plasma concentration.

Sumatriptan was the first of the family of triptans to be introduced for the symptomatic treatment of migraine. This agent was designed to act selectively on the 5-$HT_{1D/1B}$ receptor involved in migraine pathophysiology. Seven triptans are currently on the market: sumatriptan, naratriptan, rizatriptan, frovatriptan, almotriptan, eletriptan, and zolmitriptan. There are variable differences between these drugs relating to speed of onset, recurrence rate of headache, side-effect profile, and duration of effect, but they all have the same caveats regarding precautions and contraindications. Sumatriptan has the shortest half-life (approximately 2 hours) of all the triptans. This may be a factor in considering recurrence of headache. Within the triptan group, naratriptan and frovatriptan seem to have a recurrence rate comparable to that of dihydroergotamine.

The time to maximal plasma concentration (T_{max}) for a drug can be crucial when it is used to treat migraine. It is recommended that abortive medications be taken as soon as possible at the onset of the migraine attack to increase the likelihood for successful treatment. If the T_{max} for a drug is too slow, not enough of the drug gets into the system to stop the headache before it is fully developed. Current understanding of migraine pathophysiology has shown that the trigeminal nociceptors become sensitized during the early phase of the migraine attack, and the sensitization spreads rapidly to the CNS. After the trigeminal nucleus caudalis has become sensitized, the medications used to abort the headache attacks are less effective. The current recommendation is to take the abortive medication at the onset of the headache and not to wait because efficacy is significantly decreased. The T_{max} and half-lives of the triptans are listed in Table 23-2.

Sumatriptan

One advantage of sumatriptan is the range of delivery options. For some patients, speed is crucial, and a delivery system that optimizes speed of delivery and bioavailability is a definite advantage. Nausea decreases gastric absorption, slowing the intake of the medication into the system. This problem can be bypassed with the nasal spray or the injection. Both of these modalities increase the bioavailability of the medication, enhancing the likelihood of successful intervention. The nasal form of sumatriptan is more effective and more rapid in onset than the nasal form of dihydroergotamine, but the recurrence rate is higher because of the half-life of sumatriptan compared with dihydroergotamine.

Naratriptan

The main advantage of naratriptan is its long half-life of 6 hours; this is shorter than dihydroergotamine but longer than most triptans except frovatriptan. The biggest disadvantage of

naratriptan is a delayed onset of action of 2 to 3 hours. For the typical migraine that develops over ½ to 1 hour, this medication may not help because central sensitization may have occurred before the optimal blood concentration of the drug is reached. Studies have looked at using this medication as an add-on, 2 hours after taking a medication with a shorter half-life, such as sumatriptan, to achieve a longer sustained period of relief and to diminish the likelihood of recurrence. Additional use as a prophylactic agent in menstrual migraine during the migraine vulnerability period is being studied. The recommendation has been made to start the medication 3 days before the onset of menses and to continue for 6 days.[3]

Zolmitriptan
Zolmitriptan has a longer half-life than sumatriptan and a more rapid T_{max}. Although the manufacturers indicated that this drug can be taken further into the attack, the recommendation nevertheless is to take the drug as early as possible into the attack to avoid central sensitization. Zolmitriptan is also available in a "melt" version, which is liquefied in the mouth before it enters the stomach, and in an intranasal system, which is absorbed by the highly vascular nasal mucosa.

Rizatriptan
Rizatriptan has a rapid onset of action similar to zolmitriptan and a T_{max} that is reached in 1 hour. It comes in a tablet form and as a dissolvable wafer that melts on the tongue. Rizatriptan (10 mg) has greater efficacy than other oral triptans in freedom from migraine headache pain 2 hours after dosing. The dissolvable form is recommended for patients with nausea.

Frovatriptan
Frovatriptan has a 26-hour half-life, the longest of all of the triptans. This long half-life may be a distinct benefit for migraines that last longer than 4 hours, and Géraud and colleagues[12] reported that frovatriptan had the lowest recurrence rate of all the triptans. The T_{max} of frovatriptan is 2 to 4 hours for a single dose (2.5 mg), which is slower than most of the other triptans. This medication may not be as effective for migraine that develops rapidly because of this pharmacokinetic property. Frovatriptan is also used to prevent menstrually related migraine in a similar manner to naratriptan. It is recommended that the patient start the medication 2 to 3 days before menses and continue for 6 days.

Eletriptan
Eletriptan is well absorbed after oral administration and has shown a peak plasma concentration occurring approximately 1.5 hours after dosing. In patients with severe migraine, the median T_{max} is 2 hours. This rapid peak time is definitely an advantage for migraine that develops rapidly. The drug's terminal half-life is approximately 4 hours, and Géraud and colleagues[12] reported that it had a relatively low recurrence rate compared with rizatriptan, sumatriptan, and zolmitriptan.

Almotriptan
Almotriptan has a half-life of 3 to 4 hours and a low recurrence rate compared with rizatriptan, sumatriptan, and zolmitriptan. Very little has been reported on the 24-hour sustained-release preparation of almotriptan. Almotriptan has been reported to have significantly lower adverse events compared with the other triptans. Similar to frovatriptan, almotriptan is used to prevent menstrual migraine.[14]

Contraindications to ergot derivatives and triptans
Box 23-2 lists the most common contraindications, precautions, and adverse reactions noted with the triptans.

BOX **23-2**

Contraindications, Precautions, and Adverse Reactions to Triptans

Contraindications and Cautions
Drug allergy
Prinzmetal's (variant) angina
Pregnancy
Breastfeeding
Diabetes
Hepatic disease
Uncontrolled hypertension
Coronary artery disease
Basilar migraine
Use of MAO inhibitor within 14 days
Hemiplegic migraine
Peripheral vascular disease
Cerebrovascular disease
Impaired liver function
Use of ergot derivatives or other anti—5-HT medications

Adverse Reactions
Common
Asthenia
Chest pain
Neck tightness
Jaw tightness
Dizziness
Flushing
Paresthesias

Uncommon
Anaphylaxis
Coronary vasospasm
Acute myocardial infarction
Cardiac arrest
Ventricular tachycardia
Hypertensive crisis
Stroke

5-HT, 5-Hydroxytryptamine; *MAO,* monoamine oxidase.

Isometheptene
Isometheptene is a vasoconstrictor similar in action to ergotamine. Midrin is a proprietary combination medication that contains isometheptene plus acetaminophen and dichloralphenazone. This combination is useful in treating mild-moderate migraine headache. The mechanism of action probably relates to a sympathomimetic vasoactivity of isometheptene plus the analgesic effect of acetaminophen. Dichloralphenazone has a mild tranquilizing effect and possibly a central pain inhibitory effect. The medication has to be taken orally at the onset of headache because delay significantly inhibits the likelihood that it will be effective. It is used for symptomatic treatment of migraine and tension-type headache and may be combined with an NSAID to increase its effectiveness. This drug should not be used with patients taking MAO inhibitors (see Chapter 12). In addition, it should not be used in patients with partial spinal cord lesions because provocation of hypertensive crises has been reported with use of sympathomimetic medication in these patients. It should not be used concurrently with any of the triptans.

Antiemetics
Phenothiazine derivatives are neuroleptics used to give symptomatic migraine relief. Specifically, they can control the

nausea and gastric irritation that accompanies the migraine attack because the medications aid in gastric clearance and gut motility and promote absorption, which is helpful when migraine medications are taken orally. They are available in tablet, suppository, and parenteral forms. The neuroleptics are antagonists at the dopamine D_2 receptor (see Chapter 12). They may cause extrapyramidal reactions such as tardive dyskinesia, although the incidence is low for metoclopramide, promethazine, and prochlorperazine, the most commonly used agents for nausea. The antiemetic drugs commonly used specifically to reduce emetic symptoms of migraine are prochlorperazine, metoclopramide, promethazine, and trimethobenzamide.

Clinical Treatment of Migraine

Before deciding on a treatment approach, the frequency of headache must be determined. If a patient is experiencing headache less than once per week, it is appropriate to consider only symptomatic management of the headache unless the infrequent headache is so severe and disabling that it requires more specific interventions. If the headache frequency is more than once per week, preventive medication management needs to be considered. In addition, if the patient has been taking analgesics more than twice per week to treat the headaches, they are likely to develop medication-overuse headache, which requires specialized interventions to manage the headache.

The most common approach to treatment of migraine is termed *stepped care*. This treatment strategy starts the patient at the lowest level of therapeutic care, then escalates step by step if the patient does not respond at each given level. The lowest level of therapeutic care usually involves simple over-the-counter analgesics. If this medication fails to help the headache, the patient is given a prescription for a combination analgesic. If this medication is insufficient, a migraine-specific medication, usually in tablet form, is often given. If this medication fails, an injectable medication can be used. The problem with this approach is the delay in effective treatment, wasted follow-up visits, failed prescriptions, discouragement, and finally abandonment of care.

Headache specialists now recommend a stratified care approach to headache management. This approach immediately takes into account the severity and disability of the migraine attacks and gives the patient the medication appropriate for that situation. This treatment approach limits the long delay in achieving therapeutic benefits.

General guidelines for selecting medications for symptomatic relief of migraine should consider the health status of the patient and the severity and longevity of each attack (Box 23-3). Cost factors also become important, particularly in lower socioeconomic areas where patients may have inadequate health coverage and may be unable to afford some of the expensive medications more recently made available.

BOX **23-3**

Medications for Aborting Mild, Moderate, and Severe Migraine Headache in a Stratified Treatment Approach

MILD HEADACHE	MODERATE HEADACHE	SEVERE HEADACHE
Acetaminophen	NSAIDs	Ergotamine suppositories plus a prochlorperazine suppository
NSAIDs	Isometheptene	Subcutaneous/nasal sumatriptan
Isometheptene	Ergotamine	Oral naratriptan
Prochlorperazine or metoclopramide for nausea	Nasal DHE	Oral rizatriptan
Caffeine	Prochlorperazine or metoclopramide for nausea	Oral zolmitriptan
	Oral/nasal sumatriptan	DHE intramuscularly
	Oral naratriptan	
	Oral rizatriptan	
	Oral zolmitriptan	

DHE, Dihydroergotamine; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

DRUGS FOR MIGRAINE PROPHYLAXIS AND OTHER CHRONIC PAIN SYNDROMES

The following sections discuss drugs used for prophylaxis of migraine and management of other chronic pain conditions, such as cluster headaches, musculoskeletal disorders, and neuropathic pain. Although the use of the medications in each of the conditions may generally be the same, some particular differences are highlighted in the sections under discussion when relevant. Medication selection is still empiric; however, as understanding of the pathophysiologic characteristics of the various disorders and the drug interaction on receptor targets expands, medications will be selected according to what receptors the clinician wants to target.

5-HT Receptor Blockers

Methysergide and methylergonovine act at 5-HT receptors, but they may have other actions. They are considered antiserotonin medications because they block the 5-HT_2 receptor. Methysergide, a semisynthetic ergot alkaloid, prevents plasma extravasation in rat dura mater only after long-term administration, an effect that is not noted in short-term use of the drug. Saxena[39] found that methysergide produced only minimal cranial vasoconstriction in vivo during acute migraine attacks. These findings support the observation that methysergide is a better prophylactic agent than an abortive agent. Methylergonovine is an active metabolite of methysergide and is present at a three times greater concentration than methysergide. Its half-life is approximately 220 minutes, in contrast to the half-life of methysergide of only 60 minutes. Methysergide has an oral bioavailability of 13% because of its extensive first-pass hepatic metabolism to methylergonovine. Methylergonovine is rapidly absorbed orally and has a bioavailability of 60%.

Methylergonovine, the primary metabolite of methysergide, probably accounts for most of methysergide's action in the prophylactic management of chronic migraine and cluster headache. These medications are thought to act as agonists on the trigeminovascular afferent 5-HT_{1D} receptors to decrease pain fiber activity and are most useful in resistant migraine and medication-overuse headache. They have peripheral vasoconstrictive activity, although not as great as ergotamine. They also may cause vasoconstriction of the arteries in the carotid bed, where there is a greater concentration of 5-HT_{1B} receptors, but the triptans have a greater vasoconstrictive effect on these 5-HT_{1B} receptors, which may explain why they are better abortive medications.

Long-term use of methysergide and methylergonovine has been associated with retroperitoneal, pleuropericardial, and

subendocardial fibrosis. Because most patients using these medications do not develop these complications, it is believed that the fibrotic reactions are idiosyncratic. Nevertheless, protocols for medication use have been recommended in the literature and include giving the patient a drug-free holiday every 6 months and obtaining magnetic resonance imaging or computed tomography with enhancement for retroperitoneal fibrosis and chest radiograph for pleuropulmonary fibrosis. Patients placed on methysergide or methylergonovine should be warned about the possibility of a fibrotic reaction. Because of these potentially extremely serious side effects, methysergide and methylergonovine are reserved for the most recalcitrant chronic headaches. Both drugs are started at the lowest available dose for the formulation and titrated slowly to a maximum daily dose. The patient should be given a drug-free holiday of 30 days after 6 months of use and evaluated as indicated previously for fibrotic reactions.

Tricyclic Antidepressants

Opioids, aspirin, acetaminophen, NSAIDs, or combinations have been the most widely prescribed medications for treatment of headache and other pain, but use of TCAs for the treatment of chronic pain, including headaches, is the next most common. Of all the antidepressants, the first-generation TCAs have been shown to be effective in preventive treatment of neuropathic pain, migraine, and tension-type headache. The most commonly used drug of this class for neuropathic pain is amitriptyline. The effect of TCAs on pain is distinct from the modulation of depression. It had been thought that 5-HT reuptake inhibition was the primary mode of action until the SSRIs were developed and found to provide little or only modest benefit for chronic pain or headache. The mode of action of TCAs may relate to 5-HT receptor activity presynaptically and postsynaptically, but the exact action is still debated. TCAs may downregulate 5-HT_2 receptors that have been associated with excitatory perivascular inflammation. In addition, drugs that inhibit the reuptake of 5-HT and NE seem to have greater benefit than drugs that exclusively inhibit reuptake of either one or the other. Pain relief for some pain conditions is modest, and the side effects, such as sedation and parasympatholytic effects, are particularly bothersome for some patients.

The results of a meta-analysis supported the conclusion that the pain-modulating effect of antidepressants is independent of their antidepressant effect.[32] The benefit for pain occurred within a few days of initiating therapy, whereas the benefit for depression took a much longer time to occur and at a higher dose. It is possible that the 5-HT reuptake blockade alone is insufficient to relieve pain, but enhances the pain-relieving effects of NE reuptake blockade. This would explain why amitriptyline, which inhibits 5-HT reuptake more than NE, is more effective in treating pain than a medication such as desipramine, which inhibits reuptake primarily of NE (see Chapter 12). The drugs that inhibit reuptake of 5-HT also ameliorate obsessive-compulsive disorder, but drugs that primarily inhibit NE uptake, such as desipramine, do not.

The choice of a TCA is based on the reported efficacy for migraine and the side-effect profile of the medication. The anticholinergic side effects are the most troubling for patients and are often the major factor that causes patients to discontinue use of the medication (see Chapter 12). The tertiary amines have stronger anticholinergic effects than the secondary amines, but have greater efficacy for pain. The secondary amines are less effective for headache and pain, but are better tolerated.

Caution should be exercised when administering TCAs to elderly patients and patients with a history of cardiac irregularity. It is generally recommended that patients older than 50 years have an electrocardiogram before starting the medication. TCAs should be used with caution in severely depressed and suicidal patients because the margin of safety for overdosing is low as a result of the cardiac conduction–blocking effects (see Chapter 12).

TCAs are typically started at the lowest dose, followed by a slow increase in dose. The patient is advised of the side effects, such as sedation and dry mouth. Weight gain can be a significant problem for most of the TCAs, although protriptyline was associated with modest weight loss in one study that used it for tension-type headache.[5] Many of the side effects decrease as the patient accommodates to the medication. Different dosage forms and different drugs can be used to reduce the risk of sedation.

Selective Serotonin Reuptake Inhibitors

Although the analgesic effects of SSRIs have been disappointing, SSRIs may be useful in the overall management of headache and other pain syndromes. If a patient is taking a TCA and getting relief from pain, but the consequent sedation is bothersome, addition of fluoxetine, an SSRI, in the morning may help to relieve the sedation, allowing the patient to continue to have the benefit of the TCA. The combination of a TCA with fluoxetine is being used in treating fibromyalgia, probably because of the additional effect of 5-HT reuptake inhibition with drugs that inhibit reuptake of 5-HT and NE. Addition of another medication that increases 5-HT availability has to be done cautiously, however, because some patients may have 5-HT toxicity or serotonin syndrome develop, a potentially fatal side effect of having too much 5-HT in the system (see Chapter 12).

Another use of the SSRIs relates to their effect on anxiety and obsessive-compulsive behavior. Often patients who have chronic pain syndromes have concomitant anxiety or become fixated on their pain. It has been suggested that the addition of an SSRI with the medication used to ameliorate the pain may benefit these patients because it decreases the obsessive component of the pain, allowing the patients to shift their focus away from the pain issues.

Other Antidepressants

Numerous antidepressants are not SSRIs or TCAs but may have utility for chronic pain, although no direct effect on the pain itself. Venlafaxine is a serotonin-NE reuptake inhibitor class antidepressant that is more potent as a 5-HT reuptake blocker than as an NE reuptake blocker and has fewer anticholinergic side effects than TCAs (see Chapter 12). Venlafaxine has been noted to be effective in treating chronic pain, neuropathic pain, and migraine.[25] Venlafaxine also has a significant anxiolytic effect and can be useful in modulating patients' anxiety relative to their pain. Use of the extended-release form may have fewer side effects. Duloxetine, a serotonin-NE reuptake inhibitor, has also been studied in migraine patients. It was found to be effective in reduction of headache, but the effect was tied to the concomitant presence of anxiety.[43]

Trazodone, a heterocyclic antidepressant, is more selective as a 5-HT reuptake inhibitor; it has not shown utility for headache or other pain, but it is useful as a sleep medication. Trazodone has been associated with priapism in men and should be used with caution. It may cause hypotension or syncope, and patients should be closely monitored during the initial phase of treatment. Nefazodone, an analogue of trazodone, is also useful for inducing and maintaining sleep. In addition, nefazodone is a 5-HT_2 receptor antagonist and has been shown to have a benefit for headache, but it has been discontinued in the United States.

Mirtazepine has not been shown to be useful for the treatment of pain or headache, but because it is very sedating, it

TABLE **23-3**

β Blockers Useful in Preventing Migraine

NONPROPRIETARY (GENERIC) NAME	ANTIMIGRAINE EFFICACY	RECEPTOR SELECTIVITY	CNS PENETRATION
Propranolol	++++	β_1, β_2	Good
Nadolol	++++	β_1, β_2	Poor
Timolol	++	β_1, β_2	Good
Atenolol	+++	β_1	Poor
Metoprolol	+	β_1	Good

CNS, Central nervous system.

is useful as a sleep adjuvant. This medication can cause significant weight gain and should be used with caution.

β-Adrenergic Receptor Blockers

β Blockers are widely used drugs in the prevention of migraine (Table 23-3). They have not been found useful for preventing tension-type headache and are not as useful as Ca^{++} channel blockers in prophylaxis of cluster headache. The choice of a β blocker is governed by consideration of potential side effects and the patient's health history. The two β blockers with poor CNS penetration are not lipophilic and are thought to be accompanied by fewer side effects such as depression. Also, these medications are not metabolized in the liver and will not be affected by concomitant use of medications that are affected by the cytochrome P450 enzyme system. The two β blockers with selective β_1 activity are safer to use with patients having a history of asthma; nevertheless, patients should be closely monitored because the selectivity is not exclusive. Because of the risk of stroke, β blockers should not be used with patients who have basilar migraine or other headaches with significant neurologic symptoms.

The mechanism of action of the β blockers is undetermined. It was originally assumed that their effect was caused by their vasoactivity, but this is probably only part of the picture. Table 23-3 lists the β blockers with their relative antimigraine efficacy.

Antiseizure Medications

Topiramate, valproic acid, and gabapentin are also used for prophylaxis against migraine. They are discussed subsequently.

Ca^{++} Channel Blockers

The most widely used Ca^{++} channel blocker for migraine and cluster headache is verapamil. The exact mechanism of action is unknown, however. It is hypothesized that Ca^{++} channel blockers act on the nociceptive system by interfering with the Ca^{++}-dependent release of substance P (SP) and possibly other neurotransmitters from sensory nerve terminals. Ca^{++} channel blockers may also interfere with neurovascular inflammation and the initiation and propagation of Ca^{++}-dependent spreading of cortical depression, which is a pathophysiologic feature of migraine. Ca^{++} channel blockers block the transmembrane influx of Ca^{++} through slow, voltage-dependent ion channels into neurons innervating muscle (see Chapter 26). The inhibitory effect does not affect all Ca^{++}-dependent functions but mainly affects vascular and cardiac functions. Ca^{++} influx can have a cytotoxic effect, a factor that may be involved in migraine during phases of cerebral ischemia, and Ca^{++} channel blockers are thought to have a protective influence on this process. NO, which is also involved in chronic pain states, is produced through an intracellular mechanism involving Ca^{++} influx after N-methyl-D-aspartate (NMDA) receptor activation, and the Ca^{++} channel blockers may decrease the production of NO by inhibiting that influx. It has also been noted that 5-$HT_{1D/1B}$ agonists such as sumatriptan abolished NMDA receptor–evoked NO signaling in the brain cortex.[41]

Use of Ca^{++} channel blockers for the prevention of migraine is not as well founded as β blockers. Verapamil is one of the most effective medications available for prophylactic management of cluster headache. In general, the patient is started on a low dose, which slowly titrated up to tolerance. The sustained-release versions generally require increased dosing and may not be as effective for headache management as the shorter acting versions. Problems with bradycardia and hypotension require close monitoring of the patient.

Antihistamines

Except for cyproheptadine and hydroxyzine, antihistamines (see Chapter 22) have not shown particular effectiveness in managing headache. Cyproheptadine has numerous nonhistaminic actions that may account for its effectiveness, such as Ca^{++} channel–blocking activity and 5-HT_2 antagonism, making it useful for preventing migraine and managing serotonin syndrome. Cyproheptadine is an important drug for managing childhood migraine. The effect of cyproheptadine in ameliorating headache may be caused by the same mechanism as methylergonovine and methysergide; however, the definitive mechanism is unclear. The combination of propranolol with cyproheptadine may have a more beneficial effect on migraine than either drug alone. Sedation, weight gain, and anticholinergic side effects tend to limit the usefulness of the drug.

Hydroxyzine is also used in the management of headache and is commonly given with an opioid in emergency departments to abort acute migraine attacks. More recent studies have shown, however, that this approach is not as effective as using dihydroergotamine with metoclopramide or an injectable triptan. It is often used as part of the treatment protocol for headache caused by analgesic overuse.

Indomethacin and Indomethacin-Responsive Headaches

A group of uncommon primary headaches shows dramatic remission after the administration of the anti-inflammatory drug indomethacin. Because of this unique response, the International Headache Society Classification Committee has included a positive response to indomethacin in the diagnostic criteria for this group of headache disorders. The headaches that are responsive to indomethacin are listed in Box 23-4.

The fact that some of these headache disorders dramatically respond to indomethacin, whereas others respond variably and less so, has led to speculation regarding the putative pathophysiologic characteristics of these headaches and a mechanism of indomethacin that is unique from other NSAIDs. Indomethacin is a cyclooxygenase-1 and cyclooxygenase-2 inhibitor similar to other NSAIDs, but the one outstanding difference is its unique ability to alter

BOX **23-4**

Indomethacin-Responsive Headache Disorders

Exertional or cough headache
Coital headache
Hemicrania continua
Chronic paroxysmal hemicrania
Idiopathic stabbing headache

cerebral blood flow without inducing vasospasm. It has been observed that indomethacin is able to modulate cerebral blood flow through nitric oxide pathways.

Adrenocorticosteroids

Adrenocorticosteroids (see Chapter 35) are useful in the treatment of acute inflammatory pain, headache, and some neuropathic pain. Steroids are used in topical, oral, and injectable forms.

Although corticosteroids are more effective in treatment of cluster headache, they have been found to be useful in treating intractable migraine that has not responded to other forms of therapy. Normally, a high initial dose of a steroid is given, and the drug is tapered over a 1- or 2-week period. This regimen usually terminates the migraine, allowing for the institution of appropriate medications to manage the headache. There has been concern more recently regarding avascular necrosis with steroid therapy; although the condition is rare, appropriate consent forms should be obtained when using this group of drugs.

Steroids are thought to act through many mechanisms on chronic pain syndromes: steroid modulation of γ-aminobutyric acid ($GABA_A$) receptors located outside the blood-brain barrier suppresses neurogenic inflammation and CGRP-induced and SP-induced plasma extravasation.[31] Drugs that modulate $GABA_A$ receptors may provide a means of targeting the efferent nerves with specific therapies. Steroid hormones modulate neurogenic inflammation related to migraine, cluster headache, and arthritis. Steroids completely block neurogenic extravasation that is mediated by release of neuropeptides such as CGRP and SP. Steroids have also been noted to have an effect on Ca^{++} channels, showing some selectivity in their blocking effects on different high-voltage activated Ca^{++} currents. Some of these effects probably involve directly blocking Ca^{++} channels.

Injectable and oral steroid therapy is effective in management of acute and chronic TMJ inflammation. Intra-articular corticosteroids reduce pain and swelling associated with inflammatory disease of muscles and joints. Patients who have inflamed TMJs are typically started on a protocol including soft diet, moist heat, NSAIDs, and possibly steroids to suppress the joint inflammation.

Cortisone and hydrocortisone injected into the joint are beneficial, but they tend to diffuse out of the joint rapidly, not giving a sustained effect. The disodium phosphate ester of betamethasone is used with the insoluble acetate ester form, imparting a rapid effect from the phosphate ester and a sustained effect from the acetate ester. Triamcinolone acetonide and triamcinolone hexacetonide also have very low solubility and a long duration. Three injections may be given in a joint, but there should be an interval of 4 weeks between injections.

After nerve injury in which the afferent sensory fibers are crushed or severed, the proximal portion of the nerve is stimulated by nerve growth factor to repair and re-establish a connection with the distal portion. In this process, the proximal terminal forms a mass of neuronal sprouts termed a *neuroma*. The sprouts generate spontaneous ectopic discharges signaling pain centrally. Application of steroids has been shown to reduce the neuronal activity. The reduction in spontaneous discharge is not caused by a reduction in the number of sprouts, but probably arises from a stabilization of the neuronal membrane conductivity. A steroid such as dexamethasone may be injected into the area of the neuroma. Multiple injections with local anesthetic and steroid are often needed to stop the spontaneous discharge.

Corticosteroid therapy is used to control symptoms of acute herpes zoster infection, and experience has shown that the infection is not disseminated with the use of steroids. Esmann and coworkers,[9] in a double-blind study, showed that steroids were no better than placebo in preventing development of postherpetic neuralgia after zoster infection; however, Keczkes and Basheer[22] showed that treatment with prednisolone after the development of postherpetic neuralgia reduced the duration of the neuralgia. The study by Keczkes and Basheer[22] also showed that treatment with carbamazepine was no more effective than placebo in modulating the herpetic pain.

DRUGS FOR MUSCULOSKELETAL PAIN

Centrally Acting Muscle Relaxants

Centrally acting skeletal muscle relaxants are indicated for relief of acute painful musculoskeletal conditions of local origin, but they should be used only as an adjunct to a physical medicine program that includes physical therapy, moist heat and ice, and other nonpharmacologic therapies. Few studies show the efficacy of muscle relaxants, and many clinicians are skeptical about their widespread use because of a lack of evidence of benefit apart from the sedative effects of the drugs. There are many causes for muscle spasms, and muscle relaxants are not effective for all causes (see Chapter 13). The following drugs are generally considered to have muscle-relaxant abilities:

1. *Carisoprodol*. Carisoprodol is metabolized to meprobamate and has habituating potential with development of physical and psychological dependence. In 1987, the National Institute on Drug Abuse reported that carisoprodol was ranked 54th of 234 abused drugs. The recommendation is to use it only on a short-term basis.
2. *Cyclobenzaprine*. Cyclobenzaprine is a tricyclic compound similar to TCAs. It has similar anticholinergic side effects as TCAs. It is typically chosen for use for patients with myalgia and myofascial pain. It is recommended that this medication be used with caution in older patients and be used only for a short period. This drug could be chosen for patients with moderate muscle pain who are not sleeping well. Disturbed sleep is often an accompaniment of musculoskeletal pain, and normalizing the quality and duration of sleep can have a beneficial effect on the pain. The medication is typically taken once a day at bedtime.
3. *Methocarbamol*. Methocarbamol is a skeletal muscle relaxant that is most effective for muscle spasticity. Side effects include seizures, drowsiness, sedation, nausea, and blurred vision.
4. *Metaxalone*. Metaxalone is a skeletal muscle relaxant for acute painful muscle problems. Side effects include leukopenia, hepatotoxicity, rash, dizziness, headache, and nausea.
5. *Baclofen*. Baclofen is primarily a skeletal muscle relaxant, useful in spasticity states. It also has some anticonvulsant activity, making it useful as an alternative drug for trigeminal neuralgia. Side effects include confusion, blurred vision, abdominal pain, and fatigue. In contrast to carba-

mazepine, baclofen is not metabolized in the liver. Baclofen is a $GABA_B$ receptor agonist. Activation of $GABA_B$ receptors produces analgesia in acute and chronic pain models. Data indicate that a possible mechanism for this effect is a $GABA_B$ receptor–induced blockade of neurokinin-1 receptor gene expression in the spinal cord. GABA is an important neurotransmitter that mediates inhibition in the CNS. Approximately 30% to 50% of all synapses are defined as GABAergic. GABA is a neurotransmitter in cortical and hippocampal interneurons. Three pharmacologically different receptor subtypes have been identified: $GABA_A$, $GABA_B$, and $GABA_C$. The $GABA_A$ receptor is postsynaptic and localized in central and peripheral sympathetic neurons. $GABA_B$ is a presynaptic receptor located on central nerve terminals. Its agonist is baclofen. The $GABA_A$ receptor acts directly on a Cl^- ionophore, whereas $GABA_B$ activity is mediated by a G_i protein (see Chapter 13).

6. *Tizanidine*. Tizanidine acts as a central muscle relaxant and has an antinociceptive effect. It is an α_2-adrenergic receptor agonist similar to clonidine that inhibits the release of NE centrally—that is, in the locus coeruleus and spinal cord. Although it is used primarily as a muscle relaxant, one study found it useful for treatment of chronic daily headache.[38] Because of its α_2-agonist activity, it is being used as an intrathecal agent to block sympathetically mediated pain through its effect on the α_2-adrenergic autoreceptors in the sympathetic nervous system. Tizanidine is metabolized in the liver and has been reported to cause elevations in liver enzymes, so the clinician should obtain baseline blood samples to determine alanine aminotransferase and aspartate aminotransferase levels before use and check them during use to ensure the medication is not causing an increase in the enzymes. Common side effects include dry mouth, somnolence, asthenia, and dizziness. The most serious reactions to this medication include hepatotoxicity, bradycardia, and hallucinations. Because of its α_2-receptor agonist activity, it can reduce heart rate and blood pressure long-term, so these vital signs should be monitored during its use.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are discussed in Chapter 21. Most NSAIDs are similar in action; use in orofacial pain is usually limited to acute conditions. Two NSAIDs, ketorolac and indomethacin (see earlier), have characteristics that are uniquely useful for headache conditions, however, in addition to their use in musculoskeletal pain.

NSAIDs are often used long-term for TMJ arthritides, but not without adverse effects. (The newer cyclooxygenase-2 inhibitors, thought to be largely free of adverse gastric effects, are also not used long-term without problems.) Besides altering platelet function, long-term use of NSAIDs may have a detrimental effect on the endogenous reparative process within the joint. For the most part, NSAIDs are used as temporary measures to stabilize acute flare-ups of pain, and long-term use is not usually recommended.

Injectable ketorolac is a valuable tool for managing acute inflammatory pain conditions and migraine attacks and is a preemptive agent after procedures that are likely to cause postprocedure inflammation, such as TMJ mobilization with lysis, lavage, and manipulation. Ketorolac should not be used in patients whose serum creatinine is greater than 5 mg/dL. The injectable form of ketorolac offers a more rapid and effective medication in acute pain. One study on migraine found that 60 mg of ketorolac intramuscularly was equivalent to 100 mg of meperidine plus 50 mg of hydroxyzine. Overuse of the medication can cause acute renal failure and should be limited to 5 days of therapy.

Indomethacin was discussed previously under migraine medications.

Benzodiazepines

The benzodiazepines are not generally used in the management of chronic pain because they are not analgesic. Diazepam is used for short periods, however, as a muscle relaxant and as an antianxiety agent for patients with acute myogenous pain. Clonazepam does not have as great a potential for inducing habituation and is used in chronic neuropathic pain because of its function as an antiseizure medication. Clonazepam is a drug of choice for treatment of burning mouth syndrome. The mechanisms of action for this condition is not understood, but is not considered to be due to medicating anxiety. The benzodiazepine-type medications act on the $GABA_A$ chloride channel (see Chapter 13), which has a wide range of activity in the CNS, including modulating seizures, increasing behavioral effects with alcohol, anxiolysis, sedation, and muscle relaxation.

DRUGS FOR NEUROPATHIC PAIN

Trigeminal neuralgia is the most common neuropathy seen in the orofacial region. Although Jurjani described trigeminal neuralgia in the mid-1100s and postulated that it was caused by vascular compression of the involved nerves, André in 1756 wrote the first comprehensive description of trigeminal neuralgia and coined the term *tic douloureux*. His first patient had had several teeth extracted in an attempt to treat an infection in the maxilla. After the last extraction, André wrote:

> *What had been regarded as the end of a mild and tolerable ailment, became the source of the sharpest and most uncomfortable pains, I would say the start of a tic douloureux that assailed her night and day, deprived her of sleep, and forbade her some of the bodily functions necessary for life. In fact these periodic agitations became so frequent that they rarely allowed five or six minutes of peace during an entire hour. The patient could not drink, eat, cough, spit or wipe her face without renewing all her pains.*

In 1853, Trousseau, a French neurologist, proposed that the episodes of tic douloureux were caused by paroxysmal depolarization in the trigeminal pathways similar to the cortical depolarization occurring with epilepsy. He suggested that drugs used to treat epilepsy would be useful for the neuralgic epilepsy. It was not until 1942, however, that another French neurologist, Bergouignan, first tested the drug phenytoin on patients with trigeminal neuralgia. In the early 1960s, Blom, a Swedish neurologist, performed a trial with carbamazepine and found it to be effective for most of his patients. Subsequent studies showed that both these drugs depressed synaptic transmission after maxillary nerve stimulation in the spinal trigeminal nucleus.

The current understanding of neuropathic pain includes many disorders that are not discussed in detail here. Trigeminal neuropathy is grossly broken down into disorders involving peripheral and central sensitization mechanisms. Box 23-5 lists the diagnostic criteria for the various neuropathic pain conditions found in the orofacial region. It is crucial to make an accurate diagnosis before instituting treatment. The selection of medications is a complex issue that involves an understanding of the mechanism of the pain. Trigeminal neuralgia and central neuropathic pain conditions are treated by systemic medications. Surgical interventions are often considered if the disorder does not respond to medication.

BOX **23-5**

Diagnostic Criteria for Orofacial Neuropathic Pain

C-Fiber Sensitization
Continuous variable aching pain
History of trauma to area
No obvious local cause
Pain aggravated by local stimuli (hyperalgesia and allodynia)
Normal radiograph
Positive response to somatic block
Response to thermography not defined
Sympathetic block does not define this disorder

Traumatic Neuralgia
Continuous, variable aching pain
May be punctuated by sharp jolts of pain
History of trauma to area
No obvious local cause
Pain aggravated by local stimuli (hyperalgesia and allodynia)
Equivocal somatic block (may be varying degree of sympathetic involvement)
Normal radiograph
Response to thermography depends on sympathetic involvement
Response to sympathetic anesthetic block is equivocal

Trigeminal Neuralgia
Episodic sharp, electric-like pain with periods of remission
No obvious local cause
Pain is triggered with minor stimulation
Normal radiograph
Normal thermogram
Positive somatic block
Sympathetic block does not define this disorder

Sympathetically Mediated Pain (Atypical Odontalgia)
Continuous, variable, diurnal aching pain
History of trauma to area

Complex Regional Pain Syndrome (II or III?)
Pain present >4 mo
Pain aggravated by local stimuli (hyperalgesia and allodynia)
No obvious local cause
Normal radiograph
Equivocal response to somatic block
Positive response to sympathetic block (>60%) is not a defining characteristic

Sympathetically Independent Pain
Continuous, variable, diurnal pain
History of trauma to area
Pain present >4 mo
Pain aggravated by local stimuli (hyperalgesia and allodynia)
No obvious local cause
Normal radiograph
Negative response to somatic block
Negative response to sympathetic block, although not a defining characteristic

Peripheral neuropathies are often treated by application of agents to the site of pain. Systemic medications are often added to the regimen for better pain management. The following sections discuss the medications used to treat neuropathic pain.

Antiseizure Drugs

The mechanisms responsible for the action of antiseizure medications vary and depend on the type of medication. The medications most effective for trigeminal neuralgia are use-dependent Na^+ channel blockers; however, these medications are not usually the most effective for other chronic peripheral and central neuropathies.

Carbamazepine

Carbamazepine is considered the gold standard for the management of trigeminal neuralgia, but it is also used to treat other neuropathic pain conditions and headache. Although valproic acid is the only anticonvulsant that has been approved for the treatment of migraine and has shown benefit, other anticonvulsants such as carbamazepine have been used successfully in selected cases. For neuropathic pain, the primary mode of action of carbamazepine is thought to be its action as a use-dependent Na^+ channel blocker, inhibiting repetitive neuronal discharge. Structurally, it is similar and related to TCAs.

Before taking carbamazepine, the patient should have baseline laboratory values for liver function and complete blood count, platelet, and differential. An extended-release form of carbamazepine is available. This medication requires only a twice-per-day dosing schedule, which is more convenient for the patient and aids in compliance. Initially, liver function tests should be obtained every 30 days to check liver response to the medication (see Chapter 14). Carbamazepine induces CYP3A4 and other subfamilies of the cytochrome P450 system, causing increased metabolism of the drug with lowered serum levels. The result of this effect is noted after 1 to 2 weeks of therapy and requires increasing the dose to obtain better pain control. The inductive effect also reduces the effect of several other drugs.

Gabapentin

Gabapentin has been used for seizures since the mid-1980s but did not become available in the United States until the 1990s. Its use in pain has become a great subject of interest, and numerous articles have described the benefits of gabapentin for treating various chronic pain disorders, including trigeminal neuralgia, diabetic neuropathy, peripheral neuropathy, and migraine. Gabapentin is a structural analogue of GABA and was developed as a GABA agonist; however, its mode of action is not through action on GABA receptors. Gabapentin decreases hyperalgesia in the formalin test, a model for centralized neuropathy. It has been hypothesized that the $\alpha_2\delta$ subunit of voltage-dependent Ca^{++} channels maintains mechanical hypersensitivity in neuropathic pain, and recent studies have shown that gabapentin selectively interacts with these units to reduce activity[10]; however, this may not correlate with its therapeutic effects.

Gabapentin crosses membrane barriers using the L-amino acid transporter system. A small amount is also known to cross by passive diffusion. It concentrates in the brain cytosol at a ratio of 10:1 compared with the extracellular space. An analgesic effect is attained rapidly, but its anticonvulsant effect is delayed, indicating probable different mechanisms for the two effects.

Gabapentin is excreted unchanged in the kidney. It has few interactions with other medications, and the side-effect profile is benign compared with other antiseizure drugs. Gabapentin is also useful for management of migraine headache.

Valproic acid

Valproic acid was the first antiepilepsy medication approved by the U.S. Food and Drug Administration (FDA) for migraine. Valproic acid is structurally different from other anticonvulsants, and its mechanism of antiseizure and analgesic action is related to inhibition of Na^+ channels, inhibition of T-type Ca^{++}

channels, and facilitation of GABAergic neurotransmission by inhibiting GABA aminotransferase and activating glutamic acid decarboxylase. In seizures, valproic acid may have direct effects on neuronal membranes, inhibiting kindling and reducing excitatory neurotransmission by the amino acids (see Chapter 14). Valproic acid has been shown to block development of neurogenic inflammation in the Moskowitz model of migraine.[26] Valproic acid is also used as a mood stabilizer in manic-depressive disorders (see Chapter 12).

Lamotrigine

Lamotrigine is a novel anticonvulsant drug that is useful for trigeminal neuralgia through its action as a Na^+ channel blocker. The cellular mechanism of Na^+ channel blockade is the same mechanism by which carbamazepine and phenytoin exert their action; however, it is unlikely that Na^+ channel blockade is the only cellular mechanism of lamotrigine.

Topiramate

The antiseizure drug topiramate is a monosaccharide derivative that modulates voltage-dependent Na^+ conductance, potentiates GABA-evoked currents, and blocks the kainate and α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) subtypes of the glutamate receptor. The Na^+ channel effect and blocking of the metabotropic AMPA and kainate receptor may account for the ability of this medication to suppress trigeminal neuralgia and other neuropathic pain states.[44] Topiramate has been shown to have antihyperalgesic and antinociceptive activity in animal models of neuropathic pain. Topiramate is approved by the FDA for partial-onset seizures, primary generalized tonic-clonic seizures, and migraine prophylaxis. The dose range for adults is 200 to 400 mg/day in two divided doses for epilepsy, 50 to 300 mg/day for adjunctive treatment of bipolar disorder, and 50 to 200 mg/day for migraine prophylaxis.

Side effects include sedation, dizziness, nervousness, ataxia, nausea, weight loss, metabolic acidosis, kidney stones, and secondary angle-closure glaucoma. The sprinkle capsule formulation allows topiramate to be taken with a tablespoon of soft food if needed. Important drug interactions occur with carbamazepine, phenytoin, and valproate, which can decrease topiramate levels owing to increased clearance. Topiramate may increase the clearance of phenytoin and valproate and reduce the effectiveness of oral contraceptives. A modest side effect of topiramate is weight loss. A loss of about 6 kg after 12 to 18 months of use can occur, and this can be augmented with higher doses. It has been observed that the weight changes are greatest in patients with more weight to lose.

Oxcarbazepine

Oxcarbazepine is structurally similar to carbamazepine, and its mechanism may involve similar use-dependent inhibition of voltage-dependent Na^+ action potentials. Compared with carbamazepine, oxcarbazepine has an increased tolerability and safety margin. It does not require liver enzymes or complete blood count monitoring, but electrolytes should be checked for Na^+ concentrations because oxcarbazepine can induce hyponatremia. Oxcarbazepine can be titrated more rapidly than carbamazepine, which is an advantage for patients in an acute phase of trigeminal neuralgia.

Phenytoin

Phenytoin was the first antiseizure medication used to treat neuropathic pain. Its mode of action is similar to carbamazepine. Phenytoin suppresses ectopic discharge of neuromas when applied topically. This effect is probably moderated by a reduction in high-frequency repetitive firing of action potentials by blocking Na^+ channels.[27] Phenytoin is available as an intravenous preparation that has been shown to be beneficial in managing acute flare-ups of neuropathic pain.

Pregabalin

Pregabalin has been approved for the treatment for painful diabetic neuropathy and postherpetic neuralgia, and more recently it was approved for the treatment of fibromyalgia. Pregabalin is an active S-enantiomer of racemic 3-isobutyl γ-aminobutyric acid. The mechanism of action for pain is still to be determined. Similar to gabapentin, it is not metabolized in the liver and has no interaction with cytochrome P450 isoenzyme system, and it has no reported drug-drug interactions. The most common side effects are dizziness and somnolence. Pregabalin has been shown to improve slow-wave delta sleep and may be useful in sleep disorders associated with poor-quality delta sleep. In these cases, taking most of the dose at bedtime can be useful.

Pregabalin has been designated as a Schedule V controlled substance because of its potential for abuse and dependence. Patients with neuropathy are started at 50 mg three times daily and may be titrated to 300 mg daily within 1 week based on efficacy and tolerability. It is generally dosed at one third to one sixth the dose of gabapentin and is considered more potent than gabapentin. Most patients taking pregabalin need to take it only two times per day. In general, pregabalin can reduce neuropathic pain and anxiety within 1 week of initiation.[2]

Tiagabine

Tiagabine is a potent and selective GABA reuptake inhibitor with antiallodynic effects noted in rodent models of neuropathic pain (see Chapter 14). The antinociceptive effect was related to inhibition of GABA reuptake and resultant increased extracellular GABA levels. Because pretreatment of experimental animals with a $GABA_B$ receptor antagonist eliminated the antinociceptive effect of tiagabine, $GABA_B$ receptors may be involved in the tiagabine effect. The antiallodynic effects were dose dependent, with significant increases in threshold response to tactile stimulation.

Tiagabine has been compared with valproic acid as having efficacy for prophylactic management of migraine. The mechanism of action probably relates to its GABAergic characteristics. For trigeminal neuralgia, tiagabine is used as an add-on drug in combination with another antiseizure medication when better control of the pain is needed. For migraine, tiagabine is used as a prophylactic agent to decrease the frequency and intensity of migraine attacks.

N-Methyl-D-Aspartate (NMDA) Receptor Antagonists

It has been shown that 90% of C fibers contain glutamate and probably release glutamate and SP from their peripheral terminals when the stimulus is sufficiently long lasting, at least for several seconds to minutes. Glutamate is an agonist at the NMDA and AMPA receptors, but cannot activate the NMDA receptor without the presence of the co-agonist glycine. The NMDA receptor has been considered a potential target for modulating chronic pain; however, current NMDA receptor antagonists have severe side effects, limiting their usefulness. Blocking the glycine site may provide a target without the profound side effects accompanying the currently available NMDA receptor antagonists. The Ca^{++} channel is normally blocked by Mg^{++}, which is displaced, opening the channel to Ca^{++} influx when the receptor is activated. This event is responsible for the secondary allodynia noted in neuropathic pain. Ketamine is a voltage-dependent blocker of the NMDA receptor channels.

BOX **23-6**

Potential Mechanisms of Drugs Used to Treat Pain

MECHANISM	DRUG
5-HT reuptake inhibition	TCAs
NE reuptake inhibition	TCAs
Na^+ channel blockade	Carbamazepine, valproic acid, lamotrigine, phenytoin, topiramate, oxcarbazepine
Ca^{++} channel blockade	Valproic acid, gabapentin (?)
GABAergic neurotransmission	Gabapentin, valproic acid, baclofen, carbamazepine, topiramate, tiagabine
NMDA receptor antagonism	Ketamine, dextromethorphan
Substance P depletion	Capsaicin
AMPA receptor antagonism	Topiramate

AMPA, α-Amino-3-hydroxy-5-methyl-4-isoxazole propionate; *5-HT,* 5-hydroxytryptamine; *NE,* norepinephrine; *NMDA, N*-methyl-D-aspartate; *TCAs,* tricyclic antidepressants.

The NMDA receptor is an obvious target for pain intervention because it is known to have a role in long-term potentiation and central sensitization. Ketamine and dextromethorphan are NMDA channel blockers and are effective in reducing NMDA-mediated responses in the dorsal horn nociceptive system. More recent studies have shown that dextromethorphan and ketamine are able to reduce temporal summation hyperalgesia and spontaneous discharge in neuropathic pain.

These agents are used when other medications have failed to provide adequate relief in centralized neuropathies. Ketamine is a strong NMDA receptor antagonist, but its side effects are more disturbing. Dextromethorphan has fewer attendant problems associated with its use but is only a weak NMDA receptor antagonist with inconsistent benefits. Nevertheless, its antagonistic activity on the NMDA receptor has been reported to be useful for treating chronic pain. Sedation, dizziness, and rash are the most common side effects.

Ketamine may have some use in management of chronic nonresponsive neuropathy; however, as indicated, the side effects become intolerable or difficult to manage. Ketamine is available only for intramuscular or intravenous administration, but it has been used orally. It is a dissociative anesthetic that is used to provide sedation and anesthesia for short surgical procedures (see Chapter 18). Patients may have adverse psychological effects, including hallucinations, nightmares, delusions, dissociative reactions, and schizophreniform psychosis.

The NMDA receptor blocker memantine was approved for the treatment of Alzheimer's disease in 2003. The drug is classified as an NMDA receptor antagonist. The excitatory amino acid glutamate has been implicated in excitotoxic cell death, and levels of glutamate are linked to the activation of the NMDA receptor. NMDA receptor activity and glutamate have also been implicated in migraine. Some evidence suggests that memantine may be useful in the prophylaxis against migraine. The mechanisms of many relevant drugs used to treat pain are summarized in Box 23-6.

Drugs That Act at α-Adrenergic Receptors

Atypical odontalgia is a central neuropathic orofacial pain condition that is influenced by the sympathetic nervous system.[16] In studies by Graff-Radford and Solberg,[16] 60% of the patients diagnosed with atypical odontalgia responded to sympathetic nervous system blockade, relieving their tooth site pain and fulfilling the criteria for a diagnosis of sympathetically maintained pain. Pain conditions associated with sympathetically maintained pain include reflex sympathetic dystrophy and causalgia. Historically, treatment has involved sympathetic ganglion blockade with local anesthetics or clonidine to stop sympathetic outflow and relieve pain.

Phentolamine, an α-adrenergic receptor antagonist, acts on injured nociceptors to reduce sympathetically mediated pain. Continued nociceptor activity is mediated through local sympathetic fiber release of NE, stimulating the α_1-adrenergic receptors and activating the affected nociceptors. α_2-adrenergic receptors function as autoreceptors on the peripheral terminals of the postganglionic sympathetic nerve. When these receptors are activated, the release of NE from the sympathetic fibers is reduced. Tizanidine, similar to clonidine, is an α_2-adrenergic receptor agonist that decreases sympathetic release of NE. In sympathetically mediated pain states, it is desirable either to block α_1-adrenergic receptor activity to reduce the postjunctional effect of NE or to stimulate α_2-adrenergic receptors to reduce NE release. These drugs also are useful in decreasing sympathetically mediated symptoms associated with narcotic withdrawal, such as anxiety, tachycardia, tremor, and sweating.

Topical Agents

Topical application of medications to the skin to treat pain has its roots in ancient literature and lore. To treat headache, Aretaeus recommended rubbing the head with rubefacient plants to provoke localized sweating, thought to aid in eliminating humors causing the headache. Compounding pharmacists are able to combine medications in bases such as pleuronic lecithin organogel (PLO) for application to the external skin surface or in bases such as Orabase for intraoral application. Direct application of topical agents to localized areas of inflammation, irritation, and pain offers several advantages: placement of medications directly over the treatment area potentially decreases side effects, and the direct effect of topical agents on the local receptors may have greater effect than systemic medications.

PLO is a gel base that is able to penetrate the epidermal barrier, carrying the agent through the epidermis to the affected locus. Some systemic absorption occurs, but it is significantly less than would be obtained by systemic administration. The combinations of medications are virtually limitless, but the underlying principle for choosing agents to include in the mixture should be based on the assumed pathologic state underlying the painful condition. If the clinician is managing an inflamed TMJ, and the patient is unable or unwilling to take a systemic anti-inflammatory drug, an NSAID such as ketoprofen could be included in a PLO base to be applied over the inflamed joint. Presumably the NSAID would decrease pain and inflammation by inhibiting prostaglandin synthesis locally, avoiding significant systemic effects.

In the past, chronic peripheral trigeminal neuropathy defied treatment, but recent understanding of the pathophysiologic characteristics of the condition has led to development of treatment approaches with topical agents that inhibit peripheral sensitizing mechanisms such as C-fiber sensitization. When capsaicin-responsive vanilloid receptors were discovered on small-diameter unmyelinated nociceptors (assumed to be C fibers), it was realized that these receptors could be the target for topical intervention. Under new nomenclature, the capsaicin-responsive vanilloid receptors are now described as *TRPV1 receptors*. Activation causes the affiliated nociceptors to release SP. Long-term application depletes SP stores and temporarily inhibits the neuron's ability to synthesize more. Persistent application of capsaicin desensi-

tizes chronic peripheral neuropathy, rendering relief from pain. Intraoral application is enhanced by fabricating an acrylic stent to cover the affected area when applying a capsaicin mixture. Capsaicin 0.025% is mixed in Orabase-B paste to give a sticky quality to the paste, helping to hold the stent in place and limiting the dispersion of the agent throughout the mouth. Nevertheless, for conditions such as trigeminal neuralgia, systemic drugs or surgical procedures are usually required.

Topical ketoprofen combined with other agents is useful in applications over inflamed muscles and joints. Ketoprofen 10% to 20% can be mixed in a PLO base and applied three to four times per day after wiping the area with a moist washcloth. In this situation, ketoprofen has a local anti-inflammatory effect without gastric irritation because of systemic inhibition of cyclooxygenase-1. Patients should be cautioned regarding the potential for developing photosensitivity because of the sensitizing properties of the benzophenone moiety of ketoprofen. Ultraviolet light exposure of skin covered with ketoprofen cream promotes the photolysis of erythrocytes. In addition, the drug is able to induce photoperoxidation of linoleic acid, and ketoprofen may induce DNA damage. There is a concern that repeated use of ketoprofen or other topical agents could lead to sensitization, with the possibility of incurring a greater risk of systemic allergic reactions with oral NSAIDs or other drugs.

The most common neuropathies in the orofacial region include trigeminal neuralgia, traumatic trigeminal neuropathy, postherpetic neuralgia, diabetic neuropathy, cancer-induced neuropathy, and AIDS-induced neuropathy. All these neuropathies have common pain mechanisms and similar treatment protocols. Peripheral nerve damage leads to peripheral sensitization and changes in the CNS. Topical medications are useful for neuropathic pain from peripheral sensitization and may be useful for centralized neuropathy with peripheral pain trigger zones.

To deliver a drug in the orofacial region by topical application, the agent has to penetrate the natural barriers that the facial skin and oral mucosal tissues provide. The pharmaceutical industry has found different ways to improve the absorption of topical medications, such as increasing the time and contact between the medications and the target tissues and developing different delivery systems such as creams, gels, dissolvable tablets, chewing gum, adhesive patches, polymeric devices, mouth rinses, and medicated lipsticks. The use of topical drug delivery is quite familiar to the dental profession because the application of creams, gels, and rinses to mucosal sites is a daily activity in dental practice.

The medications often used for oral and perioral neuropathies are topical anesthetics and, more recently, capsaicin. Other compounds, such as NSAIDs, sympathomimetic agents, and NMDA antagonists, are now being used with variable success. Although it is possible to have other agents, such as carbamazepine, baclofen, or amitriptyline, compounded for local delivery, their use in peripheral conditions is controversial because their mechanism of action has been described as central, and a peripheral mechanism of action has not been clearly established.

The use of intraoral topical medications is accompanied by some inconveniences. These agents tend to dissolve in saliva and spread throughout the mouth and down the throat. If the topical agent does not have mucosal adhesive properties, it quickly washes away from the area where it is being applied. Several strategies and delivery systems are being used to counter this problem. The following medications are delivered through the skin by a transdermal carrier or by placing in a material such as Orabase that adheres to the mucous tissue to enhance and maintain tissue/medication contact for longer periods.

Capsaicin

Capsaicin can be applied in a 0.025% concentration to the affected area five to six times per day. Capsaicin is known to reduce C-fiber activity where applied. Initial applications cause the typical burning sensation noted when eating spicy food. The burning lasts approximately 10 minutes and then begins to resolve. Repeated application inhibits C-fiber activity, causing immediate release of SP and decreasing further production. The capsaicin should be mixed with Orabase paste in equal parts before application.

Clonidine

Clonidine is an α_2-adrenoceptor agonist that is used to reduce sympathetic activity in the target area. This agent should be compounded by a pharmacist to deliver approximately 0.1 mg of clonidine in three applications per day. Clonidine is used for neuropathies that have sympathetic involvement. Thermographic examination of the painful area may show as a cold area, indicating possible sympathetic mediation.

Ketamine

Ketamine (200 mg/mL) is applied in a transdermal or mucoadhesive base. Chronic peripheral neuropathic pain may be driven by NMDA receptor activity—hence the rationale for the use of this drug. Although controversial at present, there are reports of NMDA receptor activity in the peripheral area where nerve damage has occurred. Inhibiting NMDA activity may be the reason for these agents providing some benefit.

Eutectic mixture of local anesthetics

The eutectic anesthetic preparation consists of 2.5% prilocaine and 2.5% lidocaine; although effective, it has the inconvenience of a low melting point, rendering it liquid even at room temperature. Covering the application site with an occlusive dressing keeps the anesthetic in the desired area and, if used intraorally, protects the cream from salivary contamination. In the oral mucosa, this mixture is a superior topical anesthetic agent for pain reduction if given sufficient time of contact with the area to be anesthetized.

The rationale for the use of these agents is to decrease self-perpetuating C-fiber activity. It is thought that if the activity can be reduced for a long enough period, C-fiber function will normalize and not re-establish abnormal activity.

OTHER DRUGS USED FOR OROFACIAL PAIN

Sodium Hyaluronate

Sodium hyaluronate is derived from hyaluronic acid and is available for injection into small joints. Hyaluronic acid is a normal constituent of synovial fluid, responsible for the viscoelastic properties of the fluid. Hyaluronic acid is decreased in osteoarthritis, and use of these products produces viscosupplementation that benefits the joint by augmenting the viscosity of the joint fluid and stimulating endogenous production of hyaluronic acid. The agent also binds to specific hyaluronic acid receptors on the chondrocytes and synoviocytes, acting as a free radical scavenger and reducing the cellular production of prostaglandin E_2 and bradykinin.

Botulinum Toxin Type A and B

Botulinum toxin type A (BoNT-A) is used for involuntary movement disorders such as dystonia, blepharospasm, torticollis, and other myotonic and dystonic disorders. BoNT-A causes an irreversible presynaptic blockade of the release of acetylcholine at the motor end plates, inhibiting muscle ability to contract; however, collateral sprouting of motor axons restores function within 3 to 6 months. The effect on muscle pain occurs rapidly, although benefit for the muscle spasms

may take 2 to 3 weeks to develop fully; however, it may provide more benefit for the patient than the drug's effect on muscle spasm. Previous treatment for these problems relied on oral medications that were not particularly beneficial. When the toxin was used for muscles involved in the face, it was noted that face wrinkles were eliminated for the 3- to 4-month duration of the muscle end plate block.

Migraine patients who were having these injections for forehead wrinkles began reporting that their migraines had subsided for the duration of the drug's effect. The effectiveness of botulinum toxin for migraine and other headaches is currently being studied.[1] Evidence suggests that there is some benefit for refractory myofascial pain.[34] For a review of BoNT-A in chronic pain, see the article by Göbel and colleagues.[15]

Botulinum toxin type B (BoNT-B) is relatively new as a therapeutic agent. It has properties different from BoNT-A. The anticholinergic side effects of BoNT-B are greater than with BoNT-A, injections of BoNT-B were reported to be more painful, and dysphagia occurred more frequently in injections in the facial region.[4,19,23,33,37]

IMPLICATIONS FOR DENTISTRY

This chapter has reviewed the medications used to treat several pain syndromes, including chronic orofacial pain conditions. The medications traditionally used by dentists to treat their patients are generally limited to antibiotics, anti-inflammatory agents, opioids, local or general anesthetics, and sedatives. These medications are used to treat acute pain, inflammation, and infections or to anesthetize patients for surgical procedures. With the development of the field of orofacial pain and the increased understanding of painful non–tooth-related conditions that are seen in the orofacial environment, the dental pharmacopeia has expanded to include a vast array of medications that have not generally been considered previously. This array will continue to expand as more pharmaceuticals are developed, and the understanding of orofacial pain disorders and their mechanisms broadens.

ANTIMIGRAINE DRUGS AND DRUGS FOR NEUROPATHIC AND OTHER PAIN SYNDROMES

Nonproprietary (generic) name	*Proprietary (trade) name*
Ergots	
Dihydroergotamine	Migranal, DHE 45
Ergotamine	Ergomar, in Cafergot
Methylergonovine	Methergine
Methysergide	Sansert
Triptans	
Almotriptan	Axert
Eletriptan	Relpax
Frovatriptan	Frova
Naratriptan	Amerge
Rizatriptan	Maxalt
Sumatriptan	Imitrex
Zolmitriptan	Zomig
Antiemetics	
Metoclopramide	Reglan
Prochlorperazine	Compazine
Promethazine	Phenergan
Trimethobenzamide	Tigan
TCAs (see Chapter 12)	
β-Adrenergic receptor blockers (see Chapter 7)	
Ca^{++} channel blockers (see Chapter 26)	
Antihistamines (see Chapter 22)	
Centrally acting muscle relaxants	
Baclofen	Lioresal
Carisoprodol	Soma
Cyclobenzaprine	Cyclobenz
Metaxalone	Skelaxin
Methocarbamol	Robaxin
Tizanidine	Zanaflex
Benzodiazepines (see Chapter 13)	
NSAIDs (see Chapter 21)	
Antiseizure drugs (see Chapter 14)	
NMDA antagonists	
Dextromethorphan	Delsym
Ketamine	Ketalar
Memantine	Namenda
α-Adrenergic receptor antagonists	
Clonidine	Catapres
Tizanidine	Zanaflex
Topical drugs*	
Pleuronic lecithin organogel	—
Capsaicin	Zostrix
Others	
Botulinum toxin-A	Botox
Botulinum toxin-B	Myobloc
Dichloralphenazone	In Midrin
Indomethacin	Indocin
Isometheptene	In Midrin
Sodium hyaluronate	Hyalgan

*See also local anesthetics, Chapter 16.
NMDA, N-methyl-D-aspartate; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *TCAs*, tricyclic antidepressants.

CHAPTER 24

Antiarrhythmic Drugs

FRANK J. DOWD

Antiarrhythmic drugs are used to correct or reduce the risk of cardiac arrhythmias (dysrhythmias). They are classified into several categories on the basis of their mechanisms of action and resulting cardiac effects. All antiarrhythmic agents influence impulse generation or impulse conduction in the heart and cause definable electrophysiologic effects.

BASIC CARDIAC ELECTROPHYSIOLOGY

Under normal conditions, the chambers of the heart contract as synchronized rhythmic units driven by electrical impulses generated in and conducted throughout the heart. The normal pacemaker impulse is generated in the sinoatrial (SA) node and travels through the atria to each muscle cell, to the atrioventricular (AV) node, and through specialized conduction pathways in the common bundle of His, bundle branches, and Purkinje network to reach the ventricular muscle cells. Figure 24-1 illustrates representative action potentials for an SA nodal cell, an atrial muscle cell, an AV nodal cell, a Purkinje fiber, and a ventricular muscle cell. Three experimental measures are used to characterize the electrophysiologic properties of the heart: automaticity, refractoriness, and conduction velocity. Many of the antiarrhythmic effects of drugs result from changes in these parameters, which are reflected by action potential alterations in various regions of the heart.

Automaticity

Automaticity describes the unique ability of cells of the SA node, AV node, and specialized conducting system to exhibit spontaneous phase 4 depolarization and impulse generation. An increase in automaticity refers to an increase in the rate of impulse generation, and, conversely, a decrease in automaticity refers to a decrease in the rate of impulse generation. Under normal conditions, the pacemaker cells of the SA node exhibit the most rapid generation of impulses, making the SA node the controlling pacemaker of the heart. The rate at which pacemaker cells initiate impulses is a function of the rate of phase 4 depolarization, the maximum diastolic potential (MDP), and the magnitude of the threshold potential (Figure 24-2). An increase in the rate of phase 4 depolarization in the SA node increases heart rate, whereas a change in the threshold voltage to a more positive value or an increase in the MDP (hyperpolarization) decreases the heart rate. These functions are under nervous and hormonal control and can be altered by injury or drugs.

Refractoriness

The period after the initiation of an action potential during which another action potential cannot be initiated and propagated regardless of stimulus is known as the *effective refractory period* (ERP) (see Figure 24-2). A change in the action potential duration (APD) is accompanied by a similar change in the duration of the ERP, although the ratio of change may not be 1:1. If the ERP is lengthened with respect to the APD, the cardiac cells will have repolarized more completely before they respond to a stimulus. Many drugs with antiarrhythmic effects prolong the duration of the ERP, and some decrease it.

Conduction Velocity

Conduction velocity in cardiac fibers is altered by several factors, including anatomic characteristics, the electrophysiologic state, pathologic conditions, and many antiarrhythmic drugs. The rate of phase 0 depolarization strongly influences the conduction velocity. The rate (or slope) of phase 0 depolarization (measured as the change in voltage per unit of time [dV/dt]) depends on the membrane potential during phase 4. The more negative the membrane potential at the beginning of phase 0 depolarization, the greater is the maximal dV/dt for phase 0. In this sense, what happens in phase 4 influences what happens in phase 0.

Ion Channels

Ions and the channels that control their movements play major roles in the various phases of cardiac depolarization and repolarization. Figure 24-3 illustrates the membrane action potential in an SA nodal cell and a Purkinje fiber—two characteristically different action potentials—and the flow of ions through specific channels in the Purkinje fiber.

In Purkinje fibers and in atrial and ventricular myocardium, depolarization in phase 0 results from an initial, "fast channel" current of Na^+ in the inward direction. Na^+ channels also contribute to the pacemaker current in phase 4 of pacemaker cells. Another major inward current, carried by Ca^{++} and conducted through "slow channels," contributes to the plateau phase (phase 2) of the action potential. Ca^{++} channels are of two types, T and L. These channels remain open for different periods during the action potential and respond differently to antiarrhythmic drugs.

Outward K^+ currents are responsible for repolarizing the muscle fiber in phase 3 and, by slowly deactivating in phase 4, contribute to spontaneous depolarization in pacemaker cells, notably the SA node, AV node, and (sometimes) His-Purkinje fibers. (Na^+ and Ca^{++} also play roles in depolarization during phase 4.) As K^+ conductance through inwardly rectifying K^+ (Kir) channels decreases, and Na^+ and Ca^{++} conductance increases, spontaneous depolarization during phase 4 occurs. Another major difference between pacemaker cells (e.g., cells of the SA and AV nodes) and nonpacemaker cells (e.g., cardiac muscle cells) is the slope of phase 0. Phase 0 has a much lower slope in pacemaker cells, where the major membrane event governing depolarization in phase 0 is Ca^{++} influx through slow channels. As indicated, the faster phase 0 depolarization of the myocardium and Purkinje fibers is caused primarily by

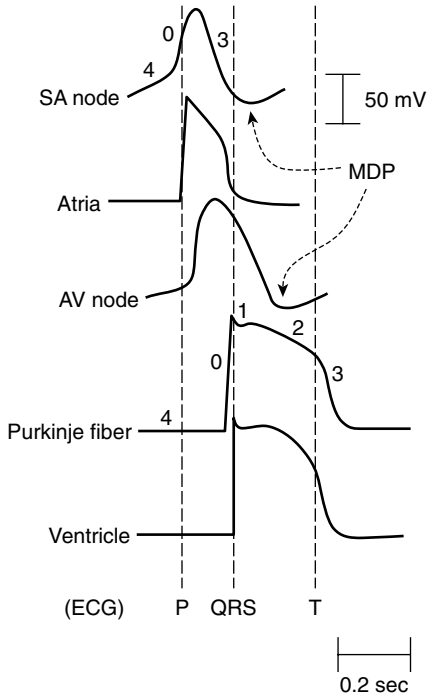

FIGURE **24-1** Action potentials of cells from five different regions of the heart. The numbers refer to the phases of the action potential as explained in the text. *Phase 0*, rapid depolarization; *phase 1*, early repolarization; *phase 2*, plateau phase; *phase 3*, repolarization, which continues until the maximum diastolic potential (*MDP*) is reached; *phase 4*, steady diastolic potential in the Purkinje fiber, slow spontaneous diastolic depolarization in the sinoatrial (*SA*) node and atrioventricular (*AV*) node. The action potentials are positioned in temporal relationship to each other and to waves of the ECG.

the Na^+ influx through fast channels. Differential effects on these ion fluxes help explain variations in the therapeutic uses and adverse effects of the antiarrhythmic drugs.

The K^+ current that is responsible for repolarization of the action potential is termed the delayed outwardly rectifying K^+ current (I_K). I_K is composed of several distinct currents carried through separate channels. Each current and its corresponding channel are defined by the rapidity with which they activate. The K^+ currents I_{Ks}, I_{Kr}, and I_{Kur}, referring to slow-activating, rapid-activating, and ultrarapid-activating currents, are conducted through Ks, Kr, and Kur channels.[13]

The complex interplay of ionic currents that constitute the cardiac action potential is based on the ability of ion channels to sense and respond to variations in the membrane potential. Channels that are in a closed, resting state open when a particular threshold potential is reached. Ions capable of diffusing through these activated channels immediately begin flowing in response to their electrochemical gradients across the cell membrane. Most ion channels spontaneously close, or become inactivated, over a characteristic time frame, and the ion flux abruptly decreases. Channels in the inactivated state are unresponsive, or refractory, to the original stimulus and remain so until the membrane potential returns to a value that permits the channels to assume again the closed, resting conformation. As discussed in subsequent sections of this chapter, many antiarrhythmic drugs bind preferentially to specific conformations of ion channels and exert differing effects on the action potential.

ORIGINS OF ARRHYTHMIAS

Rhythm disturbances, often occurring as a result of myocardial infarction, are the most common cause of death from heart disease. Arrhythmias are thought to originate from abnormal impulse generation, impulse conduction, or both in combination. Some arrhythmias caused by abnormal impulse generation result from increased automaticity. These tachyarrhythmias are usually in response to an increase in the rate of diastolic depolarization (increased slope of phase 4) in pacemaker cells. Phase 4 depolarization can be altered by auto-

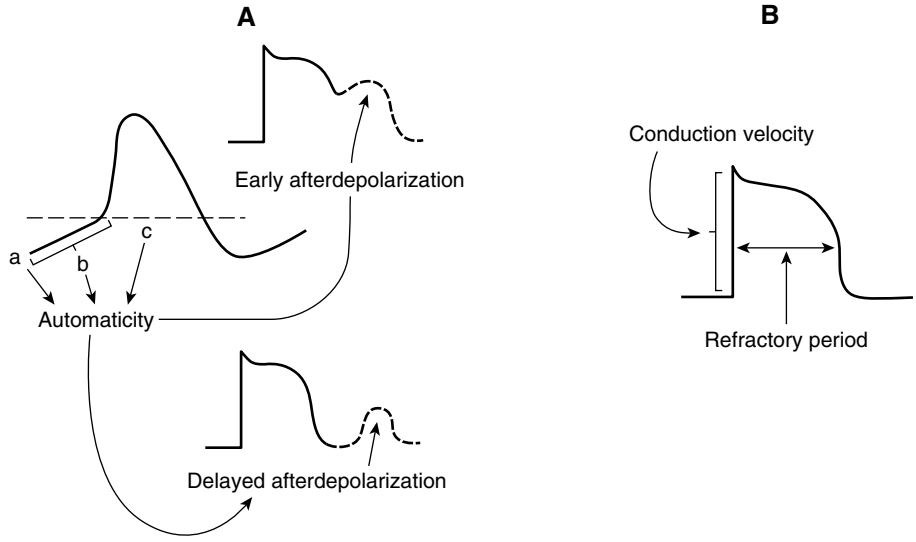

FIGURE **24-2** Parameters that are important in arrhythmias and their treatment. **A,** Automaticity is influenced by the level of the maximum diastolic potential (*a*), the slope of phase 4 (*b*), the potential at which the threshold (*dashed line*) is reached (*c*), or the presence of afterpotentials. **B,** Conduction velocity is directly related to the slope of phase 0. The refractory period is directly related to the duration of the action potential.

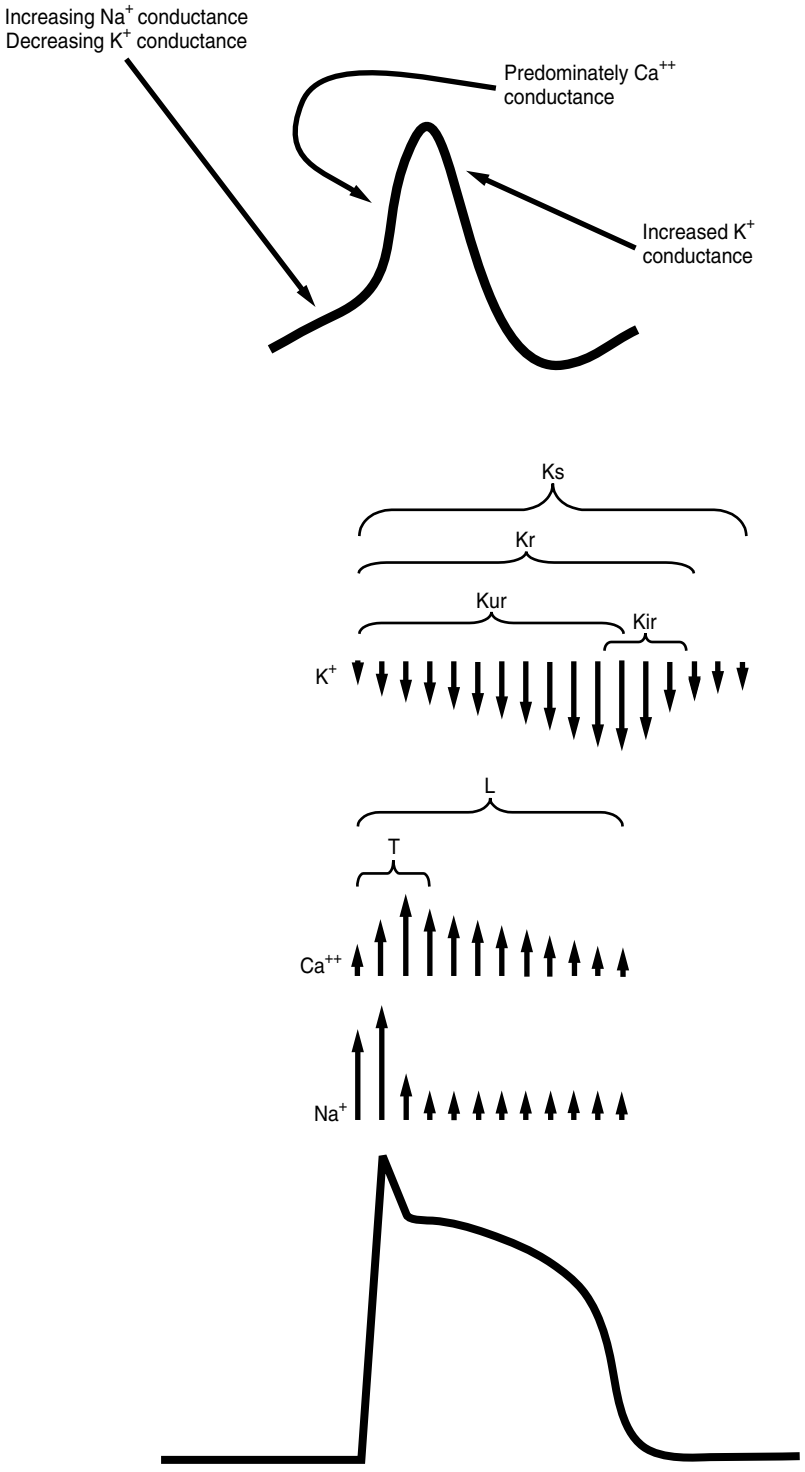

FIGURE **24-3** Characteristic membrane action potentials from a sinoatrial (SA) nodal cell (*top*) and from a Purkinje fiber (*bottom*). The relative magnitudes of the various ionic fluxes, as they apply to the Purkinje fiber, are shown by the length of the *arrows* above the Purkinje fiber; ↑ indicates a depolarizing current, and ↓ indicates a repolarizing current. Differences in ion fluxes for the SA node are described. Predominate channel subtype activities for Ca^{++} and K^+ channels are shown above the respective arrows. In the SA (and atrioventricular) node, phase 0 is slower than in the Purkinje fibers and myocardium because phase 0 primarily depends on Ca^{++} influx. There is no discernible phase 2 in the SA node. Phase 3 in the SA node depends on K^+ efflux, as in the other cells of the heart. Phase 4 for SA nodal cells results, in part, from the pacemaker current largely provided by an increase in Na^+ conductance and a gradual decrease in K^+ conductance.

nomic nervous system activity, by hormones, or by drugs. Changes in the MDP and threshold potential voltage can also affect automaticity. Abnormal impulse generation may also be triggered by afterpotentials that occur in cardiac pacemakers affected by drugs, disease, or other disturbances (see Figure 24-2). The induced afterdepolarizations may be early (before repolarization is complete) or delayed (after full repolarization has occurred) and can result in sustained tachyarrhythmias.[1] Excessive intracellular Ca^{++} is a major contributor to delayed afterpotentials, whereas delayed repolarization increases the risk for early afterdepolarizations in some cells.

An important example of an alteration in impulse conduction that is easily induced in experimental animals is the phenomenon known as *reentry*. Figure 24-4 shows how a reentrant rhythm may develop. As illustrated, conduction in branch *A* is normal, whereas impulses in branch *B* can proceed in only the reverse direction (unidirectional block). A normally conducted impulse through branch *A* can be conducted in retrograde fashion through branch *B* to re-excite an area of tissue (point *R*) that was previously excited by the normal path of conduction. For this "circus movement" to occur, the tissue at point *R* must have repolarized to a point at which

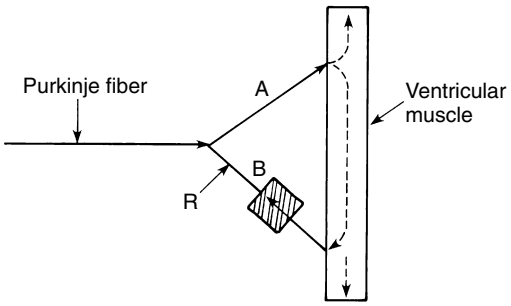

FIGURE **24-4** Reentry in the presence of unidirectional block. The hatched area in path *B* indicates a unidirectional block of impulse conduction.

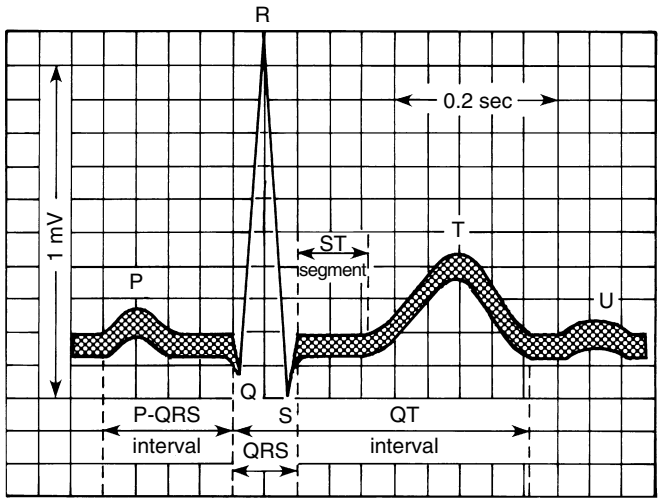

FIGURE **24-5** Normal ECG. *P,* Atrial depolarization; *QRS,* ventricular depolarization; *T,* ventricular repolarization. The *U* wave corresponds to interventricular repolarization. (From Milnor WR: The ECG. In Mountcastle VB, editor: *Medical physiology,* ed 14, St Louis, 1980, Mosby.)

excitation is possible (which usually means that the retrograde conduction is relatively slow). A wave of re-excitation traveling in a circular path through fiber *A*, the contractile cardiac muscle, and fiber *B* can result in a self-sustaining arrhythmia. Reentry is usually a major contributor to atrial fibrillation, an arrhythmia especially common in elderly individuals.

Another type of conduction abnormality, known as *heart block*, occurs in response to impaired conduction in the AV node or conducting tissues of the ventricular myocardium. In its simplest form (first-degree block), there is excessive delay between atrial and ventricular depolarizations, resulting in a prolonged PR interval. In more advanced forms, some (second-degree block) or all (third-degree block) of the impulses from the SA node are prevented from reaching the ventricles, resulting in a ventricular rate that is lower than the atrial rate.

Disturbances in the relationship of the fast and slow electrical responses of certain cardiac cells may play an important role in the genesis of arrhythmias. The *fast response* refers to the rapid phase 0 depolarization caused by rapid Na^+ influx (see Figure 24-3). This kind of activity is seen in atrial and ventricular muscle fibers and specialized conducting fibers. In addition to the rapid inward current carried by Na^+, the fast fibers exhibit a second, slower inward current carried by Ca^{++}. The slower current does not normally constitute a major factor in phase 0 depolarization of the atrial and ventricular myocardium and Purkinje fibers, but it persists after rapid depolarization and is responsible for the prolonged plateau phase characteristic of these fibers. Fibers located in the SA and AV nodes, the AV ring fibers, and the mitral and tricuspid valve leaflets show the slow response in phase 0, during which the depolarization is carried largely by the inward Ca^{++} current.

Although the fast fibers exhibit rapid yet sustained depolarization, remain refractory, and conduct impulses safely, the slow fibers exhibit a slow rate of depolarization, low resting potential, and low impulse amplitude, resulting in slow conduction and susceptibility to aberrant stimulation. In some disease states, the fast response may become inactivated, leaving the slow response dominant. These conditions favor the genesis of arrhythmias because of the low safety factor associated with the slow response. In the heart, an intricate relationship exists between conduction velocity, path length, refractory period duration, and impulse generation that, when altered through one or more mechanisms, may result in the development of arrhythmias.

Certain arrhythmias can be traced to defects in one or more ion channels. The long QT syndrome results from delayed repolarization in the ventricle. A delayed repolarization can be caused by any depolarizing current, such as a Na^+ current, that lingers into phase 3 of the action potential. It can also result from reduced activity of a repolarizing K^+ current. A defect in the Kr (rapid activating current) channel is the basis for one type of familial long QT syndrome that can devolve into *torsades de pointes*, a potentially life-threatening ventricular tachyarrhythmia (see later).[10] Torsades de pointes may also be elicited by drugs that inhibit Kr channels and increase the QT interval. These include numerous antiarrhythmic agents and some drugs of other classes. Whether the delay in repolarization is caused by a hereditary defect or by a drug, it leads to a net enhancement of inward cationic flow, which can trigger early afterdepolarizations (see Figure 24-2). Because the cells in the wall of the ventricle are not equally affected, multiple waves of reentry can occur, initiating torsades de pointes. Effort is under way to develop more selective K^+ channel inhibitors as potential antiarrhythmic drugs. Torsades de pointes is a major risk of drugs that selectively block Kr channels. Hypokalemia and hypomagnesemia increase the risk of developing torsades de pointes.[16]

ELETROCARDIOGRAPHY AND COMMON ARRHYTHMIAS

Arrhythmias are generally classified as supraventricular (originating in the atria or conducting system not in the ventricle) or ventricular. A few of the most common arrhythmias are described. For comparison, a diagram of a normal electrocardiogram (ECG) is provided in Figure 24-5. In Figure 24-5, also note the P–QRS (or PR), QT, and ST intervals and the duration of the QRS complex. Figure 24-6 contains representations of ECGs recorded during arrhythmias of ventricular and supraventricular origin.

The first arrhythmia illustrated is a simple sinus tachycardia caused by rapid impulse generation (i.e., increased automaticity) in the SA node. Higher rates of atrial activity often involve reentry, as in atrial flutter (approximately 300 beats/min) or fibrillation (400 to 700 beats/min).[7] Under these conditions, second-degree heart block occurs, as characterized by the failure of some atrial depolarizations to initiate a QRS complex. In a third-degree block (also shown), there is complete dissociation between atrial and ventricular contractions. The ventricular arrhythmias are caused by the development of ectopic foci or reentrant conduction in the ventricles. The

first one shown in Figure 24-6 is ventricular tachycardia. In ventricular fibrillation, the most immediately life-threatening arrhythmia, erratic depolarization of different areas of the ventricle totally disorganizes myocardial contraction, renders the heart ineffective, and causes the cardiac output to plummet. Immediate treatment of ventricular fibrillation, usually including defibrillation (precordial direct current shock), must be provided to avert sudden death.

Torsades de pointes (literally meaning "twisting of points") is a polymorphic ventricular tachycardia characterized by bizarre shapes in the ventricular depolarization complexes on the ECG (Figure 24-7). As mentioned previously, it often occurs in patients with defective K^+ channel (e.g., Kr) activity and occurs with certain drugs that delay repolarization of ventricular muscle cells, often by blocking Kr channels. In both cases, QT prolongation precedes and leads to torsades de pointes. In Figure 24-7, an excessively long QT interval is followed by a ventricular tachycardia in which each depolarization has a different configuration.

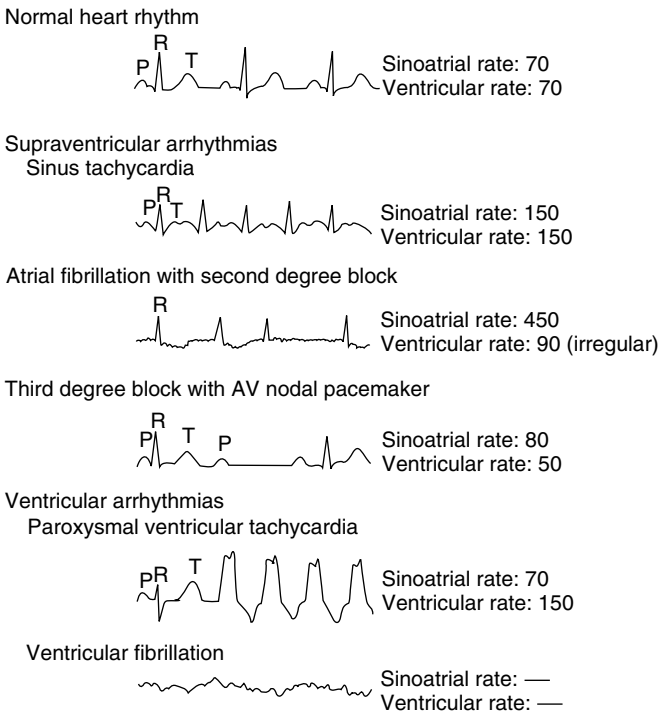

FIGURE **24-6** Various cardiac rhythms as recorded by the ECG. Arrhythmias are classified as supraventricular or ventricular in origin. Rates are given in beats per minute. (Adapted from Shepard RS: *Human physiology*, Philadelphia, 1971, Lippincott.)

ANTIARRHYTHMIC DRUGS

Antiarrhythmic drugs are used to modify, or restore to normal, aberrant electrophysiologic properties of cardiac muscle. Arrhythmias may result from various disease conditions or drug treatments. In all arrhythmias, some facet of the normal electrophysiologic system that governs cardiac contraction is behaving abnormally. Several methods of treating arrhythmias are used today. Nonpharmacologic interventions for cardiac arrhythmias include electrical cardioversion, automatic implantable cardioverter devices, ablation therapy, and pacemakers.

The type of arrhythmia is a major factor in the selection of an antiarrhythmic drug. Enhanced impulse generation can be reduced by drugs that slow phase 4 depolarization by reducing the inward Na^+ current or the inward Ca^{++} current. The treatment of reentry includes drugs that reduce Na^+ channel and Ca^{++} channel activity, which slows conduction velocity. Drugs that block K^+ channels, prolonging repolarization and the refractory period, may also be useful.

Drugs used in the treatment of cardiac arrhythmias are not easily classified because they often have more than one action. Drugs within each class vary in their magnitudes of action or types of effects produced.[1,14] The most common scheme, originally proposed by Vaughan and Williams,[14] classifies drugs according to certain specific properties. Type I drugs, such as quinidine, lidocaine, and flecainide, depress Na^+ current.[1] The type I agents are subdivided further according to their relative effects on phase 0 depolarization, conduction velocity, and APD. Na^+ channels exist in at least three states: closed, open, and inactivated. At resting membrane potentials the Na^+ channels are closed except for a Na^+ "leak" associated with phase 4 depolarization for cells that display automaticity. During rapid depolarization (phase 0, especially in Purkinje fibers and ventricular muscle), the Na^+ channels are open. The Na^+ channels convert to the inactivated state before returning to the resting, closed state. The inactivated state occurs mostly in phase 2 and 3 of the action potential.

Class IA and IC drugs bind more selectively to the open state of the channel. Class IB drugs bind more selectively to the inactivated state of the channel. Because the Purkinje fibers and ventricular myocardial cells have longer plateau

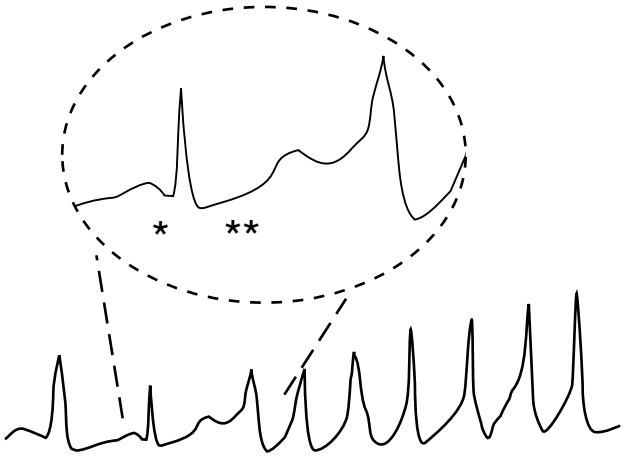

FIGURE **24-7** ECG pattern of torsades de pointes. As seen in the enlarged section, the relatively normal P wave and QRS complex (*) are followed by a prolonged QT interval (**) and initiation of polymorphic ventricular tachycardia (section not enlarged).

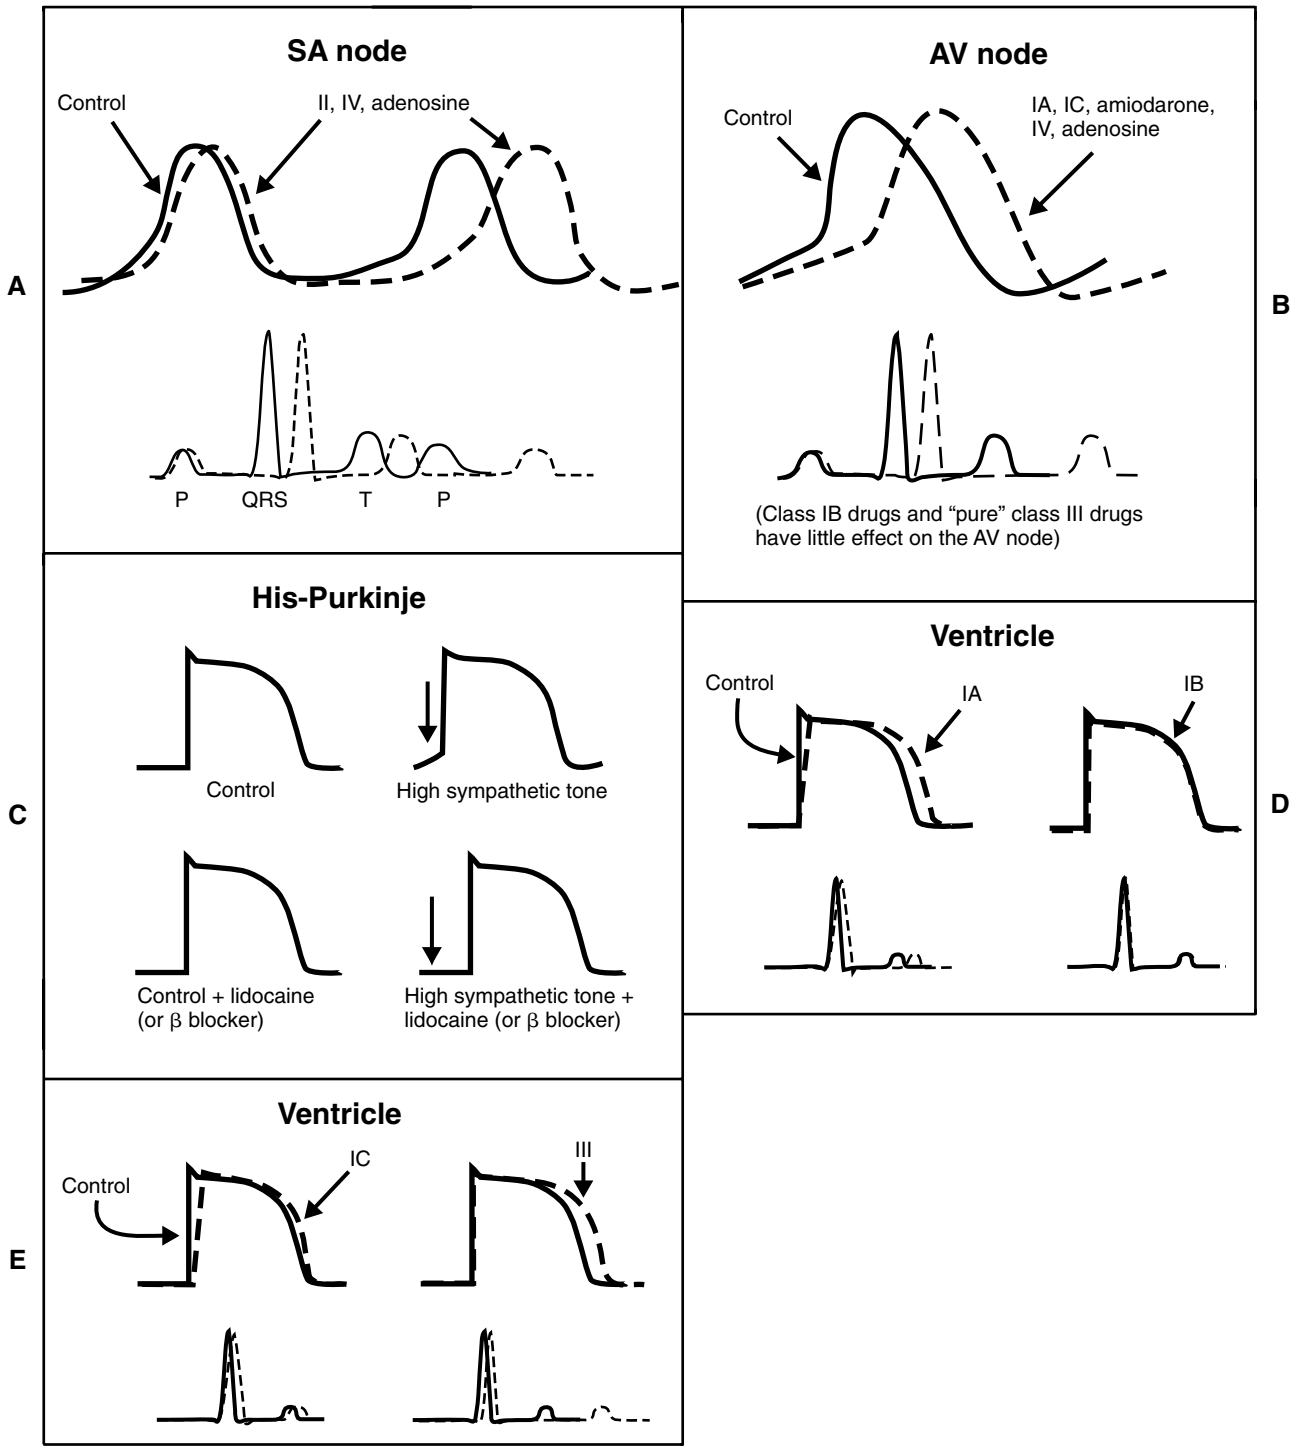

FIGURE **24-8** Effect of the various antiarrhythmic drug classes on the action potentials in the heart. Where relevant, the corresponding ECG pattern is also shown. Omitted drug classes have little effect on the action potentials depicted. The changes shown do not imply the same magnitude of change for each drug class. Amiodarone is specifically identified because, although it is classified as a class III drug, it has additional actions. **A,** Sinoatrial *(SA)* node. Note the delay in appearance of the QRS complex, T wave, and subsequent P wave caused by the identified drugs. **B,** Atrioventricular *(AV)* node. Various drugs delay conduction through the node. **C,** His Purkinje system. Active drugs reduce phase 4 depolarization *(arrows)*. **D** and **E,** Ventricular muscle. In **D,** class IB drugs minimally alter the ECG pattern in normal cardiac rhythms.

phases (phase 2), class IB drugs are able to block Na^+ channels more effectively in these tissues because the Na^+ channels remain in an inactivated state longer during systole. Inasmuch as ischemic ventricular tissue is more depolarized, it, too, is especially sensitive to Na^+ channel blockade by class IB drugs.

Quinidine-like, or class IA, drugs depress phase 0 depolarization at all heart rates. They prolong the APD of the ventricle because they also inhibit K^+ (chiefly Kr) channels (Figure 24-8). Class IB agents, such as lidocaine, block Na^+ channels more selectively, but the rapid onset and recovery

of Na^+ channel blockade results in little accumulated lidocaine effect on phase 0 and conduction velocity in healthy tissue at normal heart rates. In damaged or rapidly firing cells, lidocaine causes a frequency-dependent or use-dependent block to reduce the slope of phase 0 and lowers phase 4 in ectopic pacemakers and in Purkinje fibers under high sympathetic tone.[1] The faster the heart rate, the greater is the effect of lidocaine. (Use-dependent block is discussed in Chapter 16.) In contrast to other class I agents, lidocaine and related class IB antiarrhythmics may actually shorten the APD. Flecainide and other class IC antiarrhythmics are characterized by their profound depression of phase 0 depolarization and slowing of conduction in the atria, AV node, and ventricles at normal heart rates. This pronounced effect results from their slow dissociation from Na^+ channels and accumulation of the channel-blocking effect over several contraction cycles. There is little or no prolongation of the APD.

Propranolol and related β-adrenergic–blocking agents constitute class II drugs and inhibit cardiac stimulation brought on by β-adrenergic agonists. They depress phase 4 depolarization (see Figure 24-8). The class III group, including amiodarone and sotalol, block K^+ channels (chiefly Kr channels) and prolong the APD by delaying phase 3 repolarization. Verapamil and other class IV drugs selectively block Ca^{++} channels (L type) and depress slow fiber conduction (phase 0 of the SA and AV nodes) and phase 4 depolarization (see Figure 24-8). Drugs that cannot be classified by the Vaughan-Williams scheme include digitalis and adenosine.

Table 24-1 outlines the various categories of antiarrhythmic agents. The drugs vary widely in their clinical usefulness. Class IA drugs are less commonly used today, partly because of the introduction of class IC and class III drugs. In Table 24-1 the action responsible for the classification of each drug, which is usually its major action, is circled. In the discussion of individual agents that follows, reference should also be made to Table 24-2 for the electrophysiologic actions of representative antiarrhythmic drugs. The net effects of the relevant drug classes and various action potentials in the heart are shown in Figure 24-8. Pharmacokinetic data for specific drugs are given in Table 24-3. The use of digoxin for certain kinds of arrhythmias is discussed in Chapter 25.

Quinidine

Quinidine is effective in the treatment of some atrial and (to a lesser extent) ventricular tachyarrhythmias. It was used clinically before its antiarrhythmic properties were discovered. During treatment with quinine and quinidine for patients with malaria, the reversal of atrial fibrillation was noted in some patients. Widespread use of quinidine for supraventricular arrhythmias followed reports from Wenckebach[15] in 1914.

Quinidine, the *d* isomer of quinine, is found in the bark of the cinchona tree, which is indigenous to certain regions of South America. Synthesis of this compound has been accomplished, but the synthesized drug is expensive, and quinidine is still isolated from the natural source. Its structural formula is shown in Figure 24-9.

Pharmacologic effects

Quinidine reduces automaticity and conduction velocity and increases refractoriness. Automaticity is depressed through an increase in the threshold potential and a decrease in the slope of spontaneous diastolic depolarization (phase 4) in pacemaker fibers, particularly at sites other than the SA node. Quinidine has the potential to slow or abolish tachyarrhythmias. Quinidine decreases the slope of phase 0 depolarization and decreases conduction velocity in cells such as those of the AV node and ventricular myocardium (see Figure 24-8). By this effect, quinidine may inhibit reentrant pathways. Quinidine influences automaticity and conduction velocity by blocking Na^+ channels, particularly channels in the open state. The rate of recovery from quinidine block is intermediate between class IB and IC antiarrhythmic drugs (see Table 24-1). Therapeutic dosages increase refractoriness by prolonging the duration of the ERP in the ventricle and His-Purkinje system. This effect depends on blockade of K^+ channels, especially Kr channels, and has the potential for preventing or abolishing reentrant rhythms.

In addition to its direct actions on the heart, quinidine exerts a vagolytic action. As a consequence of its antivagal influence on the SA node, quinidine, especially given intravenously, may increase the heart rate. Because the ERP in the atria is decreased by vagal stimulation, quinidine increases the ERP directly and indirectly. The antivagal action of quinidine on AV nodal conduction is of special importance. By this mechanism, quinidine may increase the conduction velocity and decrease the refractory period of the AV node, which presents a hazard in treating atrial tachyarrhythmias because rapid atrial impulses are more readily conducted to the ventricles. This risk is greatest when the drug is used intravenously.

The ECG changes that result from quinidine administration are predictable from the electrophysiologic effects previously discussed (see Figure 24-8). The antivagal property tends to elicit sinus tachycardia, but mostly at high doses; SA nodal block may result from the drug's direct depressant effects. Increased durations of the QRS complex and the QT interval result from decreases in ventricular conduction velocity and lengthening of the ventricular ERP.

In large doses, quinidine causes peripheral vasodilation by blocking α-adrenergic receptor blockade. Hypotension is a possible outcome.

Absorption, fate, and excretion

Absorption of quinidine after oral administration is rapid and nearly 100%. Depending on the salt formulation, maximum plasma concentrations are reached within 2 hours. Given intramuscularly, peak concentrations occur in 60 minutes. When quinidine is injected intravenously, it should be administered slowly because its therapeutic effects are not instantaneous, and overdosage might occur. Adverse hemodynamic effects are more common with intravenous use. Other pharmacokinetic characteristics are listed in Table 24-3.

Adverse effects

Quinidine can precipitate various ventricular arrhythmias, including torsades de pointes (see Figure 24-7). As a result of its depressive effects on ion conductance throughout the heart, quinidine modestly reduces myocardial contractility, which might be important in the management of a patient with congestive heart disease. Quinidine can cause a group of symptoms collectively referred to as *cinchonism*: blurred vision, tinnitus, tremor, vertigo, and lightheadedness. Nausea, vomiting, and diarrhea are the most common side effects of the drug. The negative inotropic and stronger peripheral vasodilatory effects of quinidine may occasionally lead to hemodynamic deterioration, resulting in hypotension, syncope, and a decrease in coronary blood flow, especially in patients with impaired myocardial function. Intravenous use of the drug presents an added risk of hypotension and syncope.

Immune-mediated reactions may develop with quinidine therapy. Responses include hematologic reactions (thrombocytopenia, hemolytic anemia, agranulocytosis), cutaneous reactions (rash, angioneurotic edema), and very rarely bronchial asthma and anaphylactic shock. Immunologically mediated thrombocytopenia can readily lead to hemorrhagic episodes.

*The distinguishing characteristics for the main classes of antiarrhythmic drugs are the following: class I drugs block Na^+ channels. The subclassification is based on the characteristics of the block. The terms *slow, medium,* and *fast* refer to the rates of onset of, and recovery from, Na^+ channel blockade. Class II drugs block β-adrenergic receptors. Class III drugs block K^+ channels. Class IV drugs block Ca^{++} channels. The major action responsible for the classification of each drug is circled.

†Ibutilide is exceptional because its major action, not shown, is to increase conductance through a slow Na^+ channel.

TABLE **24-2**

Effects of Antiarrhythmic Drug Classes

DRUG CLASS	SINOATRIAL AUTOMATICITY	ATRIOVENTRICULAR CONDUCTION VELOCITY	ECG CHANGES: PR	ECG CHANGES: QRS	ECG CHANGES: QT	AFFINITY FOR Na^+ CHANNELS IN ISCHEMIC TISSUES	ANTIARRHYTHMIC USE: SUPRAVENTRICULAR	ANTIARRHYTHMIC USE: VENTRICULAR
IA	↓	↑*, ↓	↓*, ↑	↑↑	↑↑	+	Yes	Yes
IB	0	0	0	0	0	+++†	No	Yes
IC	0	↓	↑	↑↑↑	0	+	Yes	Yes

FIGURE **24-9** Structural formula of quinidine.

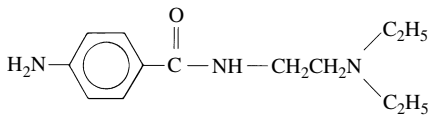

FIGURE **24-10** Structural formula of procainamide.

Procainamide

Procainamide is a drug whose antiarrhythmic mechanism of action resembles that of quinidine. The chemistry of procainamide resembles that of procaine; however, chemically, procainamide differs from procaine by having an amide linkage instead of an ester linkage (Figure 24-10). Although effective against some ventricular and supraventricular arrhythmias, procainamide is now prescribed less often than many other antiarrhythmic drugs because of its adverse effects. It is still used intravenously, however, for acute suppression of ventricular arrhythmias.

Pharmacologic effects

The effects of procainamide on the heart are similar to the effects of quinidine. Automaticity and conduction velocity are decreased, whereas refractoriness is increased. Similar to quinidine, procainamide can be described as a cardiac depressant. Procainamide exerts much less of an antivagal effect than does quinidine, but ganglionic blockade has been reported.

The most frequently observed change induced by procainamide in the ECG is an increase in the duration of the QRS complex. Lengthening of the QT and PR intervals is also observed. There are few additional effects on the cardiovascular system when procainamide is administered orally. Intravenous infusion causes a decrease in blood pressure because of peripheral vasodilation and myocardial depression and occasionally results in centrally mediated mental confusion and hallucination.

Absorption, fate, and excretion

After oral administration, procainamide is rapidly and essentially completely absorbed, with peak plasma concentrations being reached in approximately 90 minutes. Maximum plasma concentrations occur 15 to 60 minutes after intramuscular administration. Because of its short half-life, procainamide is often given in a slow-release preparation.

The major metabolite of procainamide, N-acetylprocainamide (NAPA), also has antiarrhythmic properties. Normally, approximately 25% of an administered dose of procainamide is acetylated in the liver to yield NAPA, but rapid acetylators or patients with renal disease convert more of the drug to this form. NAPA has a plasma half-life of 6 hours and is eliminated by renal excretion.

Adverse effects

Similar to quinidine, procainamide can promote ventricular tachycardia when used to treat atrial tachyarrhythmias. It can also elicit other ventricular arrhythmias when given in high doses or to susceptible patients. Hypotension is common with rapid intravenous injection.

The most frequent side effects after oral administration are anorexia, nausea, and vomiting. Other, more rarely seen effects are diarrhea, weakness, flushing, a bitter taste, and CNS manifestations such as hallucinations and depression. Allergic reactions have been reported, and cross-sensitivity to

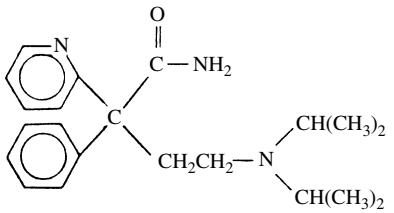

FIGURE **24-11** Structural formula of disopyramide.

procaine and other derivatives of p-aminobenzoic acid should be expected. Allergic reactions associated with procainamide include rashes, fever, chills, neutropenia, and agranulocytosis. The most noteworthy immunologically based reaction is a syndrome similar to systemic lupus erythematosus. Symptoms of lupus occur in 30% of patients receiving long-term oral procainamide therapy (more frequently with slow acetylators) and include arthralgia, fever, and occasionally pleuropericarditis, but not renal involvement. Antinuclear antibodies are present in a high percentage of patients taking procainamide; however, it is widely held that withdrawal of the drug is required only when lupus-like symptoms occur. The syndrome usually disappears after drug withdrawal. NAPA is not associated with a lupus-like reaction.

Disopyramide

Disopyramide (Figure 24-11) has actions similar to those of quinidine and procainamide, although it is structurally unrelated to either agent. Its effectiveness in the treatment of premature extrasystoles and tachycardias of supraventricular and ventricular origin has been established. The drug is only occasionally used today.

Pharmacologic effects

Similar to quinidine, disopyramide decreases the rate of diastolic depolarization (phase 4), particularly in ectopic pacemaker cells; it also decreases the upstroke velocity of the action potential (phase 0) in cardiac fibers and increases the ERP. Disopyramide tends to lessen automaticity and conduction velocity. One difference between disopyramide and other class IA agents is that the PR interval and QRS complex are less affected by disopyramide. Another is that disopyramide is more likely to depress cardiac contractility. Disopyramide also has antimuscarinic effects.

Absorption, fate, and excretion

Disopyramide is almost completely absorbed within several hours after oral administration. Other pharmacokinetic characteristics are listed in Table 24-3.

Adverse effects

The most common side effects of disopyramide are dose-dependent and largely result from its antimuscarinic action. Side effects include urinary retention; dryness of the mouth, nose, throat, or eyes; blurred vision; constipation; nausea; and skin rash. Rarely, acute psychosis, cholestatic jaundice, hypoglycemia, and agranulocytosis have occurred, but these disappear on drug withdrawal. As with other class IA antiarrhythmic drugs, various arrhythmias may develop with overdosage. Disopyramide is contraindicated in patients with cardiomyopathy or congestive heart failure because of its relatively pronounced negative inotropic effect.

Lidocaine

Lidocaine has been used as a local anesthetic for more than half a century. In contrast to procaine, it has also long been a primary drug for arresting and preventing certain ventricular arrhythmias in emergency situations. For additional discussion of its pharmacologic characteristics, see Chapter 16.

Pharmacologic effects

Lidocaine decreases automaticity but is devoid of antimuscarinic activity. Although quinidine affects electrical activity throughout the heart, lidocaine preferentially influences ventricular function. Lidocaine acts by blocking Na^+ channels, particularly inactivated Na^+ channels. This effect on Na^+ channels is rapidly reversed, which restricts its use-dependent blocking effect to patients with rapid heart rates. Because lidocaine has a preferential effect on Na^+ channels in the inactivated state, it preferentially inhibits automaticity in ischemic tissue where membrane depolarization or an enhanced frequency of excitation occurs, such as in the His-Purkinje system (see Table 24-2). Lidocaine also reduces delayed afterdepolarizations seen with digoxin toxicity. Lidocaine does not slow repolarization, but instead may hasten it. In contrast to the action of quinidine and procainamide, lidocaine tends to shorten the ERP. The drug has little effect on conduction velocity and phase 0.

Lidocaine is usually administered intravenously for the treatment of ventricular ectopic rhythms. Because lidocaine must be administered parenterally, it is largely restricted to emergency situations and hospital settings. Its use is contraindicated in supraventricular arrhythmias because it is largely ineffective against these arrhythmias and excessive ventricular rates may result.

Absorption, fate, and excretion

As an antiarrhythmic, lidocaine is usually given intravenously by injection or infusion. After intravenous administration, the plasma concentration initially decreases rapidly, followed by a slower decline. For this reason, various loading regimens are used to achieve therapeutic plasma concentrations quickly. Lower constant perfusion rates are subsequently used. Administration is monitored by measurement of plasma concentrations, and the patient is closely observed for neurologic side effects. α_1-Acid glycoprotein and albumin contribute to plasma protein binding. Lidocaine is broken down in the liver to various metabolites, including N-ethylglycine and 2,6-xylidine; 2,6-xylidine is metabolized further to 4-hydroxy-2,6-xylidine and largely excreted in the urine. At least two intermediary metabolites, glycinexylidide and monoethylglycinexylidide, have pharmacologic activity.

Adverse effects

Lidocaine exhibits only minor effects on the autonomic nervous system. Arterial pressure is not depressed by lidocaine as much as it is by quinidine. After acutely high dosages or prolonged infusion, lidocaine may cause convulsions and respiratory depression. (These reactions occur only rarely, however, with the dosages and routes of administration used in dentistry.) Cardiac arrest may occur if lidocaine is administered to a patient with preexisting heart block.

Phenytoin

Phenytoin (diphenylhydantoin) has been used since 1938 for the treatment of grand mal epilepsy and other seizure disorders. Although it has been used as an antiarrhythmic drug (class IB), it is now rarely used for this purpose. For a general discussion of its pharmacologic features, see Chapter 14.

Mexiletine

Mexiletine is a class IB antiarrhythmic drug structurally related to lidocaine (Figure 24-12). The electrophysiologic properties of mexiletine are similar to those of lidocaine. Conduction velocity in the diseased AV node and ventricular

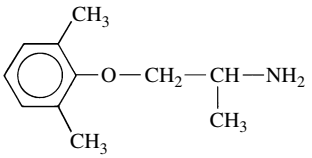

FIGURE **24-12** Structural formula of mexiletine.

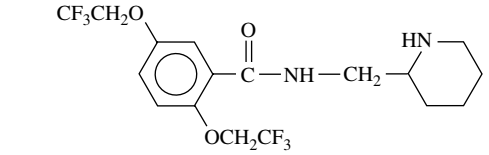
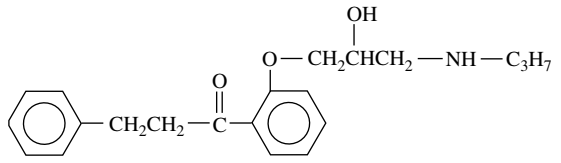


Flecainide



Propafenone

FIGURE **24-13** Structural formulas of flecainide and propafenone.

myocardium is more likely to be slowed than with lidocaine. Mexiletine is used primarily to treat life-threatening ventricular arrhythmias.

Mexiletine is well absorbed after oral administration and is useful by the oral and the intravenous routes. Mexiletine is resistant to first-pass metabolism in the liver, but it does undergo subsequent hepatic metabolism. SA node and AV conduction defects can be worsened by mexiletine, which limits the drug's usefulness in patients with these preexisting problems. Extracardiac adverse reactions include gastrointestinal (nausea, vomiting) and neurologic (tremor, diplopia, dizziness, paresthesias) effects. Hepatitis or agranulocytosis may rarely occur.

Flecainide

A third category of type I antiarrhythmics (class IC) is represented by drugs that are newer to clinical use than the drugs in classes IA and IB. Flecainide (Figure 24-13) belongs to this class (see Table 24-1). Flecainide is indicated for the treatment of disabling supraventricular arrhythmias and sustained life-threatening ventricular arrhythmias unresponsive to other medications.

Pharmacologic effects

Although possessing some similarity to lidocaine, flecainide and related class IC drugs significantly depress conduction velocity by strongly reducing Na^+ conductance during phase 0 of the action potential. This effect is felt throughout the heart but is especially strong in the atrium and His-Purkinje system. It results from the slow association of drug with, and dissociation from, Na^+ channels, especially channels in the open configuration. Recovery from Na^+ channel blockade is protracted.

Flecainide does not selectively reduce phase 0 in diseased tissues. Rather, it inhibits phase 0 more or less uniformly in diseased and healthy tissues and tends to be effective on reentry mechanisms. Flecainide increases the ERP in atrial and ventricular muscle and widens the QRS complex (as does quinidine). Flecainide also reduces conduction velocity in the AV node but to a lesser degree than in ventricular muscle (see Figure 24-8 and Table 24-2).

Absorption, fate, and excretion

Flecainide is not significantly metabolized on its first pass through the liver and has good bioavailability after oral administration. Approximately 75% of a flecainide dose is eventually metabolized to inactive products. The large range in reported half-lives for the drug stems partly from genetically determined variations in the rate of hepatic metabolism by cytochrome CYP2D6. As discussed in Chapter 4, some individuals lack this enzyme. The resulting potential differences in patient response necessitate careful monitoring of drug effects.

Adverse effects

CNS toxicity is the most common adverse effect. Dizziness, blurred vision, tremor, paresthesia, and headache may occur. Nausea and a metallic taste have been reported for flecainide. The results of the Cardiac Arrhythmia Suppression Trial[4] indicated that flecainide administration to patients with recent myocardial infarction increased the mortality rate in such patients twofold to threefold compared with placebo-treated patients. An arrhythmogenic effect of these drugs is suspected despite the fact that they suppressed premature ventricular depolarizations in these patients.[4] The results of the trial have led to cautions concerning the use of flecainide and its use after myocardial infarction. Similar concern exists for the other class IC drugs.

Propafenone

Propafenone is classified as a class IC antiarrhythmic because of its strong tendency to depress the maximum rate of depolarization and conduction velocity. The drug is indicated for life-threatening ventricular arrhythmias and is prescribed for atrial fibrillation and other types of supraventricular arrhythmias. The structure of propafenone is depicted in Figure 24-13.

Pharmacologic effects

Propafenone exerts several actions on the heart. In addition to blocking Na^+ channels, it blocks Ca^{++} channels and exerts β-adrenergic receptor–blocking effects (see Table 24-1). The drug reduces the slope of phase 0, prolongs the PR and QRS intervals, and suppresses ectopic pacemakers (see Table 24-2). Negative inotropic effects are possible but usually occur only with high doses.

Absorption, fate, and excretion

Propafenone is well absorbed orally, but approximately 80% of a given dose is destroyed in the first pass through the liver. The same genetic predisposition for efficient or slow metabolism (by CYP2D6) of the drug exists as for flecainide, and the half-life may be prolonged in patients who are slow metabolizers. At least one major metabolite is pharmacologically active.

Adverse effects

Adverse effects include dizziness, blurred vision, dysgeusia, and gastrointestinal symptoms. CNS toxicity seems to be more likely with slow metabolizers. Asthma may be exacerbated in susceptible individuals. Untoward cardiac signs include SA nodal dysfunction, AV nodal block, and worsening of heart failure. The arrhythmogenic potential of the drug must be considered in light of the problems documented for other class IC agents. Competition for metabolism by CYP2D6 is the basis for interactions involving propafenone and other

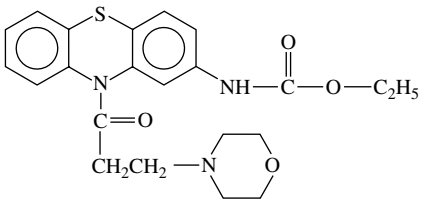


FIGURE **24-14** Structural formula of moricizine.

drugs. Propafenone may increase the anticoagulant effect of warfarin given concurrently.

Moricizine

Moricizine resembles most closely the class IC antiarrhythmics. It is sometimes classified in its own unique category, however. The structure of moricizine is shown in Figure 24-14. It is used in the treatment of life-threatening ventricular arrhythmias.

Moricizine reduces automaticity by altering the threshold voltage. It is effective against ectopic foci without producing significant negative inotropism. It also is effective in reducing afterdepolarizations. These actions bear resemblance to lidocaine. The slope of phase 0 is reduced, with an increase in the PR and QRS intervals reminiscent of quinidine. AV nodal reentry is inhibited. Despite the fact that moricizine is a phenothiazine, it has little psychotropic effect.

Moricizine is well absorbed orally; however, 60% to 70% of the drug is metabolized in the liver before it reaches the systemic circulation. The drug yields multiple metabolites; one is known to have pharmacologic activity. Dizziness, headache, nausea, and vomiting are common side effects of therapy. SA nodal depression, AV nodal block, and other arrhythmogenic effects occur in approximately 4% of patients being treated for ventricular arrhythmias.

β-Adrenergic Receptor–Blocking Drugs

Since the introduction of propranolol in 1968 for clinical use in the United States, a number of β-adrenergic receptor–blocking agents have been approved. (The β-adrenergic antagonists are discussed in Chapters 7, 26, and 28.) Three β-adrenergic blockers—propranolol, metoprolol, and esmolol—are the primary class II antiarrhythmic drugs (see Table 24-1). Sotalol, a fourth drug with ability to block the β-adrenergic receptor, is discussed under class III drugs. Propranolol is reviewed here as the prototypic agent; special features of the other β blockers are also noted.

Pharmacologic effects

Propranolol, the prototypic type II antiarrhythmic, has two types of effects on the heart: indirect effects as a consequence of blockade of β-adrenergic receptors and "membrane-stabilizing" effects similar to those of quinidine. Propranolol decreases automaticity and conduction velocity and increases refractoriness. The drug's greatest effects are on SA nodal automaticity, AV node refractoriness, and (if it exists) His-Purkinje automaticity (see Figure 24-8 and Table 24-2).

Activation of the sympathetic nervous system leading to β receptor stimulation enhances automaticity by increasing the slope of phase 4 depolarization, speeds conduction velocity, and shortens the ERP (especially in the AV node). By blocking β receptors, propranolol can produce opposite effects proportional to the sympathetic input to the heart at the time of administration. In addition to decreasing automaticity in the SA node (and decreasing the heart rate), propranolol variably reduces automaticity and conduction velocity in the atria, AV node, His-Purkinje system, and ventricles. Increased refractoriness in the AV node is an especially important manifestation of blockade. The direct actions of propranolol include decreasing the slope of phase 0 and phase 4 depolarization and prolonging the ERP. The β-adrenergic blockers, with the exception of sotalol, do not appreciably affect repolarization.

The major antiarrhythmic indication for propranolol is in the management of supraventricular tachyarrhythmias in which protection of the ventricles (by interfering with AV transmission) is the major clinical objective. Propranolol is also useful in suppressing paroxysmal supraventricular tachycardia and in treating afterdepolarizations and other ventricular arrhythmias in which catecholamine stimulation is involved. Most ventricular arrhythmias respond only to very large doses, however. Because propranolol reduces the ratio of oxygen demand to oxygen supply, arrhythmias caused by myocardial ischemia may also be relieved. Although propranolol is effective in treating cardiac glycoside–induced arrhythmias, phenytoin and lidocaine are more useful, especially if AV conduction is impaired, because propranolol tends to exacerbate the AV block induced by digitalis. β Blockers have been shown to reduce the incidence of heart attack and death in patients with previous myocardial infarction. The mechanism is not established, but it may relate to an antiarrhythmic mechanism.

Absorption, fate, and excretion

Propranolol is readily absorbed after oral administration, but more than two thirds of the drug is destroyed in its first pass through the liver. Peak plasma concentrations are reached in 1 to 2 hours. The rate of metabolism of propranolol, which involves CYP2D6, varies considerably among individuals, so plasma titers may differ markedly with long-term therapy. Propranolol is metabolized by hydroxylation, deamination, and glucuronide conjugation.

Adverse effects

The important adverse effects of propranolol can be explained by its antagonism of β-adrenergic receptors. Heart rate and myocardial contractility are reduced, at least initially, during therapy. Congestive heart failure and AV block are the major severe cardiac side effects; however, after large doses, severe bradycardia or asystole may occur. Sudden withdrawal of the drug in patients prone to angina pectoris may lead to anginal attacks or myocardial infarction. Bronchoconstriction is a predictable side effect and may be significant in susceptible individuals, such as asthmatics. Propranolol inhibits the glycogenolytic and lipolytic actions of endogenous catecholamines released in response to hypoglycemia and complicates therapy of diabetic patients.

β_1-Selective blockers

Acebutolol differs from propranolol in that it is selective for the β_1-adrenergic receptor (cardioselective). Its pharmacologic features are reviewed in Chapter 7. Esmolol is a very short-acting selective β_1-adrenergic receptor blocker that is metabolized by plasma esterases. It is used intravenously for short-term β-adrenergic receptor blockade. The adverse effects of these drugs resemble the adverse effects of propranolol. Despite their selectivity for β_1-adrenergic receptors, metoprolol and esmolol and other β blockers should be avoided if possible in asthmatic patients.

Sotalol

Sotalol, a β-adrenergic–blocking drug, also has properties of and is classified as a class III drug. It increases the ERP in addition to its β-adrenergic–blocking activity. The relative

importance of its β-blocking properties and its class III antiarrhythmic effects has yet to be determined. Sotalol is well absorbed when taken orally, with a bioavailability of nearly 100%. Sotalol is useful in supraventricular arrhythmias such as atrial fibrillation[12] and in certain cases of ventricular tachycardia. It has been shown to be effective in preventing recurrences of ventricular tachyarrhythmias.

Bretylium

Bretylium tosylate is classified as a class III antiarrhythmic because it increases the ERP and delays repolarization without having much effect on conduction velocity. The mechanism involves blockade of K^+ conductance, delaying phase 3 of the action potential. Bretylium was originally developed in the 1950s as an antihypertensive drug but was approved in the United States in 1978 for the treatment of ventricular arrhythmias. The drug has a complex pharmacologic profile, some aspects of which are still incompletely understood.

Pharmacologic effects

Bretylium interferes with sympathetic control of the heart and exerts direct influences on cardiac function. Bretylium is classified as an adrenergic neuron blocker because it produces a prolonged inhibition of norepinephrine release from sympathetic nerve endings. Bretylium also initially stimulates norepinephrine efflux and tends to exert an imipramine-like block of the neuronal uptake of catecholamines. Together, these influences on sympathetic function make the drug's effect in any particular patient difficult to predict, especially in the initial phase of therapy.

The effect of bretylium on supraventricular tissues is largely indirect. After an initial catecholamine release, it decreases sympathetic influences, reducing automaticity in the SA node (see Table 24-1). ERP in the AV node is also increased after the initial stimulation. Although atrial arrhythmias are often not responsive to the drug, the fact that bretylium significantly increases the ERP in the His-Purkinje system and ventricular myocardium supports the finding that the drug is useful in treating ventricular tachyarrhythmias, including its previous use as an adjunct in treating ventricular fibrillation. A reduction in the differences between refractory periods and APDs in diseased and normal ventricular myocardium by the drug contributes further to a lessened likelihood of reentrant arrhythmias.

Absorption, fate, and excretion

Bretylium can be administered orally, intramuscularly, or intravenously. It is, however, unpredictably absorbed from the gastrointestinal tract, as would be expected from its quaternary ammonium structure.

Adverse effects

The side effects of bretylium in most cases can be explained by its adrenergic-blocking actions. Because of its tendency to produce hypotension (to which tolerance may develop), bretylium is reserved for use in ventricular tachyarrhythmias that are not responsive to other therapeutic measures. Nausea and vomiting may occur even with intravenous use, especially when injected rapidly. Parotid gland pain and swelling may occur in 25% of patients receiving long-term oral therapy, but apparently it does not occur with parenteral use. The initial release of catecholamines induced by bretylium may be associated with hypertension or arrhythmias. Other adverse reactions include diplopia, facial flushing, weakness, and nasal congestion. The actions of bretylium on the adrenergic nerve terminals can be blocked by tricyclic antidepressants, which prevent bretylium from gaining access to the nerve terminal.

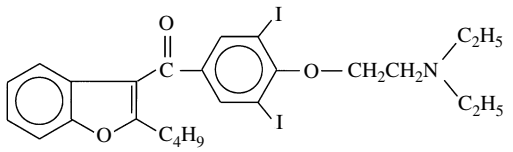

FIGURE **24-15** Structural formula of amiodarone.

Amiodarone

Amiodarone, a benzofuran derivative resembling thyroid hormone (Figure 24-15), was originally introduced in Europe as a coronary vasodilator for the treatment of angina pectoris. It is now widely used for various acute and chronic arrhythmias.

Pharmacologic effects

Amiodarone's major action is to increase the ERP by slowing the rate of repolarization. Blockade of K^+ channels is involved (see Table 24-1). Repolarization is slowed in the His-Purkinje system and in ventricular and atrial myocardium (see Figure 24-8). Although K^+ channel blockade is a major mechanism of action, amiodarone is not as likely to cause torsades de pointes as are drugs whose mechanism of action is largely limited to blocking K^+ channels ("pure" Kr channel blockers). In addition to blocking K^+ channels, amiodarone blocks Na^+ and Ca^{++} channels. Inhibition of these latter channels probably prevents much of the inward depolarizing current that can trigger early afterdepolarizations and torsades de pointes.

Amiodarone decreases automaticity in the SA node and in ectopic pacemakers, but has little effect on automaticity elsewhere in the heart. Conduction velocity is slowed in the AV node by Na^+ and Ca^{++} channel blockade (see Table 24-1), and the ERP in the AV node is lengthened. Conduction velocity in the His-Purkinje system and ventricular muscle is also slowed. The ventricular fibrillation threshold is increased.

Amiodarone has an active metabolite, desethylamidarone, that contributes to the antiarrhythmic effect. Desethylamidarone binds to thyroid hormone receptors, inhibiting thyroid hormone–induced gene expression.[3] Of the genes normally induced by thyroid hormone, several support the synthesis of certain K^+ channels. This finding is consistent with the fact that amiodarone's effects on K^+ channels are generally delayed compared with its effects on Na^+ and Ca^{++} channels. Long-term therapy with amiodarone is more likely to generate a class III antiarrhythmic effect (K^+ channel block), largely because of reduction in the number of Kr channels. Short-term therapy is more likely to limit effects to Na^+ channels, Ca^{++} channels, and β-adrenergic receptors. The resulting cardiac effects seem to be different from the effects of long-term therapy and avoid many of the adverse effects seen with long-term administration, such as pulmonary fibrosis and hypothyroidism. Amiodarone is a vasodilator, noncompetitively inhibiting the vascular effect of catecholamines.[9] The cardiac effects of catecholamines are likewise inhibited, and coronary arterial resistance is decreased, resulting in increased coronary blood flow.

Amiodarone is used for various arrhythmias, including ventricular extrasystoles, tachycardia, and fibrillation. It is also efficacious in some atrial arrhythmias, including atrial fibrillation and flutter, in which it may have unique effects on the adverse remodeling changes in the atria, which are thought to be partly responsible for the genesis of atrial fibrillation.[5,11]

Absorption, fate, and excretion

When administered orally, amiodarone's bioavailability is low (20% to 50%). Amiodarone is also administered intravenously.

A highly lipophilic drug, amiodarone is sequestered in tissues, yielding a volume of distribution of approximately 60 L/kg. It is highly bound to protein in plasma. Because the drug would normally take weeks to reach a steady-state concentration after the initiation of therapy, loading doses are routinely used. Amiodarone is extensively metabolized by the liver; a desethyl derivative, which has antiarrhythmic properties as indicated previously, has been identified. When the drug is withdrawn, the tissue concentrations decrease only gradually as the drug is eliminated. Plasma determinations of amiodarone may not reflect tissue concentrations.

Adverse effects

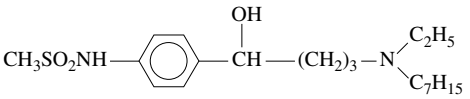
Sinus arrest may occur if amiodarone is given with β-adrenergic–blocking drugs or other antiarrhythmics, and AV nodal conduction abnormalities may be exacerbated. Because amiodarone has negative inotropic properties, its use may be associated with a decrease in cardiac function. Some preexisting arrhythmias may be worsened by the drug.

Noncardiac adverse reactions are common and occasionally life-threatening. The primary concerns are pulmonary fibrosis and pneumonitis, which may become clinically evident in a significant percentage of patients with long-term use and can be lethal. Amiodarone also commonly causes CNS disturbances (ataxia, dizziness), photosensitivity, and hepatic dysfunction as indicated by an increase of liver enzymes in the blood. The skin may take on a blue-gray hue. Corneal microdeposits occur routinely but usually do not interfere with vision and disappear after withdrawal of the drug. Changes in thyroid function (hyperthyroidism and especially hypothyroidism) have been reported, and these may be related to the aforementioned facts that amiodarone resembles thyroid hormone and influences thyroid hormone actions. Amiodarone can reduce the action of thyroid hormone by binding to the thyroid hormone receptor and blocking its cellular effects. It has also been shown that amiodarone can inhibit the action of thyroid-stimulating hormone, which could also contribute to a hypothyroid effect by amiodarone.[9] Finally, this drug inhibits the conversion of thyroxine to triiodothyronine in peripheral tissues and causes the buildup of reverse triiodothyronine (see Chapter 34).

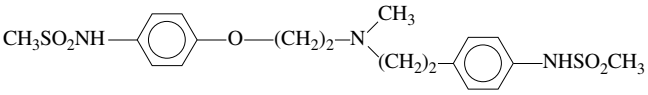
Ibutilide and Dofetilide

Ibutilide is classified as a class III drug because it delays repolarization. It blocks Kr channels but, more important, causes the opening of Ca^{++} channels, which promote Na^+ influx through slow channels, extending phase 2 of the action potential.[6] The drug is administered intravenously for atrial fibrillation and atrial flutter. It can be used to convert these arrhythmias rapidly to normal sinus rhythm. Torsades de pointes is an adverse effect.

Dofetilide is a "pure" class III drug, blocking the Kr channel selectively. It is used for acute conversion of atrial fibrillation and atrial flutter and for short-term maintenance.[8] Dofetilide is available for intravenous and oral use. Predictably, a characteristic adverse effect is torsades de pointes in response to the prolonged QT interval that is induced by the drug. The structures for ibutilide and dofetilide are shown in Figure 24-16.



Ibutilide



Dofetilide

FIGURE **24-16** Structural formulas of ibutilide and dofetilide.

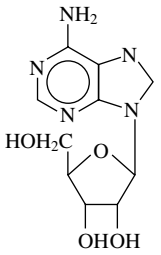


FIGURE **24-17** Structural formula of adenosine.

Ca^{++} Channel Blockers

Ca^{++} channel blockers, represented by verapamil, diltiazem, and nifedipine, are used for the treatment of certain cardiovascular diseases. Verapamil and diltiazem are prescribed primarily for their antianginal (see Chapter 26) and antiarrhythmic effects. Nifedipine, which has a greater effect on vascular smooth muscle, is a major antihypertensive drug (see Chapter 28). It is not used as an antiarrhythmic drug. In each case, the drugs are selective for potential-dependent Ca^{++} channels rather than receptor-operated channels. The potential-dependent Ca^{++} channels are of at least three types: L, N, and T. These channels are distinguished by their electrical properties and anatomic location. The L (long-lasting) channels are selectively inhibited by these drugs. The fact that they are the predominant Ca^{++} channels in the heart and vascular smooth muscle is consistent with the major effects of Ca^{++} channel blockers on these organs. The N (neuronal) and T (transient) channels are not affected by these channel blockers to a major degree, although the T-type channels play a role in phase 2 of action potentials in the heart (see Figure 24-3).

By interfering with the slow inward current in pacemaker cells, these drugs depress the rate of phase 4 depolarization; automaticity in the SA node and the AV node is decreased. The major direct cardiac effect is to reduce conduction velocity and to increase the refractory period of the AV node (see Figure 24-8).[1] Verapamil and diltiazem are useful in treating supraventricular arrhythmias and have been used successfully in terminating attacks of paroxysmal atrial tachycardia unresponsive to vagal stimulation. Verapamil and diltiazem have a negative inotropic effect. This effect is rarely seen with nifedipine because it is a more potent peripheral vasodilator, and reflex cardiac effects tend to overcome any direct actions it has on the heart. Other aspects of the pharmacologic features of the Ca^{++} channel blockers are discussed in Chapters 26 and 28.

Adenosine

The endogenous purine nucleoside adenosine is approved for terminating attacks of paroxysmal supraventricular tachycardia. It does not match the profile of any other antiarrhythmic. The structure of adenosine is shown in Figure 24-17.

Pharmacologic effects

Adenosine stimulates the A_1 adenosine receptor in the heart. This receptor is linked to the G protein G_i, which, when activated, increases K^+ conductance and decreases Ca^{++} channel activity, leading to hyperpolarization.[1] Adenosine also may reduce the release of norepinephrine from nerve endings. The net effect on the heart is to reduce automaticity in the SA node and Purkinje fibers and reduce the AV nodal conduc-

tion rate (see Figure 24-8 and Table 24-2). The drug is useful for short-term treatment of supraventricular tachycardia involving reentry with rapid ventricular rate. Adenosine also dilates coronary vessels and reduces contractility. Selective adenosine receptor agonists offer promise for future drug development.[5]

Adverse effects

Adenosine must be injected intravenously as a bolus because of its extremely short plasma half-life. Adenosine is rapidly transported into tissues, followed by incorporation into purine biosynthetic pathways. Many patients have transient flushing and dyspnea with the drug. Arrhythmias, including heart block and cardiac arrest, may also occur immediately after injection. Because of the drug's rapid uptake, however, therapeutic and adverse responses are normally short-lived.

Digoxin

Digoxin is used in treating certain supraventricular arrhythmias. Its use is discussed in Chapter 24.

Magnesium

Magnesium sulfate is used intravenously to overcome drug-induced torsades de pointes. It may be effective even in the absence of hypomagnesemia.[2]

Indications for Antiarrhythmic Drugs

Table 24-4 presents the general indications of the various agents discussed in this chapter in treating some of the most commonly encountered arrhythmias. It is not intended to be a comprehensive listing of applications of these drugs. Drugs administered orally are largely used to prevent the recurrence of arrhythmias, whereas drugs administered parenterally are usually given to treat acute disorders.[2]

Drug Interactions

Antiarrhythmic drugs can participate in a wide variety of drug interactions. Because the margin of safety with these drugs as a group is narrow, clinically significant interactions may develop whenever the activity or plasma concentration of an antiarrhythmic agent is changed. The following discussion provides an illustrative but not exhaustive list of interactions involving these drugs.

Quinidine may interact with the following drugs to yield the indicated result: with other class I antiarrhythmics and with phenothiazines, additive cardiac effects (quinidine also increases the plasma concentrations of flecainide and propafenone); with digoxin and other digitalis glycosides, increased plasma concentrations of the cardiac glycoside; with rifampin and other hepatic enzyme inducers, decreased plasma quinidine concentrations; with cimetidine and other hepatic enzyme inhibitors, increased quinidine concentrations; with oral anticoagulants, increased likelihood of hemorrhage; with neuromuscular blocking drugs, increased neuromuscular blockade; with systemic antacids that increase urinary pH, reduced urinary excretion of quinidine; and with vasodilators (e.g., nitroglycerin), hypotension. Many of these interactions result from the ability of quinidine to inhibit the activity of CYP2D6.

Quinidine, procainamide, and disopyramide all have antimuscarinic (or antivagal) properties and have additive effects with other antimuscarinic drugs. Drugs that slow AV conduction, such as the β-adrenergic–blocking drugs and amiodarone, can exaggerate the AV conduction effects of drugs with similar actions, possibly leading to bradycardia and heart block. Drugs that have negative inotropic effects (e.g., class IA drugs, Ca^{++} channel blockers, and β blockers) may precipitate heart failure, especially in the presence of other negative inotropic agents. Propranolol and related drugs prevent the tachycardia that normally results from hypoglycemic drugs.

The metabolism of flecainide and propafenone is catalyzed by CYP2D6 in the liver. Drugs that share this same pathway of metabolism increase each other's elimination half-life. Cimetidine and erythromycin can increase the plasma concentrations of flecainide and propafenone. Propranolol and cimetidine reduce lidocaine clearance, whereas induction of hepatic microsomal enzymes by phenobarbital increases it.

Amiodarone increases the effect of warfarin and the concentrations of quinidine, procainamide, and flecainide.[16] There may be more than one mechanism accounting for these interactions. In addition to its effects on metabolism, amiodarone may reduce renal clearance of these drugs by inhibiting the transport

TABLE **24-4**

Indications for Representative Antiarrhythmic Drugs

DRUG	INDICATIONS*	
	SUPRAVENTRICULAR	**VENTRICULAR**
Adenosine	PSVT	
Amiodarone	AF/F, PAC, PSVT	Acute VA, VF, PVTNQ
β Blockers	PSVT, AF/F	PVTNQ
Bretylium		VF
Dofetilide	AF/F	
Flecainide	PAF (prevention), PSVT	VA (prevention of life-threatening)
Ibutilide	AF/F	
Lidocaine		Acute VA, DVA, PVTNQ
Magnesium sulfate		PVTLQ
Procainamide	AF/F	PVTNQ, VA (life-threatening)
Propafenone	AF/F	VT (sustained and life-threatening)
Quinidine	PSVT, AF/F	
Verapamil	AF/F, PSVT (prevention)	

*The suitability of drug versus nondrug therapy for these indications often depends on circumstances. Drug therapy is usually more effective in treating atrial fibrillation of recent origin than if it is long-standing. Maintenance therapy for atrial fibrillation often differs from strategies for converting atrial fibrillation to normal sinus rhythm.

AF/F, Atrial flutter/fibrillation; *DVA,* digitalis-induced ventricular arrhythmias; *PAC,* premature atrial contractions; *PAF,* paroxysmal atrial fibrillation/flutter; *PSVT,* paroxysmal supraventricular tachycardia; *PVTLQ,* polymorphic ventricular tachycardia with long QT interval; *PVTNQ,* polymorphic ventricular tachycardia with normal QT interval; *VA,* ventricular arrhythmias; *VF,* prevention of ventricular fibrillation; *VT,* ventricular tachycardia.

function of P-glycoprotein in the kidney.[16] Verapamil, propafenone, amiodarone, and flecainide (and quinidine) have been reported to increase plasma digoxin concentrations. These interactions may also involve the P-glycoprotein.

IMPLICATIONS FOR DENTISTRY

Patients who are being treated on a long-term basis with antiarrhythmic drugs, if under adequate control, are usually not a management problem for the dentist. Because some antiarrhythmic agents may depress cardiovascular function, the potential for an increased incidence of orthostatic hypotension and hypotensive syncope exists. There is also a greater probability that arrhythmias will develop in a patient with a previous history of arrhythmias who is undergoing stressful treatment. The dentist may wish to consult with the patient's cardiologist regarding the use of epinephrine or other adrenergic vasoconstrictors in patients with a significant arrhythmia history.

As described in Chapter 7, the combination of epinephrine and propranolol may lead to hypertensive reactions. Quinidine, disopyramide, and procainamide, because of their antimuscarinic (or antivagal) activity, interact additively with antimuscarinic antisialagogues. This combination can result in enhancement of antimuscarinic side effects. Quinidine blockade of dealkylation reactions by CYP2D6 may limit the effectiveness of certain oral opioid analgesics, especially codeine, that are converted in the liver to highly active metabolites (e.g., codeine metabolized to morphine). Amiodarone and propafenone also inhibit CYP2D6, which could be the basis for a reduction in analgesic effect of codeine. No interactions with these two drugs and codeine have been reported, however. The additive effect of lidocaine when used as an antiarrhythmic with all local anesthetics is of special importance to the dentist.

The dentist should be aware of the manifestations of adverse drug reactions that occur in the oral cavity. Quinidine has been associated with thrombocytopenia in a few cases. This reaction may lead to oral hemorrhaging and petechiae. Blockade of β-adrenergic receptors is associated with a change in the profile of salivary proteins. The implications of this effect on oral health have not been fully determined. Table 24-5 lists some adverse effects of representative antiarrhythmic drugs.

TABLE **24-5**

Unique and Typical Adverse Effects of Representative Antiarrhythmic Drugs

DRUG	ADVERSE EFFECT(S)
Adenosine	Flushing, asthma, dyspnea, SA nodal arrest, AV nodal block
Amiodarone	Pulmonary fibrosis, thyroid abnormalities, skin discoloration, corneal deposits, peripheral neuropathy
Calcium channel blockers	Flushing, AV nodal conduction defects, reduced contractility of the heart, bradycardia
Flecainide	Cardiac risk with recent myocardial infarction
Lidocaine	Convulsions
Procainamide	Mental changes, torsades de pointes, lupus
Propranolol	AV nodal conduction defects, bronchoconstriction in asthmatics, bradycardia
Quinidine	Cinchonism, hypotension, torsades de pointes

AV, Atrioventricular; *SA,* sinoatrial.

ANTIARRHYTHMIC DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Adenosine	Adenocard
Amiodarone	Cordarone
Acebutolol	Sectrol
Bretylium	Bretylol
Diltiazem	Cardizem
Disopyramide	Norpace
Dofetilide	Tikosyn
Esmolol	Brevibloc
Flecainide	Tambocor
Ibutilide	Corvert
Lidocaine	Xylocaine
Magnesium sulfate	—
Mexiletine	Mexitil
Moricizine	Ethmozine
Procainamide	Pronestyl, Procanbid
Propafenone	Rythmol
Propranolol	Inderal
Quinidine*	Cardioquin, Quinaglute, Quinidex Extentabs
Sotalol	Betapace
Verapamil	Calan, Isoptin

*Several different salts are available for oral and parenteral administration.

CHAPTER 25

Drugs Used in Treating Heart Failure

FRANK J. DOWD

Heart failure is characterized by a decreased ability of the heart to pump blood in adequate amounts. In addition to changes in the heart, multiple adaptive mechanisms occur, which provide targets for drug therapy. The severity of heart failure is often rated according to the New York Heart Association (NYHA) classification, ranging from class I, in which signs of heart failure occur only at higher exercise levels, to class IV, in which signs of heart failure occur at rest. In addition to drug therapy, other strategies for treating heart failure include auxiliary mechanical pumps (ventricular assist devices)[4] and ventricular pacing (resynchronization).

CARDIAC MUSCLE CONTRACTION AND HEART FAILURE

In addition to its role in the action potential, Ca^{++} is intimately involved in the contractile process. The contraction of cardiac muscle is initiated by extracellular Ca^{++} entering the cell with the slow inward current. The immediate source of contractile Ca^{++} in the heart comes largely from intracellular stores, however. Ca^{++} entering the cell during an action potential must first traverse the plasma membrane through voltage-sensitive Ca^{++} channels. This influx of Ca^{++} during the slow inward current triggers the release of much larger amounts of intracellular Ca^{++} from the sarcoplasmic reticulum (SR). The sudden increase in cytoplasmic Ca^{++} stimulates contraction.

Tropomyosin and troponin, which are associated with actin, regulate the interaction between actin and myosin. The binding of Ca^{++} to troponin C initiates a series of conformational changes in troponin and tropomyosin that alter the interaction of tropomyosin and troponin I with actin, favoring the coupling of actin with myosin. Adenosine triphosphate (ATP) is hydrolyzed by myosin-bound adenosine triphosphatase (ATPase) when the actomyosin complex is formed, and chemical energy is converted into mechanical work. The contraction cycle is completed by the active reuptake of Ca^{++} by the SR (and mitochondria) and extrusion from the cell by Na^{+}-Ca^{++} exchange.

Drugs such as the β-adrenergic receptor agonists increase cardiac contractility by increasing intracellular cyclic 3′,5′-adenosine monophosphate (cAMP), which enhances Ca^{++} influx and accelerates uptake of Ca^{++} by the SR, ultimately making more Ca^{++} available for contraction.[12] The latter effect results from the phosphorylation of phospholamban, a protein associated with the Ca^{++} pump of the SR. The effect of Ca^{++} on troponin may also be enhanced by cAMP.

In heart failure, the heart is unable to maintain the requisite cardiac output. The mechanics underlying this failure are incompletely understood. The ability of the SR to participate in the trafficking of Ca^{++} seems to be hindered.[21] The Na^{+}-Ca^{++} exchange sites seem to be increased in heart failure, leading to a decrease in intracellular Ca^{++}. There are likely to be multiple biochemical defects in heart failure, however.

According to Starling's law of the heart, cardiac output, or, more precisely, the ventricular stroke volume, increases as ventricular filling pressure increases. Stated simply, the heart pumps whatever is supplied to it by way of venous return, maintaining a near-optimal heart size. As ventricular end-diastolic pressure increases, ventricular stroke work and stroke volume increase. Normal heart function is within well-defined limits and is described by a single curve (Figure 25-1).

When cardiac contractility is reduced in heart failure, three mechanisms are available by which the heart can compensate for the defect: (1) an increase in ventricular end-diastolic pressure, which enhances cardiac output (Frank-Starling preload mechanism); (2) an increase in number of contractile units (hypertrophy); and (3) use of chronotropic and inotropic reserves of the heart through reflex mechanisms (sympathetic activity). If these mechanisms are sufficient to produce normal cardiac output, the heart failure is said to be compensated. In this condition, a new ventricular function curve is generated (see Figure 25-1). For any given ventricular end-diastolic pressure, however, ventricular stroke work, stroke volume, and cardiac output are lower in the failing heart than in the normal heart. Consequently, the heart enlarges to maintain cardiac output, and heart rate increases to help compensate for poor cardiac function.

If the ventricular end-diastolic pressure becomes too elevated (i.e., the heart is working to the far right along the Frank-Starling curve), venous pressures upstream also increase excessively, leading to symptoms of "backward" heart failure. Signs and symptoms include pulmonary congestion and dyspnea (left-sided failure) and systemic venous distention and edema (right-sided failure). If compensatory mechanisms are unable to maintain cardiac output sufficient for the needs of the peripheral tissues, "forward" heart failure ensues. Adverse effects from impaired tissue perfusion include weakness, lassitude, and acute renal failure. In chronic heart failure, aspects of backward and forward failure interact to produce clinical manifestations. Salt and water retention caused by forward failure contributes to the venous hypertension and edema associated with backward failure. Conversely, impaired gas exchange in the congested lungs augments muscle weakness and fatigue associated with reduced cardiac output and delivery of oxygen to skeletal muscle.

Heart failure occurs whenever the workload placed on the heart exceeds the ability of the heart to perform. Heart failure often arises from myocardial infarction or hypertension.

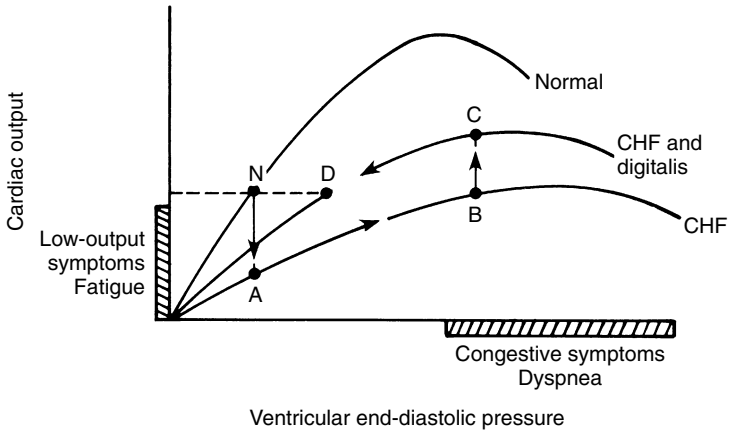

FIGURE **25-1** Operation of the Frank-Starling mechanism in the preload compensation for heart failure. The three *curves* represent ventricular function curves in the normal state, in congestive heart failure (*CHF*), and in heart failure after treatment with digoxin. Points *N* through *D* indicate, in sequence, normal cardiac status (*N*), depression of contractility with decompensated heart failure (*A*), Frank-Starling compensation (*B*), increase in contractility with digoxin (C), and reduction in use of Frank-Starling preload compensation that digoxin allows (*D*). Points *N*, *D*, and *B* indicate the same cardiac output on the vertical axis, but each point is at a different end-diastolic pressure on the horizontal axis. The excessive end-diastolic pressures causing congestive symptoms and the lowered levels of cardiac performance resulting in low-output symptoms are shown by the hatched areas. (From Mason DT: Regulation of cardiac performance in clinical heart disease: interactions between contractile state mechanical abnormalities and ventricular compensatory mechanisms, *Am J Cardiol* 32:437-448, 1973.)

Myocardial infarction can lead to heart failure as a result of a reduction in the heart's ability to perform work (pump failure).

An increase in total peripheral vascular resistance, as seen in hypertension or as a reflex reaction in congestive heart failure, can contribute to heart failure because of increased outflow resistance on cardiac contraction. The first reaction of the heart to an increase in outflow resistance is often enlargement, resulting in temporary higher efficiency in cardiac function. This initial reaction is followed, however, by progressive signs of cardiac failure characterized by decreased stroke volume and stroke work, as indicated earlier. Reducing preload and afterload by reducing peripheral resistance is an important strategy in treating heart failure.

Figure 25-2 shows some important adaptive mechanisms that result from heart failure. These changes, including an increase in sympathetic discharge, can compensate for the heart failure. If these and other responses are insufficient, however, the heart failure becomes uncompensated. Adaptive mechanisms also include an increase in production of angiotensin II, leading to remodeling of the heart over time.[10] Remodeling results in cardiac hypertrophy, and several cellular changes, which, although they tend to compensate for heart failure, may hasten the course of the disease. This cardiac remodeling in heart failure has a parallel in hypertension, in which vascular smooth muscle slowly undergoes hypertrophy and hyperplasia.

As a result of the complexity of changes in heart failure, there are numerous processes that can be targeted by drugs: neurohumoral events, vascular dynamics, fluid volume, the sympathetic nervous system, and contractility of the heart.[10] The pharmacologic features of angiotensin-converting enzyme (ACE) inhibitors and other vasodilators, diuretics, β blockers, and catecholamines are discussed elsewhere in this book. They are also discussed in this chapter in relation to the treatment of heart failure. The cardiac glycosides are not extensively discussed elsewhere in the book and so are discussed more fully in this chapter than other drugs used for heart failure.

DRUGS USED IN THE TREATMENT OF CHRONIC HEART FAILURE

Table 25-1 lists the drugs used to treat heart failure and their mechanisms of action. The drugs are often used in combination. Heart failure can be classified as diastolic or systolic failure. In diastolic failure, the heart has inadequate distention and inadequate filling capabilities. Contraction as measured by the ejection function may be normal. This type of heart failure is often seen in patients with hypertension. Systolic heart failure is a deficiency in contractility with a low ejection fraction.

The primary drugs used to treat chronic heart failure are ACE inhibitors, angiotensin II receptor blockers, thiazide and loop diuretics, β-adrenergic receptor blockers, aldosterone antagonists, digoxin, and directly acting vasodilators. For short-term acute treatment, certain catecholamines, nesiritide, other vasodilators, and the phosphodiesterase III inhibitors have special application. Figure 25-3 shows the drugs used in each type of heart failure.[4,7]

Diuretics

Therapy of mild congestive heart failure has often involved salt restriction and the use of diuretic drugs to reduce tissue edema and blood volume. The resulting reduction in the preload, or diastolic filling pressure, helps decrease wall tension in the heart and lessen myocardial oxygen demand. The vasodilation caused by the thiazide diuretics also aids in reducing the afterload, or the arterial pressure against which the heart has to pump in moving blood. Diuretics also indirectly reduce sympathetic nervous system activity.

Aldosterone Antagonists

The action of spironolactone as a diuretic is caused by its antagonism of aldosterone at the convoluted tubule of the kidney. Antagonism of aldosterone leads to several other effects that are beneficial in patients with heart failure. These are shown in Figure 25-4. K^+-sparing actions help in preventing hypokalemia. Reducing Mg^{++} loss seems to reduce

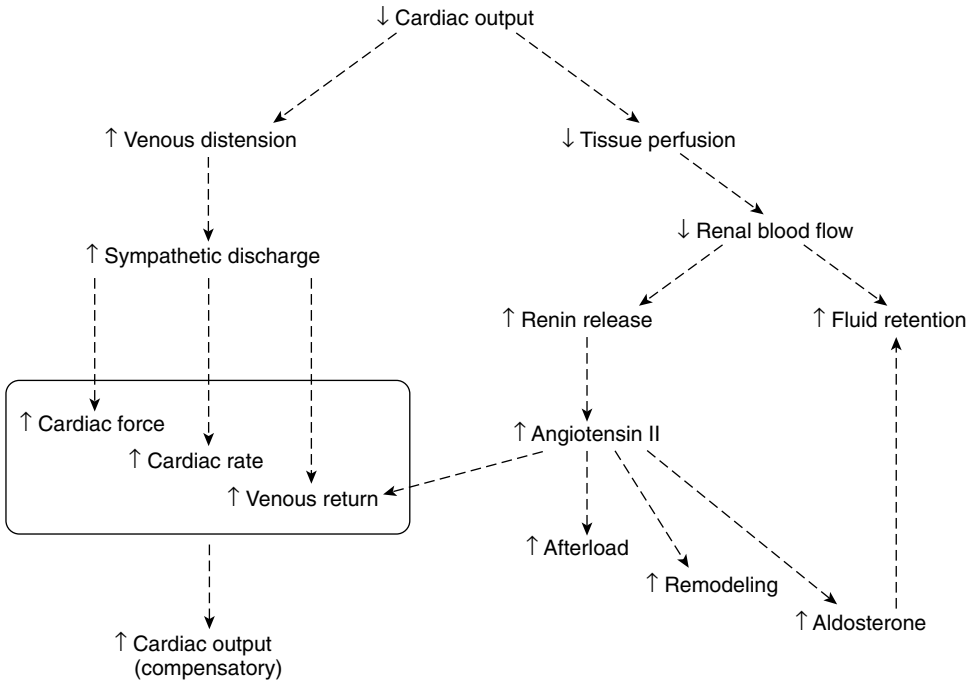

FIGURE **25-2** Adaptive mechanisms in heart failure. A decrease in cardiac output leads to a cascade of events that result in a compensatory increase in cardiac output (*box*). In addition, activation of the renin-angiotensin system leads to changes that put further burden on the failing heart and promote detrimental and long-term remodeling of the cardiovascular system.

TABLE **25-1**

Treatment of Heart Failure

DRUG OR DRUG CLASS	MECHANISM(S)
Long-Term Treatment	
Thiazide and loop diuretics	Reduce fluid volume (reduce preload and afterload)
ACE inhibitors	Reduce effect of angiotensin II, prevent remodeling
Angiotensin II receptor blockers	Reduce effect of angiotensin II, prevent remodeling
β Blockers*	Reduce sympathetic effect, prevent remodeling, prevent arrhythmias
Aldosterone antagonists	Inhibit effect of aldosterone
Digoxin	Direct cardiotonic effect
Isosorbide dinitrate-hydralazine	Reduce afterload and preload
Short-Term Treatment†	
Dobutamine	Direct cardiotonic effect
Dopamine	Direct cardiotonic effect
Nesiritide	Reduces preload and afterload
Phosphodiesterase III inhibitors	Reduce preload and afterload; direct cardiotonic effect
Nitroglycerin	Reduces preload and afterload
Nitroprusside	Reduces preload and afterload

*Carvedilol is a β blocker that also blocks α_1 adrenoceptors.
†Usually only for a few days.
ACE, Angiotensin-converting enzyme.

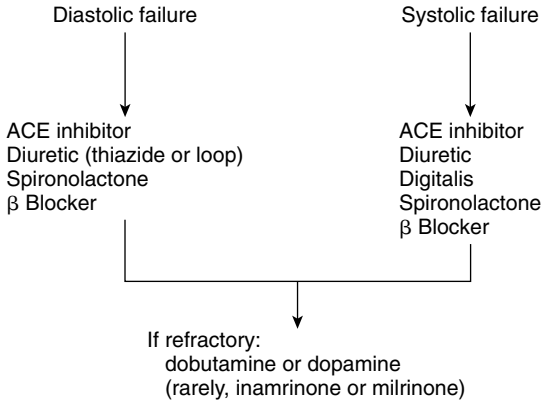

FIGURE **25-3** Heart failure and choice of drug. The choice of digoxin depends on the presence of systolic failure, especially if it occurs with atrial fibrillation. Dobutamine, dopamine, nesiritide, nitroglycerin, nitroprusside, inamrinone, and milrinone are reserved for short-term therapy in refractory cases. *ACE,* Angiotensin-converting enzyme.

ventricular arrhythmias in patients with heart failure. Because aldosterone can inhibit norepinephrine uptake (uptake 2), spironolactone prevents the enhanced sympathetic activation from aldosterone.[18] Spironolactone also blocks the inhibition of the baroreceptor reflex seen with aldosterone. A consequence of inhibiting the baroreceptor reflex is the lack of parasympathetic nerve response.[13] The latter response is important in counteracting the adverse effects of sympathetic stimulation, such as arrhythmias and cardiac ischemia. Myocardial fibrosis is also inhibited by spironolactone.

Spironolactone has many salutary effects in heart failure. These beneficial effects also occur when it is used with other

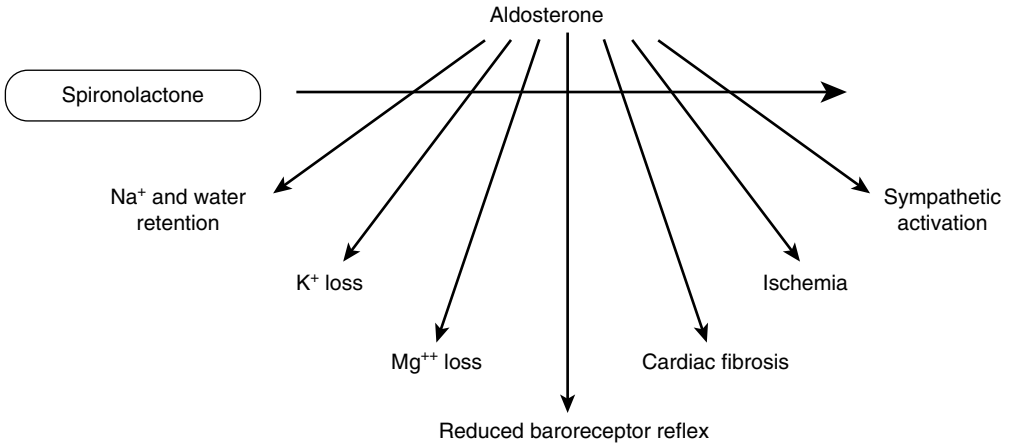

FIGURE **25-4** Effects of spironolactone in treating congestive heart failure. The beneficial effects of spironolactone are the result of inhibiting the several effects of aldosterone at its receptors.

drugs such as ACE inhibitors. Because the reduction of aldosterone release by ACE inhibitors is only partial, an added benefit is gained from the use of an aldosterone antagonist.

Eplerenone is another aldosterone receptor antagonist for the treatment of heart failure. Compared with spironolactone, it has a lower affinity for the androgen receptor and is reported to have a lower incidence of related side effects including gynecomastia.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin II Receptor Blockers

A major effect of ACE inhibitors is to reduce afterload and preload. These drugs improve symptoms in patients with heart failure. In addition, the progressive deterioration of the heart is slowed with ACE inhibitors. ACE inhibitors control remodeling that occurs with chronic heart failure. Remodeling results from growth of the myocardial cell and myocardial fibrosis. This probable cardioprotective effect provides added support for the use of ACE inhibitors in heart failure. Inhibiting the production of angiotensin II or blocking its receptor reduces aldosterone secretion, which reduces Na^+ and water retention. Reduction of aldosterone release by ACE inhibitors also reduces sympathetic discharge, as described in Chapter 28 (see Figure 25-4).

Evidence also suggests that ACE inhibitors stimulate the proliferation of capillaries in the coronary circulation, increasing blood flow. It is unknown whether this action of ACE inhibitors occurs as a result of the decrease in angiotensin II, an increase in bradykinin, or both. Most likely, the ability of ACE inhibitors to reduce blood pressure in hypertensive patients also contributes to a cardioprotective effect. Early treatment of congestive heart disease with an ACE inhibitor could be a major factor in slowing the progress of the disease and in relieving symptoms. Enalapril is one of the first drugs whose administration was associated with an increased survival time in patients with heart failure.[15] These drugs also are useful in combination with other drugs, including digoxin and diuretics, in treating heart failure.

Angiotensin II antagonists, such as losartan and valsartan, are additional candidates for treating heart failure.[7,10] They share the benefits of ACE inhibitors, while avoiding such side effects as angioedema and persistent coughing. The pharmacologic features of angiotensin II antagonists and ACE inhibitors are discussed in detail in Chapter 28.

β-Adrenergic Receptor Antagonists

The use of β-adrenoceptor blockers to reduce the adverse cardiac effects of heightened sympathetic discharge that occur as heart failure progresses is a strategy used in the long-term treatment of heart failure.[20] β Blockers reduce the work of the heart, reduce renin secretion, prevent remodeling of the heart, act as antiarrhythmic drugs, and reduce the downregulation of β_1-adrenergic receptors in heart failure. All of these effects are beneficial in heart failure. Their use is consistent with a neurohumoral component of heart failure. Bisoprolol, betaxolol, and metoprolol are selective β_1-adrenergic receptor blockers that are used in treating heart failure.

Carvedilol is a nonselective β-adrenoceptor blocker and selective α_1-adrenoceptor blocker used in patients with heart failure. β-adrenergic blockade reduces remodeling, whereas α_1-adrenergic blockade reduces preload and afterload. It also has antioxidant properties that result in cell protection against free radicals, in addition to the other effects of β blockers. The relative importance of each mechanism in achieving favorable results in heart failure is unknown.

Directly Acting Vasodilators

Vasodilators such as nitrates and hydralazine reduce the load on the heart, improve tissue perfusion in heart failure, and increase survival rates in these patients. Vasodilators are usually administered in combination with other drugs, such as inotropic agents or ACE inhibitors. Disadvantages of nitrates and hydralazine include the indirect enhancement of sympathetic discharge and activation of the renin-angiotensin pathway. Added interest in vasodilator therapy resulted from evidence supporting the clinical efficacy of two vasodilators in combination: isosorbide dinitrate and hydralazine. The fixed-dose therapy was found to be effective in patients of African descent with class III and class IV heart failure.[3,17] This drug combination may be particularly effective in this group of patients, who may be less responsive to drugs such as ACE inhibitors. The isosorbide dinitrate–hydralazine combination may also be useful as added therapy in resistant cases or in patients who cannot tolerate other heart failure medications. The pharmacologic characteristics of nitrates and hydralazine are discussed in Chapters 26 and 28, respectively.

DIGOXIN

Digoxin is a cardiac glycoside that is often called *digitalis*, referring to the plant from which it is derived. Digoxin is currently indicated for the treatment of congestive heart failure and the management of atrial flutter and fibrillation.

The first detailed scientific study of digitalis on record was made by Sir William Withering[19] of Shropshire, England, in 1785. In his treatise, "An Account of the Foxglove, and Some of Its Medical Uses; With Practical Remarks on Dropsy, and Other Diseases," Withering detailed clinical uses for the leaf of the *Digitalis purpurea* (purple foxglove) plant and described its effects on the heart. His recognition of the potential usefulness of digitalis plant derivatives was occasioned by their extensive use in local folk medicines. Withering ascribed the beneficial effects of digitalis in treating dropsy to a direct diuretic effect, although he was aware of beneficial effects on the heart as well. He also detailed many toxic effects of the plant.

The history of the use of digitalis since Withering's time has been characterized by a realization of its potential therapeutic benefits on the one hand and its low margin of safety on the other. Advances in digitalis research and clinical use up to the present have contributed greatly to our knowledge of this drug class.

Chemistry and Classification

The term *digitalis* is often used interchangeably with the term *cardiac glycoside*. Both terms refer to many compounds, naturally occurring or semisynthetic, that have similar cardiotonic effects. Only one such compound, *digoxin*, is commonly used clinically in the United States today. Another agent, digitoxin, is available in Canada and elsewhere. The structure of digoxin is shown in Figure 25-5. The molecule is composed of a steroid ring structure. Other distinguishing molecular characteristics include an α,β-unsaturated lactone ring, and a carbohydrate moiety in glycosidic linkage at C_3. The presence of a sugar in glycosidic linkage accounts for the name *glycoside*. A steroid plus lactone lacking the sugar group is generically called a *genin* or *aglycone*. The genin of digoxin is digoxigenin.

Mechanism of Action

Digoxin has a direct inotropic effect on the heart; it directly increases the force of contraction. The inotropic action of digoxin does not depend on release of endogenous catecholamines. Rather, digoxin has a direct action on heart cells. Digoxin is known to be a specific inhibitor of the Na^+-K^+ pump, by inhibiting Na^+,K^+-activated ATPase (Na^+,K^+-ATPase), which is the enzymatic equivalent of the Na^+-K^+ pump. The α subunit of Na^+,K^+-ATPase is responsible for pumping sodium and potassium and contains the binding site for digoxin (Figure 25-6). Inhibition of Na^+,K^+-ATPase leads to a small but significant increase in intracellular Na^+ near the plasma membrane. This increase in Na^+, amounting to approximately 2 mmol/L, reduces the rate of Na^+-Ca^{++} exchange (three Na^+ exchanged into the cell for one Ca^{++} transported out of the cell) because the increase in Na^+ reduces the net binding of Ca^{++} to its binding sites on the exchange system. This alteration results in a reduced efflux of Ca^{++} and an increase in Ca^{++} available to the contractile apparatus. In addition, the increase in Ca^{++} stimulates the release of additional Ca^{++} from the SR, further stimulating contraction.

Digoxin may also increase the influx of Ca^{++} through other channels. The added intracellular Ca^{++} increases the amount of Ca^{++} taken up into the SR during diastole. After several contractions, the amount of Ca^{++} released from the SR is also increased. The positive inotropic effect results from the increased Ca^{++} available for contraction during the systolic phase. The inhibition of Na^+,K^+-ATPase resulting in increased intracellular Na^+ and a reduced diastolic membrane potential has important implications for other ion movements and electrical properties of heart cells. Some of these are described subsequently. The relationship between Na^+,K^+-ATPase inhibition by digoxin and its inotropic effect is shown in Figure 25-6.

Pharmacologic Effects

The most important actions of the digitalis glycosides are those exerted on the cardiovascular system. Resulting changes in hemodynamics may indirectly influence other systems, yielding beneficial or adverse responses. Some therapeutic effects may be exerted through the nervous system. Direct actions on the central nervous system (CNS), gastrointestinal tract, and cardiovascular system also contribute to the toxic profile of digoxin.

Cardiac effects

Digoxin has two powerful influences on the heart: it increases myocardial contractility, and it alters electrical activity

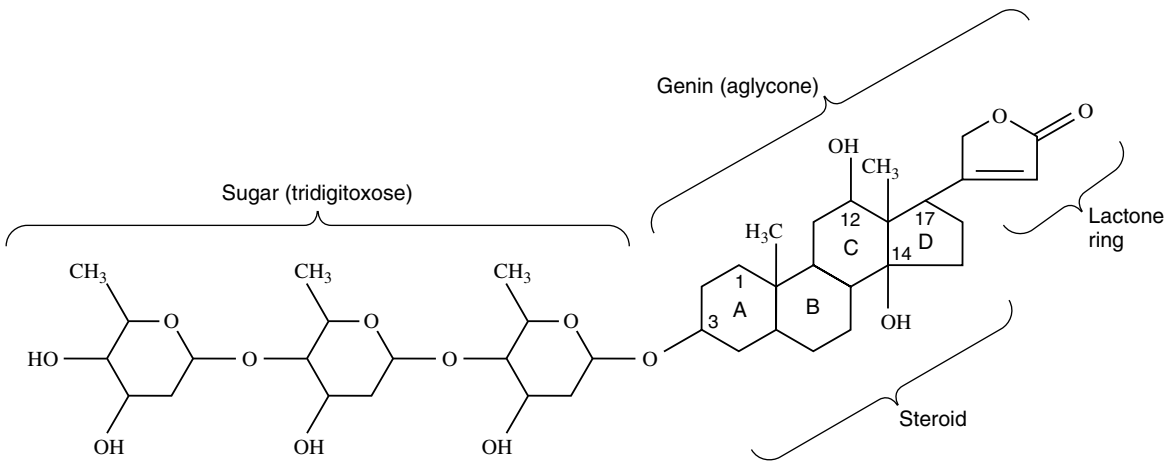

FIGURE **25-5** Structural formula and composition of digoxin.

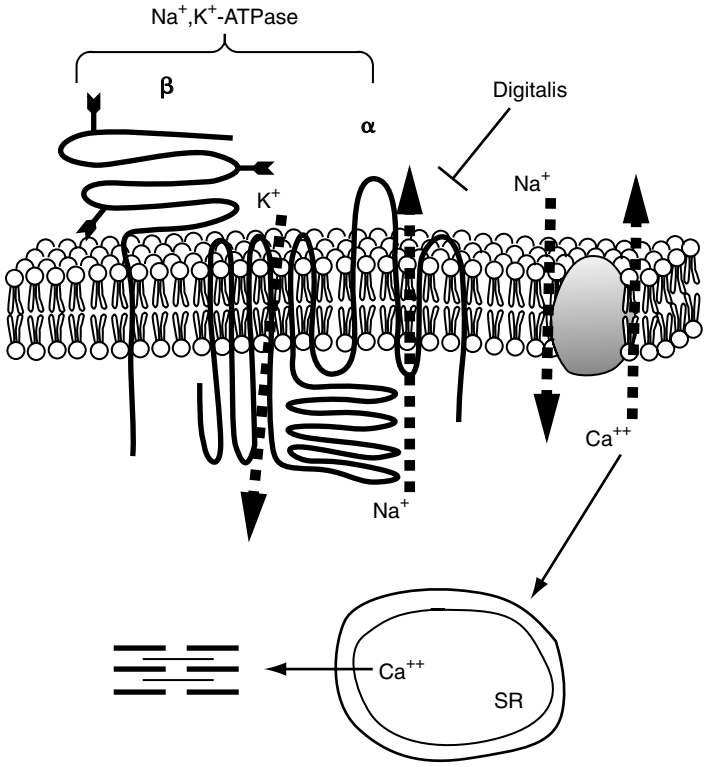

FIGURE **25-6** The role of Na^+,K^+-ATPase and the Na^+-Ca^{++} exchange in cardiac contractility and the mechanism of the positive inotropic action of digoxin. Digoxin binds to the extracellular face and transmembrane region of the β subunit *(β)* of Na^+,K^+-ATPase, inhibiting Na^+ efflux and K^+ influx. The α subunit *(α)* of Na^+,K^+-ATPase is also shown. The increase in intracellular Na^+ results in reduced binding of Ca^{++} to the Na^+-Ca^{++} exchange system and reduced Ca^{++} efflux. The concentration of intracellular Ca^{++} is increased, and more Ca^{++} is made available to intracellular storage sites, notably the sarcoplasmic reticulum (*SR*). This leads to enhanced Ca^{++} release to the contractile apparatus and a greater force of contraction.

throughout the heart. A complex interplay of direct actions and autonomically mediated changes contributes to effects clinically observed.[1,2]

Contractility. The experiments of Cattell and Gold[5] clearly showed that cardiac glycosides have direct effects on the isolated heart. The drugs increase the force of contraction of the myocardium (positive inotropic effect). Maximum tension developed and rate of tension development are increased, whereas time from onset of contraction to peak contraction is decreased. The duration of the contractile process during systole is abbreviated because of an increase in the rate at which tension is developed. The overall cardiodynamic effect of digoxin on the isolated heart can be summarized as an increased force of contraction caused by an increased rate of force development by the myocardium, resulting in a systolic phase of shorter duration but greater effectiveness.[5,16]

In vivo, many factors complicate the effects of digoxin on contractility. In the normal intact individual, cardiac glycosides directly increase the force of contraction of the heart, but this effect is more than negated by compensatory autonomic reflexes. Digoxin, in addition to its cardiac effects, constricts peripheral blood vessels by a direct action on vascular smooth muscle. The outcome of such vasoconstriction and the resultant increase in blood pressure is a reduction in myocardial contractile force and cardiac output because of reflex mechanisms. The net effect in normal individuals is that reflex mechanisms cancel out the positive effects of digoxin on heart contractility. Sarcomere shortening with digoxin in the normal heart offsets the increased contractility in vivo.

In patients with failing hearts, a different situation prevails. Vasoconstriction, a physiologic sympathetic response to reduced cardiac output, is significant in peripheral vessels. The renin-angiotensin-aldosterone system is also highly activated in heart failure, and antidiuretic hormone is elevated. In these compromised patients, compensatory mechanisms do not cancel out the cardiac effects of digoxin. Digoxin increases cardiac output, reducing the need for high sympathetic tone in the blood vessels. Sympathetic tone is consequently decreased in the vasculature when these patients receive digoxin, and vasodilation tends to occur. Digoxin enhances baroreceptor sensitivity and corrects an impaired baroreceptor response in patients with heart failure. The net result is to reduce sympathetic activity. The effect of digoxin in vivo depends on the state of the cardiovascular system at the time of administration.

In compensated and decompensated heart failure, digoxin can improve cardiac function so that a greater cardiac output can be achieved without as much reliance on compensatory mechanisms. Figure 25-1 shows that a new ventricular function curve is generated as a result of digoxin. This curve more closely approximates the normal situation.

Cardiac size and rate of contraction. Congestive heart failure is accompanied by an increase in heart size. As the heart begins to fail, it is unable to eject as much blood per stroke as the normal heart, and the size of the heart increases, compensating for the loss of contractility. The right or left side of the heart, or both, may be affected.

Digoxin, by increasing the force of contraction, reduces the size of the heart. Digoxin enables the heart to pump with greater force at any given filling pressure. This increased force leads to a reduction in diastolic pressure and cardiac distention.[14]

In the clinical management of congestive heart failure, the administration of digoxin is most often associated with a reduction in heart rate. This reduction results from a vagal and a direct effect on the heart by digoxin. The cardiac glycosides stimulate the vagus nerve—probably indirectly by an effect on baroreceptors, afferent nerve pathways, and central vagal nuclei—and at therapeutic doses reduce the sympathetic tone of the heart indirectly by improving cardiac function and sensitizing the baroreceptor mechanism. Both effects account for a reduction in heart rate. The effect of digitalis on heart rate during the treatment of certain cardiac arrhythmias is discussed subsequently.

TABLE **25-2**

Electrophysiologic Effects of Digoxin

SITE	AUTOMATICITY	DURATION OF EFFECTIVE REFRACTORY PERIOD	EXCITABILITY	CONDUCTION VELOCITY
SA node	↓,↑A			
Atrial myocardium		↓,↑A	↑*, ↓T	↑*, ↓T
AV node		⇑		⇓
Purkinje fibers	⇑	↑*, ↓T	↑*, ↓T	↓
Ventricular myocardium		⇓	↑*, ↓T	↑*, ↓T

*Lower therapeutic doses only.
↑, Increased; ↓, decreased; ⇑, ⇓, most important effects.
A, After atropine; *AV,* atrioventricular; *SA,* sinoatrial; *T,* at toxic doses.

Electrophysiology. The effects of digitalis on the electrical properties of the heart can be divided into at least four interrelated categories: automaticity, refractoriness, excitability, and conduction velocity. Because digoxin has vagal and nonvagal effects on the heart and because the areas of the heart affected by the vagus include the sinoatrial (SA) node, the atrial myocardium, and the upper portions of the atrioventricular (AV) node, a discussion of discrete regions of the heart is necessary. The direct effects of digoxin on the electrophysiology of the heart are as follows (Table 25-2): reduced conduction velocity and increased duration of the ERP in the AV node, increased automaticity of subsidiary pacemaker activity in the conductive tissues of the ventricle (e.g., Purkinje fibers), and decreased duration of the ERP of the ventricular myocardium. Cardiac vagal effects of digoxin are limited to effects on the atria, the SA node, and the AV node. They consist of a decrease in the duration of the ERP of the atrial myocardium, a decrease in the automaticity of the SA node, and an increase in the duration of the ERP along with a decrease in the conduction velocity of the AV node.

Electrocardiogram. Therapeutic and toxic effects of digoxin are associated with changes on the electrocardiogram (ECG) that reflect the electrophysiologic effects listed in Table 25-2. They include alterations in the shape of the T wave, the configuration of the ST segment, the lengths of the QT and PR intervals, AV dissociation, and the presence of extrasystoles (Figure 25-7).

At therapeutic doses, changes often occur in the T wave and the ST segment configuration. The T wave may be inverted or distorted, whereas the ST segment may appear "sunken" (lead II of the ECG). These changes are caused by alterations in the sequence of repolarization of various ventricular myocardial cells. Also at therapeutic doses, the PR interval is lengthened by digitalis as a result of decreased conduction velocity in the AV node. The QT interval is shortened because of the shortened ventricular action potential.

Although several cardiac effects of digoxin are observed at toxic doses, two effects are typical. The first is heart block caused by excessive reduction in AV nodal conduction; the second is any of several ventricular arrhythmias caused by ectopic pacemaker activity.

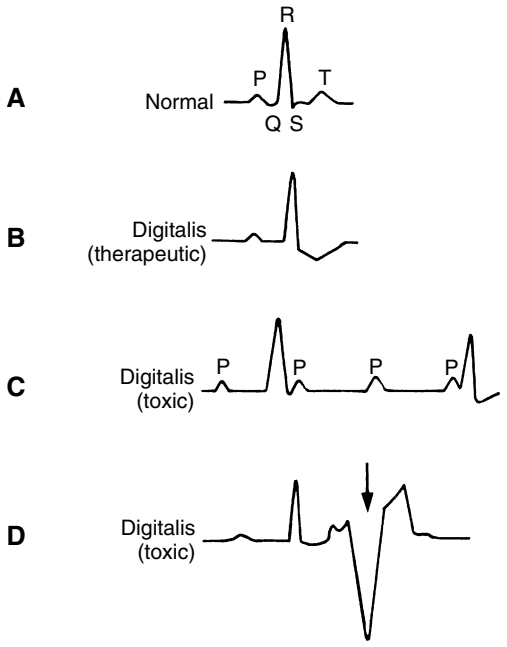

FIGURE **25-7** Some effects of digitalis on the ECG (lead II). **A,** Normal ECG. **B,** Typical changes at therapeutic concentrations include depression of the ST segment and lengthening of the PR interval. **C,** Toxic effect of digoxin on atrioventricular (AV) conduction promotes AV dissociation, such as complete AV block. Notice the lack of relationship between the P waves and QRS complexes. **D,** Toxic effect of digoxin on ventricular impulse generation results in ectopic ventricular beats. An example of an ectopic beat is marked by the *arrow*.

Effects on systemic vasculature

Although digoxin is a vasoconstrictor, vasoconstriction by digoxin is usually not observed in patients with congestive heart failure because sympathetic vascular tone is already elevated. Vasodilation often results from digoxin administration because of the improvement in cardiac function. Nevertheless, caution should be used when administering digoxin by the intravenous route because significant vasoconstriction may occur even in a patient with heart failure.

Diuretic effects

At one time, digitalis was thought to act primarily on the kidney because diuresis is such a prominent feature of its use in congestive heart failure. The diuretic effect results primarily from improved cardiac function and a direct effect on afferent nerves in the heart that are involved in the central regulation of blood volume. Together, these actions result in reduced peripheral sympathetic tone and increased blood flow to the kidney. Glomerular filtration is increased, renin secretion in most cases is decreased, and aldosterone secretion is indirectly inhibited. The retention of Na^+ and water is reduced. Digoxin also promotes fluid mobilization and the reduction

*Intravenous administration.
†Other marketed formulations may yield different absorption percentages.

of venous pressure, which increases the return of edema fluid to the vascular space and indirectly increases renal excretion. Some of the diuretic effect of digoxin may result from its direct action on the Na^+-K^+ pump in the kidney, but this is of secondary importance to the diuresis based on improved cardiovascular dynamics and reduced sympathetic activity.

Miscellaneous effects

Digoxin can cause anorexia, nausea, and vomiting, especially at toxic doses. Excessive salivation often accompanies these effects. Significant neurologic effects of digoxin, usually seen in toxic situations, are discussed later in the chapter. Although digoxin contains a steroid ring structure, it rarely elicits effects associated with steroid hormones. Perhaps the only important endocrine influence is a weak estrogen effect. Digoxin is not an aldosterone receptor antagonist.

Absorption, Fate, and Excretion

Digoxin is usually given by the oral route. Dose schedules are extremely important for digoxin because attaining a therapeutic effect without toxicity requires precise regulation of the amount of drug administered. Digoxin dosages depend on individual patient variations and disease states and concurrent drug therapy. In all cases, patients must be continually monitored, and final judgment on optimal dosages depends on clinical observations.

A comparison of various oral digoxin preparations has shown variability in drug bioavailability, the difference apparently resulting from unequal dissolution rates of the tablets. The highest bioavailability of digoxin has been noted with the use of a solution of digoxin in soft gelatin capsules. Digoxin is excreted by the kidney largely in the active form. The mechanism involves glomerular filtration and tubular secretion and accounts for almost all the elimination of the drug. Because digoxin is largely eliminated in the kidney, patients with kidney hypofunction may require downward dosage adjustments of the drug. The pharmacokinetics of digoxin are summarized in Table 25-3.

Adverse Effects

Signs and symptoms

Although allergic reactions to digoxin are rare, toxic reactions are not. Withering[19] was well aware of many toxic effects of digitalis when he wrote:

> *In the year 1775 my opinion was asked concerning a family recipe for the cure of dropsy. I was told that it had long been kept a secret by an old woman in Shropshire who had sometimes made cures after the more regular practitioners had failed. I was informed also that the effects produced were violent vomiting and purging; for the diuretic effects seemed to have been overlooked. This medicine was composed of twenty or more different herbs; but it was not very difficult for one conversant in these subjects to perceive that the active herb could be no other than foxglove.*

BOX **25-1**

Common Signs and Symptoms of Digoxin Toxicity

Gastrointestinal
Salivation
Anorexia
Nausea
Vomiting
Diarrhea

Central Nervous System
Headache
Visual disturbances
Fatigue
Drowsiness

Cardiac
AV block
Excessive slowing of the heart
Ventricular extrasystoles
Other arrhythmias

Miscellaneous
Excessive urination

AV, Atrioventricular.

Digoxin toxicity still represents a significant clinical problem today. The therapeutic index for digoxin is very low. Toxic signs are often seen at roughly twice the minimum effective dose. In practice, adverse reactions usually result from accumulation of the drug or from K^+ depletion caused by diuretic coadministration, or both. Individual differences in patient response exist and may account for unexpected clinical results; dosages have to be tailored for each patient. Common toxic effects of digoxin are listed in Box 25-1.

Extracardiac toxic effects include anorexia, nausea, diarrhea, and vomiting. Gastrointestinal symptoms may also occur at nontoxic concentrations. The mechanism involves stimulation of the chemoreceptor trigger zone of the medulla. Excessive salivation, headache, fatigue, drowsiness, and abdominal pain often accompany these toxic signs and symptoms. Visual disturbances, such as the appearance of halos and distortions in color perception, can also occur, perhaps because of a direct effect of digoxin on the visual cortex. Objects often appear yellow or green. Giddiness and trigeminal neuralgia are sometimes observed; excessive urination often occurs with digoxin

intoxication. Gynecomastia may occasionally develop in men. This side effect is of little value in determining toxicity, however, because it seldom occurs. The drugs may also suppress follicle-stimulating hormone and lead to vaginal cornification. Such effects are probably caused by an interaction with estrogen receptors.

In approximately half the cases of digoxin toxicity, extracardiac signs of toxicity precede the cardiac signs. A typical pattern would be the development of anorexia, followed in 1 or 2 days by nausea and vomiting and other signs. Nevertheless, the absence of extracardiac signs is no guarantee that cardiac toxicity is not occurring.

Cardiac toxicity is the most serious consequence of digoxin therapy. Although it is difficult to characterize specifically, cardiac toxicity caused by digoxin, two effects stand out as the most typical—AV nodal block and ventricular tachyarrhythmias. Complete AV dissociation can occur at toxic concentrations of digoxin. This effect is an extension of a therapeutic effect of the drug and is mediated by a reduction in AV nodal conduction. Dropped ventricular beats caused by partial heart block are also a sign of toxicity. The effect on AV conduction accounts in great measure for the excessive slowing of the heart seen in some toxic situations. Excessive cardiac slowing may be an important sign of toxicity in many patients.

Digoxin also produces tachyarrhythmias in toxic situations. Increased electrical activity can result in premature beats and extrasystoles of ventricular origin, which may progress to ventricular fibrillation. Tachyarrhythmias may be caused by one of several mechanisms. Some may be caused by increased automaticity of Purkinje fibers, others may be due to a reentry process (see Chapter 24), and still others may be due to delayed afterpotentials whose depolarizations follow quickly on the action potential and in some cases generate a new action potential. Afterdepolarizations are most likely caused by release of intracellular Ca^{++} from overloading of the intracellular Ca^{++} stores. Afterpotentials may also interfere with conduction by reducing the phase 4 resting potential. Other arrhythmias of atrial and of ventricular origin may also occur. Examples of toxic effects on AV conduction and ventricular impulse generation are shown in Figure 25-7.

The arrhythmic effects of digoxin result largely from inhibition of cardiac Na^+,K^+-ATPase. Vagal effects of digoxin can contribute to certain cardiac effects, such as heart block. In addition, at toxic concentrations, digoxin may exert significant stimulatory effects on the sympathetic nervous system, and these actions may account for some arrhythmias. Enhanced sympathetic activity is most likely caused by inhibition of Na^+,K^+-ATPase in the CNS and inhibition of active reuptake of norepinephrine at adrenergic nerve endings.

Drug monitoring

Attempts have been made to correlate blood concentrations of cardiac glycosides with signs of toxicity. These attempts create a technical problem because serum digoxin at therapeutic doses is only 0.7 to 1.2 ng/mL, and toxic effects may start to appear at approximately 2.3 ng/mL or lower.

The plasma concentration of cardiac glycosides can be measured by a specific radioimmunoassay. This assay is of limited use, however, in confirming toxic states of patients because of the proximity of toxic and therapeutic plasma titers. Monitoring drug toxicity can best be accomplished by measurement of drug serum concentrations and, more importantly, careful clinical examination. Patient education is a necessary prerequisite for the early detection and prevention of digoxin toxicity.

Treatment of digoxin toxicity

When digoxin toxicity is diagnosed, the drug and any diuretics that may have exacerbated the problem are temporarily discontinued. If digoxin must be readministered before signs of toxicity have abated, small doses are given with constant monitoring. Potassium chloride can be administered intravenously in cases of hypokalemia. In general, it is not used if AV conduction is significantly impaired because K^+ can worsen this condition. Atropine can be helpful in controlling AV block, sinus bradycardia, and SA nodal arrest.

Lidocaine may be useful in treating digoxin toxicity. It is given intravenously in these situations. Lidocaine is useful in suppressing ectopic pacemaker activity; however, it has little effect on slowing of AV nodal conduction by digoxin. Phenytoin may also be useful in treating ventricular arrhythmias caused by digoxin.

In severe digoxin toxicity, an antidigoxin drug designated digoxin immune Fab (Digibind) may be administered.[11] Digoxin immune Fab consists of antigen-binding fragments derived from sheep antibodies to digoxin. The antidote is given intravenously and inactivates digoxin by forming a complex with the drug. The complex is excreted by the kidney, with an elimination half-life of 15 to 20 hours. With an adequate dose, the reversal of toxicity is rapid. One potential hazard in its use is the induction of hypokalemia if body stores of K^+ are low. Digoxin immune Fab also affects radioimmunoassays for digoxin designed to monitor plasma levels of digoxin. Fab fragments, although less likely than the entire antibody to cause an immune response, are associated with some allergic reactions. Insertion of a cardiac pacemaker may also be helpful in extreme cases.

General Therapeutic Uses of Digoxin

Congestive heart failure

In the United States, the cardiac glycoside used clinically is digoxin, and the term *digitalis* refers in effect to digoxin. The primary use for digoxin is in the treatment of congestive heart failure. The direct effect of digoxin on the myocardium in most cases enables the heart in congestive failure to increase its contractile force and output. Digoxin is most effective in patients with chronic, continuous systolic heart failure,[1,2] in which the ventricle is enlarged at rest, early ventricular filling is rapid, and the compliance of the heart wall has not been reduced because of a condition such as hypertrophy or amyloid infiltration.

Cardiac arrhythmias

Digoxin is effective in reducing an increased ventricular rate caused by atrial fibrillation. Vagal effects on the AV node account for most of the decrease in conduction. This reduction protects the ventricle from atrial electrical impulses arriving in rapid succession. The dosage can be adjusted to titrate the drug to a given ventricular rate. Occasionally, atrial fibrillation reverts to normal sinus rhythm during therapy; however, this is not the main goal of digoxin therapy, which is to reduce the ventricular rate despite the rapid rate of the atria (rate control). The use of digoxin in treating patients with acute atrial fibrillation has declined because of the use of antiarrhythmics, including β-adrenergic blockers and Ca^{++} channel blockers, and other treatment (see Chapter 24). Digoxin is more appropriately used when systolic heart failure accompanies the atrial fibrillation and where controlling the resting ventricular rate is an added benefit.

CONDITIONS AFFECTING DIGOXIN THERAPY

Electrolyte Concentrations

Because the mechanism of action of digoxin most likely involves an increase in a crucial Ca^{++} "pool" in the heart, high plasma Ca^{++} concentrations can worsen digoxin toxicity.

TABLE **25-4**

Effects of Plasma Electrolyte Concentrations on Digoxin Toxicity

	NORMAL TOTAL PLASMA CONCENTRATION (mmol/L)	DIGOXIN TOXICITY MORE LIKELY IF PLASMA ELECTROLYTE CONCENTRATION IS:
K^+	3.8-5.4	Decreased
Ca^{++}	2.2-2.8	Increased
Mg^{++}	0.8-1.1	Decreased

Mg^{++} inhibits many Ca^{++}-induced events; Mg^{++} deficiency can increase susceptibility to digoxin toxicity.

Hypokalemia in particular can predispose a patient to digoxin toxicity. Low plasma K^+ concentrations allow greater binding of digoxin to Na^+,K^+-ATPase and independently alter myocardial membrane properties to increase cardiac automaticity. Together, these factors may account for increased digoxin toxicity at low plasma K^+ concentrations. (For drugs that reduce plasma K^+, see the subsequent section on drug interactions.) Loss of intracellular K^+ also plays an important role in digoxin toxicity. When digoxin is administered, intracellular K^+ concentrations gradually decrease, reducing the ratio of intracellular to extracellular K^+. This ratio change and the membrane potential alterations that follow make the heart more sensitive to digoxin toxicity. Reduced intracellular K^+ may be present without a significant reduction in plasma K^+ concentrations. The effects of major electrolyte changes on digoxin toxicity are summarized in Table 25-4.

Drug Interactions

Drugs affect digoxin therapy mainly by reducing its absorption, by altering the rate of its metabolism, by changing plasma and intracellular K^+ concentrations, or by directly influencing the myocardium. Kaolin-pectin and oral antacids reduce the intestinal absorption of digoxin by forming a complex with the drug. Sulfasalazine, neomycin, and metoclopramide have also been reported to reduce the intestinal absorption of digoxin. Cholestyramine is used to bind bile acids in the gastrointestinal tract and reduce plasma concentrations of cholesterol. It is also able to bind certain drugs in the intestine, including digoxin. Digoxin given concurrently by mouth is prevented from being absorbed.

Numerous drugs can predispose a patient to digoxin toxicity by reducing plasma K^+ concentrations, including amphotericin B, corticosteroids, and, most notably, thiazide and loop diuretics. The clinical problem is a significant one, especially because diuretics are often used with digoxin to treat congestive heart failure or reduce blood pressure. In these situations, the use of K^+-sparing diuretics or supplementation with oral K^+ is especially important.

Several reports have indicated a substantial interaction between quinidine and digoxin. The most important clinical results of concurrent therapy are enhanced digoxin toxicity and enhanced quinidine toxicity. Adverse reactions can occur at normal therapeutic dosages. Quinidine increases plasma digoxin concentrations by two mechanisms: first, renal clearance of digoxin is decreased; second, digoxin is displaced from tissue stores as a result of quinidine administration. Because of the interaction with digoxin, concurrent therapy usually requires a reduction in the dose of both drugs, although this interaction varies from patient to patient. Quinine, the levo stereoisomer of quinidine, and amiodarone, verapamil, and diltiazem can also increase plasma digoxin concentrations.

Sympathomimetic amines interact with digoxin because both classes of drugs increase the possibility of ectopic cardiac pacemaker activity. Cardiac arrhythmias are more likely to occur when β-adrenergic receptor agonists are used concurrently with digoxin. β-adrenergic receptor antagonists increase the risk of bradycardia and AV nodal block when given with digoxin, even though β blockers and digoxin are both used to treat heart failure.

Cholinergic and anticholinergic drugs alter responses to digoxin. The cholinergic agents enhance and the anticholinergic drugs antagonize the atrial, SA nodal, and AV nodal effects of digoxin. Succinylcholine, by increasing vagal tone and altering the K^+ distribution, may acutely increase digoxin toxicity.

Spironolactone reduces digoxin clearance. This reduction in digoxin clearance may necessitate a lower digoxin dose when these drugs are used concurrently. Spironolactone may also interfere with serum digoxin assays.

In approximately 10% of patients, enteric bacteria, especially *Eubacterium lentum*, metabolize a significant portion of ingested digoxin. In these patients, antibiotics, by inhibiting these bacteria, can increase the amount of digoxin absorbed and increase the potential for digoxin toxicity. Erythromycin, other macrolides, and tetracyclines may increase digoxin plasma concentrations. In some cases, the interaction between antibiotics and digoxin has resulted in a twofold increase in serum digoxin concentrations.

DRUGS USED FOR ACUTE THERAPY OF HEART FAILURE

Catecholamines

Drugs that stimulate β_1 adrenoceptors, such as dobutamine and dopamine, are cardiotonic. An undesirable chronotropic response may occur, but it is less likely than with other catecholamines, such as epinephrine. Dobutamine and dopamine are used to treat heart failure in the acute setting. Dobutamine is a selective β_1-adrenergic agonist, which accounts for the positive cardiac inotropic response. A β_2-adrenergic effect seems to account for its effect of reducing vascular resistance. The effect of dobutamine on α-adrenergic receptors is complex. The negative isomer is an α_1-adrenergic agonist, whereas the positive isomer is an α_1-adrenergic antagonist. The combination of both isomers in the clinically available preparation ensures primarily a β_1-adrenergic effect of the drug. At low doses, dopamine stimulates D_1-dopaminergic receptors selectively. This effect accounts for vasodilation of coronary, renal, and mesenteric blood vessels. At higher doses, dopamine has a greater net effect in stimulating β_1-adrenergic receptors, leading to an inotropic effect. Finally, at still higher doses, dopamine significantly stimulates α_1-adrenergic receptors and increases vascular resistance. The choice of catecholamine depends largely on the vascular state of the patient. The pharmacologic features of the catecholamines are discussed in Chapter 6.

Nesiritide

Nesiritide is a human B-type natriuretic peptide that is produced using recombinant DNA methods. The drug binds to and stimulates membrane-bound guanylate cyclase, causing an increase in cyclic 3′,5′-guanosine monophosphate (cGMP) in blood vessels.[6,9] This increase in cGMP leads to relaxation of vascular smooth muscle. The half-life of the drug is about 18 minutes; however, the effect of the drug may last several hours. It is used in the acute management of heart failure.

Inamrinone and Milrinone

Inamrinone and milrinone are bipyridine drugs that have a positive inotropic action on the heart. The bipyridines act by

inhibiting phosphodiesterase III, also termed *cGMP-inhibited phosphodiesterase*. As a result of this inhibition, cardiac concentrations of cAMP are elevated, and a sympathomimetic effect on the heart is achieved. Inamrinone and milrinone also reduce arterial and venous pressures because of the increase in vascular smooth muscle relaxation, which aids in relieving heart failure. The latter effect is the major mechanism operable in heart failure patients.

Inamrinone and milrinone are available for intravenous use. The half-lives of inamrinone and milrinone are approximately 4 to 6 hours (inamrinone) and 3 hours (milrinone). Adverse effects of inamrinone include nausea and vomiting, thrombocytopenia, hepatotoxicity, cardiac arrhythmias, and fever. Milrinone is less likely to cause thrombocytopenia and more likely to cause arrhythmias. The drugs are used clinically for short-term use, especially in cases in which the heart is refractory to other cardiotonic agents and vascular resistance is elevated. Studies have failed to show long-term benefits, however, and evidence indicates that survival is worsened with long-term administration because of an arrhythmogenic effect of the drugs.

Directly Acting Vasodilators

Nitroprusside and nitroglycerin are sometimes used for acute treatment of heart failure. These drugs are discussed in Chapters 28 (nitroprusside) and 26 (nitroglycerin).

Ca^{++} Sensitizers

Although not yet available in the United States, another strategy in treating heart failure is the use of Ca^{++} sensitizers. These agents increase the sensitivity of the myofilaments to Ca^{++} without overloading the Ca^{++} in the cell or increasing heart rate.[8] It remains to be seen if these drugs will become useful clinical drugs. Levosimendan is an investigational drug that works by this mechanism.

IMPLICATIONS FOR DENTISTRY

Stress Factors

The practitioner should strive to eliminate needless stress for cardiac patients, especially anxiety or pain associated with dental procedures. Patients being treated for heart failure possess limited cardiac function. These patients are at special risk in stressful situations because stress puts a greater workload on the heart and stimulates the release of endogenous catecholamines. By increasing the likelihood of ectopic pacemaker activity of the heart and possibly by temporarily decreasing plasma K^+ concentrations, catecholamines increase the risk of digoxin-induced arrhythmias. Fear and apprehension may also increase the likelihood of adverse CNS reactions to digoxin. One practical conclusion is that antianxiety therapy or analgesics should be used preemptively if emotional stress or pain is likely.

Drug Interactions

The use of catecholamines in local anesthetic injections for patients taking digoxin is not contraindicated but should be approached with special caution. Proper injection technique to avoid intravascular injection should be followed. Many factors influence the decision to use vasoconstrictors in local anesthetic solutions, including the ability to achieve adequate anesthesia without vasoconstrictors and the volume of anesthetic solution required. The chief danger of sympathomimetic vasoconstrictors for patients taking digoxin is that the combination of drugs increases the risk of cardiac arrhythmias if significant amounts of vasoconstrictor enter the vascular space.

The use of gingival retraction cords impregnated with epinephrine is not recommended in patients taking digoxin. Cardiac disease in general is a contraindication for their use. Considerable amounts of vasoconstrictor may be absorbed systemically from these retraction cords, and the possibility of cardiac arrhythmias developing is significant. If hemostatic retraction cords are to be used in patients who are on digoxin, the cords should be impregnated with an astringent in place of a vasoconstrictor.

The effects of digoxin on the SA node, the atria, and the AV node are mediated primarily by the vagus nerve. Many beneficial effects of digoxin depend on vagal influences, especially in the treatment of atrial fibrillation. Muscarinic and antimuscarinic drugs can influence digoxin therapy. Antisialagogues such as atropine and methantheline should not be used in patients taking digoxin because they tend to reduce the effects of digoxin. Muscarinic receptor agonists such as pilocarpine enhance the effect of digoxin on the SA node, the atria, and the AV node.

Antibiotic therapy may alter the intestinal flora and, in so doing, increase the absorption of digoxin in patients whose gastrointestinal flora metabolizes digoxin. Erythromycin, and presumably other macrolides, has been shown to have this effect. Tetracyclines also seem to interact through this mechanism. When the need arises, concurrent antibiotic therapy, especially with erythromycin (or other macrolide) or a broad-spectrum antibiotic, should be undertaken with sufficient cognizance given to its possible interaction with digoxin. Other dental drug interactions are discussed in chapters in which other drugs addressed in this chapter are discussed in greater detail.

Adverse Effects of Dental Importance

Excessive salivation may be a sign of toxicity owing to digoxin. Adverse effects related to dentistry for other drugs used in the treatment of heart failure are discussed in Chapters 27 and 28.

DRUGS USED IN TREATING HEART FAILURE

Nonproprietary (generic) name	*Proprietary (trade) name*
Diuretics (see loop and thiazide diuretics*)	
ACE inhibitors	
Benazepril	Lotensin
Captopril	Capoten
Enalapril	Vasotec
Fosinopril	Monopril
Lisinopril	Zestril
Moexipril	Univasc
Perindopril	Aceon
Quinapril	Accupril
Ramipril	Altace
Trandolapril	Mavik
Angiotensin II receptor blockers	
Candesartan	Atacand
Eprosartan	Teveten
Irbesartan	Avapro
Losartan	Cozaar
Olmesartan	Benicar
Telmisartan	Micardis
Valsartan	Diovan

DRUGS USED IN TREATING HEART FAILURE—cont'd

Nonproprietary (generic) name	*Proprietary (trade) name*
β Blockers	
Bisoprolol	Zebeta
Carvedilol	Coreg
Metoprolol	Lopressor
Aldosterone antagonists	
Eplerenone	Inspra
Spironolactone	Aldactone
Directly acting vasodilators	
Hydralazine + isosorbide dinitrate	BiDil
Cardiac glycosides	
Digoxin	Lanoxin
Drugs for acute treatment	
Dobutamine	Dobutrex
Dopamine	Intropin
Inamrinone	Inocor IV
Milrinone	Primacor
Nesiritide	Natrecor
Nitroglycerin	—
Nitroprusside	Nitropress

*Diuretics are discussed in Chapter 27.
ACE, Angiotensin-converting enzyme.

CHAPTER 26

Antianginal Drugs

EILEEN L. WATSON AND FRANK J. DOWD

Angina pectoris (from the Latin, literally meaning "pain in the chest") is usually manifested as severe, transient, retrosternal pain that sometimes radiates to the left arm, back, or jaw. It is frequently accompanied by fear, anxiety, feelings of suffocation, and a sensation of tightening of the chest. There is a wide variation among individuals in the intensity and quality of the pain, and some ischemic episodes may occur without prominent symptoms. The pain and associated changes in the electrocardiogram (e.g., depressed ST segment) result from ischemia (hypoxia) of some area of the myocardium, usually a subendocardial area. The most frequent pathologic cause of angina is epicardial coronary artery atherosclerosis leading to compromised blood flow and reduced oxygen delivery to a region of the myocardium. Angina may also result from vasospasm; the coronary vasoconstriction frequently occurs at an atherosclerotic site on the artery.

As shown in Figure 26-1, the normal response to increased myocardial oxygen demand is satisfied by vasodilation of the small coronary resistance vessels, increased blood flow, and increased oxygen supply. In contrast, in the classic anginal patient with exertional (exercise-induced) episodes, significant sclerosis (>70% narrowing of the luminal diameter) of the large conductance arteries precludes increased vasodilation in response to increased myocardial work because the poststenotic resistance vessels are already dilated, and the resultant demand for oxygen cannot be met. Cardiac determinants of oxygen consumption and factors that can precipitate changes in these determinants are also shown in Figure 26-1.

The intraventricular pressure is important in determining flow in subendocardial regions because of compression of blood vessels in the involved area. Coronary blood flow occurs primarily during diastole, when the intraventricular pressure is least. Increased heart rate decreases the diastolic time more than the systolic and requires increased oxygen supply in concert with the increased rate of metabolism. Alterations of ventricular size also cause concurrent changes in ventricular work and oxygen demand. Finally, the inotropic state of the myocardium is also a factor in determining oxygen consumption. An important control of myocardial contractility is exerted by the sympathetic nervous system through catecholamine release.

It is beyond the scope of this chapter to consider in detail the specific changes in the cardiac determinants of myocardial oxygen consumption caused by each of the factors that may precipitate an anginal attack. It is sufficient to say that any factor that compromises the balance between oxygen demand and oxygen supply may cause an attack of angina. Anginal pain may follow exercise, emotional upset, or exposure to cold or may occur after meals or smoking. Certain individuals have nocturnal attacks of angina, probably because recumbent posture can increase venous return to the heart and cardiac work. Anginal attacks in susceptible patients may also result from self-medication with various drugs, such as cocaine and cold remedies that contain sympathomimetic agents.

There are three types of angina pectoris: chronic stable angina (classic exertional angina), variant (Prinzmetal's) angina, and unstable angina (also known as *preinfarction angina*, *intermediate coronary syndrome*, *acute coronary insufficiency*, and *accelerated an*gina). Chronic stable angina occurs in patients who have fixed atherosclerotic coronary artery disease. Pain in these individuals occurs when the myocardial oxygen requirement reaches a given stable value. Variant angina occurs as a result of coronary artery spasm and a subsequent decrease in coronary blood flow and oxygen supply. These patients usually also exhibit coronary atherosclerosis, although it may be minimal in some. Variant angina is characterized by chest pain occurring at rest and, frequently, during sleep. The third type, unstable angina, refers to a new onset of severe, frequent angina, anginal pain at rest, or a sudden worsening of pain in a patient with previously stable exertional angina.[18] The cause of unstable angina is often sudden platelet aggregation or plaque emboli in coronary vessels. Most of these patients have severe coronary artery disease; coronary spasm may also be involved. Of patients with chest pain, 30% have unstable angina, and it was estimated that 20% of these patients will have a myocardial infarct within a year and most within a month.[11] More recent studies suggest that compared with conservative management, early invasive treatment of patients with unstable angina using coronary angiography with or without revascularization reduces mortality and myocardial infarction at 2 and 5 years.[10]

Six classes of drugs are used extensively in the treatment of angina pectoris; Figure 26-2 shows the sites of action of β-adrenergic receptor blockers, Ca^{++} channel blockers (CCBs), and nitrates/nitrites. The first class, organic nitrites and nitrates, comprises drugs (e.g., sublingual nitroglycerin) that provide immediate relief from anginal symptoms or provide prophylaxis of an attack and nitrate formulations (e.g., topical nitroglycerin, oral isosorbide dinitrate) that are promoted for long-term protection from anginal episodes.

The second class contains β-adrenergic receptor–blocking agents (β blockers). These drugs are administered on a long-term basis, frequently in conjunction with organic nitrates, to decrease the frequency and severity of anginal attacks.

The third class of drugs useful in the management of angina comprises calcium channel blockers (CCBs). This class includes verapamil, diltiazem, nifedipine, and others. These agents, similar to the β blockers, are used prophylactically in angina therapy.

The fourth class of drugs targets blood-clotting mechanisms and comprises aspirin, other antiplatelet drugs, and anticoagulants. Aspirin is used to treat stable and unstable

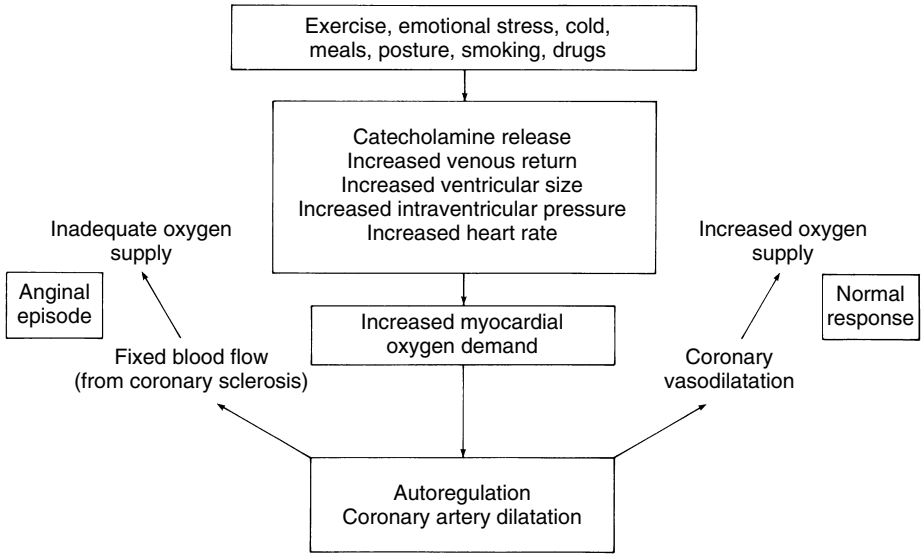

FIGURE **26-1** Pathophysiologic characteristics and precipitating causes of classic angina pectoris.

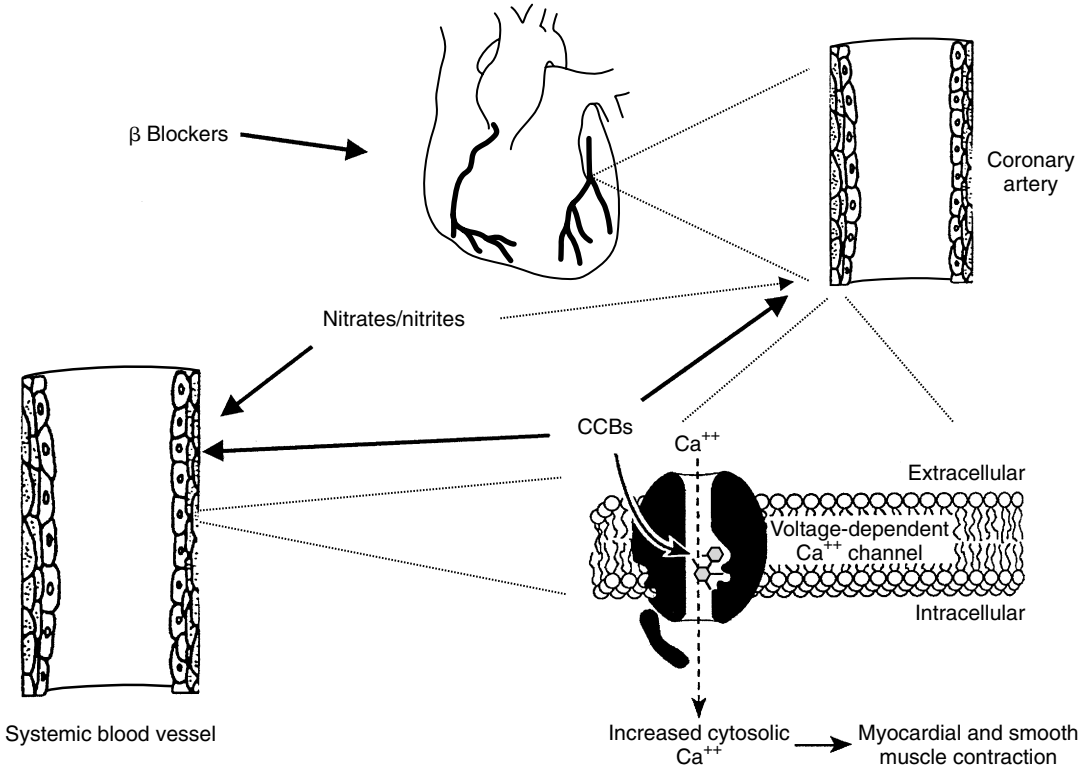

FIGURE **26-2** Sites of action of β-adrenergic receptor blockers, Ca^{++} channel blockers (*CCBs*), and nitrates/nitrites. β Blockers reduce the rate and contractility of the heart, reducing energy and oxygen demand of the heart. CCBs reduce vasoconstriction in coronary and noncoronary vessels, increasing coronary blood flow and reducing cardiac load. The nitrates/nitrites act primarily on systemic blood vessels to reduce cardiac load. The effect on coronary arteries is less a factor in alleviating classic angina but plays a major role in variant angina. Three anatomic levels are shown: cardiac anatomy, cell layers of the blood vessel walls, and a blood vessel smooth muscle cell membrane showing a Ca^{++} channel and the effect of CCBs in preventing Ca^{++} entry.

angina. The pharmacologic features of aspirin are discussed in detail in Chapter 21. It acts by inhibiting platelet aggregation through irreversible inhibition of cyclooxygenase.

The fifth class is represented by ranolazine, which was approved by the U.S. Food and Drug Administration in 2006 for the treatment of chronic angina in patients who have failed to respond to other angina therapy. The sixth class is represented by trimetazidine, a novel anti-ischemic drug with properties unrelated to changes in myocardial oxygen supply/demand ratio.[3] Trimetazidine is considered to be a metabolic

agent that modifies substrate use in chronic heart failure.[1] This drug can lessen oxidation of free fatty acids via inhibition of the enzyme long-chain 3-ketoacyl coenzyme A thiolase, which is crucial in the β-oxidation pathway. Trimetazidine has a favorable side-effect profile and exhibits no notable vasodilator properties at rest or during dynamic exercise.[15] It is not discussed further.

NITRITES AND NITRATES

Amyl nitrite was introduced for use in angina pectoris in 1867, and nitroglycerin (glyceryl trinitrate) was introduced in 1879. Since then, nitroglycerin has remained the drug of choice for the relief of acute symptoms of angina pectoris. Nitroglycerin is administered sublingually as a tablet or aerosol spray and has a quick onset and short duration of action. Various organic nitrates and sustained-release forms of nitroglycerin have been developed in attempts to find a suitable, long-lasting preparation for the control and prevention of anginal pain. Amyl nitrite is used by inhalation for angina pectoris. Its use in the treatment of cyanide poisoning is discussed in Chapter 52.

Chemistry

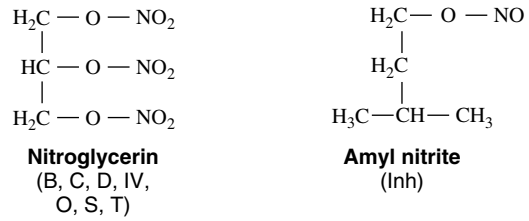
Nitroglycerin is chemically a simple compound. Figure 26-3 shows its structure and, for comparison, the structures of some of the other organic nitrates marketed for oral, topical, sublingual, buccal, inhalant, or intravenous administration. All nitrites and nitrates with antianginal activity are esters of nitrous or nitric acid. Organic nitrites and nitrates are capable of being metabolized to yield the free radical nitric oxide (NO). Research in this area led to the Nobel Prize for Physiology/Medicine being awarded in 1998 to Robert Furchgott, Louis Ignarro, and Ferid Murad for their discovery of NO as a signaling molecule in the cardiovascular system. Previous studies had identified a vasodilator substance released from endothelial cells and referred to as *endothelium-derived relaxing factor*. Experimental evidence from several laboratories indicates that endothelium-derived relaxing factor is NO.[12] NO is the active intermediate of vasoactive nitrites and nitrates, which are appropriately referred to collectively as *nitrovasodilators*. (See Figure 8-3 for further information on NO.)

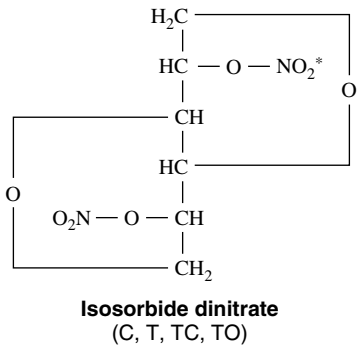
Pharmacologic Effects

The pharmacologic effects of all the members of this class are similar and result from actions of NO released by denitration reactions of the parent drugs in the tissues. It is likely that mitochondrial aldehyde dehydrogenase plays an essential role in the synthesis of NO from nitroglycerin bioactivation, resulting in dilation of blood vessels.[6] NO has been shown to stimulate the synthesis of cyclic 3′,5′-guanosine monophosphate (cGMP) by a direct action on cytosolic guanylyl cyclase or indirectly by being converted to S-nitrosothiols, which stimulate the enzyme (Figure 26-4; see also Figure 8-3). cGMP initiates a cascade of reactions involving cGMP-dependent protein kinases leading to the various cellular responses that relax vascular smooth muscle.

The most important action of nitrovasodilators is the direct relaxation of vascular smooth muscle by the metabolite NO, resulting in vasodilation first in veins at low doses and then in arteries at higher doses. Nitroglycerin has been shown to cause varying degrees of change in coronary flow in normal and diseased mammalian hearts. Its efficacy in the various types of angina is attributed in part to a preferentially increased oxygen supply to ischemic areas, with variable actions on total coronary blood flow. More important, through a reduction in venous tone, there is a reduction in venous pressure, pulmonary arterial pressure, and end-diastolic filling pressure. These actions lead to a decrease in ventricular volume, producing a decrease in intramyocardial tension and a decline in myocardial oxygen demand. Nitrovasodilators tend to cause redistribution of coronary blood flow to the more ischemic areas. As implied earlier, arterial smooth muscle is relaxed by these drugs, although to a lesser degree than venous smooth muscle. The efficacy of nitrates and nitrites in relieving variant angina probably stems from a direct alleviation of coronary artery spasm.

Nitrates and nitrites also relax nonvascular smooth muscle. Bronchial, biliary, and gastrointestinal smooth muscle is relaxed. This action is the basis for the use of nitrates such as isosorbide dinitrate for the treatment of esophageal spasms. The major use of these drugs is based, however, on their cardiovascular actions.





*The nitrate group is replaced by a hydrogen atom in **isosorbide mononitrate** (C, TO).

Absorption, Fate, and Excretion

Nitroglycerin is rapidly absorbed after sublingual administration (onset 1 to 3 minutes, duration 30 to 60 minutes). An advantage of the aerosol spray over the sublingual tablet is the better absorption in patients with dry mucous membranes. Nitroglycerin has a much slower onset when applied topically to the skin in a patch or ointment, but has a comparably longer duration of action. Although organic nitrates administered orally are readily absorbed, they are extensively metabolized during the first pass through the liver.

In addition to undergoing denitration reactions in tissues, nitrates are metabolized in the liver by glutathione–organic nitrate reductase. The products of hepatic biotransformation, including the released nitrite ions, are much less effective than the parent compound; they are subsequently excreted in the urine, at least in part, in the form of glucuronide conjugates. Isosorbide dinitrate is exceptional because its principal metabolite, the mononitrate, is responsible for most of its action and is now available separately for clinical use.

Long-Acting Drugs

Although sublingual nitroglycerin is highly effective for the treatment of acute anginal episodes, its short duration of action makes it unsuitable for long-term prophylaxis. Several nitrates formulated for oral administration have been marketed for many years for the prevention of anginal attacks. The vasodilatory effects of isosorbide dinitrate were discovered in the 1930s, and the drug was introduced in the 1960s as an oral preparation. When administered sublingually, isosorbide dinitrate (see Figure 26-3) was shown to be comparable to nitroglycerin. When administered orally in recommended dosages, this compound offered no protection against exercise-induced angina. Subsequent investigations showed, however, that large doses of isosorbide dinitrate (and nitroglycerin) improve exercise tolerance in patients with angina. There is a concomitantly increased possibility of drug toxicity.

Newer long-acting mononitrates, which are major active metabolites of isosorbide dinitrate, offer the advantage of improved bioavailability because they avoid first-pass hepatic elimination. Isosorbide-5-mononitrate, which is at least as effective as isosorbide dinitrate, is available as immediate-release tablets and as a sustained-release formulation for once-daily administration. The clinical efficacy of a single dose of isosorbide mononitrate formulated as a 30% immediate-release/70% sustained-release formulation is observed within a few minutes to increase work and exercise capacity.[2] More recent evidence indicates that nitrates reduce platelet aggregation and adhesion in patients with acute myocardial infarction. This finding suggests a possible added benefit of nitrates.[9]

To avoid the first-pass phenomenon that plagues orally administered nitrates, nitroglycerin has been prepared in several other forms. The first of these, nitroglycerin ointment, is effective prophylactically, but it must be administered every 3 to 4 hours. A further development is the nitroglycerin transdermal system, which comes in the form of an adhesive patch. When applied to the skin, the transdermal patch slowly releases nitroglycerin over a 24-hour period. This system minimizes the potential for toxicity inherent in large-dose oral administration, and it overcomes the inconvenience and frequency of application associated with the ointment. Nitroglycerin is also marketed in a transmucosal preparation. Supplied in a matrix, the drug is made available in a sustained-release fashion when placed between the upper lip and teeth. Swallowing or chewing increases the rate of absorption and could lead to toxicity. The advantages of this preparation are its rapid onset and extended action.

One problem shared by all the long-acting preparations is the development of tolerance. In vitro studies suggest that the causes include volume expansion and tissue tolerance resulting partly from enzyme changes. Such tolerance is not observed with the intermittent administration of sublingual nitroglycerin. Intermittent transdermal administration (12 hours on, 12 hours off) has been used to avoid the development of tolerance; however, questions still remain concerning the increased risk of precipitating unstable angina and myocardial infarction during the nontreated periods, especially if they occur during the early morning hours.

Nitrates have a place in the prophylactic treatment of patients with angina pectoris because their efficacy is not in doubt. Some practical problems are associated with their use, however, such as unreliable absorption, short duration of action, treatment-induced headache, development of nitrate tolerance, and a suggested rebound phenomenon observed during intermittent dosing. Patient convenience regarding the treatment schedule should also be considered. Controlled-release formulations that produce sufficiently high nitrate concentrations during part of the day, followed by nitrate-poor rather than nitrate-free intervals, have the potential to prevent tolerance and rebound phenomena and to produce a sufficiently long duration of action with a convenient once-daily regimen. The combination of immediate and sustained-release formulations, used once daily, produces a fast onset of action and a longer period during which nitrate concentrations are sufficient to prevent ischemia during the active part of the day.[2] During the night, nitrate levels decrease but offer some protection with low risk of tolerance.

Adverse Effects

Almost all side effects of these drugs are direct results of their effects on the cardiovascular system. Headache, due to dilation of meningeal arteries, is the most common untoward response and can be very severe.[16] Tolerance to this effect may develop in some patients before tolerance to other cardiovascular effects occurs. Orthostatic hypotension resulting in reflex tachycardia, cerebral ischemia, weakness, dizziness, flushing, and syncope may follow drug administration. Syncope is likely to occur if the patient is standing and immobile while taking medication or has ingested alcoholic bever-

ages. Nitrates should not be administered to a patient taking sildenafil (Viagra) because severe, long-lasting hypotension may occur. Significant hypotension may cause anginal pain if coronary blood flow is compromised. Because it dramatically reduces placental blood flow, amyl nitrite is contraindicated for use in pregnant women (pregnancy risk category X; see Table 3-7).

Nitrite ions and high doses of nitrates readily oxidize hemoglobin to methemoglobin; large amounts of methemoglobin can seriously impair the oxygen-carrying capacity of the blood, resulting in anemic hypoxia. Infants are especially sensitive to this effect of nitrates because of their relative inability to reduce methemoglobin back to hemoglobin. Drug rash occasionally may occur, most frequently with topical nitroglycerin.

β-ADRENERGIC RECEPTOR–BLOCKING DRUGS

The history and pharmacology of β-blocking agents are reviewed in depth in Chapter 7. In addition, the use of these compounds in the treatment of cardiac arrhythmias and hypertension is discussed in Chapters 24 and 28. Discussion here is limited to the role that these drugs play in the management of angina pectoris.

Several β blockers are available for use in the treatment of angina pectoris. All these drugs, whether or not they have partial agonist activity, membrane-stabilizing actions, or general or selective β-blocking properties, can increase the pain-free work capacity of patients with angina pectoris. Some of the most frequently used agents for this purpose include propranolol, metoprolol, atenolol, and nadolol. Selection of β blockers depends on other clinical factors. Cardioselective agents are advantageous in patients who have pulmonary disease or peripheral vascular disease. Consideration must be given to the dosage used, however, because all β-blocking drugs have nonselective effects at higher dosages (see Chapter 7).

Pharmacologic Effects

Because exercise and emotional stress are possible precipitating factors in angina (see Figure 26-1), increases in sympathetic nervous system activity can bring on attacks of angina in susceptible individuals. The blockade of adrenergic responses can be beneficial in the treatment of this condition. Effects of β blockers that are helpful in treating angina include decreased heart rate and protection from reflex tachycardia, depressed myocardial contractility, decreased cardiac output, and, in some cases, reduced blood pressure. These effects are more prominent when sympathetic activity is elevated, such as during exercise or emotional stress. Total coronary blood flow may be reduced after β receptor blockade, but this reduction in flow seems to be in well-perfused areas and is not detrimental in classic angina. Drug-induced vasoconstriction (from unopposed α receptor activity) may be problematic, however, in patients with variant angina.

The beneficial effect of β receptor–blocking drugs in angina probably results from their common action: blockade of cardiac β-adrenergic receptors. Although exercise tolerance is improved with β-adrenergic blockade, and changes in heart rate and blood pressure with exercise are blunted, the rate-pressure product (heart rate × systolic arterial pressure) at which pain occurs is decreased. This finding explains why exercise tolerance is increased less than might be expected on the basis of simple single cardiovascular measurements.

Absorption, Fate, and Excretion

The absorption, fate, and excretion of β-adrenergic receptor antagonists are discussed in Chapter 7.

Use in Treatment of Angina

As mentioned previously, most β blockers are effective in treating the various types of angina pectoris. Their use is questionable, however, in the management of variant angina in the absence of other drugs. Long-term administration of β blockers can make the attacks of angina less frequent and individual attacks less severe. Nonetheless, patients receiving long-term treatment with β-blocking agents usually still require nitroglycerin for the treatment of acute anginal attacks. This combined drug therapy with a β-adrenergic antagonist and nitroglycerin or a related drug works well because the drugs have different mechanisms of action. In addition, nitrates and β-adrenergic antagonists may work especially well together in angina because β blockers inhibit the reflex tachycardia caused by nitrates and because nitrates (by causing vasodilation) reduce the preload and afterload of the heart and tend to reduce the impact of a negative inotropic effect from β receptor blockade.

Adverse Effects

As mentioned in Chapter 7, blockade of β receptors may cause bronchoconstriction or prevent the normal response to insulin-produced hypoglycemia in susceptible patients. These problems are less severe with the more selective β_1 blockers, such as metoprolol, which have been used without serious adverse effects in some patients with bronchospastic disease. Drugs such as metoprolol are β_1-selective, not β_1-specific, however, and are capable of eliciting bronchospasm in susceptible patients. Because of the association between β_2-adrenergic receptors and glycogenolysis and gluconeogenesis in the liver, β_1-selective blockers are associated with less risk of hypoglycemic reactions in diabetics than the nonselective β receptor blockers.

A problem encountered with selective and nonselective blockers, because they are related to the inhibition of cardiac β receptors, is that severe myocardial depression and heart failure may occur if initial dosages are too high or if there is concomitant myocardial incompetence (see Chapter 25 for a discussion of the use of β blockers in the treatment of heart failure). For this reason, dosages should be gradually increased until concentrations offering therapeutic effects in the management of angina are reached. The sudden discontinuance of β blockers has been implicated in rebound overstimulation of the heart, worsening of angina, and myocardial infarction.

Ca^{++} CHANNEL BLOCKERS

CCBs are also referred to as *Ca^{++} entry blockers* and less accurately as *Ca^{++} antagonists*. These drugs exert their effect on voltage-dependent Ca^{++} channels in vascular smooth muscle and cardiac muscle (see Figure 26-2). This class of drugs (Figure 26-5) includes verapamil, nifedipine, diltiazem, and several other agents. Many of these compounds have been shown to be effective in the prophylactic treatment of chronic stable exertional angina, variant angina, and unstable angina. They have also proved to be useful in the treatment of other cardiovascular disorders, such as supraventricular tachyarrhythmias and hypertension (see Chapters 24 and 28). Additional indications for certain CCBs include peripheral vascular disease, pulmonary hypertension, hypertrophic cardiomyopathy, and cerebral vasospasm after subarachnoid hemorrhage.

Chemistry and Classification

Verapamil, the first CCB, is a diphenylalkylamine derivative. The only member of its type clinically available, verapamil is closest in pharmacologic profile to diltiazem, a benzothiazepine. The largest category of CCBs consists of dihydropyri-

dines, of which nifedipine is the prototype. Dihydropyridines are characterized by their prominent arterial vasodilatory properties and relative lack of direct cardiac actions.

Pharmacologic Effects

CCBs exert their primary action on Ca^{++} channels that carry the slow inward Ca^{++} current. CCBs differ from local anesthetics, which are primarily fast channel blockers inhibiting the rapid inward influx of Na^+. Although the primary action of CCBs is on the slow current, they may also act through other mechanisms. Diltiazem, especially at higher doses, has been shown to depress the Na^+ or fast channels.

Some of the diverse effects of CCBs can be explained by the roles that Ca^{++} and slow channels have in different cardiovascular cell types (Box 26-1). In the sinus and atrioventricular (AV) nodes, slow channels are the primary conduit for the generation and propagation of action potentials. They may additionally be involved in regulating sinus node automaticity by altering diastolic depolarization. Ca^{++} channels also govern conduction velocity in the AV node. The actions of CCBs as antiarrhythmics are discussed in Chapter 24.

CCBs directly and preferentially block voltage-dependent Ca^{++} channels as opposed to receptor-operated channels. By this mechanism, they reduce intracellular Ca^{++} activity and interfere with the replenishment of Ca^{++} stores in vascular smooth muscle. Tonic and phasic muscle contractions are depressed in a dose-dependent manner. The major types of voltage-dependent Ca^{++} channels are designated *L*, *N*, and *T*. Only the L (large, long-lasting current) channel is inhibited by CCBs. Verapamil, diltiazem, and the nifedipine-like CCBs apparently bind to different receptor sites on the L channel. The degree of binding is influenced by the functional state of the channel (resting, open, or inactivated) in a manner similar to the use dependency described for local anesthetics and Na^+ channels (see Chapter 16). A CCB of one chemical classification can also affect the binding of another, positively or negatively, through allosteric mechanisms.

CCBs induce coronary and peripheral arterial dilation. Their action on coronary vessels is especially prominent in vessels that undergo transient vasospasm in variant angina. The vasodilator action in large measure explains their use as antianginals and antihypertensives.

Although all CCBs directly depress the myocardium and slow conduction velocity in the heart, the overall response in vivo depends on the relative mix of direct and indirect effects of each drug on the cardiovascular system. For verapamil and diltiazem, the direct cardiac effects usually predominate (Table 26-1). Nifedipine and other dihydropyridine CCBs typically elicit prominent vasodilation at doses that do not greatly affect Ca^{++} channels in the heart. Reflex sympathetic activity causes an increase in heart rate and conduction through the AV node and may result in a net positive inotropic effect. Factors that contribute variety to the pharmacologic profile of the different CCBs include the drugs' binding dependence on the frequency of stimulation of the tissue, their binding characteristics to L channels in different tissues, and, at least with some agents, their ability to influence other voltage-gated ion channels.

CCBs are important drugs in the treatment of all forms of angina pectoris. They inhibit Ca^{++} flux in cardiac and smooth muscle and are effective in the treatment of stable angina because of their coronary vasodilator effect, negative inotropic and chronotropic effects, enhancement of diastolic relaxation of the left ventricle, and hypotensive effect mediated through peripheral arterial dilation. These effects lead to an increase in coronary blood flow and myocardial perfusion with a decrease in myocardial oxygen demand.

Absorption, Fate, and Excretion

All CCBs are rapidly and almost completely absorbed after oral administration. Bioavailability is reduced, however, by extensive first-pass hepatic metabolism. To extend their duration of action, many CCBs are marketed in sustained-release formulations. Verapamil and diltiazem are converted in part to active metabolites; biotransformation of nifedipine causes complete inactivation. Most CCBs are highly protein bound, especially to plasma albumin. Excretion of the metabolites is primarily by the kidney.

Use in the Treatment of Angina

CCBs as a class have been shown to be effective in the treatment of all types of angina regardless of whether coronary spasm is involved. They seem to be especially effective in preventing coronary vasospasm. In chronic stable exertional angina, CCBs may afford relief of pain through one or more mechanisms: coronary and peripheral vasodilation, attenuation of increased heart rate caused by exercise, or a negative inotropic effect on the heart.

TABLE **26-1**

Comparative Pharmacologic Effects of Ca^{++} Channel Blockers

AV, Atrioventricular.

Adverse Effects

The toxicity of CCBs varies with the individual agent; however, some side effects are common to this class of drugs, including dizziness, headache, and nausea and effects related to systemic vasodilation, such as sensation of heat, facial flushing, hypotension, reflex tachycardia (primarily with nifedipine), and peripheral edema. Verapamil is the most likely, and nifedipine-like drugs the least likely, to reduce myocardial contractility. Verapamil and diltiazem usually lead to a net decrease in conduction through the AV node. Myocardial depression and reduction of AV conduction are rarely a problem clinically with these agents, unless predisposing factors exist. Coadministration with a β-adrenergic antagonist may also lead to a deterioration in cardiac performance, especially when verapamil is used in a patient with abnormal AV conduction. Nifedipine and other dihydropyridines, which can reflexly increase AV conduction velocity, are often used to advantage in combination with β receptor blockers because of their complementary actions.

The abrupt vasodilation caused by short-acting CCBs may lead to myocardial ischemia. This is especially the case for dihydropyridines such as nifedipine, which have a greater net effect on blood vessels compared with the myocardium. The peripheral vasodilation can significantly reduce coronary blood flow, causing a condition known as *coronary steal*. An increased incidence of a heart attack and sudden death may result, and short-acting dihydropyridines should not be used for angina therapy. Long-acting agents, including slow-release formulations of nifedipine, are now recommended for the treatment of hypertension. Also for this reason, verapamil and diltiazem are preferred over dihydropyridines for the treatment of angina.

Drug influenced gingival enlargement has been reported during long-term therapy with verapamil, diltiazem, nifedipine, and felodipine. Clinically and histologically, the overgrowth seen with CCBs resembles that previously described for phenytoin (see Chapter 14), but it seems to occur less frequently with CCBs.[4]

RANOLAZINE

Ranolazine is an antianginal agent approved for the treatment of chronic stable angina pectoris for use as combination therapy when angina is not adequately controlled with other antianginal agents.[7,14]

Chemistry and Pharmacologic Effects

Ranolazine is a piperazine derivative whose mechanism of action is not well understood. It is a cell membrane inhibitor of the late Na^+ current and alters glucose and fatty acid metabolism, but it is unknown whether these actions account for its antianginal action.[7] This drug exerts its antianginal and antiischemic effects without reducing heart rate or blood pressure and does not increase the rate-pressure product at maximal exercise levels.[5] Typically, the drug is used in combination with amlodipine, a β blocker, or nitrates.

Absorption, Fate, and Excretion

Ranolazine is administered twice a day by mouth in an extended-release preparation. It undergoes extensive metabolism, some in the intestine and most in the liver. The metabolites are excreted chiefly in the kidney. The terminal half-life of ranolazine is about 7 hours. Ranolazine tends to increase the plasma levels of digoxin and some other drugs. Ketoconazole, diltiazem, and verapamil increase plasma levels of ranolazine and should not be administered with it.

Adverse Effects

Constipation, nausea, dizziness, and headache are the most common adverse effects. Tinnitus, vertigo, and dry mouth may also occur. Some cardiac disorders have been reported. Ranolazine increases the QT interval of the heart. The drug should be avoided in patients with congenital long QT syndromes, patients with tachycardia, and patients taking other medications that increase the QT interval.

COMBINATION THERAPY

Combination therapy is indicated for a patient who becomes intolerant or continues to have angina with an optimal dosage of a single medication. The rationale for combining a nitrate and a β-adrenergic blocking drug has been previously discussed. If monotherapy fails, nitrates may be used in combination with diltiazem or verapamil, and a β-adrenergic blocking agent may be used with nifedipine. Trimetazidine has also been tested as an antianginal in combination with classic antiischemic compounds. In patients treated with nifedipine, the addition of trimetazidine reduced the number and duration of anginal attacks and improved exercise capacity.[3] Comparative trials of ranolazine with other antianginal agents and trials examining its effects on long-term morbidity in patients with ischemic heart disease are required to determine the place of the drug in current antianginal therapy. Combinations of antiplatelet drugs may also be useful as discussed subsequently. Although combination therapy may be beneficial, consideration must be given to the potential for a higher incidence of untoward effects.

PREVENTION OF MYOCARDIAL INFARCTION

The use of drugs to prevent myocardial infarction (especially reinfarction) has received considerable attention in recent years. In addition to the drugs already discussed, the following classes of drugs are used for this purpose, especially in patients at risk, such as patients with acute coronary syndrome: antiplatelet drugs, cholesterol-lowering drugs, angiotensin-converting enzyme inhibitors, and anticoagulants. Because β blockers have been consistently shown to be beneficial in reducing sudden death in patients with unstable angina, they are now discussed further in this context.

The primary action of β blockers is to inhibit the effects of sympathetic stimulation on the heart. The result is a reduction in heart rate, arterial blood pressure, and the force of myocardial contraction at rest and during exercise. These changes reduce the overall myocardial oxygen requirement and limit the intensity, extent, and duration of myocardial ischemia. The combination of the antiarrhythmic and antiischemic actions of β blockers contributes to a favorable effect on survival rate after myocardial infarction.

Antiplatelet agents are a much more heterogeneous group than β-adrenergic blockers. The traditional antiplatelet drug is aspirin. It is effective in reducing the occurrence of myocardial infarction in patients with ischemic heart disease. Aspirin can reduce the incidence of transient ischemic attacks in patients with cerebrovascular disease.

Dipyridamole is an antiplatelet drug that is used with aspirin to prevent cerebrovascular disease. It is also used with warfarin in prophylaxis against thromboembolism in patients with prosthetic heart valves. It inhibits platelet aggregation and adhesion by increasing platelet cyclic 3′,5′-adenosine monophosphate through inhibition of phosphodiesterase. It also decreases adenosine uptake, which results in stimulation of adenosine A_2 receptors on platelets. Dipyridamole is also a coronary vasodilator that exerts little action on peripheral blood vessels. It seems to act primarily on small cardiac arterioles. Dipyridamole does not prevent or alleviate anginal attacks because it does not sufficiently increase blood flow to ischemic areas.

Clopidogrel is a thienopyridine antiplatelet drug that is an aspirin substitute for use in unstable angina and to prevent myocardial infarction and stroke. The drug irreversibly inhibits adenosine diphosphate (ADP) receptors on platelets and prevents aggregation and other effects of ADP on platelets. Clopidogrel is also used in combination with aspirin in acute coronary syndrome and acute myocardial infarction. Ticlopidine is another thienopyridine antiplatelet drug. Ticlopidine may induce life-threatening blood dyscrasias, however, such as thrombocytopenia, neutropenia, and aplastic anemia. For this reason, clopidogrel is generally preferred over ticlopidine.

Abciximab is the Fab fragment of a chimeric human-murine monoclonal antibody that binds to integrin glycoprotein (GP IIb/IIIa) receptors on human platelets. This binding prevents the formation of platelet-platelet bridges resulting from fibrinogen or von Willebrand factor. Abciximab must be given intravenously. This drug reduces the incidence of stroke and death during percutaneous transluminal coronary angioplasty or atherectomy. Bleeding is the most common adverse reaction.[13] Tirofiban and eptifibatide are two other drugs used clinically that are GP IIb/IIIa inhibitors. All three inhibitors are injected.

Anticoagulants are discussed in Chapter 31. Heparin and low-molecular-weight heparins are used in unstable angina; however, the benefit of warfarin in this setting is not established. Cholesterol-lowering drugs, particularly the statins, are also used to prevent myocardial infarction and coronary artery disease on a long-term basis. This drug class is discussed in Chapter 29. Angiotensin-converting enzyme inhibitors and angiotensin II receptors blockers have a beneficial role in that they reduce the risk of myocardial infarction and stroke.[8,17] They are discussed in Chapters 25 and 28.

IMPLICATIONS FOR DENTISTRY

Anginal attacks can be precipitated by physical or emotional stress. Because these situations often arise in the dental operatory, dentists must be aware of the symptoms and treatment of angina. A complete medical history reveals whether a patient is being treated for angina. If so, the dentist should ensure that the patient has medication (e.g., nitroglycerin) available before a procedure is performed. The patient will know when an attack is imminent; for ready access, the patient's medication may be placed on a nearby tray or counter. Also, nitroglycerin or amyl nitrite should be included on the emergency tray. Although nitroglycerin tablets are now stabilized against breakdown, unused tablets should be discarded 6 months after the original bottle has been opened.

The patient should be medicated in a sitting or supine position because standing may lead to hypotension and syncope. In most cases, anginal pain subsides rapidly (2 to 3 minutes), and the patient may have a headache or a stinging sensation under the tongue or both. As a precaution, patients should be treated carefully, be fully informed about the procedure, and, if they feel it necessary, be given prophylactic medication. Preoperative sedation may be helpful and is not contraindicated if significant cardiovascular depression is avoided.

The use of epinephrine in gingival retraction cord is contraindicated in patients with angina pectoris because of the potential for an excessive workload on the heart. Similar considerations dictate prudence with, although not avoidance of, local anesthetics with adrenergic vasoconstrictors. Orthostatic hypotension might be a problem in patients receiving CCBs, but cardiac depression is not usually clinically significant. Sensations of heat or facial flushing may be evident in these patients.

As previously mentioned, gingival inflammation and overgrowth occasionally develop in patients as a result of therapy with CCBs, especially when taken concurrently with other agents that promote gingival enlargement (e.g., phenytoin, cyclosporine). Strict oral hygiene measures, including regular dental prophylaxis, reduce this problem.

CHAPTER 27

Diuretic Drugs

WILLIAM B. JEFFRIES AND DENNIS W. WOLFF

The kidney serves the vital function of maintaining fluid and electrolyte homeostasis. Through the processes of glomerular filtration and selective tubular reabsorption and secretion, the kidney maintains plasma volume and the plasma concentration of electrolytes, glucose, amino acids, and other substances within tight physiologic limits, while eliminating metabolic waste products and toxins. The kidneys filter approximately 180 L of plasma each day, one fifth of the cardiac output, producing approximately 1.5 L of urine.

The kidney selectively reabsorbs approximately 99% of the filtered load of water and solute. Many of the filtered solutes are reabsorbed by specific transport proteins located on the luminal membrane of the nephron. When inside of a nephron cell, solute movement back into the plasma is often directly or indirectly coupled to the actions of Na^+-K^+ activated adenosine triphosphatase (Na^+,K^+-ATPase) located on the basolateral surfaces of the nephron cells. Transepithelial electrochemical potential differences can also drive the reabsorption of various ions by paracellular pathways.

The reabsorption of water in the kidney is passive, following osmotic gradients created by the movement of solutes along the nephrons to the extent permitted by the water permeability of the various segments of each nephron.[10] Water readily equilibrates across the nephron as solute is reabsorbed from the tubular fluid or in response to the medullary osmotic gradient as it descends toward the tip of the loop of Henle. The ascending portion of the nephron is relatively impermeable to water, however.

The selective reabsorption of solute while trapping water in the lumen in these regions creates the dilute tubular fluid that could ultimately become maximally dilute urine. The solute selectively reabsorbed during the passage of tubular fluid through the ascending loop of Henle creates the medullary osmotic gradient that pulls water from the tubular fluid of the descending loop of Henle and the collecting duct. With the exception of the terminal portions of the collecting duct, where urea is recycled from concentrated urine, relatively little net solute reabsorption occurs in this nephron segment. Instead, this is the portion of the nephron that governs water reabsorption.

Antidiuretic hormone (ADH), also known as *vasopressin*, determines the extent to which this segment is permeable to water.[21] If ADH is absent, the tubular fluid that reaches the collecting duct becomes, after some solute exchange, the maximally dilute excreted urine. If the collecting duct is responding maximally to ADH, the most concentrated urine that the kidney can generate is excreted; ADH makes collecting duct cells permeable to water, which permits passive water extraction from the tubular fluid as it passes through the progressively more concentrated osmotic gradient of the medullary interstitium. The more solute that reaches the collecting duct, the greater is the volume of urine for any amount of ADH.

Renal function can become disturbed in many clinical conditions, producing metabolic abnormalities such as edema. There is a therapeutic need for drugs that modulate renal function.

All the drugs discussed in this chapter affect renal function by inhibiting the reabsorptive capacity of the renal nephrons. This action produces an increase in the rate of urine production. Substances that increase the quantity of urine are called *diuretics*. Many substances produce this effect, including caffeine, alcohol, and water itself; however, most clinically useful diuretics produce their effects by inhibiting Na^+ reabsorption by the nephrons.[10] Such drugs are properly called *natriuretics*; even so, in most circumstances, all these drugs are referred to as *diuretics*. All clinically useful diuretics produce their effects by acting at specific segments of the nephron. Common conditions for which diuretics are used include essential hypertension and congestive heart failure.[5,15,17,18]

CLASSES OF DIURETICS

This discussion of diuretics proceeds up the nephron in a retrograde direction. As shown in Figure 27-1, this order of consideration moves from diuretics with a low maximal effect to diuretics with a high maximal effect. The effects of blockade of Na^+ reabsorption upstream on tubular fluid composition are acted on by downstream mechanisms—mechanisms that act to limit or offset these effects. The effects of the various classes of diuretics on urine volume, urine pH, and urine electrolytes are summarized in Table 27-1.

K^+-Sparing Diuretics

The pathway by which Na^+ is reabsorbed in the late distal tubule/cortical collecting duct is shown in Figure 27-2. The apical membrane of these cells contains Na^+ channels. The entry of Na^+ through these channels carries a net positive charge along with it (i.e., Na^+ entry is electrogenic), leaving the lumen with a net negative charge. This negative charge in the lumen acts as a driving force for movement in the opposite direction of other cytosolic cations such as K^+ and H^+ by the collecting duct (see Figure 27-2), resulting in Na^+ retention and K^+ excretion. Aldosterone, acting through nuclear receptors in the principal cells of the cortical collecting duct, enhances the conductance of apical Na^+ channels. For a given amount of aldosterone, more Na^+ delivered to this site means

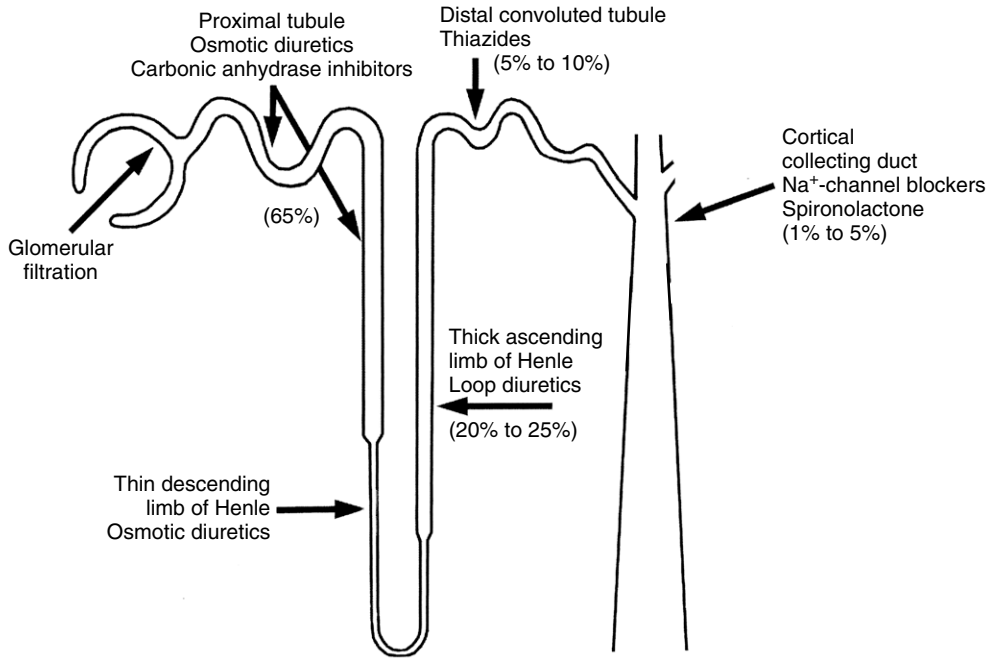

FIGURE **27-1** Sites of action of diuretics along the nephron. The percentages shown illustrate the approximate amount of the filtered load of Na^+ that is reabsorbed by each nephron segment. Each diuretic, with the exception of spironolactone, acts on the tubular lumen to produce its effect.

TABLE **27-1**

Summary of Urinary Effects and Mechanisms of Action of Diuretic Drugs

	VOLUME (mL/min)	pH	Na^+	K^+	Cl^-	HCO_3^-	MECHANISM OF ACTION
Control	1	6	50	15	60	1	—
Thiazides (e.g., chlorothiazide)	3	7.4	150	25	150	25	Decreases Na^+ and Cl^- cotransport in distal tubule*
Loop diuretics (e.g., furosemide)	8	6	140	10	155	1	Decreases Na^+, K^+, $2Cl^-$ cotransport in medullary ascending loop of Henle
Amiloride, triamterene	2	7.2	130	5	120	15	Decreases Na^+ reabsorption in late distal tubule and collecting ducts; less K^+ secretion and Na^+-H^+ exchange
Spironolactone	2	7.2	125	5	120	15	Inhibits aldosterone receptor activation; net effects similar to effects of amiloride
Carbonic anhydrase inhibitors (e.g., acetazolamide)	3	8.2	70	60	15	120	Inhibits carbonic anhydrase and H^+ production in proximal tubules; less Na^+ and HCO_3^- reabsorption
Osmotic diuretics (e.g., mannitol)	10	6.5	90	15	110	4	Osmotically retains water in proximal tubule and loop of Henle

Values are average peak diuretic responses in humans with a normal water and electrolyte balance. Electrolyte concentrations are given in mEq/L.
*Thiazide diuretics also variably inhibit carbonic anhydrase.

more Na^+ reabsorption and more K^+ secretion, a coupled process referred to as *Na^+/K^+ exchange*.[3] Because of the Na^+/K^+ exchange at this portion of the nephron, any diuretics acting further upstream to block Na^+ reabsorption and increase distal Na^+ delivery result in enhanced urinary excretion of K^+.

Pharmacologic effects

K^+-sparing diuretics are so named because, by blocking Na^+ reabsorption in the cortical collecting duct region of the nephron, they do not produce the hypokalemic effects of the other natriuretic drugs.[20] The three drugs of this class—spironolactone, triamterene, and amiloride—are structurally dissimilar (Figure 27-3), but each produces similar effects (mild natriuresis with a decrease in K^+ excretion) because of the blockade of Na^+ reabsorption by this pathway.[11] Spironolactone is a 17-spirolactone steroid that is structurally similar to aldosterone and functions as an aldosterone antagonist. Triamterene, a pteridine derivative with structural similarities to folic acid, and amiloride, a pyrazine derivative, exert similar effects by directly blocking the apical membrane Na^+ channels of the principal cells of the collecting duct. By preventing Na^+ entry into these cells, these diuretics reduce the electrogenic driving force for K^+ or H^+ secretion, or both, in this segment. The net effect is a mild diuresis with a K^+-sparing effect.

The amount of additional Na^+ excretion and K^+ retention is small when drugs of this class are administered alone. When natriuresis from other diuretics is present, the capacity of K^+-sparing diuretics to inhibit K^+ excretion is significantly increased. This characteristic provides the rationale for com-

bining loop and thiazide diuretics with a K^+-sparing diuretic to prevent hypokalemia.

Absorption, fate, and excretion

Spironolactone is administered orally and is rapidly absorbed. The onset of action takes 2 to 4 days, however, and full clinical efficacy is not seen for several weeks. Spironolactone is metabolized by the liver and has two active metabolites, canrenone and canrenoate. Canrenone is prescribed as a K^+-sparing diuretic in Europe.

Amiloride is given orally, despite its poor gastrointestinal absorption. Diuresis begins within 2 hours, and its duration of action is approximately 24 hours. Amiloride does not undergo metabolism and is excreted unchanged in the urine and feces. Triamterene is better absorbed by the gastrointestinal tract and produces a response within 2 hours of administration. Triamterene has a short plasma half-life and is extensively metabolized to products that are excreted in the urine and feces. The duration of diuresis is longer (approximately 14 hours), however, because the hydroxylated metabolites are also active Na^+ channel blockers.

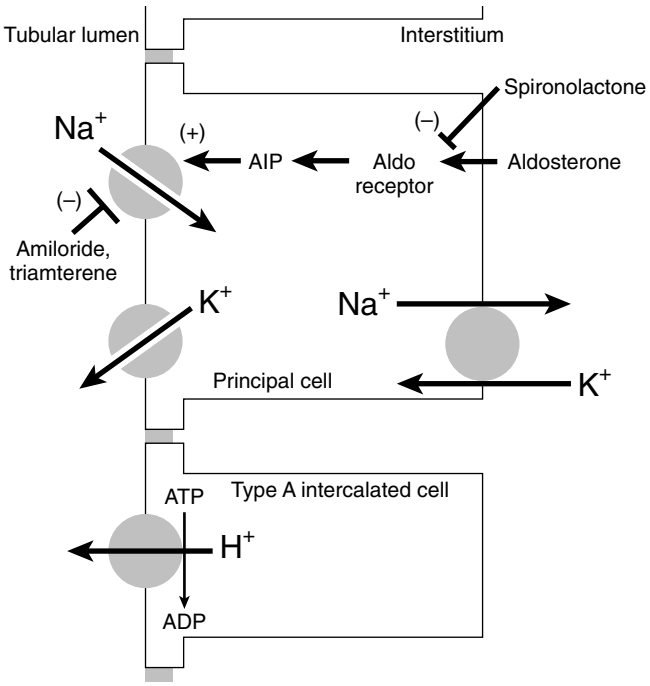

FIGURE **27-2** Actions of K^+-sparing diuretics in the cortical collecting duct. In this segment, Na^+ is transported passively through channels located on the apical membranes of principal cells. The conductance of this channel is enhanced by an aldosterone-induced protein *(AIP)*. The apical entry of Na^+ (removal of positive charges) creates a negative electrostatic driving force in the tubule lumen that enhances the secretion of K^+ from principal cells and H^+ from type A intercalated cells. Amiloride and triamterene are antagonists of apical membrane Na^+ channels, producing a mild natriuresis and preventing K^+ excretion in this segment. Spironolactone, by antagonizing the action of aldosterone, prevents AIP activation of Na^+ conductance, producing natriuresis with a K^+-sparing effect. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate.

Therapeutic uses

K^+-sparing diuretics are most often used to prevent hypokalemia caused by thiazide and loop diuretics. Spironolactone, triamterene, and amiloride are each available as combination preparations with thiazide diuretics to facilitate this use. Spironolactone is also sometimes used in the treatment of hyperaldosteronism. More recently, spironolactone has been found to be especially useful in the treatment of congestive heart failure (see Chapter 25). Plasma aldosterone concentration is inappropriately elevated in patients with congestive heart failure, and it contributes to the development of edema, direct hypertrophic effects on the myocardium, and other adverse effects in heart failure. Spironolactone effectively antagonizes these effects and has been shown to reduce the mortality rate of patients with congestive heart failure.

Adverse effects

The primary toxic effect of K^+-sparing diuretics is hyperkalemia. This effect is most common when these drugs are given alone or concomitantly with other inhibitors of K^+ excretion, such as angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists. Dietary K^+ supplementation can also precipitate hyperkalemia in patients taking these drugs. Hyperkalemia is infrequent when these drugs are administered in the presence of loop or thiazide diuretics. Spironolactone, because of its steroid structure, can also produce gynecomastia or decreased libido or both in men. Menstrual irregularities have been reported for women. Triamterene and amiloride infrequently cause other effects, such as nausea and vomiting, muscle cramping, and dizziness. Triamterene can sometimes accumulate in the renal pelvis and produce renal stones.

Thiazide Diuretics

Benzothiazide diuretics (commonly referred to as *thiazides*) are derived from 1,2,4-benzothiadiazine-7-sulfonamide 1,1 dioxide (Figure 27-4). Chlorothiazide was originally synthesized in an attempt to produce more potent carbonic anhydrase inhibitors. Investigators soon observed that although chlorothiazide produced prompt diuresis as predicted, it did not do so by increasing the excretion of $NaHCO_3$. Rather, it produced a large increase in the excretion of NaCl, suggesting a novel natriuretic and diuretic mechanism: inhibition of Na^+-Cl^- cotransport in the distal nephron.[22] Structural congeners

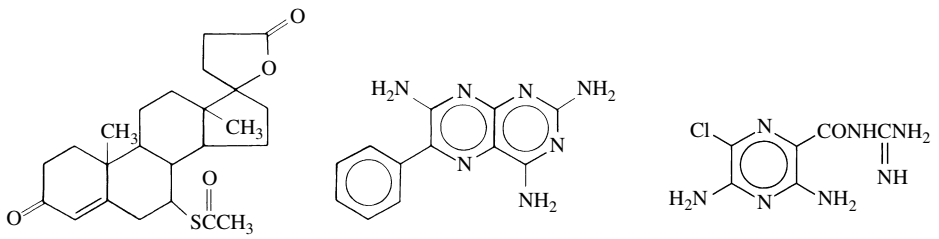

FIGURE **27-3** Structural formulas of K^+-sparing diuretics.

Thiazide and K^+-Sparing Combination Drugs

PROPRIETARY (TRADE) NAME	THIAZIDE	ADDITIONAL DRUG
Moduretic	Hydrochlorothiazide 50 mg	Amiloride 5 mg
Aldactazide, Spirozide	Hydrochlorothiazide 25 mg	Spironolactone 25 mg
Aldactazide	Hydrochlorothiazide 50 mg	Spironolactone 50 mg
Maxzide	Hydrochlorothiazide 25 mg	Triamterene 37.5 mg
	Hydrochlorothiazide 50 mg	Triamterene 75 mg

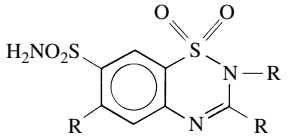

FIGURE **27-4** Structural formula of the parent compound of the thiazide diuretics.

of chlorothiazide, including hydrochlorothiazide, hydroflumethiazide, and methyclothiazide, also share this mechanism. Several other compounds (chlorthalidone, indapamide, metolazone, and quinethazone) that are not structurally related to thiazides also inhibit renal Na^+-Cl^- cotransport and produce natriuresis and diuresis that is indistinguishable from thiazides. For this reason, it is a common convention to refer to all drugs that inhibit renal Na^+-Cl^- cotransport as "thiazides" regardless of their structure.

Table 27-2 lists diuretics of the thiazide class available for prescription in the United States. Hydrochlorothiazide is also available in combination form with K^+-sparing diuretics (Table 27-3). In addition, there are at least 21 formulations on the market that combine hydrochlorothiazide with another antihypertensive drug.

Pharmacologic effects

Thiazide and thiazide-like diuretics enter the lumen of the nephron by glomerular filtration and through secretion by the organic acid transporters of the proximal tubule. Thiazide diuretics can achieve a luminal concentration that is higher than their free plasma concentration. Inhibitors of organic acid transport, such as probenecid, can inhibit the action of thiazide diuretics by lowering the luminal concentration. When the drug reaches the distal convoluted tubule, it binds to the Na^+-Cl^- cotransporter (most likely at the Cl^- binding site) and inhibits its turnover (Figure 27-5).[17] The result is a reduction in Na^+-Cl^- reabsorption by the distal convoluted tubule and an increase in the amounts of Na^+-Cl^- delivered to the cortical collecting duct.[22] Some of the Na^+ that is delivered to the collecting duct is excreted with an equivalent amount of water, producing natriuresis and diuresis, and some is reabsorbed in the cortical collecting duct as it is exchanged for K^+ or H^+; thiazides also produce kaliuresis (increased excretion of K^+).

In addition to increasing the excretion of Na^+-Cl^- and K^+, thiazide diuretics increase the reabsorption of filtered Ca^{++}. This action distinguishes thiazides from loop diuretics, which promote Ca^{++} excretion. The mechanism for this action is not completely understood, but Ca^{++} reabsorption apparently is increased at the proximal tubule as a result of decreased glomerular filtration (because of reduced plasma volume) and at the distal convoluted tubule as a direct result of Na^+-Cl^- cotransport inhibition. Ca^{++} influx into the distal convoluted cells is governed in part by hormones such as parathyroid hormone, and its efflux is powered by a basolateral Na^+/Ca^{++} exchanger. Less Na^+ inside the cell from blockade of apical Na^+-Cl^- cotransport creates a larger gradient for the influx of extracellular Na^+ through the basolateral Na^+/Ca^{++} exchanger, resulting in increased Ca^{++} reabsorption. Depending on their structure, some thiazides are also weak inhibitors of carbonic anhydrase; this may result in alkalinization of the urine from increased HCO_3^- excretion.

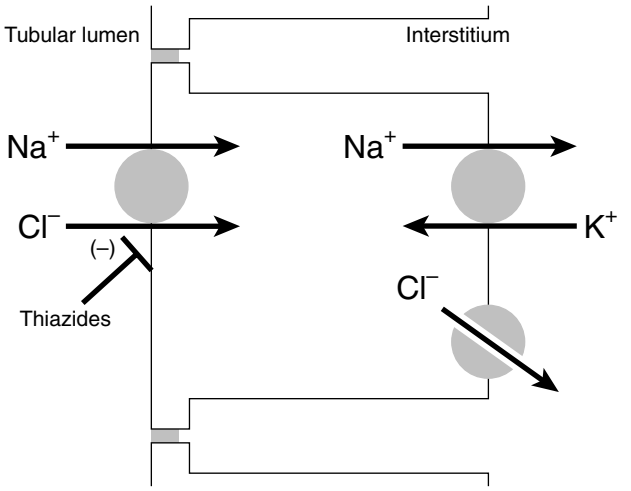

FIGURE **27-5** The action of the thiazide diuretics on the distal convoluted tubule. Na^+ and Cl^- enter the cell from the tubular urine by the electroneutral Na^+-Cl^- cotransporter. Intracellular Na^+ is removed by the action of basolateral Na^+,K^+-ATPase, and Cl^- exits through basolateral Cl^- channels. Thiazides bind to the Cl^--binding site of the Na^+-Cl^- cotransporter, causing an increase in Na^+-Cl^- delivery to more distal tubule segments, increasing Na^+-Cl^- excretion.

At the level of the whole organism, long-term administration of a thiazide diuretic produces a reduction in the extracellular fluid volume.[2] The decrease in blood volume activates the renin-angiotensin system, causing angiotensin II–mediated aldosterone release from the adrenal gland. Aldosterone acts on the cortical collecting duct to increase the conductance of the principal cell Na^+ channels. Blood volume reduction leads to aldosterone-induced increases in the recovery of Na^+ in the cortical collecting duct, which increases the excretion of K^+ in this segment further. Thiazides also lead to a long-term decrease in blood pressure. The mechanism for this effect is controversial. A reduction in blood volume would be expected to decrease arterial blood pressure. Blood volume returns to near-normal values, however, after several weeks of thiazide administration. A direct vascular effect—vasodilation caused by reductions in vascular Na^+ content—has been proposed to explain the continued reduction in total peripheral resistance that persists during thiazide administration.[14]

Absorption, fate, and excretion

Absorption of thiazides from the gastrointestinal tract varies with the particular agent. The plasma elimination half-life and duration of diuretic effect for each of the thiazide diuretics are listed in Table 27-2. Plasma protein binding varies considerably among this class of drugs. The parent compounds or metabolites or both are primarily excreted through renal elimination after glomerular filtration and secretion in the proximal tubule.

Therapeutic uses

Thiazide diuretics are primarily used to treat essential hypertension. The Joint National Commission VII and the World Health Organization recommend thiazide diuretics as a first-line treatment for essential hypertension because of their demonstrated efficacy and low cost (see also Chapter 28).[5,12,15,16] The antihypertensive dosage of thiazide diuretics should normally not exceed the equivalent of 25 mg/day of hydrochlorothiazide because clinical studies have shown that doses greater than this produce equivalent antihypertensive effects but greater toxicity. Thiazide diuretics can be given as monotherapy for essential hypertension or as an adjunct agent.[5,8,16,17] Thiazide diuretics enhance the effectiveness of most other antihypertensive agents, especially vasodilators such as hydralazine and minoxidil, which by themselves promote volume expansion. Thiazide diuretics can also mobilize mild edema and are sometimes used for this purpose, but loop diuretics are generally used to treat edema.

Ca^{++} is absorbed from the diet in response to Ca^{++} loss in the urine, and some individuals have higher Ca^{++} turnover than others.[7] Excessive Ca^{++} excretion promotes the formation of calcium oxalate kidney stones. Thiazide diuretics can be used to lower the concentration of Ca^{++} in the excreted urine, an effect that can prevent the formation of renal stones.

Thiazide diuretics are also sometimes (paradoxically) useful in the treatment of the polyuria of nephrogenic diabetes insipidus. The plasma volume contraction that occurs from thiazide diuretic use leads to a decreased glomerular filtration rate and other compensatory changes that increase Na^+-Cl^- and water reabsorption in the proximal nephron. Less delivery of water to the collecting duct in nephrogenic diabetes insipidus means less urine volume.[6]

Adverse effects

Thiazide diuretics are generally safe and effective drugs. Toxicity usually is the result of plasma electrolyte disturbances, which can result in extracellular volume depletion, hyponatremia, and hypokalemia. Most prevalent among these is hypokalemia, which results from the combined effects of volume depletion–induced aldosterone release and increased delivery of Na^+ and Cl^- to the collecting duct. Both of these effects increase reabsorption of Na^+ through apical channels in the cortical collecting duct, which increases the driving force for the secretion of K^+.

Hypokalemia reduces the resting membrane potential, decreasing the likelihood of action potentials in nerves and muscles. Predictable symptoms occur, such as flaccid muscles; paralytic ileus; confusion and lethargy; and various cardiac arrhythmias such as sinus bradycardia, atrioventricular block, and paroxysmal atrial tachycardia. Hypokalemia also causes hyperglycemia by decreasing insulin production in the pancreatic β cells. Hyperglycemia can occur in nondiabetic patients treated with thiazide diuretics, and glucose control can be destabilized in diabetic patients. Because insulin-dependent glucose uptake promotes cellular uptake of K^+, this hyperglycemia blunts the full effects of diuretic-induced hypokalemia. Severe, sometimes fatal, hypokalemia could result if insulin is administered under these circumstances. Hypokalemia can be avoided by eating foods rich in K^+, especially fruits such as bananas, or by taking K^+ supplements. The concomitant use of K^+-sparing diuretics with thiazide diuretics is an alternative strategy for avoiding hypokalemia, and several combination drugs with hydrochlorothiazide are available for this purpose (see Table 27-3).

Because thiazide diuretics can cause a Na^+ loss in excess of the water loss, they can cause volume depletion and hyponatremia. Hyponatremia causes systemic cellular edema and brain swelling, leading to symptoms such as irritability, depression, and confusion, whereas plasma volume depletion adds symptoms such as postural hypotension, tachycardia, weak pulse, dry mouth, thirst, and oliguria. Other adverse effects of thiazide diuretics include hypercalcemia and hypophosphatemia, simulating hyperparathyroidism. Thiazide diuretics can also precipitate attacks of gout, a potential consequence of hyperuricemia. Urate is freely filtered by the glomerulus, reabsorbed in the proximal tubule, secreted by more downstream portions of the proximal tubule, and later largely reabsorbed again. Urate is poorly soluble, and its concentration is normally close to that at which crystals form.

Thiazide diuretics interfere with urate transport in a manner that promotes urate retention.[9] This effect combined with thiazide diuretic–induced water loss can increase the plasma urate concentration beyond its solubility limits, leading to the formation of urate crystals that can trigger the inflammatory response known as *gout*. Hyperlipidemia was seen in the past when higher doses of thiazide diuretics (e.g., >25 mg/day of hydrochlorothiazide) were routinely administered to treat hypertension.[17]

Allergic reactions are uncommon with thiazide diuretics, but can lead to fever, skin rash, interstitial nephritis, and renal failure. Patients allergic to sulfonamides should not receive thiazide diuretics.

Loop Diuretics

Loop diuretics are so named for their site of action on the thick ascending limb of the loop of Henle (TALH), where they inhibit Na^+ and Cl^- reabsorption (Figure 27-6). Because 20% to 25% of filtered Na^+ is reabsorbed in this segment, the resulting natriuresis can be of a much larger magnitude compared with other diuretics. These drugs are sometimes referred to as high ceiling or high efficacy diuretics. Diuretics that act at segments distal to the TALH have a much smaller maximum effect on Na^+ reabsorption. Loop diuretics are structurally dissimilar (Figure 27-7). Furosemide and bumetanide are sulfonamide derivatives of aminobenzoic acid, torsemide is a pyridine sulfonylurea, and ethacrynic acid is an unsaturated ketonic derivative of aryloxyacetic acid.

Pharmacologic effects

Na^+ and Cl^- are reabsorbed in the medullary and cortical TALH by the Na^+, K^+, $2Cl^-$ cotransporter, as described in Figure 27-6.[22] Evidence obtained with radiolabeled bumetanide suggests that loop diuretics bind to one of the Cl^--binding sites on the cotransporter because bumetanide binding is enhanced by Na^+ and K^+ but inhibited by Cl^-. Loop diuretic binding to the Na^+, K^+, $2Cl^-$ cotransporter effectively arrests ion transport, preventing the reabsorption of Na^+ and Cl^-. K^+ reabsorption is also inhibited, which reduces the intraluminal positive electrical potential normally present in the TALH; this reduces the driving force for the paracellular reabsorption of cations in this segment (see Figure 27-6).[22] Additional K^+ excretion occurs in the collecting duct in response to increased Na^+ delivery to the collecting duct and increased aldosterone secretion, as described for the thiazide diuretics. The amount of titratable acid secreted by the collecting duct is also enhanced by loop diuretics by the same mechanism. Loop diuretics increase the excretion of Na^+, K^+, Ca^{++}, Cl^-, H^+, and Mg^{++}. The effect on Ca^{++} is particularly noteworthy because the hypercalciuric effect of loop diuretics is the opposite of the hypocalciuric effect seen with thiazides.

At the level of the whole kidney, inhibition of Na^+ and Cl^- reabsorption in the TALH reduces the medullary interstitial osmotic gradient, which is the driving force for water reabsorption by the adjacent descending loops of Henle and collecting ducts. By blocking NaCl reabsorption in the TALH, a more isotonic tubular fluid is delivered to the collecting duct, impairing the ability of the kidney to excrete a dilute urine. The associated reduction in the interstitial medullary gradient means that less water can be extracted from the tubular fluid, impairing the ability of the kidney to excrete a concentrated urine.[19] The urine excreted in the

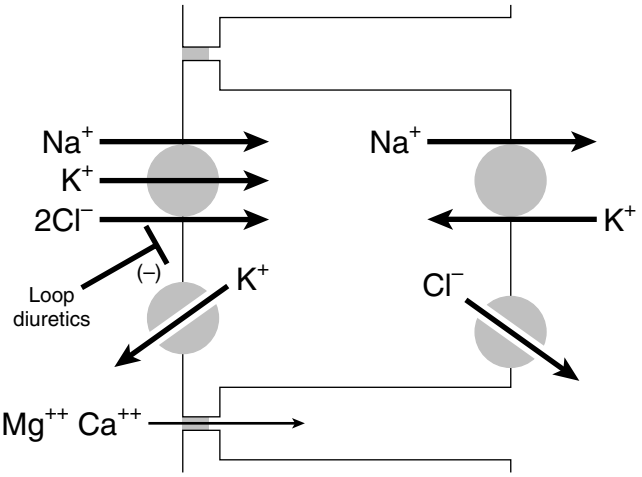

FIGURE **27-6** The action of the loop diuretics on the thick ascending limb of the loop of Henle. Na^+, K^+, and Cl^- enter the cell from the tubular urine by the Na^+, K^+, $2Cl^-$ cotransporter. Intracellular Na^+ is removed by the action of basolateral Na^+,K^+-ATPase, and Cl^- exits through basolateral Cl^- channels. K^+ is partially recycled as it exits by an apical channel. This action creates a net positive potential in the tubular lumen, which acts as an electrogenic driving force for the paracellular reabsorption of cations such as Na^+, Mg^{++}, and Ca^{++}. Loop diuretics bind to one of the Cl^--binding sites of the Na^+, K^+, $2Cl^-$ cotransporter, causing an increase in Na^+ and Cl^- delivery to more distal tubule segments, increasing Na^+ and Cl^- excretion. K^+ recycling is also disrupted, causing an increase in the excretion of Mg^{++} and Ca^{++}.

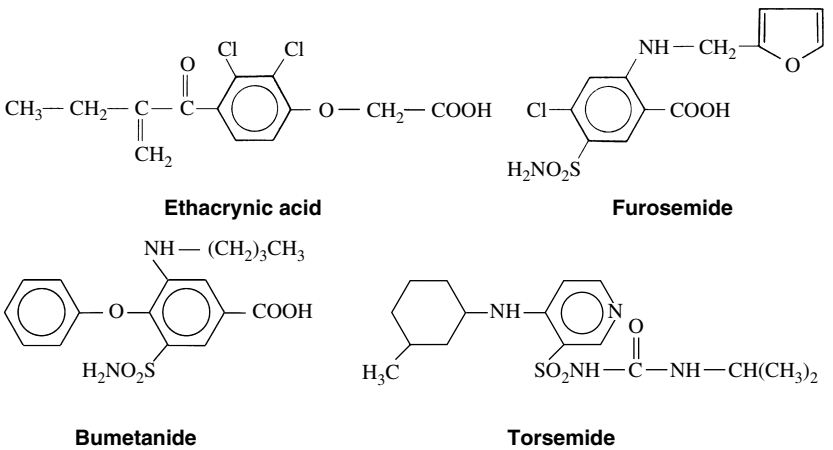

FIGURE **27-7** Structural formulas of loop diuretics.

presence of loop diuretics does not differ much from that of plasma, regardless of ADH levels (i.e., free water clearance is reduced).

At the level of the whole body, loop diuretics reduce the extracellular fluid volume and reduce blood pressure as described for thiazides except that these effects are typically of greater magnitude for loop diuretics. Furosemide also increases venous capacitance, which reduces left ventricular filling pressure. This effect seems to be mediated by prostaglandins and occurs before diuresis. This effect is especially useful with intravenous furosemide to treat acute pulmonary edema.

Absorption, fate, and excretion

Although structurally dissimilar, there is substantial similarity among loop diuretics regarding absorption, fate, and excretion. Furosemide is available in oral and injectable forms, with approximately 65% absorption of the oral form. Diuresis begins within 5 minutes of intravenous administration, with a duration of 2 hours, and begins in approximately 30 minutes after oral or intramuscular administration and lasts 6 to 8 hours. Furosemide is highly protein bound, metabolized by the liver, and excreted in the urine and feces. With normal renal function, it has a half-life of 30 to 70 minutes, but this increases to approximately 9 hours in patients with end-stage renal disease.

Torsemide is available in oral and intravenous forms and is rapidly absorbed after oral administration with 80% to 90% bioavailability. Diuresis begins in 30 to 60 minutes and lasts approximately 6 hours. Torsemide is highly protein bound and is 80% metabolized by the hepatic cytochrome P450 system before excretion in the urine. The half-time for elimination is typically 2 to 4 hours but is increased to 7 to 8 hours by cirrhosis of the liver.

Bumetanide is available in oral and injectable forms. Diuresis begins within 2 to 3 minutes of intravenous administration and 30 to 60 minutes after oral or intramuscular administration and has a duration of approximately 6 hours. Bumetanide is highly protein bound, metabolized by the liver, and excreted in the urine.

Ethacrynic acid is available in oral and intravenous forms. Diuresis begins within 5 minutes of intravenous administration and lasts 2 hours, whereas the onset of the diuretic effect after oral administration requires 30 to 60 minutes and has a duration of approximately 12 hours. Ethacrynic acid is highly protein bound, metabolized by the liver, and excreted in the urine and bile. With normal renal function, ethacrynic acid has a half-life of 2 to 4 hours.

Therapeutic uses

Loop diuretics are predominantly used to treat edema.[12,18] In cardiac failure, low cardiac output results in poor renal perfusion, which causes volume retention.[23] If cardiac dysfunction is severe, this volume retention results in edema and cardiac dilation, which worsen cardiac failure. Fluid retention in the lungs can also produce grave consequences in heart failure. Loop diuretics reduce plasma volume to cause migration of edema fluid from the tissues back into the circulation, from where it can be excreted. Many primary and secondary kidney diseases are characterized by salt and water retention and hyperkalemia. Thiazide diuretics can be used in some of these patients, but they become ineffective when the glomerular filtration rate decreases to less than 30 mL/min.

Loop diuretics are the primary drugs of choice for volume management in renal failure. Edema can originate from a primary liver disease. Edema in this setting is the result of low plasma oncotic pressure from hypoalbuminemia, ascites formation, low renal perfusion, and increased aldosterone release. Loop diuretics have a place in the management of this complex syndrome by reducing fluid and electrolyte retention by the kidney. Some patients with liver disease can be resistant to loop diuretics, however, and these drugs can produce dangerous hypovolemia in others. Great care is needed in the use of loop diuretics in the treatment of edema and ascites in liver disease.

Loop diuretics are also the drugs of choice for the treatment of acute pulmonary edema.[6] In this condition, furosemide is usually administered parenterally, producing a rapid reduction in pulmonary congestion. As stated previously, this response occurs even before the onset of significant natriuresis and seems to be partly caused by a prostaglandin-mediated increase in venous capacitance. This action causes a decrease in left ventricular filling pressure, which relieves the pulmonary edema. Longer term reduction of fluid and electrolyte retention by furosemide maintains the response.

In addition to their use in edema, loop diuretics are useful in the management of other conditions. In refractory hypertension, loop diuretics are used to combat the fluid and electrolyte retention caused by powerful vasodilators such as minoxidil and hydralazine. In such cases, a K^+-sparing diuretic is also included in the regimen to prevent hypokalemia. Loop diuretics are also used to treat hypercalcemia.[5] As discussed earlier (see Figure 27-6), loop diuretics decrease Ca^+ reabsorption in the TALH. In patients with hypercalcemia, furosemide is given intravenously, which produces a prompt reduction in plasma Ca^+ concentration. To maintain plasma volume and prevent Na^+ and K^+ wasting, normal saline must be infused simultaneously at a rate that matches urine flow.

Adverse effects

Similar to thiazide diuretics, toxicity from loop diuretics is usually the result of plasma electrolyte disturbances such as hyponatremia and hypokalemia and extracellular volume depletion. The magnitude of these effects can be greater than the effects produced by thiazides because of the more prominent natriuresis produced by loop diuretics. The hypokalemia produced by loop diuretics occurs by a mechanism similar to that described for thiazide diuretics (increased exchange of K^+ for Na^+ in the collecting duct) and can be associated with metabolic alkalosis.[9] Also similar to thiazide diuretics, hypokalemia is the most prevalent among these electrolyte disturbances and exerts various neuromuscular and metabolic effects. Inasmuch as loop diuretics are routinely used to help regulate plasma volume in patients with congestive heart failure, this is the appropriate place to draw attention to an important drug interaction. Digoxin and other digitalis-like cardiac glycosides are used to increase myocardial contractility in the failing heart. Various toxic effects are associated with the use of cardiac glycosides (see Chapter 25). Digitalis toxicity increases under conditions of hypokalemia. Thiazide and loop diuretics increase the likelihood and severity of digitalis toxicity.[9]

Hyponatremia causes systemic cellular edema and brain swelling, leading to symptoms such as irritability, depression, and confusion. Plasma volume depletion adds symptoms such as postural hypotension, tachycardia, weak pulse, dry mouth, thirst, and oliguria. Similar to thiazide diuretics, disruption of urate excretion or dehydration or both can lead to hyperuricemia and acute gout. Some loop diuretics can cause potentially severe allergic skin reactions similar to thiazide diuretics.

The adverse effects discussed earlier are generally shared with thiazide diuretics. In addition, loop diuretics have some adverse effects that are not shared with thiazide diuretics. Because of their impairment of paracellular reabsorption of Mg^{++} and Ca^{++}, loop diuretics can also cause hypomagnesemia

(a risk factor for cardiac arrhythmias and digitalis toxicity) and hypocalcemia (which, in rare instances, can cause tetany). Loop diuretics can cause various gastrointestinal problems, including pancreatitis, jaundice, anorexia, malaise, and abdominal pain. They can elicit thrombocytopenia and, rarely, aplastic anemia or agranulocytosis, and they can cause systemic allergic reactions, such as systemic vasculitis. Finally, loop diuretics affect the central nervous system, with the most important adverse effects being tinnitus and hearing loss, vertigo, and paresthesias. Because of the ototoxic effects of loop diuretics, they should not be administered concurrently with other ototoxic drugs, such as aminoglycosides.

Carbonic Anhydrase Inhibitors

Acetazolamide is the prototype for this class of drugs, which are nonbacteriostatic sulfonamides, and is among the few members of this class that is still marketed as a diuretic. Carbonic anhydrase inhibitors were among the earliest diuretics available, and the search for new members in this family resulted in the discovery of thiazide diuretics.

Pharmacologic effects

Acetazolamide is a potent inhibitor of the enzyme carbonic anhydrase, the enzyme that catalyzes the reversible reaction of carbonic acid to form either water and carbon dioxide or HCO_3^- and H^+. By blocking this enzyme, reabsorption of HCO_3^- is impaired in the proximal tubule, which leads to increased delivery of Na^+, K^+, and HCO_3^- to the distal nephron and ultimately an alkaline diuresis.[13]

Absorption, fate, and excretion

Acetazolamide is readily absorbed from the gastrointestinal tract, with peak concentrations reached in 2 hours. Extended-release capsules are available. Acetazolamide is not metabolized. It is tightly bound to carbonic anhydrase and concentrates in cells with high amounts of this enzyme, such as erythrocytes and the renal cortex. It is excreted unchanged in the urine as a result of active secretion and some passive reabsorption and has a half-life of 2.5 to 6 hours.

Therapeutic uses

Carbonic anhydrase inhibitors can be used to treat the edema of congestive failure but are no longer widely used for this purpose. When used to treat edema, best results are obtained when the drug is skipped every other day or every 2 days, giving the kidneys an opportunity to recover lost HCO_3^-. Carbonic anhydrase inhibitors also suppress aqueous humor formation in the eyes and can be used to reduce interocular pressure in open-angle glaucoma and before surgery in cases of angle-closure glaucoma. Treatment of glaucoma is the therapeutic indication for most carbonic anhydrase inhibitors that are now on the market. For reasons that are not well established, but perhaps because of the tendency toward acidosis with these drugs, carbonic anhydrase inhibitors are also useful for treating epilepsy (especially absence seizures in children). A final use for these drugs is the treatment of altitude sickness when taken before the ascent and, if necessary, to suppress symptoms for a few days afterward.

Adverse effects

Common side effects with carbonic anhydrase inhibitors include a tingling sensation in the extremities, tinnitus, alterations of taste, loss of appetite, nausea, and vomiting. These side effects are especially common early during therapy. The alkaline diuresis caused by carbonic anhydrase inhibitors can also alter the elimination of other drugs; the excretion of weak acids is increased (an effect sometimes harnessed during treatment for drug toxicities), whereas the excretion of weak bases is decreased. In addition, because these drugs are sulfonamide derivatives, some individuals do have allergic reactions typical of these kinds of drugs. These usually manifest as rashes, but are rarely fatal because of more severe reactions, such as anaphylaxis and Stevens-Johnson syndrome.

Osmotic Diuretics

Mannitol is the prototypic osmotic diuretic, a class of drugs that differs from the drugs previously discussed in two important respects: the amounts needed to exert their effects and the site at which they cause diuresis.

Pharmacologic effects

In contrast to the other drugs, which are administered in small amounts to block transporters, mannitol is administered intravenously in gram quantities (typically 50 to 200 g over a 24-hour period) and functions as an impermeable solute in the extracellular space. By selectively increasing the osmolality of the extracellular space, water is extracted from the intracellular space to equilibrate these osmotic differences. Mannitol is freely filtered at the glomerulus, is poorly reabsorbed (<10%), and is not secreted. Mannitol carries water extracted from cells with it into the urine. In contrast to the other diuretics discussed here, mannitol selectively decreases intracellular volume. (Na^+ and Cl^- excretion is also increased, however.)

Absorption, fate, and excretion

Mannitol must be administered intravenously to exert its diuretic effects. When administered to treat cerebral edema, decreases in intracerebral volume are seen within 15 minutes, and diuresis is evident within 1 to 3 hours. There is little metabolism of mannitol, and it is excreted in the urine with a half-time for elimination of 70 to 100 minutes.

Therapeutic uses

There are three major indications for mannitol administration. The first indication is to increase or maintain urine flow. Maintaining the flow of urine during the oliguric phase of acute renal failure can block the progression of acute renal failure to irreversible chronic renal failure. This effect can also be harnessed to hasten the elimination of toxins from the body that can be trapped in the urine. Second, by extracting intracellular water, mannitol can be administered to decrease brain edema and intracranial pressure. Finally, mannitol is administered preoperatively to reduce intraocular pressure before surgery for glaucoma.

Adverse effects

Adverse effects are common during and after the infusion of mannitol. The redistribution of fluid from the intracellular to the extracellular compartment causes various problems, such as pulmonary congestion, electrolyte imbalances, dryness of the mouth, thirst, blurred vision, convulsions, nausea and vomiting, and fever, along with pain, thrombophlebitis, and infection at the injection site. The cardiovascular status of patients must be carefully assessed before administering mannitol because it can cause severe congestive heart failure.

Antidiuretic Hormone Antagonists

In contrast to natriuretics, this class of drugs primarily prevents water reabsorption, producing a selective increase in free water clearance. Several available drugs produce this effect, such as lithium and the antibiotic demeclocycline, but these drugs are rarely used for this purpose in practice. Conivaptan and an orally active congener, tolvaptan, have been approved more recently for the treatment of acute hyponatremia. Other orally active congeners (lixivaptan, satavaptan) are currently in development.

Pharmacologic effects

Conivaptan is a nonpeptide competitive antagonist of vasopressin V_2 receptors.[1] The drug prevents ADH (vasopressin)-induced insertion of water channels (aquaporins) into the apical membranes of principal cells in the collecting duct. This prevents the absorption of water by the collecting ducts, causing increased water excretion. The increase in free water clearance increases urine volume, decreases urine osmolality, reduces plasma volume, and increases plasma osmolality, primarily because of an increase in Na^+ concentration. These actions make conivaptan particularly suited for the treatment of hyponatremia.

Absorption, fate, and excretion

Conivaptan is available only for intravenous administration. It is extensively bound to plasma proteins with an elimination half-life of approximately 8 hours. Conivaptan is metabolized by cytochrome P450 enzymes in the liver, and it and its metabolites are primarily excreted in the feces.

Therapeutic uses

Conivaptan was originally approved for the treatment of euvolemic hyponatremia in hospitalized patients. In 2007 this approval was extended to patients with hypervolemic hyponatremia.[4] This drug is useful primarily in the treatment of the syndrome of inappropriate antidiuresis and the hyponatremia of congestive heart failure. Conivaptan can be used only in hospitalized patients because it is administered intravenously.

Adverse effects

Conivaptan is generally well tolerated, with few adverse effects reported. Common adverse effects due to V_2 receptor blockade include thirst, headache, hypokalemia, and vomiting.[1] Conivaptan also blocks vascular vasopressin V_{1A} receptors at therapeutic concentrations, which can lead to vasodilatation and hypotension. Skin reactions at the infusion site are common. Care should be taken not to reverse hyponatremia too rapidly because this can lead to osmotic demyelination.[4] Caution should be exercised in patients with renal impairment, which reduces drug elimination. Drugs that induce cytochrome P450 can reduce the action of conivaptan and vice versa. Conivaptan has been shown to be teratogenic in laboratory animals and should not be used in pregnant women.

IMPLICATIONS FOR DENTISTRY

The major drug interactions of diuretics are summarized in Table 27-4, and some additional concerns related to herbal remedies are presented at the end of this section. Diuretic therapy does not usually influence dental practice. Nonetheless, epinephrine, sedatives, opioid analgesics, adrenocorticosteroids, and nonsteroidal anti-inflammatory drugs (NSAIDs) used in dentistry can interact with patients receiving diuretic agents to cause clinically important adverse effects. Most patients taking diuretics are doing so because of essential hypertension, and the implications of hypertension and its treatment to dental practice are discussed in Chapter 28.[16] Extra caution is especially warranted when dental patients have congestive heart failure, cardiac arrhythmias, and any other conditions in which subtle worsening of hypokalemia could have an adverse effect.

As previously discussed, thiazide and loop diuretics are K^+-losing diuretics that can cause hypokalemia. Strategies used to compensate for this K^+ loss include increasing the dietary intake of K^+ or prescribing K^+ supplements or a simultaneous K^+-depleting diuretic. Nonetheless, these patients may still have low plasma K^+ concentrations. Under these circumstances, the epinephrine present in gingival retraction cords and local anesthetic solutions can produce a transient hypokalemia, which increases the propensity of epinephrine to trigger cardiac arrhythmias.

The use of anti-inflammatory dosages of adrenocorticosteroids with even modest mineralocorticoid activity, such as

TABLE **27-4**

Drug Interactions of Diuretic Agents

DIURETIC	INTERACTING DRUG	EFFECT
Thiazides, loop diuretics, K^+-sparing diuretics	Anticoagulants	Increased concentration of clotting factors from reduction of plasma volume, decreasing anticoagulant effect
	Aspirin, NSAIDs	Natriuresis and hypotensive effect blocked by cyclooxygenase inhibition
	Lithium salts	Decreased Li^+ excretion, leading to increased Li^+ toxicity
	Adrenergic receptor antagonists, α_2-adrenergic receptor agonists, vasodilators, ACE inhibitors, ARBs	Increased antihypertensive response
	Uricosurics	Enhancement of uric acid reabsorption, reducing efficacy of uricosuric agent
Thiazides, loop diuretics	Oral hypoglycemics, insulin	Hypokalemia-induced hyperglycemia
	Nondepolarizing neuromuscular blockers	Hypokalemia-induced potentiation of paralysis
	Adrenergic receptor agonists	Hypokalemia-induced arrhythmias
	Digoxin	Hypokalemia-induced potentiation of digitalis toxicity
	Corticotropin, adrenal steroids	Deceased diuresis, increased hypokalemia
Thiazides	Cholestyramine, colestipol	Decreased thiazide absorption
Loop diuretics	Aminoglycosides, cisplatin	Ototoxicity
	Clofibrate, warfarin	Competition for binding to plasma proteins by furosemide increases their free concentration
	Cephalosporin antibiotics	Increased renal toxicity
K^+-sparing diuretics	ACE inhibitors, K^+ supplements, cyclosporine	Hyperkalemia

ACE, Angiotensin-converting enzyme; *ARBs,* angiotensin II receptor blockers; *NSAIDs,* nonsteroidal anti-inflammatory drugs.

hydrocortisone, can also promote hypokalemia by exaggerating the hypokalemic effect of thiazide and loop diuretics. In contrast to the rapid-onset transient effects of epinephrine on plasma K^+ concentrations, the hypokalemic effects of adrenocorticosteroids are slow in onset and slow in termination. They may not be of clinical significance until after the patient has left the dental office. Anything that can cause hypokalemia is of greatest concern in patients with congestive heart failure who are receiving digitalis therapy because hypokalemia is a well-known cause of fatal cardiac arrhythmias in these patients.

In addition, there is an increased likelihood of syncope in dental patients taking diuretics because of a depletion of intravascular volume. Sedative-hypnotics and opioid analgesics are among the drugs that more readily cause orthostatic hypotension in the presence of diuretics.

NSAIDs used for dental pain may antagonize the antihypertensive effect of diuretics. With short-term use, this interaction should not be clinically significant, but it can become relevant if NSAIDs are prescribed to treat chronic dental pain.

Most diuretics are in pregnancy class D, meaning that there is a proven risk of fetal harm. Similarly, breastfeeding is generally contraindicated because most of these drugs enter breast milk.

Because various herbal remedies are touted for their diuretic properties, some patients may be taking diuretic therapy without proper medical supervision, and others may choose to combine the use of herbal remedies with contemporary diuretic pharmacotherapy in the potentially erroneous belief that all diuretics work well together. Herbs used as diuretics include dandelion, horsetail, stone root, cleavers, gravel root, hydrangea, pipsissewa, goldenrod, lovage, and parsley. The mechanism of action for these herbs has generally not been established. Claims that dandelion is a rich source of K^+ while functioning as a K^+-depleting diuretic could be of concern, however, if taken by patients who are also taking a K^+-sparing diuretic. Lastly, the glycyrrhizic acid of "real" (e.g., European) licorice used in candy and for various medicinal purposes has mineralocorticoid properties. Overindulgence in this type of licorice candy has caused hypertension and, if consumed with diuretics, could exacerbate the K^+-depleting effects of thiazide and loop diuretics or inhibit the activities of spironolactone. The possibility of drug interaction between diuretics and alternative therapies should not be overlooked.

DIURETIC DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Thiazides and related derivatives	
Bendroflumethiazide	Naturetin
Benzthiazide	Exna
Chlorothiazide	Diuril
Chlorthalidone	Hygroton, Thalitone
Hydrochlorothiazide	Esidrix, HydroDIURIL, Hydro-Par
Hydroflumethiazide	Diucardin, Saluron
Indapamide	Lozol
Methyclothiazide	Aquatensen, Enduron
Metolazone	Zaroxolyn, Mykrox
Polythiazide	Minizide, Renese
Quinethazone	Hydromox
Trichlormethiazide	Diurese, Metahydrin, Naqua
Loop diuretics	
Bumetanide	Bumex
Ethacrynic acid	Edecrin
Furosemide	Lasix
Torsemide	Demadex
K^+-sparing agents	
Amiloride	Midamor
Eplerenone	Inspra
Spironolactone	Aldactone
Triamterene	Dyrenium
Osmotic nonelectrolytes	
Glycerin (glycerol)	Osmoglyn
Isosorbide	Ismotic
Mannitol	Osmitrol
Carbonic anhydrase inhibitors	
Acetazolamide	Dazamide, Diamox
Brinzolamide	Azopt
Dichlorphenamide	Daranide
Dorzolamide	Trusopt
Methazolamide	Neptazane
Antidiuretic hormone receptor antagonist	
Conivaptan	Vaprisol

CHAPTER 28

Antihypertensive Drugs

FRANK J. DOWD AND WILLIAM B. JEFFRIES

About 29% of Americans have hypertension, and it is the leading cause of cardiovascular disease worldwide.[10] Careful examination of the prevalence of hypertension reveals that it is distributed disproportionately among subgroups in the U.S. population. Hypertension increases with advancing age, but its prevalence is much lower in women before menopause than in men of comparable age. There also seems to be a racial component to hypertension[3]: the prevalence is approximately 23% in whites and Mexican Americans but is 32% in African Americans.

Because of the asymptomatic nature of this disease, approximately one third of affected individuals are unaware of their condition. Isolated systolic hypertension affects more than 15% of all people older than 60 years. Studies suggest that only half of hypertensive patients receive pharmacologic treatment at all, and, of this fraction, only half have adequate control of blood pressure levels. Because the long-term consequences of hypertension (e.g., coronary artery disease, stroke, renal failure) are so devastating to health, screening programs are essential to detect the disease early so that treatment can be instituted before major complications ensue. Education of patients is also essential to ensure compliance with recommended therapy because of the insidious nature of the disease and because unpleasant side effects of the drugs used to treat it may cause the patient to feel better when not receiving medication. An individual is considered hypertensive if his or her systolic or diastolic arterial blood pressure (or both) is elevated above normal (i.e., systolic arterial pressure >140 mm Hg or diastolic arterial pressure >90 mm Hg).[2]

CLINICAL ASPECTS OF HYPERTENSION

Classification

The severity of hypertension is classified as shown in Table 28-1. Hypertension can arise as a primary disease or as a result of an underlying illness. *Essential hypertension* is a term used to describe the presence of sustained, elevated blood pressure for which no cause is apparent. When this term was coined, it was believed that the elevation of blood pressure was essential to maintain organ perfusion in the affected patient. This idea is no longer widely accepted, but the term is still in use. Essential hypertension remains of unknown etiology and represents 80% to 90% of all cases of hypertension. Although much is known about the cardiovascular changes that occur as a consequence of prolonged elevation of blood pressure, no single pathologic change can be cited as the primary cause. Many theories abound regarding the causes of essential hypertension, some of which are discussed subsequently.

Secondary hypertension results from a known disorder, such as renal, vascular, or parenchymal disease, or from an endocrine disorder such as pheochromocytoma. Treatment of secondary hypertension usually consists of therapy for the underlying disease process. Hypertension may be systolic or diastolic, or both. Until more recently, less emphasis had been placed on the importance of systolic hypertension. More recent evidence indicates, however, its close association with untoward outcomes.[23] Treatment of isolated systolic hypertension in elderly patients with an antihypertensive drug has been shown to reduce mortality rates, especially from stroke.[14,19] The results are independent of mean arterial pressure. The risk of heart failure is also decreased with reduction in systolic hypertension.[13] It has been suggested that the incidence of dementia is reduced as systolic pressure is reduced in elderly patients.[16]

In metabolic syndrome, hypertension is accompanied by abdominal obesity, hyperlipidemia with atherosclerosis, and hyperglycemia or insulin resistance or both.[22] In this syndrome, hypertension is only one target of therapy. Questions that are still being explored are to what extent each sign of the syndrome is related and how.

Regulation of Blood Pressure

Pressure in a hydraulic system is the product of flow through the system and the resistance to such flow. The relationships between mean arterial blood pressure (MAP), cardiac output (CO), and total peripheral resistance (TPR) can be described in the following equation:

$$MAP = CO \times TPR$$

CO is determined by the load presented to the heart (venous return or preload) and the inotropic and chronotropic state of the myocardium. TPR depends on the diameter and compliance (stiffness) of the arterioles. These factors are regulated by the resting vascular smooth muscle tone, intrinsic reactivity of the vasculature, vasoactive substances in the blood, and sympathetic nervous system activity. Another important factor in the governance of blood pressure is the blood volume, which is regulated by the kidneys. The interrelationships among all these factors are illustrated in Figure 28-1.

Blood pressure tends to remain at a constant value, and there are many physiologic control mechanisms to protect the organism from harmful perturbations in blood pressure. Two of the most important regulatory mechanisms are short-term control afforded by the sympathetic nervous system and long-term control, which is a function of the renal system.

Moment-to-moment control of blood pressure largely depends on baroreflexes, in which sympathetic nervous

Diabetes	Lack of exercise

system output to the heart, resistance vessels, and capacitance vessels is adjusted in response to feedback from baroreceptors in the carotid sinus and aortic arch. These baroreceptors respond to mechanical stretch (increased pressure) by increasing the firing rate of sensory neurons that innervate blood pressure control areas of the central nervous system (CNS). If blood pressure increases, the resultant increased activity of these sensory neurons inhibits efferent sympathetic nervous system activity, reducing heart rate, vascular tone, and blood pressure. Conversely, if blood pressure suddenly decreases, baroreceptor output is reduced, allowing increased peripheral sympathetic discharge. This reflex is responsible for the maintenance of blood pressure during rapid stresses to cardiovascular homeostasis, as induced by a change in posture.

Long-term stresses on the maintenance of blood pressure (e.g., alterations in water and salt intake) are handled by the kidneys. A change in blood pressure is sensed by the kidneys as a corresponding change in renal perfusion pressure. This disturbance invokes two compensatory mechanisms. First, the tubular reabsorption of Na^+ and water either decreases (in high perfusion pressure) or increases (in low perfusion pressure). This alteration adjusts blood volume and secondarily changes CO to bring blood pressure back to normal. The kidneys also influence resistance vessel tone more directly by releasing renin (activating the renin-angiotensin system) when renal perfusion is diminished. The resultant increase in vasoactive angiotensin peptides increases peripheral vascular resistance by causing vasoconstriction. Angiotensin peptides also promote volume retention by increasing the release of aldosterone and contribute to muscular hypertrophy and other structural changes in the heart and vasculature (collectively referred to as *remodeling*).[4]

The physiologic mechanisms that control blood pressure are important in the treatment of hypertension in two respects. First, each of these mechanisms represents a potential therapeutic target for reducing blood pressure in a hypertensive patient. Second, because these mechanisms are in place to prevent changes in blood pressure, they become activated in an attempt to restore blood pressure to its former (high) level when steps are taken to reduce the hypertension.

Pathophysiologic Characteristics of Essential Hypertension

The physical findings of a patient with essential hypertension usually reveal that CO is normal and TPR is elevated. In a hypertensive patient, the baroreceptor reflexes function normally, but have been "reset" to maintain MAP at a higher than normal value. The reasons for this shift are not yet understood and are the subject of intensive research. It is evident that there is a genetic component to essential hypertension and that certain risk factors lead to a worsening of blood pressure elevation (Box 28-1). In many patients, long-term cardiovascular complications of hypertension can be controlled solely by making appropriate lifestyle changes.

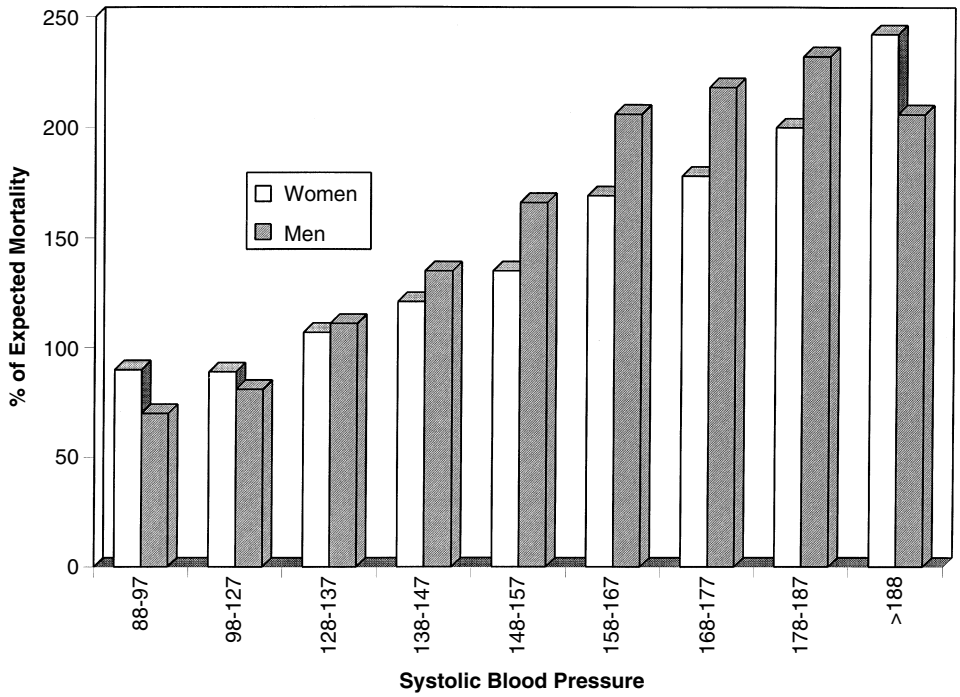

FIGURE **28-2** Expected mortality as a function of systolic blood pressure at all ages without regard to treatment. (Adapted from *The Society of Actuaries and the Association of Life Insurance Medical Directors of America: Blood pressure study 1979*, Boston, 1980, The Society.)

Although the cause of essential hypertension is unknown, it is well established that high blood pressure leads to cardiovascular and renal disease. Elevated blood pressure is directly correlated with overall mortality (Figure 28-2). It is accepted that reducing the blood pressure in hypertensive patients reduces the risk of cardiovascular events including myocardial infarction and stroke, and kidney failure.[23,26] The damage caused by decades of elevated arterial pressure can be seen in the form of left ventricular hypertrophy, medial thickening of arteries, and nephropathy.[18,26] These changes contribute to the development of diseases such as congestive heart failure, coronary artery disease, stroke, aneurysm, and renal failure (Box 28-2). Numerous clinical trials have shown a reduction in morbidity and mortality rates after pharmacologic reduction in blood pressure in hypertensive patients.

Diabetic patients are particularly vulnerable to targeted organ damage resulting from hypertension. The current standard of care dictates that antihypertensive therapy be prescribed in diabetics whose blood pressure is in the high-normal range or above (see Table 28-1). Angiotensin-converting enzyme (ACE) inhibitors are most commonly used for this purpose because of their well-documented protective effects in diabetic patients.[4,21]

General Aims of Antihypertensive Drug Therapy

Treatment of essential hypertension consists of therapy aimed at reducing the blood pressure into the normal range. As shown in Figure 28-1, many factors play a role in the determination of blood pressure, and consequently pharmacologic agents with diverse mechanisms of action can be used singly or in combination to treat essential hypertension. Antihypertensive agents can be categorized according to their mechanism of action and therapeutic use: diuretics, drugs affecting angiotensin, Ca^{++} channel blockers (CCBs), drugs affecting sympathetic function, direct-acting vasodilators, and miscellaneous drugs. Because the basic pharmacologic properties of many drugs useful in treating hypertension are discussed elsewhere, only pharmacologic features pertinent to the treatment of hypertension are discussed in detail in this chapter. Figure 28-3 shows the major sites of action of antihypertensive agents.

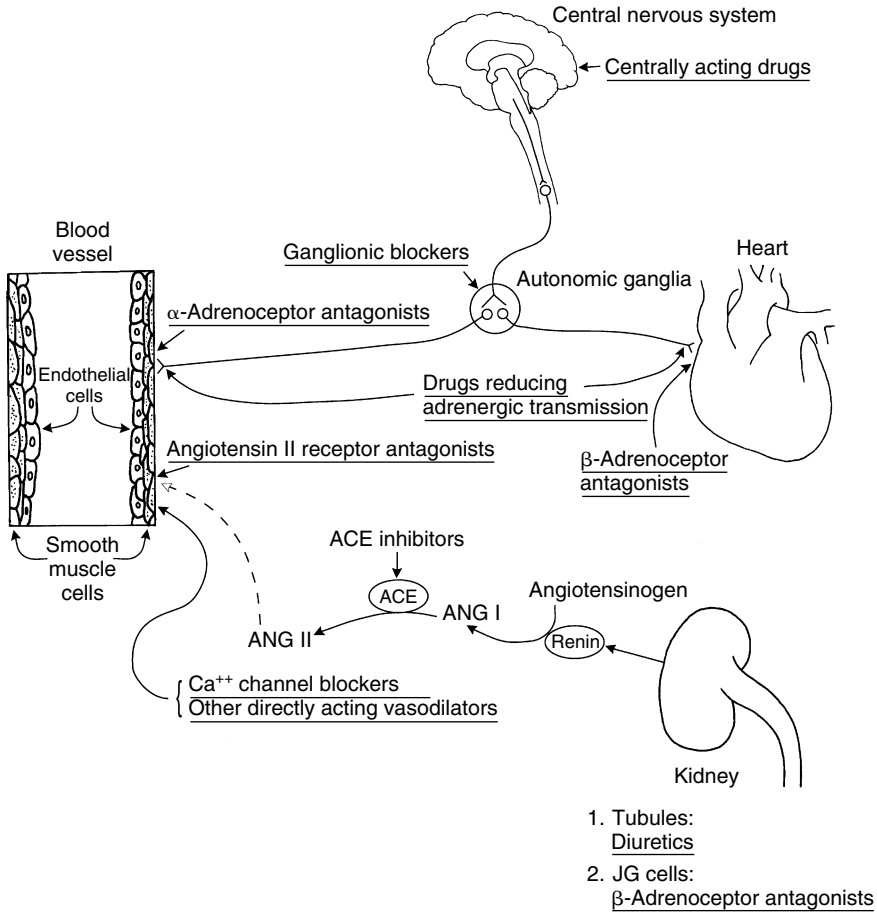

FIGURE **28-3** Sites of action of antihypertensive drugs. The diagram indicates by drug class the targets for antihypertensive action. *ACE*, Angiotensin-converting enzyme; *ANG*, angiotensin; *JG*, juxtaglomerular.

DIURETICS

Thiazide diuretics are currently among the most widely used drugs for the initial management of essential hypertension. K^+-sparing diuretics are commonly used together with thiazides for their additive effect and to prevent thiazide-induced hypokalemia. Thiazide diuretics may be used alone or in combination with other antihypertensive drugs. Loop diuretics such as furosemide are also useful as adjunctive agents in refractory hypertension.

Diuretics reduce plasma volume by increasing Na^+ and water excretion. Initially, this effect reduces blood pressure by decreasing CO. With time, CO and extracellular fluid volume return toward normal values, but the hypotensive effect persists because of a reduction in peripheral resistance. It is probable that electrolyte changes in vascular smooth muscle account for the vasodilation. For a complete discussion of diuretics used in the treatment of hypertension, see Chapter 27.

DRUGS AFFECTING ANGIOTENSIN

The role played by the renin-angiotensin system in hypertension has received much attention in recent years.[4,25] Renin catalyzes the conversion of angiotensinogen, a glycoprotein found in the blood, to angiotensin I, a decapeptide with little cardiovascular activity (see Figure 28-3). Angiotensin I is activated by conversion to the octapeptide angiotensin II. This reaction is catalyzed by ACE, otherwise known as *dipeptidyl carboxypeptidase* or *peptidyl dipeptidase*. Under its designation as *kininase II*, ACE is also the enzyme that inactivates bradykinin.

Angiotensin II is metabolized by aminopeptidase enzymes to yield the less active and shorter lived heptapeptide angiotensin III. Increased renin activity leads to heightened production of angiotensin II and angiotensin III, vasoconstriction of peripheral arterioles, and elevation of blood pressure. Angiotensin peptides stimulate thirst and the secretion of aldosterone and antidiuretic hormone; the resultant increase in extracellular fluid and electrolytes augments the direct pressor effects. Angiotensin II also influences sympathetic nervous system function centrally and peripherally to increase cardiac activity and peripheral vascular resistance.

Patients with essential hypertension can be divided into three groups according to their renin-Na^+ index (i.e., plasma renin activity relative to Na^+ excretion). Approximately 15% of patients have renin concentrations higher than normal, 25% have renin concentrations lower than normal, and the remaining 60% exhibit normal renin titers. Renin titers tend to decrease with age. African American and elderly individuals tend to have a higher incidence of low-renin hypertension.

The percentage of hypertensive patients with normal renin activity may be misleading because renin release is ordinarily depressed as the result of increased blood pressure. Renin release may still be inappropriately high even in the "normal" group. Although angiotensin II may be the main causative agent in high-renin hypertension and may be a factor in the normal-renin hypertension group, other influences are implicated in low-renin hypertension, and these may contribute to normal-renin hypertension as well.

Pharmacologic intervention to reduce blood pressure theoretically can be anywhere along the angiotensin system—

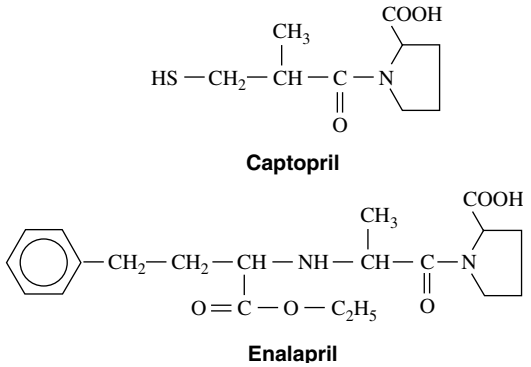

FIGURE **28-4** Structural formulas of two angiotensin-converting enzyme inhibitors.

from the release of renin by the kidney juxtaglomerular cells, to the formation of angiotensin peptides, to the binding of angiotensin II and angiotensin III to receptors in vascular smooth muscle and other effector sites. In the following discussion, attention is limited to drugs whose primary mechanism of action is interference with renin synthesis, renin activity, conversion of angiotensin I to angiotensin II, or action of angiotensin II at its receptor. Other antihypertensive drugs also affect the renin-angiotensin system, however. β-Adrenergic receptor antagonists inhibit renin release by acting at β_1-adrenergic receptors in the juxtaglomerular apparatus of the kidney. Undesired reflex actions can also occur in which diuretics and direct-acting vasodilators stimulate renin release. Studies indicate that, regardless of the specific drug regimen, treatment of hypertension eventually tends to restore renin to normal levels, whether it was initially high or low.

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are among the most commonly used drugs for the treatment of essential hypertension. Captopril, the first drug of this class to be developed, was specifically designed to disrupt the renin-angiotensin pathway. Its structure is shown in Figure 28-4. Captopril differs from other ACE inhibitors because it contains a sulfhydryl group. Enalapril, lisinopril, and most of the other ACE inhibitors have an amino acid substitution. Fosinopril contains a phosphorus linkage.

Pharmacologic effects

Drugs that inhibit ACE block the conversion of angiotensin I to angiotensin II (Figure 28-5; see Figure 28-3).[4] ACE inhibitors markedly decrease blood concentrations of angiotensin II and induce an immediate decrease in blood pressure. They may also act to maintain the lowered blood pressure by elevating bradykinin (a potent vasodilator) concentrations in the blood (see Figure 28-5). (As previously mentioned, ACE, as kininase II, is responsible for the breakdown of bradykinin.) ACE inhibitors have an antihypertensive effect even in patients without high renin activities. Over the course of several weeks, blood pressure is progressively reduced, mainly through decreased peripheral resistance, with little effect on CO or renal blood flow. Salt and water retention is not induced, and orthostatic hypotension and tachycardia are not problems.

The reduction in angiotensin II concentrations as a result of ACE inhibition leads to a decrease in aldosterone secretion, which results in an increase in Na^+ and water excretion. Correspondingly, there is a net increase in the reabsorption of K^+ in the kidney tubule. Hypokalemia is not an adverse effect of ACE inhibitors. K^+ supplements and K^+-sparing diuretics should not be used concurrently with ACE inhibitors to avoid hyperkalemia. With long-term ACE inhibitor therapy, deleterious cardiovascular remodeling may be reduced or even reversed.[4,5,26] ACE inhibitors are also renoprotective and because of this are useful drugs in patients with chronic renal disease and diabetes. The presence of high normal (or above normal) blood pressure and diabetes is a clear indication for the use of an ACE inhibitor.

Absorption, fate, and excretion

The onset of action of captopril is rapid, and the duration of effect is short, requiring administration two to three times daily. Its elimination half-life is approximately 2 hours. Because food in the gastrointestinal tract significantly reduces the absorption of captopril, the drug should be taken 1 hour before meals. Approximately 40% of captopril is metabolized in the liver, and most of the metabolites and the parent drug are excreted by the kidney.

Lisinopril is less well absorbed than captopril, resulting in peak plasma concentrations after approximately 7 hours. The slow elimination half-life of roughly 12 hours permits single daily dosing of the drug. Lisinopril is excreted unchanged in the urine.

Enalapril (see Figure 28-4) is a prodrug that must be hydrolyzed in the liver to become fully active. Its absorption is not influenced by food, and it has a longer duration of effect than captopril. The active metabolite enalaprilat, with a plasma half-life of 11 hours, provides for the extended action. Enalaprilat is not absorbed from the gastrointestinal tract but is effective after intravenous administration; it has been marketed for such use in patients unable to take drugs orally. Other ACE inhibitors with an esterified carboxyl side chain are also activated (by hydrolysis) in the liver to "prilat" metabolites that avidly bind to ACE and provide durations of effect sufficient for single daily dosing. The other ACE inhibitors are listed at the end of this chapter. They differ primarily in their pharmacokinetic properties.

Adverse effects

The most frequent side effect of the ACE inhibitors is coughing, which occurs in 20% of patients.[4] Altered or reduced taste sensation is also common, especially with captopril. These adverse effects may disappear after continued use. The significance of reported cases of proteinuria is not established at this time. Other adverse effects that have been documented are skin rash; angioedema of the face, mucous membranes of the mouth, or extremities; and flushing, pallor, and hypotension. Angioedema is a serious condition that demands withdrawal of the drug. Hyperkalemia and neutropenia may rarely occur.

ACE inhibitors may cause renal insufficiency in patients with bilateral renal stenosis. The mechanism is the reduction of renal angiotensin II production, leading to a disproportionate dilation of efferent renal blood vessels compared with afferent vessels. This vascular imbalance results in a significant decline in the glomerular filtration rate. ACE inhibitors can help preserve renal function in diabetic patients.[4,26] ACE inhibitors have the beneficial effect of reducing proteinuria in patients with some renal diseases.

Although ACE inhibitors are not known to be teratogenic during the first trimester of pregnancy, they can cause significant developmental defects and fetal death later on. After pregnancy has been established, discontinuance or substitution with another antihypertensive agent is mandatory.

Angiotensin Receptor Antagonists

Losartan (as losartan potassium) was the first orally active angiotensin II receptor antagonist to be introduced (Figure 28-6). Other angiotensin II antagonists include candesartan, eprosartan, irbesartan, telmisartan, and valsartan. These nonpeptide analogues of angiotensin bind to the angiotensin II receptor and competitively inhibit the action of angiotensin

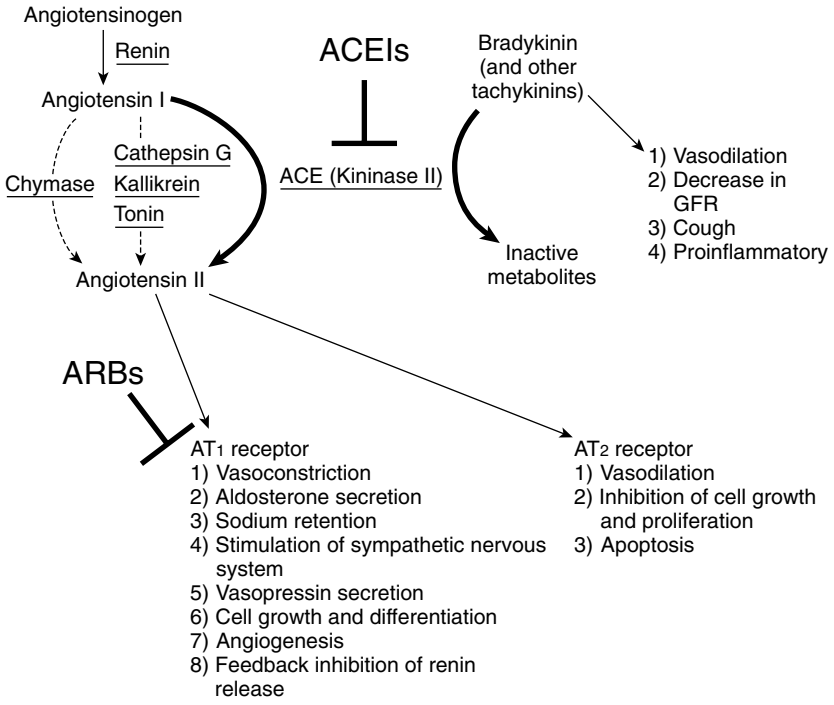

FIGURE **28-5** The role of angiotensin-converting enzyme inhibitors *(ACEIs)* and angiotensin II receptor blockers *(ARBs)* in treating hypertension. ACEIs block the major, but not the only, synthetic pathway to angiotensin II. ACEIs also increase the concentration of bradykinin and other tachykinins, leading to vasodilation and some undesirable effects. ARBs block the effect of angiotensin II by whatever synthetic pathway because they block the AT_1 receptor and the response to AT_1 receptor stimulation. The ARBs do not block the AT_2 receptor. This is considered a benefit of ARBs because the AT_2 receptor mediates vasodilation, inhibition of growth and proliferation, and apoptosis. Angiotensin-converting enzyme *(ACE)* located in tissues is less affected by ACEIs. Enzymes are underlined. *GFR*, Glomerular filtration rate.

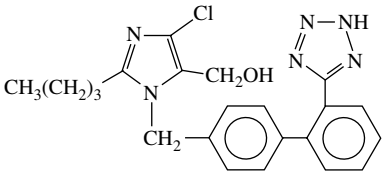

FIGURE **28-6** Structural formula of losartan.

II and angiotensin III.[4,6] They are selective inhibitors of the AT_1 receptor, the angiotensin receptor subtype that accounts for the major physiologic effects of angiotensin II. The effect is to inhibit the consequences of AT_1 receptor stimulation without affecting potentially beneficial effects mediated by the AT_2 receptor (see Figure 28-5).[23] As is the case with ACE inhibitors, AT_1 receptor blockers reduce the blood pressure and the tissue remodeling seen in hypertension and reduce organ damage resulting from hypertension.[4,15,26]

Losartan has a half-life of only 1.5 hours, but it is metabolized to an active metabolite with a longer half-life. Valsartan has a plasma half-life of 6 hours; it is excreted in the bile largely in the unchanged form. The half-lives for the other angiotensin II blockers range from 6 hours for eprosartan to 24 hours for telmisartan. The selectivity of angiotensin II antagonists avoids some of the side effects of ACE inhibitors, such as coughing and angioedema, because the bradykinin pathway is not affected by the angiotensin II antagonists (see Figure 28-5). Orally effective angiotensin II receptor antagonists now constitute a major drug group for treating hypertension.[5]

Renin Inhibitors

The renin inhibitor aliskiren has been approved for use in the United States as a once-daily treatment for stage 1 hypertension (see Table 28-1). Aliskiren binds with high specificity to the proteolytically active site of human renin.[21] Renin is the rate-limiting step in the renin-angiotensin system, so inhibition of this enzyme provides a logical control point for pharmacologic intervention. Aliskiren reduces circulating concentrations of angiotensin I and angiotensin II, producing a decrease in systolic and diastolic blood pressure, comparable to reductions seen with ACE inhibition or AT receptor antagonism. Early reports on toxicity are favorable. Based on the mechanism of action, expected adverse events include hyperkalemia and hypotension. Aliskiren administration produces hyperreninemia owing to a compensatory increase in renin release. This effect is not clinically significant. Aliskiren does not interfere with ACE-induced catabolism of bradykinin, and it is not expected that cough or angioedema would be produced by this class of drugs (as seen in ACE inhibitors). Similar to other inhibitors of the renin-angiotensin system, aliskiren is contraindicated in patients with bilateral renal artery stenosis and during pregnancy. Aliskiren has a poor bioavailability and is greater than 90% excreted unchanged in the feces, so minimal drug metabolism interactions are expected from this drug.

CA^{++} CHANNEL BLOCKERS

Verapamil, diltiazem, and nifedipine were the first CCBs to be marketed. The pharmacologic features of nifedipine and its dihydropyridine congeners, including amlodipine, felodipine, isradipine, nicardipine, nimodipine, nisoldipine, and nitrendipine, are addressed in this chapter. Other CCBs are discussed in Chapters 24 and 26.

Pharmacologic Effects

All CCBs prevent Ca^{++} influx into smooth and cardiac muscle cells. The potency of these drugs for each of these actions varies, however, producing some important clinical distinctions between the dihydropyridines and verapamil and diltiazem. These latter two drugs inhibit Ca^{++} influx into vascular smooth muscle and the heart with roughly the same potency. The effect of verapamil and diltiazem is to reduce blood pressure by vasodilation and reduced CO. Dihydropyridines such

as nifedipine are much more potent at inhibiting Ca^{++} influx at vascular smooth muscle than in the heart. At clinically relevant plasma concentrations, nifedipine produces a pronounced vasodilation with little direct effect on cardiac function. Reflex tachycardia is a common side effect with dihydropyridines but is almost never seen with verapamil and diltiazem. CCBs are contraindicated in patients with cardiac conduction defects and in heart failure. CCBs are useful drugs for treating low-renin hypertension.

Dihydropyridines enhance the glomerular filtration rate and renal blood flow. Some patients taking dihydropyridines develop pedal edema. This condition does not result from fluid retention but rather from precapillary dilation. Renal Na^+ excretion may be enhanced. The antihypertensive effect and an apparent direct renoprotective effect of these drugs may make them useful in treating chronic renal failure.

Absorption, Fate, and Excretion

The plasma half-lives of most CCBs (diltiazem, isradipine, nicardipine, nifedipine, and verapamil) are 2 to 8 hours. The half-lives of the others are as follows: amlodipine, 30 to 50 hours; felodipine, 10 to 16 hours; nimodipine, 1 to 2 hours; nisoldipine, 7 to 12 hours; and nitrendipine, 10 to 20 hours. Long-term therapy may be associated with some increase in half-lives for some CCBs.

The elimination half-life and duration of action influence the clinical use of these agents. The short time course of nimodipine, along with its relative ability to cross the blood-brain barrier, limits the drug's suitability for the treatment of chronic disease but permits its use to prevent vasospasm subsequent to subarachnoid hemorrhage. Short-acting nifedipine has been associated with an increased cardiovascular mortality rate during long-term use, and it is no longer used for treating hypertension. The drug's short duration of action causes the blood pressure to wax and wane with each dose. A slow-release version of the drug stabilizes blood concentrations and now is the recommended formulation. CCBs with long half-lives and slow-release preparations are recommended for this reason.

Adverse Effects

Toxic reactions and side effects of CCBs are described in Chapter 26.

DRUGS REDUCING SYMPATHETIC FUNCTION

A major homeostatic role of the autonomic nervous system is control of cardiovascular function. Drugs affecting autonomic activity are useful in controlling blood pressure in essential hypertension. This section describes drugs that exert their antihypertensive action on the sympathetic division of the autonomic nervous system. These drugs can conveniently be divided into four groups according to their site of action: (1) α-adrenergic receptor–blocking drugs, (2) β-adrenergic receptor–blocking drugs, (3) drugs altering peripheral adrenergic transmission, and (4) drugs acting on the CNS. (Other drugs that alter adrenergic function, such as monoamine oxidase inhibitors, have been used in treating hypertension, but their use has been superseded in almost all cases by newer agents with fewer adverse effects and greater effectiveness.) Only actions and side effects pertinent to antihypertensive use of agents affecting adrenergic function are described here. For discussion of other uses and actions of these drugs, see Chapter 7.

β-Adrenergic Receptor—Blocking Drugs

The structures of several β-adrenergic receptor–blocking drugs are shown in Figure 28-7. Propranolol, the prototype for this class of drugs, and its congeners are not only used as antihypertensives, but also are used in many other disorders, including cardiac arrhythmias, angina pectoris, and migraine headache. As indicated in Chapter 7, some of these agents, including propranolol, block β_1 and β_2 receptors, whereas others, such as metoprolol, have a selective effect on β_1 receptors of the heart. Some drugs classified as β-adrenergic blocking drugs are actually partial agonists, and some exert a membrane-stabilizing effect analogous to that of the local anesthetics. Because the local anesthetic action of β-blocking drugs occurs at doses higher than those used clinically, it may not be clinically relevant.

Pharmacologic effects

The various β-adrenergic receptor–blocking drugs are about equally effective in the management of hypertension, regardless of subtype selectivity. They can be used alone or in combination with diuretics and other antihypertensive medications. Although much information is available, the exact mechanisms by which these drugs decrease blood pressure remain equivocal. Their effects have been attributed to the following actions: blockade of β_1 receptors resulting in decreased CO, decreased renin secretion, decreased central sympathetic outflow, blockade of prejunctional β receptors on adrenergic nerve endings, and resetting of baroreceptors.[20] Of these mechanisms, the first two are probably the most important for blood pressure control. Some investigators believe that hypertension characterized by high CO or high plasma renin activities represents a specific indication for β receptor antagonist therapy. Partial β receptor agonists produce less bradycardia than β receptor antagonists. Cardioselective β-adrenergic receptor antagonists, having less affinity for bronchial β_2 receptors, are less likely to precipitate asthmatic attacks in susceptible individuals.

Absorption, fate, and excretion

The pharmacokinetics of β-adrenergic receptor–blocking drugs are strongly influenced by lipid solubility, as illustrated by the highly lipophilic propranolol and the poorly lipid-soluble nadolol and atenolol. Propranolol and most β-adrenergic blocking agents are readily absorbed from the gastrointestinal tract, although bioavailability of an administered dose is often restricted to 50% or less by extensive first-pass metabolism in the liver. The bioavailability of nadolol and atenolol is limited to a similar extent because of incomplete absorption. Plasma protein binding, a factor that also tends to correlate with lipid solubility, ranges from 10% (atenolol) to 90% (propranolol).

Metabolism and excretion also vary with the particular β blocker. Propranolol is almost entirely biotransformed in the liver; nadolol and atenolol are essentially excreted unchanged in the urine; agents of more intermediate lipid solubility show a mixture of elimination pathways. Although the plasma half-life of most β-adrenergic receptor antagonists approximates that of propranolol (3 to 5 hours), the slow excretion of nadolol (half-life up to 24 hours) gives the drug an extended duration of action that permits once-daily dosing.

Adverse effects

β-Adrenergic receptor antagonists cause various side effects; tolerance may develop to some but not to others. The side effects to which early tolerance may develop include nausea, vomiting, anorexia, confusion, dizziness, fatigue, sleep disturbances, and depression.

A major toxic effect of β-adrenergic receptor antagonists is the aggravation of an existing defect in myocardial contractility or atrioventricular conduction. Congestive heart failure and bradyarrhythmias may be exacerbated. (β blockers are used in the treatment of heart failure, however, as discussed in Chapter 25.) Blockade of β receptor–mediated vasodilation

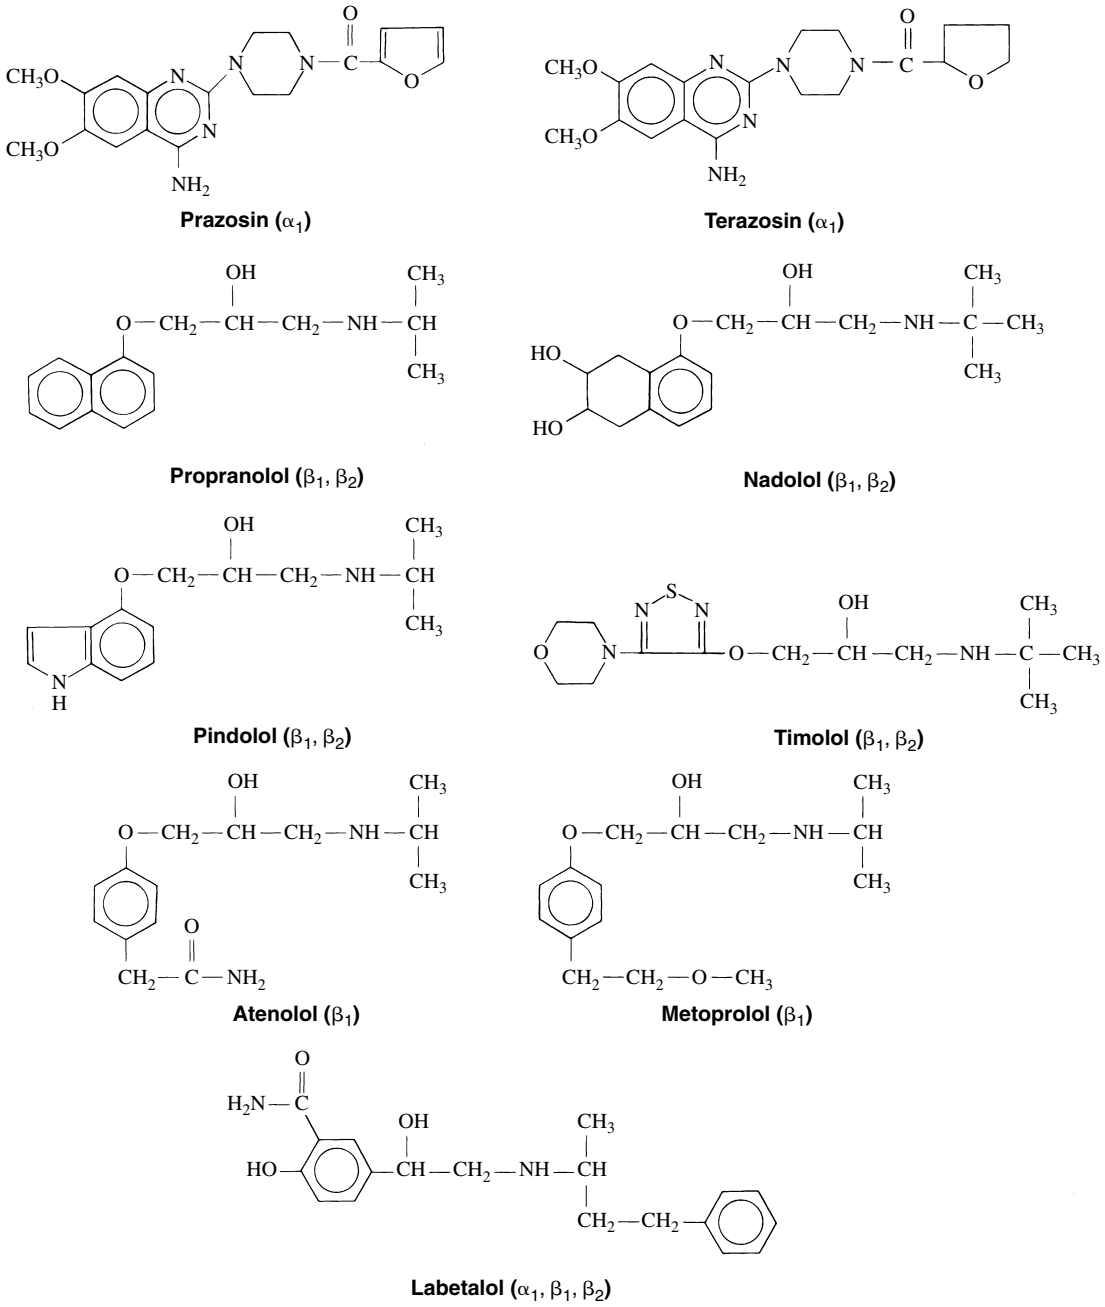

FIGURE **28-7** Structures of some α-adrenergic and β-adrenergic receptor–blocking drugs and their receptor selectivity.

may worsen peripheral arterial insufficiency, intermittent claudication, and Raynaud's phenomenon. Bronchospasm may also be induced in asthmatics, particularly with nonselective β antagonists.

Nonselective β blockers and, to a lesser extent, selective β_1-adrenergic receptor antagonists, inhibit the ability of endogenous catecholamines to elevate plasma glucose concentrations and should be used with caution in patients prone to hypoglycemia or patients being treated with insulin or sulfonylureas for diabetes. All blockers can reduce the tachycardia resulting from hypoglycemia. They may mask an important sign used to indicate overdosage of hypoglycemic agents.

Abrupt withdrawal of β-adrenergic receptor antagonists in patients with coronary heart disease increases the likelihood of severe ischemic events and may lead to anginal pain, myocardial infarction, or life-threatening arrhythmia. Abrupt withdrawal in hypertensive patients may result in increased blood pressure and heart rate, palpitation, tremors, and sweating. It is important that dosages be gradually decreased when drug treatment with β blockers is terminated.

Salt and water retention, which is a problem with some antihypertensive medications, has not been reported with the β-adrenergic receptor–blocking drugs. Postural hypotension is also not generally encountered.

Selective α_1-Adrenergic Receptor—Blocking Drugs

Prazosin is the first of a group of selective α_1-adrenergic receptor–blocking agents used for the treatment of hypertension. Terazosin and doxazosin have a similar action. The chemical structures of these drugs are shown in Figure 28-7,

and their general pharmacologic characteristics are discussed in Chapter 7.

Pharmacologic effects

The hypotensive effect of these drugs is ascribed to vasodilation of arterioles and capacitance veins. The action is a result of blockade of α_1 receptors on vascular smooth muscle. In contrast to older, nonselective α blockers such as phenoxybenzamine, these drugs have a low affinity for α_2 receptors. They can be used in hypertension ranging from mild to severe, alone, with diuretics, or with other antihypertensive drugs.

Nonselective α-adrenergic receptor blockers are used only occasionally in therapy. Their ability to block α_1 and α_2 receptors is useful in treating hypertension resulting from pheochromocytoma. With this disease, α_1 and α_2 receptors play a major role in the hypertensive response to the elevated circulating catecholamine concentrations. Phentolamine is a competitive antagonist, whereas phenoxybenzamine is a noncompetitive antagonist. Tolazoline is another drug that is a competitive antagonist at α_1 and α_2 receptors, with a slight preference for α_2 receptors. It has limited clinical use.

The adverse effects of nonselective α-adrenergic receptor antagonists are more notable than the adverse effects of selective α_1-adrenergic receptor blockers. Inhibition of prejunctional α_2 receptors accounts for the greater reflex tachycardia seen with nonselective blockers. There is a higher incidence of orthostatic hypotension and fluid retention compared with selective α_1-adrenergic receptor antagonists.

Absorption, fate, and excretion

Prazosin and terazosin are rapidly absorbed from the gastrointestinal tract and are available only for oral use. Prazosin undergoes more first-pass metabolism than terazosin or doxazosin. Prazosin is bound significantly to plasma α_1-acid glycoprotein and is excreted principally as glucuronide conjugates, with approximately 90% appearing in the feces and 10% appearing in the urine. The plasma half-life of prazosin (approximately 2 hours) does not correlate with the duration of its hypotensive effect because of tissue binding and the formation of active metabolites, and the drug is administered two to three times daily. Terazosin is eliminated more slowly (half-life of 12 hours), which usually permits once-daily dosing. The half-life of doxazosin is approximately 22 hours. Terazosin and doxazosin are highly bound to plasma proteins and extensively metabolized.

Adverse effects

Prazosin and other α_1-adrenergic receptor blockers produce less reflex tachycardia than direct vasodilators or nonselective α-adrenergic receptor blockers. Nevertheless, reflex tachycardia may be significant. Syncope from orthostatic hypotension may occur with the initiation of therapy. This heightened response early in therapy has been termed the *first-dose effect*.[6] Postural hypotension usually abates with continued therapy. These drugs share an array of other side effects, including gastrointestinal upset, palpitation, tinnitus, headache, rash, edema, and urinary incontinence. Inhibition of ejaculation may also occur.

α_1-Adrenergic and β-Adrenergic Receptor Blockers

Labetalol is a competitive blocker of α_1, β_1, and β_2 receptors, with a greater affinity for β receptors. It also exerts some β_2-agonistic activity and inhibits norepinephrine uptake by the presynaptic nerve terminal. This extensive pharmacologic profile results from the fact that the drug is composed of four different diastereoisomers, each of which has distinct effects. Labetalol has been used singly and in combination with other antihypertensive agents. Used orally and intravenously, labetalol undergoes significant first-pass metabolism in the liver, accounting for approximately 75% of an oral dose. It has a half-life of approximately 8 hours and is metabolized to the glucuronide conjugate. Labetalol is especially useful in treating pheochromocytoma and hypertensive emergencies. Its adverse effects include gastrointestinal disturbances, dry mouth, fatigue, nervousness, paresthesias, orthostatic hypotension, and bradycardia. Patients with asthma are at risk of bronchospasm.

Carvedilol is the second drug with mixed α_1-adrenergic and β-adrenergic receptor–blocking activity to be marketed for the treatment of hypertension and heart failure. As with labetalol, several stereoisomers contribute to the drug's complex pharmacologic characteristics. The pharmacokinetic profile is similar to that of labetalol; however, one of the isomers of carvedilol, which contributes roughly half of the drug's α-blocking activity, accumulates up to threefold in patients genetically deficient in cytochrome P4502D6 activity. Carvedilol is available only for oral use.

Drugs That Affect Adrenergic Transmission

Guanethidine, guanadrel, and the rauwolfia alkaloid reserpine exert their primary antihypertensive action on peripheral postganglionic adrenergic nerve endings and are classified as adrenergic neuron–blocking drugs. They are rarely used today for the treatment of hypertension.

Pharmacologic effects

The ultimate effect of reserpine, guanethidine, and guanadrel is depletion of norepinephrine from adrenergic nerve endings, although the mechanism by which depletion occurs with reserpine differs from that of guanethidine and guanadrel. All three drugs must enter the adrenergic nerve ending to exert an antihypertensive effect. Reserpine inhibits the active uptake of catecholamines into the storage vesicles of the nerve terminal. Inhibition of synaptic transmission occurs in concert with the progressive depletion of neurotransmitter. The mechanisms of action of guanethidine are the same as guanadrel. After intravenous injection, guanethidine yields a complex response. Guanethidine may lead to an initial increase in blood pressure caused by the release of catecholamines, which gives way several hours later to extended hypotension associated with inhibition of evoked norepinephrine release. Only the hypotensive effect is usually observed with oral use. The inhibition of norepinephrine release seems to result from a local anesthetic effect on the adrenergic nerve terminal. Competition between norepinephrine and guanethidine for uptake into the nerve terminal and storage in the adrenergic vesicles eventually causes depletion of norepinephrine, but this outcome, although supportive of a decrease in sympathetic activity, is not crucial to the therapeutic effect.

The cardiovascular manifestations that result from these actions and make these agents useful in treating hypertension are decreases in peripheral resistance and CO. Reserpine enters the CNS, and some of its antihypertensive action may be caused by effects at this site. Guanethidine and guanadrel do not readily cross the blood-brain barrier and exert their actions solely on peripheral postganglionic neurons.

Absorption, fate, and excretion

Reserpine is readily absorbed from the gastrointestinal tract, but exhibits a slow onset of antihypertensive effect (3 weeks for maximum effect). Its duration of action is long, probably owing to its strong binding to amine transport sites in storage granules. It is excreted as the parent compound and as various metabolites.

Although available only for oral use, guanethidine is poorly absorbed from the gastrointestinal tract, varying from 3% to 30% among different individuals. Guanethidine and its metabolites are slowly excreted in the urine, and small

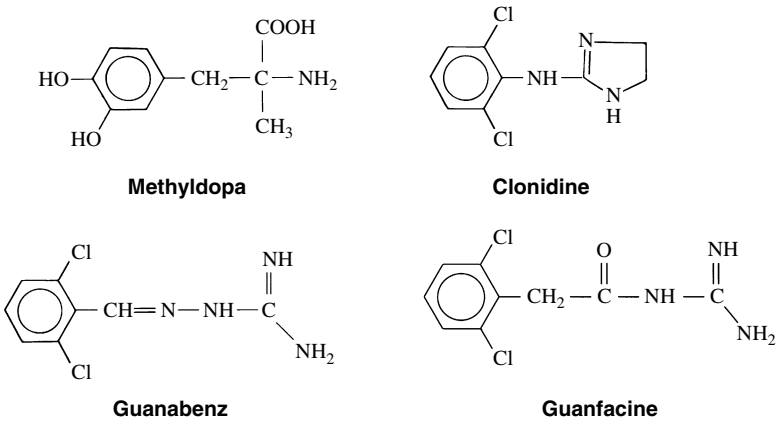

FIGURE **28-8** Structural formulas of centrally acting antihypertensive drugs.

amounts remain in the tissues for prolonged periods (2 weeks). Guanadrel has better absorption, a more rapid onset, and a shorter duration of action than guanethidine.

Adverse effects

The most frequent untoward effects of reserpine are results of actions on either the CNS or the gastrointestinal tract. Sedation is common. Nightmares and emotional depression leading to suicidal tendencies are possible with large doses. Abdominal cramps and diarrhea result because reserpine reduces sympathetic function, resulting in greater parasympathetic effects. Reserpine can also cause nasal congestion. This effect is not serious in adults. Reserpine passes the placental barrier, however, and can cause nasal congestion, cyanosis, drowsiness, and gastrointestinal disturbances in newborns when given before term.

The major troublesome adverse effect of guanethidine is orthostatic hypotension. Other side effects include difficulty in ejaculation, nocturia, intestinal cramps, Na^+ and water retention, bradycardia, flushing, weakness, depression, and diarrhea. Pharmacologic properties of guanadrel are essentially the same as those of guanethidine, but its use is associated with a lower frequency of diarrhea.

Centrally Acting Antihypertensive Drugs

Methyldopa, clonidine, guanabenz, and guanfacine are drugs that exert their antihypertensive effect by stimulating α_2 receptors in the brainstem. As a result, these drugs reduce sympathetic outflow from the brain. The structures of methyldopa, clonidine, guanabenz, and guanfacine are shown in Figure 28-8. The structural similarity of methyldopa to the catecholamine transmitter norepinephrine is obvious. Clonidine, guanabenz, and guanfacine are not chemically related to norepinephrine but are very similar in structure to the α-adrenergic receptor–blocking drug tolazoline.

Pharmacologic effects

Methyldopa, a prodrug, is biotransformed in the brain to α-methyldopamine and then to α-methylnorepinephrine. The latter metabolite probably stimulates important α_2-adrenergic receptor sites in the medulla, resulting in inhibition of central sympathetic outflow. In addition, there is evidence that vagal activity to the heart is increased. Clonidine, guanabenz, and guanfacine seem to act directly as central α_2-adrenergic receptor agonists. With all four drugs, the reduction in central sympathetic outflow and increased vagal activity lead to reduced peripheral vascular resistance and CO. It is uncertain whether presynaptic or postsynaptic medullary α_2 receptors play the predominant role in mediating the antihypertensive response.

Absorption, fate, and excretion

Methyldopa can be given orally or intravenously (as methyldopate hydrochloride). Approximately 25% to 50% of an orally administered dose of methyldopa is absorbed from the gastrointestinal tract. Although methyldopa and its metabolites appear rapidly in the urine, significant concentrations remain in the body for longer periods. It has a long duration of action (up to 24 hours), probably because α-methylnorepinephrine is not metabolized by monoamine oxidase, but is stored in synaptic vesicles in central adrenergic nerve terminals.

Clonidine is available for oral and parenteral use and is well absorbed after oral administration. Peak plasma concentrations are achieved in 3 to 5 hours; its half-life is approximately 10 hours. Approximately 50% is metabolized in the liver. The remaining clonidine and its metabolites are primarily excreted in the urine.

Approximately 75% of an oral dose of guanabenz is absorbed, but hepatic metabolism decreases bioavailability. Peak plasma concentrations appear 2 to 5 hours after administration. The plasma half-life is approximately 6 hours. A large percentage of guanabenz is metabolized in the liver and excreted by the kidney. Guanfacine is rapidly and nearly completely absorbed from the gastrointestinal tract. It has a half-life of 14 to 17 hours. The drug is partly hydroxylated, and parent drug and metabolites are excreted in the urine.

Adverse effects

Untoward effects of methyldopa include drowsiness, depression, nightmares, dry mouth, and nasal stuffiness.[24] The drowsiness caused by this drug, although usually transient, may be particularly bothersome. Orthostatic hypotension may occur but is less frequent than with guanethidine because the baroreceptor reflex is not greatly affected by centrally acting drugs. Extrapyramidal reactions, prolactin release, and impotence may also occur. Hepatitis, a lupus-like syndrome, drug fever, and blood dyscrasias are rare adverse manifestations.

The most common side effects of clonidine are dry mouth and sedation.[24] The incidence of these effects is high, but some tolerance may develop during long-term therapy. Other side effects include parotid gland pain, nightmares, and insomnia. Constipation and impotence occur in a small percentage of patients treated with clonidine. Other, less frequent adverse effects are allergic reactions and orthostatic hypotension. Rebound hypertension has been observed on abrupt withdrawal of clonidine therapy. The sudden withdrawal of clonidine is also associated with tachycardia, anxiety, and insomnia. When withdrawal is necessary, the dosage should be reduced gradually.

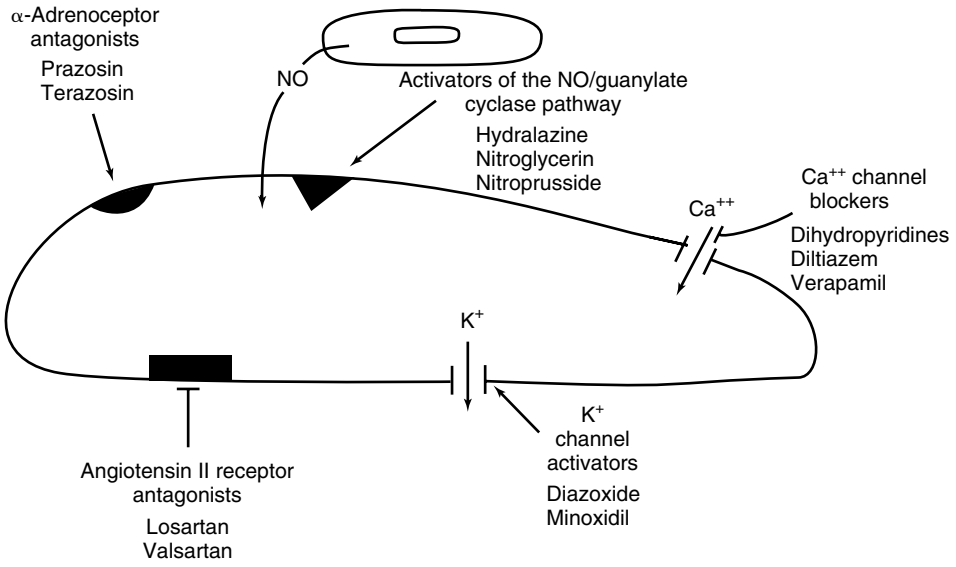

FIGURE **28-9** Sites of action of drugs that relax vascular smooth muscle. Various drug types that act on the vascular smooth muscle cell (*bottom*) are depicted. An endothelial cell (*top*) that releases nitric oxide (*NO*) is also shown. *PDE-5*, Phosphodiesterase 5.

Guanabenz has not been found to cause postural hypotension. Adverse side effects, listed in order of decreasing frequency, are drowsiness, dry mouth, dizziness, weakness, and headache. Side effects of guanfacine are mild and dose-related. The side effects include fatigue, dizziness, dry mouth, insomnia, and impotence, but they tend to be less disturbing than with clonidine or guanabenz. Abrupt withdrawal of guanabenz and guanfacine has been associated with rebound hypertension.

Direct-Acting Vasodilators

Hydralazine, minoxidil, diazoxide, nitroprusside, nitroglycerin, and epoprostenol are considered together in this section because they exert their primary antihypertensive effect through a direct action on vascular smooth muscle. Figure 28-9 summarizes the functional relationship between vascular endothelial cells and vascular smooth muscle and depicts the site of action of the direct-acting vasodilators and other drugs that relax vascular smooth muscle by inhibiting membrane-bound proteins involved in contractile responses.

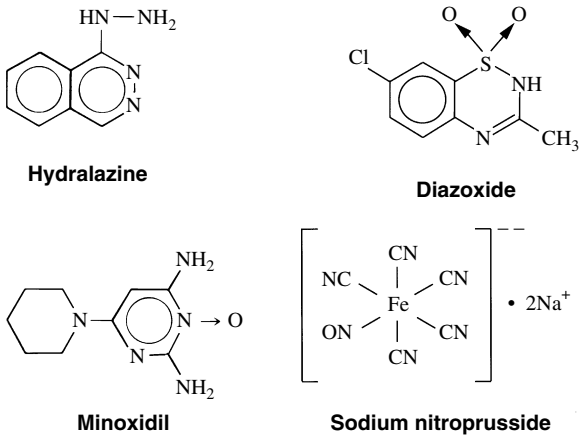

FIGURE **28-10** Structural formulas of some direct-acting vasodilators.

Hydralazine

Hydralazine is one of a series of phthalazine derivatives that have been shown to reduce blood pressure and is the only agent of this series available in the United States. The chemical structure of this compound is shown in Figure 28-10.

Pharmacologic effects. Hydralazine exerts a preferential effect on arterioles compared with veins. The resulting changes are decreased peripheral resistance; decreased blood pressure; and reflexively increased heart rate, stroke volume, and CO. It stimulates guanylyl cyclase in vascular smooth muscle cells, leading to a decrease in muscle tone. The preferential effect on arterioles reduces the incidence of orthostatic hypotension. Reflex inotropic and chronotropic effects that accompany hydralazine vasodilation may cause exacerbation of existing angina pectoris. Hydralazine has no important therapeutic actions on systems other than the cardiovascular system.

Absorption, fate, and excretion. Hydralazine is available for parenteral and oral use. It is readily absorbed from the gastrointestinal tract, and peak blood concentrations are reached in 1 hour. The plasma half-life is also approximately 1 hour; however, hydralazine exhibits a high affinity for vascular muscle and is slowly removed from these sites. Only a small percentage of hydralazine is excreted unchanged, with the major portion undergoing acetylation. A dichotomous distribution exists in the rate of metabolism, with half of the population being characterized as fast acetylators.

Adverse effects. A high incidence of side effects is associated with hydralazine therapy. More common untoward effects are palpitation (and angina in susceptible patients), headache, anorexia, nausea, dizziness, and sweating. Less frequently encountered effects include nasal congestion, flushing, tremors, cramps, postural hypotension, and depression. Tolerance to these effects may develop, especially if the initial dosage is gradually increased. Long-term administration of hydralazine in large doses may cause a syndrome resembling lupus erythematosus, particularly in slow acetylators.

Minoxidil

Minoxidil is another antihypertensive drug that acts chiefly through arteriolar vasodilation. The chemical structure of this piperidinopyrimidine is shown in Figure 28-10. Minoxidil is reserved for use in patients refractory to other therapy.

Pharmacologic effects. Minoxidil, similar to other peripheral vasodilators, reduces blood pressure by decreasing TPR. Minoxidil activates K^+ channels, resulting in hyperpolarization, stabilization of the smooth muscle plasma membrane, and reduced contraction. The drug is a prodrug requiring conversion to minoxidil sulfate (a quantitatively minor metabolite) for its vasodilator effect.

The decrease in blood pressure from minoxidil is accompanied by reflex increases in cardiac function, renin secretion, and fluid retention. These potentially adverse responses may be corrected by coadministration of β-adrenergic receptor–blocking agents and diuretics. Minoxidil has no central depressant effects.

Absorption, fate, and excretion. The onset of action of minoxidil after oral administration is rapid, and its hypotensive action is of long duration. This compound is primarily excreted in the urine as the glucuronide conjugate, along with small amounts of the parent compound and hydroxylated derivatives.

Adverse effects. The marked fluid retention caused by minoxidil can lead to congestive heart failure. There are reports of pericardial effusion and cardiac tamponade, sometimes with fatal outcomes. As with other vasodilators, the reflex tachycardia may initiate or intensify angina. Dermatologic reactions and breast tenderness may also occur. Finally, abnormal hair growth, or hypertrichosis, is very common and limits the use of this drug. Topical minoxidil is approved for the treatment of alopecia and baldness, and these indications represent its main therapeutic uses.

Diazoxide

Diazoxide is a nondiuretic thiazide derivative (see Figure 28-10) with direct action as a vasodilator. It reduces blood pressure rapidly, making it useful in hypertensive emergencies and malignant hypertension. Orally, the antihypoglycemic action of diazoxide makes it occasionally useful in the treatment of hypoglycemia caused by insulin.

Pharmacologic effects. Similar to minoxidil, diazoxide acts by opening K^+ channels. Diazoxide has its major effect on arterioles, with much less effect on capacitance vessels. Intravenous administration of the drug routinely leads to tachycardia and increased CO. In contrast to the thiazide diuretics, diazoxide promotes salt and water retention. The opening of K^+ channels accounts for its inhibition of insulin release.

Absorption, fate, and excretion. Diazoxide is restricted to the intravenous route for the treatment of hypertension. In plasma, it is 90% bound to albumin. Its plasma half-life is 20 to 60 hours. Approximately two thirds of the drug is metabolized in the liver. Excretion of metabolites and the parent drug is by the kidney.

Adverse effects. Fluid retention and hyperglycemia can occur, especially if therapy is extended. A diuretic is often required to overcome the fluid retention, and diabetic patients may require added therapy to treat the hyperglycemia. Hyperuricemia, severe hypotension, angina, and cerebral ischemia also may occur.

Sodium nitroprusside

Sodium nitroprusside (see Figure 28-10) is a direct vascular smooth muscle relaxant. Its principal uses are to provide controlled hypotension during surgery and to treat hypertensive emergencies, as described later in this chapter.

Pharmacologic effects. Nitroprusside is a nitrovasodilator. It generates nitric oxide, which activates guanylyl cyclase in vascular smooth muscle.[11] The resulting relaxation of smooth muscle accounts for its antihypertensive response. The drug affects veins and arterioles and reduces preload and afterload. Because capacitance and resistance vessels are dilated, cardiac ischemia and angina are not as frequently associated with nitroprusside as with arteriolar vasodilators.

Absorption, fate, and excretion. Nitroprusside works rapidly after intravenous administration. It is not used orally. In addition to producing nitric oxide, it is converted nonenzymatically to cyanide by red blood cells and metabolized further to thiocyanate in the liver and kidney. The half-life of nitroprusside is measured in minutes; thiocyanate may persist with a half-life of approximately 3 days. Thiocyanate is excreted by the kidney.

Adverse effects. Adverse reactions can be classified as acute or chronic. Acute effects include a precipitous decline in blood pressure, with resultant sweating, vomiting, headache, nervousness, and palpitation. Metabolic acidosis, methemoglobinemia, and cardiac arrhythmias have occurred. Cyanide accumulation may occur in some individuals, leading to toxicity. Thiocyanate may accumulate in patients with renal insufficiency. Thiocyanate may cause psychosis, muscle weakness, and hypothyroid symptoms.

Nitroglycerin

Nitroglycerin is described in detail in Chapter 26. When given intravenously, nitroglycerin is an effective treatment for perioperative hypertension and to induce controlled hypotension during surgery. Similar in mechanism of action to nitroprusside, nitroglycerin exerts a relatively greater effect on capacitance vessels. Continuous infusion with careful monitoring of blood pressure is required for proper control of blood pressure.

Prostacyclin

Epoprostenol, better known as prostacyclin, is a naturally occurring vasodilator (see Chapter 21). Prostacyclin is an autacoid that is released from the endothelium and serves to counterbalance the vasoconstrictor and proclotting influences of thromboxane A_2. It does so by stimulating cell surface prostacyclin (IP) receptors. Epoprostenol is an extremely potent and short-acting (half-life of 6 minutes) vasodilator administered by continuous intravenous infusion to patients with primary pulmonary hypertension refractory to other drugs. The annual costs, including the necessary administration pumps, make this therapy prohibitive for many patients.

Fenoldopam

Fenoldopam is a vasodilator that is used in emergency situations.

Pharmacologic effects. Fenoldopam (Figure 28-11) is an agonist at dopamine D_1 receptors. It stimulates D_1 receptors in blood vessels and results in vasodilation, especially in renal vessels.[9] As such, it increases renal blood flow and decreases blood pressure.

Absorption, fate, and excretion. Fenoldopam is given by continuous intravenous administration and has an elimination

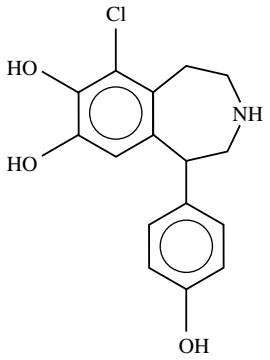

FIGURE **28-11** Structural formula of fenoldopam.

half-life of approximately 5 minutes. Hepatic metabolism by conjugation accounts for the termination of its pharmacologic effects because the metabolites are inactive. Most of the metabolites are excreted by the kidney.

Other Drugs for Treating Hypertension

Endothelin receptor antagonists

Bosentan is a nonselective antagonist at endothelin receptors A and B. Endothelin is a vasoconstrictor peptide released from the endothelial cells of blood vessels. Bosentan is used to treat pulmonary arterial hypertension.

The drug is given orally and its bioavailability is about 50% by this route. Its half-life is about 5 to 6 hours. Adverse effects include headache, dizziness, swelling of the lower extremities, and occasional allergic reactions. Hepatotoxicity has been reported. The drug should not be used in pregnancy.

Darusentan is an investigational drug that is a selective antagonist at the endothelin A receptor. Darusentan, and perhaps other blockers of the endothelin A receptor, seems to be effective in reducing blood pressure in patients who are resistant to other antihypertensive drugs.

Sildenafil

Sildenafil is a drug that is better known by its generic name, Viagra. It has been shown to be effective in improving exercise capacity in patients with pulmonary arterial hypertension.[7] Sildenafil inhibits phosphodiesterase 5, an enzyme that metabolizes cyclic 3′,5′-guanosine monophosphate (cGMP). By increasing cGMP levels in blood vessel smooth muscle cells, it causes relaxation of blood vessels and presumably reduces growth of vascular smooth muscle cells.[8]

MISCELLANEOUS DRUGS

Numerous drugs have limited application in the treatment of hypertension. Some of these agents, such as monoamine oxidase inhibitors and *Veratrum* alkaloids, were previously widely used but have been replaced by more effective or less toxic compounds and are not considered further. Others are restricted to defined roles exclusive of the routine treatment of essential hypertension and are mentioned briefly.

Ganglionic blocking drugs, discussed in Chapter 10, previously were used for the long-term treatment of hypertension. They are rarely prescribed today because of postural hypotension, impotence, and other side effects associated with their use. Trimethaphan infused intravenously is effective in some hypertensive emergencies and to induce a hypotensive state during surgery.

Metyrosine (α-methyltyrosine) is an inhibitor of tyrosine hydroxylase, the rate-limiting enzyme in the formation of norepinephrine and epinephrine. Although not recommended for essential hypertension, metyrosine is useful, often in combination with phentolamine, in the pharmacologic amelioration of pheochromocytoma.

BOX **28-3**

Drugs for Long-term Treatment of Hypertension

Drugs More Commonly Used
Diuretics
Angiotensin-converting enzyme inhibitors
Angiotensin II receptor blockers
Ca^{++} channel blockers
β-adrenergic receptor blockers
α_1-adrenergic receptor blockers

Drugs Less Commonly Used
Aliskiren
Centrally acting antihypertensive drugs
Hydralazine
Minoxidil
Reserpine
Guanethidine, guanadrel

TREATMENT OF HYPERTENSION

Treatment of hypertension often includes pharmacologic and nonpharmacologic approaches for optimal control. Although the latter subject is beyond the scope of this discussion, dietary modification to reduce body weight and decrease Na^+ intake causes demonstrable reductions in blood pressure. Na^+ restriction, even within the well-controlled DASH diet, has been shown to reduce blood pressure.[1] The reduction in blood pressure is proportional to the reduction in Na^+ intake.[17] Restriction of fat intake and alcohol ingestion and cessation of smoking are also important considerations in lessening the dangers of cardiovascular diseases associated with hypertension. Optimal pharmacotherapeutic treatment is based on appropriate diagnosis, proper drug and dose selection, and good patient compliance. Inasmuch as essential hypertension in its early states is asymptomatic, compliance depends strongly on the avoidance of side effects and the simplicity of the therapeutic regimen.

Six drug classes are currently the most commonly used antihypertensive drugs: diuretics, ACE inhibitors, angiotensin II receptor blockers, CCBs, β-adrenergic receptor blockers, and α_1-adrenergic receptor blockers (Box 28-3). Diuretics are considered the most appropriate first choice for most hypertensive patients.[2] A second drug from one of the other categories, such as a β blocker, is often required for blood pressure control.

Therapy needs to be tailored to the patient. When used alone, ACE inhibitors are usually less effective in African American patients than in white patients, whereas diuretics may be nearly equally useful in both groups. This selectivity of effect correlates with the typically lower contribution of the renin-angiotensin system to hypertension in African Americans and their greater Na^+ sensitivity. Age may also contribute to the response. Certain disease states can also affect the choice of drug. β-Adrenergic receptor blockers are especially useful in patients with a history of migraine headache, angina pectoris, heart failure, or myocardial infarction. β-Adrenergic receptor blockers may be particularly useful in certain cases of blood lipid disorders because they can decrease low-density lipoprotein and increase the high-density lipopro-

tein/total cholesterol ratio. Diabetic patients gain added benefit from treatment with an ACE inhibitor because of the renoprotective effect of the drugs.

For initial therapy of hypertension, a low dose of a thiazide diuretic is recommended. An ACE inhibitor is also considered a logical first choice for many patients.[12] When a single drug is ineffective, combination therapy may be required. Drugs such as the β-adrenergic receptor blockers, ACE inhibitors, or angiotensin II receptor blockers are commonly used with diuretics, sometimes in combination with additional agents. Centrally acting antihypertensives can be combined with CCBs with or without a diuretic. Hydralazine, when used, is combined with a β-adrenergic receptor blocker. The addition of the β blocker prevents tachycardia resulting from hydralazine and enhances the antihypertensive response. In addition to their hypotensive effect, the diuretics reduce fluid retention caused by some antihypertensive drugs.

Severe hypertension almost always requires use of more than one drug. Certain drugs are used only in refractory hypertension. These drugs include guanethidine and minoxidil, each used in combination with a diuretic and other drugs.

Hypertensive Emergencies

In contrast to the gradual increase in blood pressure seen in essential hypertension, a sudden elevation of blood pressure to severely hypertensive levels may sometimes occur. Hypertensive emergencies may arise in the course of any hypertensive disease, including renal hypertension, toxemia of pregnancy,[9] or pheochromocytoma. These situations, regardless of cause, are life-threatening and require immediate reduction of blood pressure.[9] Although it is beyond the scope of this discussion to examine in detail the causes of hypertensive emergencies or the pharmacologic management of these conditions, a brief review is provided.

Acute hypertensive episodes can be characterized on the basis of the potential danger to the patient. True emergencies are situations in which greatly elevated blood pressure must be lowered immediately to avoid progression of end-organ damage. Hypertensive urgencies call for control within several hours to reduce patient risk.[9] Management of a true hypertensive emergency necessitates parenteral therapy and intensive monitoring. Table 28-2 lists the various parenteral drugs indicated for such emergencies and salient facts pertaining to their use. Although rapid control of excessively high blood pressure is sometimes needed to avert necrotizing arteriolitis, hemorrhage, and tissue damage, it is not without risk. A rapid reduction in blood pressure may lead to inadequate tissue perfusion, cerebral ischemia, and angina pectoris. When time permits, as in the treatment of hypertensive urgencies, the use of oral medications (see Table 28-2) provides a safer approach that minimizes the possibility of excessive hypotension and lessens the need for constant monitoring.

Antihypertensive Drug Withdrawal Syndrome

Withdrawal of antihypertensive drug therapy has been associated with several signs and symptoms, depending on the abruptness of the withdrawal, the degree of hypertension, and the drugs involved. The classes of drugs involved in withdrawal reactions include centrally acting agents, β-adrenergic receptor–blocking drugs, neuronal blocking agents, and some vasodilators (e.g., minoxidil, sodium nitroprusside, and nifedipine). Reported responses include rebound hypertension, tachycardia, angina, heart attack, and sudden death.

Recommendations for managing hypertensive patients on drug therapy include encouraging patient compliance and avoiding excessive dosage. To avoid complications, antihypertensive drugs should be withdrawn slowly, and patients should be carefully monitored, especially patients with coronary artery or cerebrovascular disease.

TABLE 28-2

Drugs Used in Acute Hypertension

DRUG	COMMENT
Hypertensive Emergencies (Parenteral)	
Sodium nitroprusside	Often used; requires continuous monitoring
Nitroglycerin	Indicated in patients with ischemic heart disease
Labetalol	Useful in thyrotoxicosis and pheochromocytoma and as a substitute for Na^+ nitroprusside when continuous monitoring is unavailable; contraindicated in patients with systolic heart failure, airway disease, or heart block
Diazoxide	Occasionally used when continuous monitoring is unavailable
Fenoldopam	Has rapid onset and short half-life
Hydralazine	Used in hypertensive states associated with pregnancy
Nifedipine	Short-acting, also used for hypertensive emergencies during pregnancy
Hypertensive Urgencies (Oral Preferred)	
Clonidine	Requires good patient compliance
Captopril	Responses unpredictable
Labetalol	See labetalol above

IMPLICATIONS FOR DENTISTRY

Drug Interactions

Because there are several categories of antihypertensive drugs (each class having a different mechanism of action), there are numerous possibilities for drug interactions. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) antagonize many antihypertensive drugs (see Chapter 21). The antihypertensive effect of ACE inhibitors is reduced by aspirin. In addition, the effect of diuretics is inhibited by NSAIDs. This interaction apparently results from the inhibitory effect of NSAIDs on prostaglandin synthesis. NSAIDs also reduce the antihypertensive effect of β blockers. Although the role of prostaglandins in antihypertensive therapy is unknown, these autacoids are important in maintaining renal blood flow and urine output. Patients should be advised of this drug interaction; in the event that blood pressure control is lost, substitution with acetaminophen with or without opioid supplementation is advised.

In general, the use of vasoconstrictors in local anesthesia is not contraindicated in hypertensive patients, especially in patients whose blood pressure is well controlled. A possible exception to this statement is a patient receiving an adrenergic neuron–blocking or adrenergic neuron–depleting drug, such as guanethidine or reserpine, or a nonselective β-adrenergic receptor–blocking drug such as propranolol. Long-term use of guanethidine-related drugs produces supersensitivity to the actions of exogenously administered catecholamines. Injudicious use of sympathomimetic amine vasoconstrictors in local anesthetic solutions could possibly lead to serious disturbances of blood pressure and cardiac rhythm. Nonselective β-adrenergic receptor blockers prevent the decrease in peripheral vascular resistance normally caused by doses of epinephrine used in local anesthesia. Unopposed α-agonistic action may lead to an acute hypertensive episode. To avoid potential

complications, the blood pressure of a patient on any of these medications should be taken before and 5 minutes after the injection of a small amount of local anesthetic (e.g., 1 mL of 2% lidocaine with 1:100,000 epinephrine). If no significant reaction is observed, dangerous hypertensive responses to additional local anesthetic are unlikely.

The use of epinephrine-impregnated retraction cord is contraindicated in patients with compromised cardiovascular function, including hypertensive patients. Significant amounts of epinephrine can be absorbed, especially if the gingiva is abraded or multiple teeth are involved.

Although not widely used, centrally acting sympatholytics, which have a sedative side effect, are important to the dentist. In dealing with patients taking these drugs, the dentist must proceed cautiously when using antianxiety agents or other drugs that depress the CNS. In combination with antihypertensives with sedative side effects, these agents may lead to excessive CNS depression. Use of a smaller dose is advised in the premedication of a patient taking methyldopa, clonidine, guanabenz, guanfacine, or reserpine for hypertension.

Adverse Effects

One adverse effect of significance to the dentist that is associated with antihypertensive medication is orthostatic, or postural, hypotension. After being in a supine position, many patients receiving antihypertensive therapy may be unable to compensate adequately for a sudden change in position. Such patients should be observed carefully at the end of dental appointments. Drugs affecting peripheral adrenergic transmission are most likely to cause orthostatic hypotension, although other drugs may also have this action.

Another adverse effect that has implications in dentistry is inhibition of salivary secretion leading to dry mouth. Xerostomia is especially common in patients medicated with reserpine and centrally acting antihypertensive agents (methyldopa, clonidine, guanabenz, and guanfacine).

Hypertension Detection

The American Heart Association has stressed the need for more effective hypertension detection, and dentists are encouraged to include blood pressure determinations as a part of routine office visits. Studies indicate that many patients identified by dentists as being hypertensive were unaware of their condition. Most of those identified sought medical attention to treat the hypertension.

Screening for hypertension in the dental office is a simple procedure that can be carried out effectively by auxiliary personnel. Because hypertension is a dangerous but asymptomatic disease in its early stages, the dentist's efforts to identify and aid these patients by its detection are worthwhile. The dentist can advise against abrupt withdrawal from antihypertensive medication and inform the patient of the possible hazards of such action.

ANTIHYPERTENSIVE DRUGS

CHAPTER 29

Lipid-Lowering Drugs

GEORGE A. COOK

The transport of lipids in the blood requires their association with proteins. Fatty acids are transported in association with albumin, and triglycerides derived from dietary fat are transported in large macromolecular, cholesterol-containing particles known as *lipoproteins*. Cholesterol plays an essential role in human life as an important component of cell membranes and a precursor of steroid hormones and bile acids in addition to its role in triglyceride transport. Blood cholesterol levels previously thought to be normal are the cause of premature death, however, from coronary artery disease. Atherosclerosis remains the primary cause of premature death in the United States and in other industrialized countries. The major clinical sequelae of elevated lipoprotein levels, known as *hyperlipidemias* or *hyperlipoproteinemias*, are coronary artery disease, cerebrovascular disease, and peripheral vascular disease. The term *hyperlipemia* (which causes acute pancreatitis) is restricted to elevated plasma triglycerides without elevated cholesterol.

Because the deposition of cholesterol in arteries is a defining feature of atherosclerosis, strategies for its prevention and treatment include methods to reduce plasma cholesterol. Dentists need to understand lipid-lowering drugs as the overall dental patient population of the United States matures, and increasing numbers of patients take these drugs for prevention and therapy of atherosclerosis. Dentists also need to follow the development of the cholesterol synthesis inhibitors because of their implication in the stimulation of bone formation through inhibited isoprenoid synthesis leading to decreased osteoclast activity and increased osteoblast differentiation.[23,28]

Guidelines on patient cholesterol management are issued periodically by the Adult Treatment Panel of the National Cholesterol Education Program (NCEP).[18] More recent guidelines have included recommendations for improved lifestyle changes, such as increasing exercise and decreasing consumption of saturated fat and cholesterol, which improve cholesterol levels in some patients without drug therapy.

CHOLESTEROL AND ATHEROSCLEROSIS

Atherosclerosis is caused by development of fatty streaks and plaques in large and medium-sized arteries, especially the aorta, coronary arteries, carotid arteries, renal arteries, and arteries of the legs. Plaques develop in the intimal wall of the vessels after deposition of cholesteryl esters derived from certain lipoproteins. The particular clinical manifestation of atherosclerosis depends on the degree to which the lesions have progressed in a particular part of the vasculature. The presence of atheromatous lesions can have several effects on the circulation to a prescribed area: (1) blood flow may be obstructed by the plaques themselves or by associated thrombi, (2) vascular reactivity and control of blood flow may be lost, and (3) vessels may become weakened and subject to rupture. Observations of initial lesions in young children have shown that this disease begins at an early age and progresses gradually, with clinical symptoms generally appearing much later in life.[35,43]

Foam cells are a primary characteristic of atheromatous plaques. These cells arise from macrophages that invade the injured arterial endothelium and accumulate large pools of cholesteryl esters from nearby trapped lipoproteins. As with all other cells, macrophages possess a mechanism for converting free cholesterol to cholesteryl esters as a protective mechanism to avoid excessive accumulation of free cholesterol in their membranes. Macrophages also possess scavenger receptors in their plasma membranes that bind chemically modified lipoproteins that arise from free radical–mediated oxidation or glycosylation because of poorly controlled diabetes.

The accumulation of foam cells results in a fatty streak visible to the naked eye. Particularly in vascular areas subject to high mechanical shear stresses and turbulent flow, microscopic tearing and disruption of the local endothelium may expose the underlying tissue, resulting in accelerated lipoprotein accumulation, platelet aggregation, and deposition of fibrin. Eventually, an atherosclerotic plaque forms with a thick fibrous cap covering a necrotic center composed of cellular debris and cholesteryl ester deposits.

Lipoprotein Metabolism

Classification of plasma lipoproteins is based on the density of the complexes, with a lower density indicating higher lipid content (Table 29-1). Chylomicrons are the largest particles and possess the greatest proportion of lipid. The other lipoproteins are very-low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), high-density lipoprotein (HDL), and lipoprotein(a). Two separate lipoprotein-producing systems or metabolic pathways are responsible for the transport of lipids (Figure 29-1): the *exogenous pathway*, producing chylomicrons in the intestinal mucosa primarily from dietary fat, and the *endogenous pathway*, producing VLDL in the liver with triglycerides from hepatic metabolism of dietary carbohydrates.

A crucial factor in the understanding of physiologic and pathophysiologic aspects of lipoprotein metabolism is the role played by specific *apoproteins*, the proteins associated with lipoprotein particles. Chylomicrons serve to transport dietary lipids to the sites of use and storage. The major protein component of chylomicrons is apoprotein B48, which initially plays an entirely structural role in formation and transport. It

TABLE **29-1**

Classification and Characteristics of Major Plasma Lipoproteins

LIPOPROTEIN	MAJOR LIPIDS	MAJOR APOPROTEINS	DENSITY (g/mL)	DIAMETER (nm)
Chylomicrons	Dietary triglycerides	B48, CI, CII, CIII, E	<0.98	80-500
Chylomicron remnants	Dietary cholesteryl esters	B48, E		
VLDLs	Endogenous triglycerides	B100, CII, CIII, E	0.98-1.006	30-80
IDLs	Cholesteryl esters, triglycerides	B100, CII, CIII, E	1.006-1.019	25-35
LDLs	Cholesteryl esters	B100	1.019-1.063	15-25
HDLs	Cholesteryl esters	AI, AII*	1.063-1.210	5-12
Lp(a)	Cholesteryl esters	B100, (a)	1.055-1.085	30

*HDL serves as a reservoir for C and E apoproteins, transferring them to newly synthesized chylomicrons (in exchange for A apoproteins) and VLDL particles and removing them as these particles are depleted of triglyceride.
HDLs, High-density lipoproteins; *IDLs,* intermediate-density lipoproteins; *LDLs,* low-density lipoproteins; *Lp(a),* lipoprotein(a); *VLDLs,* very-low-density lipoproteins.

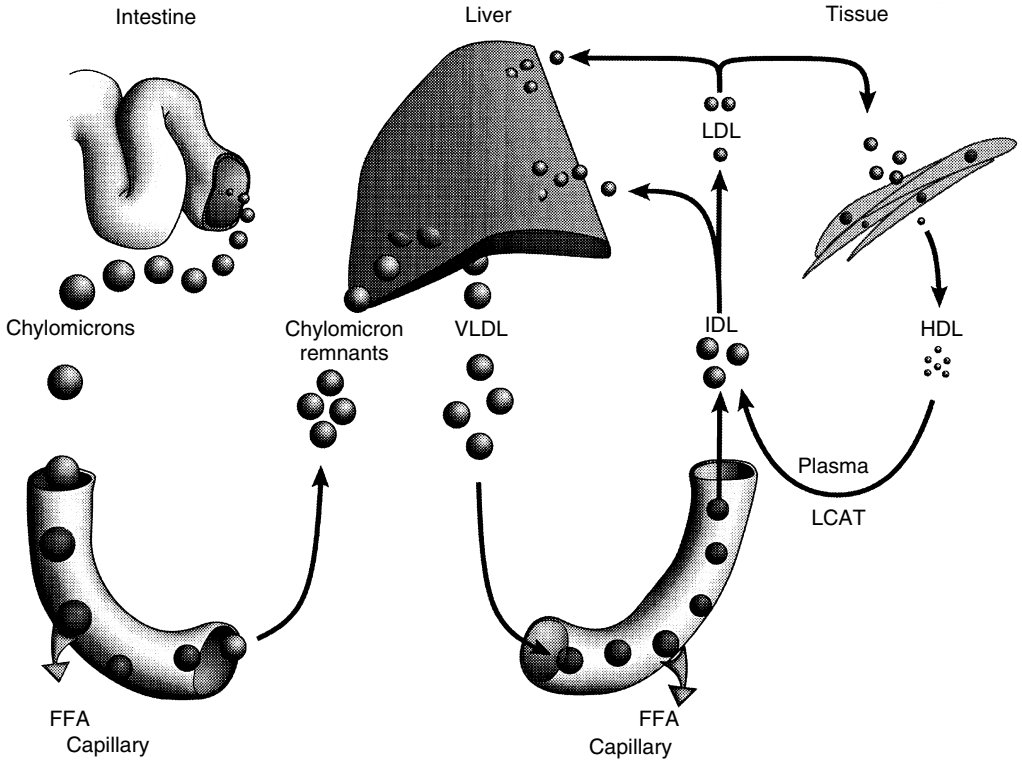

FIGURE **29-1** Pathways of lipid transport. *FFA,* Free fatty acid; *HDL,* high-density lipoprotein; *IDL,* intermediate-density lipoprotein; *LCAT,* lecithin cholesterol acyltransferase; *LDL,* low-density lipoprotein; *VLDL,* very-low-density lipoprotein.

forms the amphipathic coating of the particle along with unesterified cholesterol and phospholipid, which surrounds the hydrophobic core containing triglycerides and cholesteryl esters and allows the particle to remain suspended in an aqueous environment. On reaching the capillary endothelium of muscle and adipose tissue, the chylomicron triglycerides are rapidly degraded to fatty acids, glycerol, and monoglycerides by the enzyme lipoprotein lipase.

Apoprotein CII serves as a stimulus for endothelial lipase activity. The remaining *chylomicron remnants,* depleted of triglycerides and CII but relatively enriched in cholesterol and apoproteins B48 and E, are released back into the circulation. The exogenous pathway terminates in the liver, where the chylomicron remnants are actively taken up by hepatocytes. Apoproteins B48 and E help trigger this receptor-mediated endocytosis. Within the liver, the remnants are digested, releasing the remaining lipids for further metabolism (Figure 29-2).

The hepatic synthesis and release of VLDL particles initiates the endogenous pathway of lipid transport. VLDL is primarily triglyceride and is subject to attack by lipoprotein lipase on activation by apoprotein CII. The resulting IDL particle, greatly reduced in triglyceride content, has two possible fates: (1) a few particles are released and undergo receptor-mediated endocytosis by the liver and lysosomal degradation, or (2) most particles continue further removal of triglyceride and all apoproteins other than B100 to yield LDL. The cholesterol content of LDL is 50% to 60% by weight and normally accounts for 75% of the total plasma cholesterol. Particles of LDL are subject to apoprotein B100–dependent, LDL

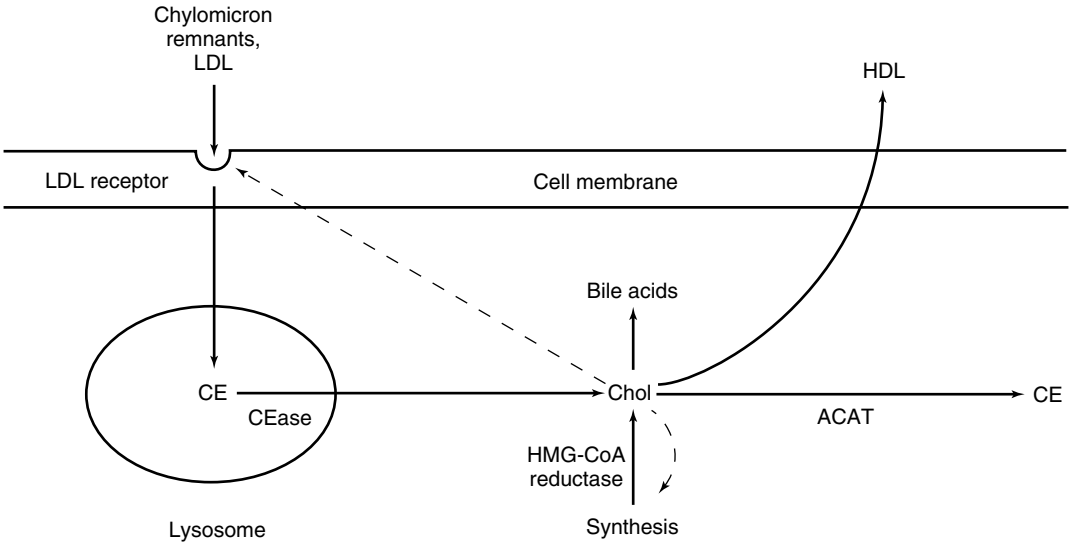

FIGURE **29-2** Cholesterol metabolism and transport. Chylomicron remnants and low-density lipoprotein (*LDL*) particles are actively taken up by hepatocytes through receptor-assisted endocytosis and are metabolized in lysosomes to yield cholesteryl esters (*CE*). Cholesterol-rich LDL is similarly transported and metabolized. In addition, reticuloendothelial cells and phagocytic cells of the vascular wall can ingest LDL by an LDL receptor–independent process. Under the influence of lysosomal acid cholesterol esterase (*CEase*), cholesterol (*Chol*) is made available to the cell. Cholesterol limits its own intracellular concentration by (1) inhibiting LDL receptor synthesis, (2) stimulating its own reconversion to CE by the enzyme acyl CoA cholesterol acyl transferase (*ACAT*), and (3) downregulating the production of 3-hydroxy-3-methylglutaryl–coenzyme A (*HMG-CoA*) reductase, the rate-limiting enzyme of cholesterol synthesis. The inhibitory actions of cholesterol are indicated by *dashed lines*. Cholesterol may also leave the cell to reenter the bloodstream in association with HDL. Cholesterol is converted to bile acids.

receptor–mediated endocytosis by various tissues, most importantly the liver. Excess IDL and LDL, through scavenger uptake by intimal macrophages, account for the cholesterol accumulation in atheromatous lesions. There is no evidence that chylomicrons are involved in this disease process.

The synthesis of cholesterol, regulated by the initial enzyme of the pathway (3-hydroxy-3-methylglutaryl–coenzyme A [HMG-CoA] reductase), is an energetically expensive process because every carbon atom of cholesterol is derived from acetylcoenzyme A, so the maintenance of total body cholesterol is a priority. This is exemplified further by the fact that there is no mechanism in the human body for removal of cholesterol other than conversion to bile acids and fecal excretion. Cholesterol is conserved through *enterohepatic cycling* and *reverse cholesterol transport*, processes that play important roles in energy conservation and sites of action for lipid-lowering drugs.

Enterohepatic cycling includes the following processes[36]: (1) synthesis of cholesterol and conversion to bile acids by the liver, (2) secretion of biliary cholesterol and bile acids into the small intestine, (3) absorption of bile acids from the terminal ileum, and (4) transfer through the portal system and reuptake by the liver. Reverse cholesterol transport is the process by which HDL synthesized by the liver and intestine takes up cholesterol from peripheral cells and transports it back to the liver. HDL cholesterol is sometimes referred to as the "good" cholesterol because it represents the amount of cholesterol being removed from most of the body and because higher levels of HDL cholesterol are associated with decreased risk of atherosclerosis. HDL also assists in the removal of triglycerides from the bloodstream by delivering to chylomicrons and VLDL the C and E apoproteins necessary for their processing.

Role of Lipoproteins in Atherosclerosis

The presence of cholesterol as an integral component of arterial plaques has been known for decades, and many studies have been done to determine whether abnormal concentrations of cholesterol are involved in the origin or progress of plaque formation. These studies have shown that plasma cholesterol concentrations are higher in patients with coronary artery disease than in normal patients, and that the relationship between serum cholesterol concentration and risk of premature death from coronary artery disease is continuous and graded.[38,42] More recent studies of cholesterol reduction therapy in patients with hyperlipidemia have shown that reduction of plasma cholesterol can cause regression of plaque formation and decrease the mortality rate from atherosclerosis.[18,44]

An increase in plasma LDL may be caused either by overproduction of its VLDL precursor or, more commonly, by retarded clearance of LDL from the blood. The plasma half-life of LDL is much longer than the half-lives of VLDL and IDL. Although LDL receptor–dependent uptake predominates normally, only the alternative phagocytic pathway is available in patients with severe familial hypercholesterolemia, who congenitally lack functional LDL receptors.[7] LDL contains most cholesterol in the plasma, and it is the lipoprotein group most directly associated with coronary heart disease.[27,41] High plasma concentrations of HDL are inversely related to the risk of coronary heart disease.[10,41]

Hyperlipidemia may be primary (i.e., genetic in origin) or result from dietary factors; disease states such as diabetes mellitus, hypothyroidism, or uremia; drugs such as alcohol, oral contraceptives, or glucocorticoids; or a combination of causes. A summary of various types of primary hyperlipidemias is provided in Table 29-2.

TABLE **29-2**

Primary Hyperlipoproteinemias: Types and Characteristics

TYPE	LIPOPROTEIN ELEVATED*	BIOCHEMICAL DEFECT (INHERITANCE)†	INCIDENCE	CLINICAL FINDINGS (AGE OF ONSET)	TREATMENT
Monogenic					
Familial lipoprotein lipase deficiency	Chylomicrons (I, V)	Decreased lipoprotein lipase activity (R)	$1:10^6$	Eruptive xanthomas, pancreatitis, abdominal pain, hepatosplenomegaly, lipemia retinalis (childhood)	Fat-free diet
Familial apoprotein CII deficiency	Chylomicrons, VLDL (I, V)	Decreased apoprotein CII activity (R)	$1:10^6$	Pancreatitis, abdominal pain (childhood or adulthood)	Fat-free diet
Familial type 3 hyperlipoproteinemia	Chylomicron remnants, IDL (III)	Dysfunctional apoprotein E plus other defect (R)	$1:10^4$	Palmar and tuberous xanthomas, premature atherosclerosis (adulthood)	Correction of other defect (e.g., hypothyroidism), gemfibrozil or clofibrate, nicotinic acid
Familial hypercholesterolemia	LDL (IIa, IIb)	Dysfunctional LDL receptor (D)	1:500	Xanthomas, arcus corneae, xanthelasma, early and severe atherosclerosis (childhood or adulthood)	Low cholesterol and saturated fat diet, HMG-CoA reductase inhibitor, bile acid—binding resin
Familial hypertriglyceridemia	VLDL (rarely chylomicrons) (IV, V)	Unknown; probably multiple subtypes (D)	1:500	Obesity, hyperglycemia, hyperinsulinemia, increased incidence of hypertension and atherosclerosis (puberty)	Low saturated fat diet, correct contributing factors, avoidance of alcohol and oral contraceptives, nicotinic acid, gemfibrozil
Multiple lipoprotein—type hyperlipidemia	VLDL, LDL (IIa, IIb, IV)	Unknown; probably multiple subtypes (D)	1:250	Premature atherosclerosis (adulthood)	Low saturated fat diet, correction of contributing factors, avoidance of alcohol and oral contraceptives, lipid-lowering drugs
Lp(a) hyperlipoproteinemia	Lipoprotein(a)	Decreased binding to LDL receptor, decreased fibrinolysis	Not determined; wide variance among ethnic groups	Increased incidence of atherosclerosis (adulthood)	Nicotinic acid
Polygenic					
Polygenic hypercholesterolemia	LDL (IIa, IIb)	Unknown but including normal variation in cholesterol metabolism	1:24	Increased incidence of atherosclerosis (adulthood)	Low cholesterol and saturated fat diet, HMG-CoA reductase inhibitor, bile acid—binding resin

*The electrophoretic pattern, or phenotypic expression, of the lipoproteinemia is indicated in parentheses.
†All the monogenic disorders are autosomal.
D, Dominant; *HMG-CoA,* 3-hydroxy-3-methylglutaryl—coenzyme A; *IDL,* intermediate-density lipoprotein; *LDL,* low-density lipoprotein; *Lp(a),* lipoprotein(a); *R*, recessive; *VLDL,* very-low-density lipoprotein.

Risk Factors in Atherosclerosis

In addition to high plasma cholesterol, several risk factors have been identified with an increased incidence of atherosclerosis, including hypertension, cigarette smoking, sedentary habits, obesity, diabetes mellitus, hypothyroidism, male gender, and a family history of atherosclerosis or diabetes. As shown in Table 29-2, the clinical manifestations of genetic or familial hyperlipoproteinemias are severe. The lipid-lowering agents discussed in this chapter have proved quite useful in treating many of these disorders and even in reversing the progression of atherosclerosis in patients without specific metabolic defects in lipid metabolism.

Treatment Guidelines From the National Cholesterol Education Program

The primary guidelines from NCEP for treatment of patients with hyperlipidemia are to increase exercise, decrease saturated fat and cholesterol in the diet, and lower elevated LDL-cholesterol levels using drugs.[18] Diabetes also predicts a high risk for coronary heart disease, and these patients benefit from treatment with hypolipidemic drugs. Diabetic patients usually have elevated triglycerides and low HDL cholesterol, requiring different types of drug treatment. Diabetic patients who have confirmed coronary heart disease are at even greater risk and need more specific, aggressive treatment to decrease risk of mortality.

There is also a greater awareness today of numerous individuals in the United States who have a condition known as *metabolic syndrome*, which is characterized by abdominal obesity, elevated fasting glucose, low HDL cholesterol, elevated plasma triglycerides, and high blood pressure. These patients benefit from increased exercise, modified diet, and treatment of lipid abnormalities.

THERAPEUTIC AGENTS

Therapy with drugs that reduce plasma cholesterol is used to delay or reverse the progression of atherosclerosis and decrease the mortality and morbidity rates from the associated clinical manifestations of this disease. Strong evidence supports the idea that correction or lowering of plasma lipid concentrations is beneficial in many instances.[18,41] These drugs are helpful in treating many familial hyperlipidemias, and they are recommended for use in patients with hyperlipidemias of secondary etiology that cannot be corrected by other means. Lipid-lowering drugs are most frequently administered to patients with a history of ischemic heart disease in an attempt to avoid future fatal episodes of myocardial infarction.

The goal of therapy is to reduce lipid levels as much as possible without producing metabolic derangements or adverse drug effects.[38,42] Altering the diet is generally the initial therapeutic measure, along with correcting any disease state or condition contributing to hyperlipidemia. If nonpharmacologic therapy is insufficient, drug administration should be considered depending on determinants such as age, gender, presence of ischemic vascular disease, and coexistence of other risk factors. Even when pharmacologic antihyperlipidemic treatment is instituted, however, nonpharmacologic management, including reduction of dietary cholesterol and saturated fatty acids, weight reduction, exercise, and smoking cessation, remains the cornerstone of therapy.

The following hypolipidemic agents are considered in this chapter: (1) derivatives of fibric acid, including clofibrate and gemfibrozil; (2) nicotinic acid; (3) the bile acid sequestrants cholestyramine and colestipol; (4) inhibitors of HMG-CoA reductase; (5) cholesterol absorption inhibitors; and (6) other agents. The effects of the major drugs on the various classes of lipoprotein are listed in Table 29-3.

The choice of a drug depends on the lipoprotein profile of the patient, the efficacy of the drug in treating the abnormality, and the ability of the patient to tolerate the agent. Drug therapy to reduce plasma LDL concentrations often begins with an HMG-CoA reductase inhibitor, a bile acid sequestrant, or a combination of the two in reduced dosages. Multiple-drug therapy with agents acting through different mechanisms is common if LDL control is not achieved with a single drug.[31]

Fibric Acid Derivatives

One of the first drugs to be approved for the treatment of hyperlipidemia was clofibrate, a derivative of phenoxyisobutyric acid, which is also known as *fibric acid* (Figure 29-3). Gemfibrozil is safer and more effective than clofibrate, and several second-generation fibrates such as fenofibrate are also more effective. These drugs can influence all the lipoproteins, but are most effective in familial type 3 hyperlipoproteinemia and in patients with elevated VLDL concentrations. Fibric acid derivatives act as ligands for the DNA transcription regulator peroxisomal proliferator–activated receptor α (PPARα),[17] modifying rates of synthesis of specific enzymes. They have been shown to increase significantly the activity of extrahepatic lipoprotein lipase, decrease the hepatic synthesis of fatty acids, and increase hepatic fatty acid oxidation in mitochondria and peroxisomes.

Changes in apoprotein content help increase VLDL catabolism and remnant particle uptake. An inhibition of cholesterol synthesis and an increase in the biliary excretion of cholesterol promote a reduction in LDL in patients without coexisting hypertriglyceridemia. The LDL concentration is often increased, however, by fibrates in patients with elevated amounts of VLDL. Of the more recently developed fibrates, fenofibrate, bezafibrate, and ciprofibrate have been developed in Europe; gemfibrozil and fenofibrate are approved for use in the United States. More recent studies indicate that gemfibrozil is effective in reducing coronary heart disease and stroke by increasing HDL in patients with low HDL and elevated triglycerides.[39,40] The induction of peroxisome proliferation by fibrates has raised the possibility of increased risk of cancer, but more recent studies with gemfibrozil have indicated no increased risk of death from noncoronary heart disease–related events.[40] Fibrates also increase blood urea and creatinine, indicating renal dysfunction, but gemfibrozil seems to be devoid of this side effect.[6]

Clofibrate treatment lowers elevated plasma cholesterol and triglyceride concentrations in most patients.[32,33] It also has been shown to decrease the plasma free fatty acid concentration.[30] The major effect on lipoprotein is a reduction in plasma VLDL concentrations. Clofibrate was the most commonly prescribed lipid-lowering drug in the early 1970s. A failure to reduce fatal heart attack and cardiovascular complications, coupled in some studies with a statistical increase in mortality and morbidity rates from other disorders (e.g., cholelithiasis and gastrointestinal carcinoma),[1] has restricted the use of clofibrate to patients with severe hyperlipoproteinemia intolerant of or unresponsive to gemfibrozil. Infrequent side effects of clofibrate therapy are nausea, diarrhea, muscle cramps, and myalgia. Clofibrate may rarely cause chest pain and cardiac arrhythmias. Clofibrate potentiates the effects of coumarin

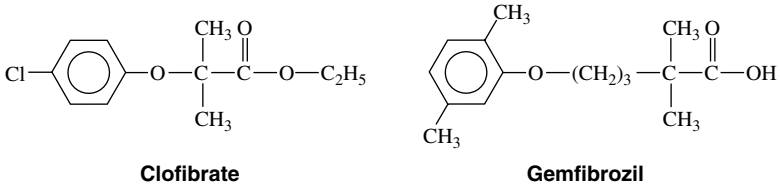

FIGURE **29-3** Structural formula of the fibric acid derivatives clofibrate and gemfibrozil.

TABLE **29-3**

Properties of Lipid-Lowering Drugs

	LIPOPROTEIN CONCENTRATIONS	PLASMA CHOLESTEROL	PLASMA TRIGLYCERIDE	TOXICITY	DRUG INTERACTIONS
Clofibrate	↓ VLDL, ↓ IDL	↓	↓	Nausea, diarrhea, myositis, abnormal liver function tests, skin rash, ventricular ectopy, increased incidence of noncardiac death	Enhanced effect of coumarin anticoagulants
Gemfibrozil	↓ VLDL, ↓ IDL, ↑ HDL	↓	↓	Abdominal pain, epigastric pain, diarrhea, nausea, vomiting, flatulence, rash, headache, dizziness, anemia, eosinophilia, leukopenia	Enhanced effect of coumarin anticoagulants; myopathy with HMG-CoA reductase inhibitors
Nicotinic acid	↓ Chylomicrons, ↓ VLDL, ↓ IDL, ↓ LDL, ↑ HDL	↓	↓	Flushing, pruritus, nausea, diarrhea, glucose intolerance, hyperuricemia, hepatotoxicity	Myopathy, rhabdomyolysis, renal failure with HMG-CoA reductase inhibitors
Cholestyramine, colestipol	↑ VLDL (transient), ↓ LDL	↓	May increase modestly in some patients	Constipation, nausea, abdominal pain, flatulence, biliary tract calcification, steatorrhea, hyperchloremic acidosis	Decreased absorption of thiazides, tetracycline, phenobarbital, thyroxine, digitalis, coumarin anticoagulants
HMG-CoA reductase inhibitors	↓ IDL, ↓ LDL, ↑ HDL	↓	↓	Headache, flatulence, abdominal pain, diarrhea, rash, increased creatine kinase and other enzyme activities, myopathy	Enhanced effect of coumarin anticoagulants; myopathy, rhabdomyolysis, renal failure with nicotinic acid, gemfibrozil, erythromycin, cyclosporine
Ezetimibe	↓ LDL, ↓ HDL	↓	↓	Headache, sinusitis, pharyngitis	Cholestyramine binds ezetimibe and lowers its bioavailability; does not alter bioavailability of digitalis or coumarin anticoagulants

↓, Decrease; ↑, increase.
HDLs, High-density lipoproteins; *HMG-CoA,* 3-hydroxy-3-methylglutaryl—coenzyme A; *IDLs,* intermediate-density lipoproteins; *LDLs,* low-density lipoproteins; *VLDLs,* very-low-density lipoproteins.

anticoagulants, partly by displacing them from protein-binding sites, but mostly because fibrates interfere with the synthesis of several clotting factors (fibrinogen and factor VII).

Gemfibrozil is chemically distinct from other fibrates because it has a propylene connector between the phenoxy and isobutyrate ends of the molecule. The drug has been shown to decrease the concentrations of blood triglycerides, cholesterol, VLDL, IDL, and sometimes LDL. It also tends to increase HDL concentrations more reliably than clofibrate. In contrast to clofibrate, gemfibrozil has been shown to decrease the incidence of myocardial infarction by 34% over 5 years.[16] Principal side effects of gemfibrozil include abdominal pain, diarrhea, nausea, and vomiting. Less frequent adverse effects are headache, dizziness, anemia, rash, eosinophilia, and leukopenia. Similar to clofibrate, gemfibrozil enhances the action of oral anticoagulants and may cause cholelithiasis. When combined with an HMG-CoA reductase inhibitor, muscle damage leading to rhabdomyolysis and myoglobinuria has been reported.

Fenofibrate is the first of the second-generation fibric acid derivatives to be tested in the United States. Although the drug has been available in Europe since the early 1980s, it has not been studied in a large prevention trial, as have clofibrate and gemfibrozil. Nevertheless, the basic pharmacologic features of fenofibrate are similar to the features of the previous agents. A potential advantage of the second-generation drugs is their greater ability to reduce LDL concentrations. Side effects include the gastrointestinal disturbances common to all fibrates and the potential for causing cholelithiasis.

Nicotinic Acid

Nicotinic acid, otherwise known as *niacin,* has been recognized since the late 1930s as a member of the vitamin B complex whose deficiency results in the disease pellagra. In 1955, it was reported that doses of nicotinic acid greater than 1 g (i.e., >50 times the recommended daily allowance of niacin as a vitamin) reduce plasma cholesterol concentrations,[2] subsequently decreasing triglyceride concentrations.[9] The function of niacin in the body, after conversion to nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate, is to act as important enzyme cofactors. The action of niacin as a lipid-lowering drug is not related

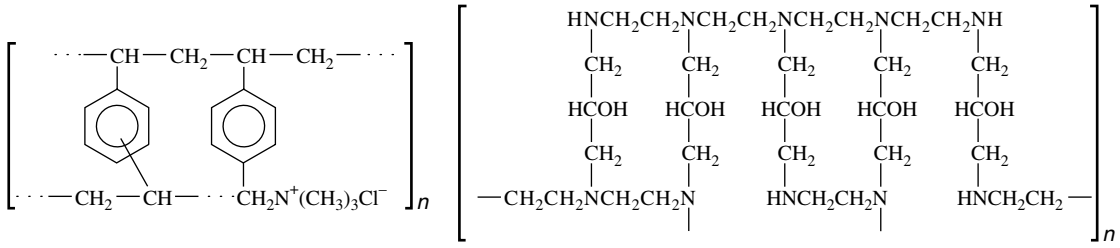

FIGURE **29-4** Structural formula of bile acid sequestrants cholestyramine and colestipol.

to its function as a vitamin. Nicotinamide, interchangeable with nicotinic acid as vitamin B_3, has no effect on plasma lipids and should not be used.

Nicotinic acid is used most often to reduce VLDL and LDL while increasing HDL levels. It has been used alone or in combination with other lipid-lowering drugs. Its mechanism of action seems to involve inhibition of VLDL synthesis through inhibition of adipose tissue lipolysis and inhibition of subsequent delivery of fatty acids to the liver to produce triglycerides for packaging into VLDL particles.[19] Increased clearance of VLDL may also play a role in the mechanism because of elevated lipoprotein lipase activity. Nicotinic acid has the broadest spectrum of activity of the lipid-lowering agents and is potentially useful in most forms of hyperlipidemia.

The major disadvantage of nicotinic acid, which affects 50% or more of the patient population, has been its tendency to produce adverse effects sufficient to impair patient compliance or force cessation of therapy. Common side effects include cutaneous flushing, pruritus, and gastrointestinal distress. An additional side effect in some diabetic patients is increased insulin resistance and hyperglycemia. If treatment is instituted slowly, with a gradually increasing dosage, tolerance to the cutaneous flushing occurs, and therapy can be continued. Aspirin or ibuprofen taken beforehand ameliorates prostaglandin-dependent flushing. Withdrawal of nicotinic acid is most frequently necessitated by gastric disturbances. Other side effects include hyperuricemia, decreased glucose tolerance, and abnormal liver function tests. Extended-release preparations of nicotinic acid marketed in the past few years have made this drug more tolerable to many patients, but do not eliminate flushing in all patients.

Nicotinic acid is absorbed rapidly, usually reaching a peak plasma concentration in less than 1 hour. The short half-life is primarily due to rapid excretion of unmetabolized nicotinic acid by the kidneys; this necessitates frequent administration of the drug, usually three times a day with meals. Because of the frequent lack of tolerance, doses are started at 100 mg three times per day and are gradually increased at 100-mg intervals until a dose of 1 to 1.5 g is reached. The usual therapeutic dose is 2 to 6 g/day. Extended-release preparations are taken once each day, in the evening, and can be started at a higher dose. These preparations have been shown to have less incidence of side effects even in patients with diabetes.

Bile Acid Sequestrants

Bile acid sequestrants are nonabsorbable anion exchange resins that bind bile acids in the intestinal lumen, prevent their reabsorption, and promote their excretion in the feces. Enterohepatic cycling of cholesterol is markedly reduced by this mechanism, which blocks reabsorption of bile acids from the jejunum and ileum, 95% of which are normally reabsorbed, and increases bile acid excretion rate by 10-fold. Bile acids are synthesized in the liver from cholesterol by 7α-hydroxylase, which is regulated through negative feedback by bile acids. Hepatic cholesterol conversion to bile acids is accelerated, and plasma cholesterol and LDL concentrations are decreased. LDL concentrations are also reduced by these drugs because of upregulation of LDL receptors and hepatic uptake, whereas the VLDL concentration may be unchanged or increased.[26] These resins have no effect in patients with homozygous familial hypercholesterolemia who have no functioning LDL receptors.

Cholestyramine and colestipol are the two clinically available drugs in this category (Figure 29-4). They are very large resins that are insoluble in water. The dry resin is mixed with a liquid such as fruit juice and drunk as a slurry. Cl^- is released from the resin as bile acids bind to it, and the released Cl^- is absorbed, but the resin itself is not absorbed. Because it is not absorbed, it has a high safety factor and absence of serious side effects, but the annoying gastrointestinal side effects (nausea, vomiting, abdominal distention, and constipation) limit the use of these drugs. An unpleasant taste adds to the problem of patient compliance with these agents. Because cholestyramine and the hydrochloride salt of colestipol clinically exchange Cl^- for other anions, hyperchloremic acidosis may develop when large doses are given to small patients. Both resins decrease the absorption and the therapeutic effect of other drugs, such as warfarin, thyroxine, digitalis, propranolol, and thiazides. This interaction can be partially overcome by proper timing of the dosage.

Bile acid–binding resins are used alone or in combination with nicotinic acid and cholesterol synthesis inhibitors. Cholestyramine was used in the Lipid Research Clinics Program Primary Prevention Trial.[27] In this trial of almost 4000 healthy men with hypercholesterolemia, there was a 20% decrease in LDL cholesterol with the resin and a 24% reduction in deaths from myocardial infarction.

The newest bile acid sequestrant to be approved for use in the United States is colesevelam hydrochloride, which is available in tablet form. Colesevelam has been found to lower LDL cholesterol as effectively as cholestyramine,[11] but has less danger of interaction with other drugs such as warfarin through adsorption.[12] There are also somewhat fewer gastrointestinal side effects, and, because of the tablet form, compliance is greater.

3-Hydroxy-3-Methylglutaryl—Coenzyme A Reductase Inhibitors

The development of drugs that specifically inhibit the biosynthesis of cholesterol has been the most important aspect of hypolipidemic drug development. This class of drugs, called the *statins*, currently includes lovastatin, pravastatin, simvastatin, fluvastatin, cerivastatin, atorvastatin, and rosuvastatin. These agents structurally resemble an intermediate in the HMG-CoA reductase reaction (Figure 29-5) and are potent competitive antagonists of HMG-CoA binding.[20] (Lovastatin and simvastatin are actually prodrugs in that they require cleavage of their lactone ring to become active.) Numerous clinical studies have now shown these drugs to be the best tolerated and most effective drugs for lowering LDL cholesterol and for reducing stroke, coronary heart disease, and overall mortality. In addition to lowering LDL cholesterol,

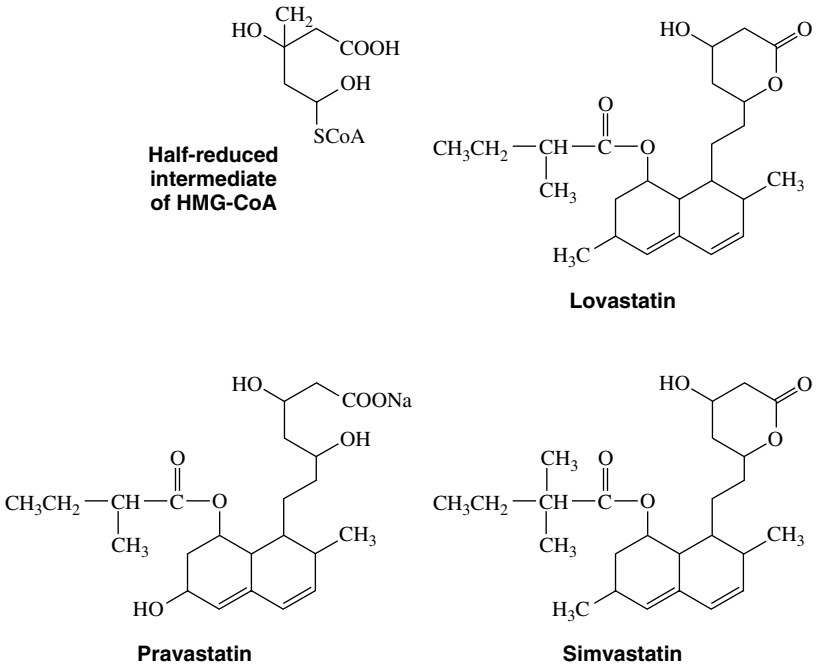

FIGURE **29-5** Structural formula of 3-hydroxy-3-methylglutaryl–coenzyme A (*HMG-CoA*), half-reduced intermediate, and several HMG-CoA reductase inhibitors.

some studies have shown that statins are useful in reducing triglycerides. Fewer studies have been conducted with patients having low HDL cholesterol, but these have indicated that some statins are effective in elevating HDL cholesterol.

The antihyperlipidemic effect of this class of drugs depends on inhibition of hepatic HMG-CoA reductase, the rate-controlling enzyme in the pathway of cholesterol synthesis. The subsequent depletion of intracellular cholesterol has two effects: (1) sterol inhibition of the transcription of HMG-CoA reductase and HMG-CoA synthetase genes is released, resulting in increased synthesis of these two enzymes, but the continuous presence of the drug keeps cholesterol synthesis inhibited in all tissues, and (2) synthesis of hepatic LDL receptors is stimulated, resulting in increased hepatic uptake of LDL and IDL. The net result of these changes is a reduction in LDL and IDL concentrations, a related decrease in lipoprotein cholesterol and triglyceride concentrations, and a slight increase in HDL concentrations.[5]

HMG-CoA reductase inhibitors are the most commonly prescribed lipid-lowering drugs. They are indicated for the treatment of hypercholesterolemia caused by elevated LDL concentrations in patients who have not responded to dietary or other measures. Statins may also be useful for the reduction of LDL levels in patients with combined hyperlipidemia (hypercholesterolemia and hypertriglyceridemia). They are ineffective in rare patients with familial hypercholesterolemia who are homozygous for the defective LDL receptor gene. More recent studies have suggested that some, but not all, statins may produce beneficial effects beyond decreasing LDL cholesterol, including decreased inflammation resulting from modulation of isoprenylation reactions, stimulation of nitric acid synthesis, decreased C-reactive protein levels, and antioxidant effects.

Adverse effects of HMG-CoA reductase inhibitors include myalgia, blurred vision, constipation, diarrhea, gas, heartburn, stomach pain, dizziness, headache, nausea, skin rash, impotence, and insomnia. The incidence varies among the different agents, with blurred vision more frequent with lovastatin and pravastatin and impotence and insomnia more frequent with lovastatin. HMG-CoA reductase inhibitors increase the anticoagulant effect of warfarin. Lovastatin has been linked with severe myopathy (rhabdomyolysis) when administered in combination with erythromycin, cyclosporine, gemfibrozil, or nicotinic acid. Other HMG-CoA reductase inhibitors have also been found to produce rhabdomyolysis in a small percentage of patients, but there is increased risk with higher doses, in elderly patients, or in combination with other drugs. Cerivastatin was removed from the market by its manufacturer because of rhabdomyolysis. It has been suggested that certain statins may cause rhabdomyolysis by inducing autophagy in muscle cells.[3] Another side effect of statins that may be important in some patients is the potential for reduction in ubiquinone levels.[29] The safety of the statins in pregnant patients or in nursing infants has not been established, so women who are pregnant or nursing should avoid these drugs.[25,41]

Cholesterol Absorption Inhibitors

The most recent class of lipid-lowering drugs to be developed and approved for use are cholesterol absorption inhibitors.[13] These agents inhibit cholesterol uptake by the intestinal absorptive epithelium. Dietary cholesterol is normally absorbed in the jejunum from bile acid micelles by enterocytes, in which the cholesterol is immediately converted to cholesteryl esters for assembly of chylomicrons. The uptake of cholesterol is mediated by specific transporters in the brush border of these cells.[21] The cholesterol absorption inhibitor ezetimibe blocked an elevation in plasma cholesterol in one study in which feeding of high-cholesterol diets increased plasma cholesterol in the control group.[45] This compound also reduced LDL cholesterol in human trials in a concentration-dependent manner at doses of 1 mg.[8]

In addition to these agents, inhibitors of bile acid uptake by the intestinal epithelium and inhibitors of acyl CoA cholesterol acyltransferase, the enzyme that produces cholesteryl esters, are being developed as lipid-lowering drugs.[8] The combination of ezetimibe with HMG-CoA reductase inhibitors produces even greater control of hyperlipidemia than is possible with either drug used in monotherapy. An advantage of ezetimibe over bile acid sequestrants is that while inhibiting cholesterol uptake, it does not inhibit uptake of triacylglycer-

ols, bile acids, fatty acids, lipid-soluble drugs, or fat-soluble vitamins by the small intestine.

Other Agents

Some agents with moderate antihyperlipidemic activity may be clinically useful for specific patients. These include the very-long-chain polyunsaturated fatty acids found in fish oil, neomycin, and β-sitosterol. Others, typified by dextrothyroxine, can decrease cholesterol concentrations yet provide no therapeutic benefit to the patient.

Fish oils

Evidence exists to support a role for polyunsaturated fish oils in decreasing plasma lipid concentrations.[22,37] Specifically, the omega-3 polyunsaturated fatty acids (PUFAs) eicosapentaenoic acid and docosahexaenoic acid have been identified, whether consumed as dietary constituents or as purified supplements. The mechanisms of action of these agents are unclear. Some commercial preparations contain antioxidants, such as vitamin E, in varying concentrations. The actions of the antioxidants and their effect on the action of the fish oils are not defined.

Increasing dietary omega-3 PUFAs has been shown to increase their concentration in platelet phospholipids. This increase allows them to compete with arachidonic acid for cyclooxygenase in the cascade that normally produces prostaglandins, thromboxanes, and prostacyclins.[22] The prostaglandins derived from omega-3 PUFAs have biologic effects different from prostaglandins derived from arachidonic acid, and this alteration in prostaglandin synthesis is thought to result in a reduction of platelet aggregation and an increase in bleeding time.[14,24] Eicosapentaenoic acid in particular may be converted to prostaglandin I_3, which is an antiaggregatory agent.[24]

Although results vary, some evidence exists to show that fish oils can modestly decrease the levels of plasma cholesterol, triglycerides, and VLDL and modestly increase HDL levels. Patients with severe familial hypertriglyceridemia often have significant improvement on a diet high in fish oil. Before these agents can be recommended for widespread use in hyperlipidemia or to reduce the risk of coronary artery disease, however, long-term studies are needed to establish their safety and efficacy, with special emphasis on contaminants that may be present in some preparations.[23]

Thyroid-active substances

Early animal experiments indicated that the dextroisomers of thyroxine and liothyronine (triiodothyronine) decrease plasma lipid levels with no increase in oxygen consumption, an effect that might be useful in treating hyperlipidemias.[34] These compounds have been shown to increase the incidence of angina pectoris and death, however, in patients with coronary artery disease.[10] These findings restrict the use of these drugs as lipid-lowering agents and indicate that they should be used with extreme caution, if at all, in patients with heart disease.

Inhibitors of cholesteryl ester transfer protein

Clinical investigations are currently under way to examine the effects of drugs that inhibit cholesteryl ester transfer protein (CETP). CETP is a protein synthesized in the liver that transfers cholesteryl esters from circulating HDL particles to circulating LDL and VLDL particles. In animals and in humans, the inhibition of CETP causes an increase in HDL cholesterol. Phase III trials of one of these drugs has been halted because of significantly higher mortality in a high-risk treatment group, but the adverse effect may be unrelated to the drug's inhibition of CETP, and other drugs in the same class may not have the same adverse effect.[4,15]

COMBINED-DRUG THERAPY

Lipid-lowering drugs from the different categories are used in combination for three reasons. First, combined-drug therapy may result in a more profound reduction of lipid levels than can be achieved by single-drug therapy. Second, as previously stated, some drugs may elevate certain lipid concentrations; combined therapy with a drug of another category can be used to overcome this unwanted effect. Third, the use of combined-drug therapy may allow smaller doses of the drugs to be used than in single-drug therapy, decreasing potential side effects. Examples of multiple-drug therapies having demonstrable value include the combination of a bile acid sequestrant (cholestyramine or colestipol) with either nicotinic acid or an HMG-CoA reductase inhibitor.[6] Other drug combinations that have been shown to be useful include a bile acid sequestrant and a fibrate and a resin plus nicotinic acid plus an HMG-CoA reductase inhibitor. Colesevelam plus an HMG-CoA reductase inhibitor may also be a useful combination. The newest combined-drug therapy is the use of a cholesterol absorption inhibitor with an HMG-CoA reductase inhibitor. The combination of ezetimibe and atorvastatin achieved a 50% reduction in LDL cholesterol at low doses (10 mg) of each drug. This result was approximately equal to the effect of 80 mg of atorvastatin alone.

LIPID-LOWERING DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Atorvastatin	Lipitor
Cholestyramine	Questran
Clofibrate	Atromid-S
Colesevelam	WelChol
Colestipol	Colestid
Ezetimibe	Zetia, Vytorin (combination with simvastatin)
Fenofibrate	Tricor, Lofibra
Fish oils (n-3 PUFAs)	Max-EPA, Promega, Sea-omega, Super EPA
Fluvastatin	Lescol
Gemfibrozil	Lopid
Lovastatin	Altoprev, Mevacor, Advicor (combination with niacin)
Nicotinic acid (niacin)	Niacor, Niaspan, Niacin SR, Slo-Niacin
Pravastatin	Pravachol
Rosuvastatin	Crestor
Simvastatin	Zocor

PUFAs, Polyunsaturated fatty acids.

CHAPTER 30

Antianemic and Hematopoietic Stimulating Drugs

BARTON S. JOHNSON

Hematopoiesis is the intricate system of growth and differentiation of immature pluripotent/multipotent stem cells into all the formed elements of the blood (Figure 30-1). These stem cells, derived embryologically in the liver and later from bone marrow,[33] divide early in development into either myeloid or lymphoid precursors. The myeloid precursors differentiate into the erythrocytes, megakaryocytes (which give rise to thrombocytes [platelets]), neutrophils, and monocytes. The lymphoid precursors give rise to the T-cell and B-cell lymphocytes, natural killer cells, and all their respective subtypes. The derivation of eosinophils and basophils lies in the myeloid stem line, but appears to be downstream of the common myeloid precursors.[26] Hematopoietically active bone marrow retains essentially the same mass throughout life, and although cell-producing bone marrow is found in practically all bones through adolescence, it becomes restricted to the vertebrae, sternum, ribs, pelvis, scapulae, parts of the skull, and epiphyseal ends of the long bones after approximately age 20 years.

Hematopoiesis is a dynamic, continuous process because mature cells of the blood have a limited life span in periods of sickness and health. Because of its complexity, ubiquity, and high rate of activity, the hematopoietic system is often the first organ system to show evidence of underlying systemic disease. This chapter discusses the pharmacologic interventions currently available to correct perturbations in marrow function. Conditions such as anemia, thrombocytopenia, neutropenia, and volume depletion and novel approaches to medical care that involve the hematopoietic system are discussed in detail.

ANEMIA

Anemia comprises a multifactorial group of illnesses with a wide range of underlying causes. As a result, *anemia* is a generic term indicating only that the concentration of hemoglobin in whole blood is less than normal. Anemia is not a disease, but a sign of underlying disease. When discussing anemia, it is important to diagnose the nature and the cause of the anemia. There are three general categories of diseases that cause anemia: (1) diseases that cause blood loss, (2) diseases that disturb red blood cell production, and (3) diseases that increase endogenous destruction of red blood cells.

Blood loss can occur either acutely, as in hemorrhage from trauma or surgery, or chronically, as with excessive menstrual bleeding or the occult bleeding of esophageal varices or gastric/duodenal ulcers. Disturbed red blood cell production is associated with nutritional deficiencies, disorders that suppress erythrocyte production (such as in aplastic anemia and with some antiretroviral therapy), and myelophthisic (marrow-displacing) diseases. Finally, anemia can be caused by increased destruction of the red blood cells, such as in sickle cell disease, thalassemia, hemolytic immune reactions, and genetic disorders such as glucose-6-phosphate dehydrogenase deficiency.

When a patient is suspected to have a type of anemia, the first tests to consider are a simple hematocrit and erythrocyte count. These two tests tell whether the production-to-loss ratio of red blood cells is normal. The hematocrit is defined as the ratio of red blood cells to the total blood volume. It is expressed as a percentage and is determined by comparing the packed cell volume (which is composed largely of erythrocytes) to the total volume of centrifuged whole blood. Normal values for women are 36% to 45%, and normal values for men are 38% to 50%. In an anemic patient, the hematocrit level is reduced, often into the 20s and in severe cases into the teens or lower. Conversely, the hematocrit increases (referred to as *polycythemia vera* if moderate and *erythroleukemia* if severe) in patients with poor pulmonary function, in patients with some chronic cardiac conditions, in patients with certain marrow tumors, and in patients living at high altitudes. In acute hemorrhage, because plasma and red blood cells are lost together, the hematocrit does not initially reflect the loss until the body or exogenous medical intervention has had the opportunity to replenish the lost plasma volume. In these cases, there may be no indication of a problem until several hours later.

The erythrocyte (reticulocyte) count is a simple determination of the absolute number of cells (in millions) per microliter. Normal values for women are 3.8 to 5 million/μL, and normal values for men are 4.4 to 5.6 million/μL.

After anemia has been detected, it can be characterized by evaluating the hemoglobin in the erythrocytes. Normal amounts of hemoglobin per unit volume of blood (assayed on peripheral blood draw) are 15.2 ± 2.2 g/dL for men and 13.7 ± 2.1 g/dL for women. Hemoglobin is the oxygen-carrying component of red blood cells. It comprises three components: iron, porphyrin rings, and globin chains. Alterations in any one of these three components can be a cause for a clinical anemia. In normal hemoglobin, iron in the ferrous form (Fe^{++}) is chelated into the middle of the porphyrin chemical ring to yield heme, the nonprotein component of hemoglobin (Figure 30-2).

The globin chains constitute the main protein constituents of hemoglobin. There are four forms of globin chains: α (141 amino acids), β (146 amino acids), δ, and γ (δ and γ are variants of β). Approximately 97% of normal hemoglobin (hemoglobin A) consists of two α and two β chains ($\alpha_2\beta_2$); 1% to 2% consists of the $\alpha_2\delta_2$ combination (hemoglobin A_2). The

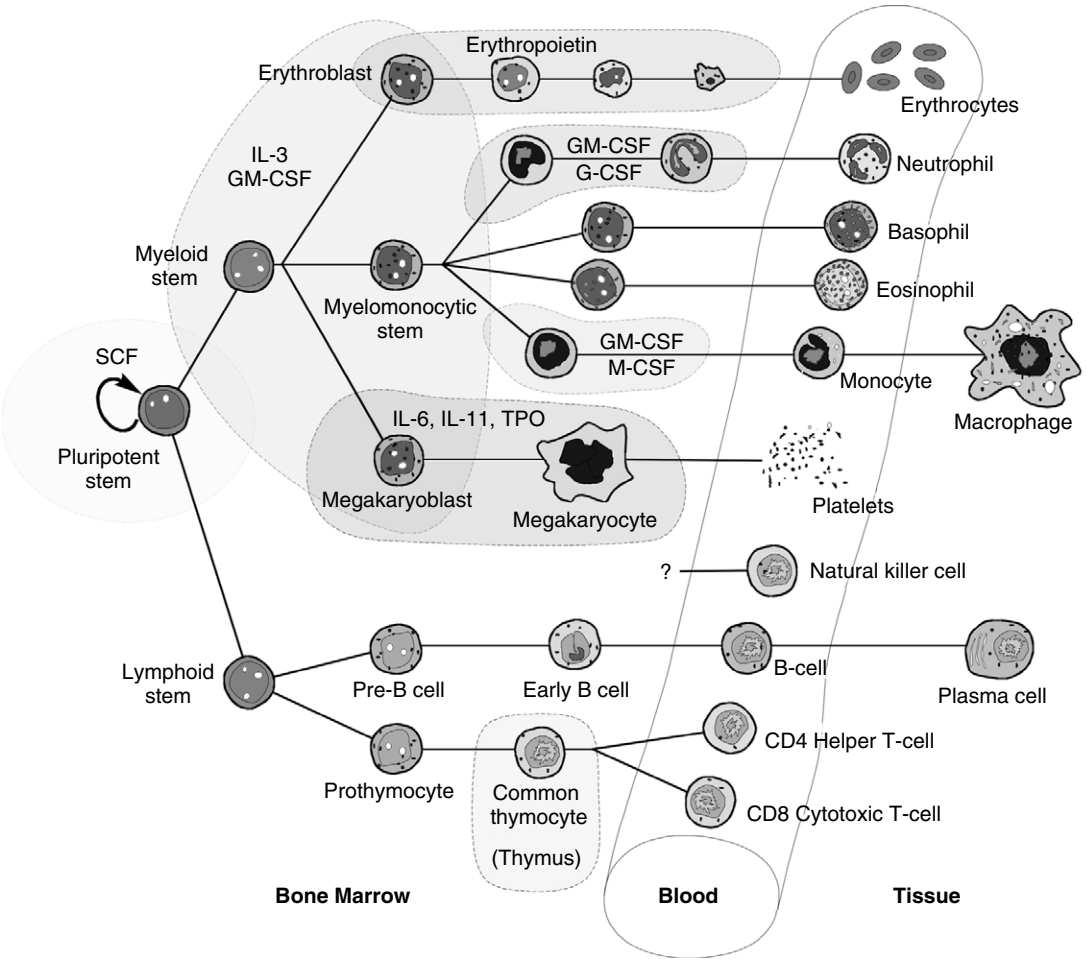

FIGURE **30-1** Overview of hematopoiesis. *G-CSF,* Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IL-3*, *IL-6*, *IL-11*, interleukin-3, interleukin-6, interleukin-11; *M-CSF,* monocyte/macrophage colony-stimulating factor; *SCF,* stem cell factor; *TPO,* thrombopoietin.

$\alpha_2\gamma_2$ tetramer forms hemoglobin F, or fetal hemoglobin. Hemoglobin F is the major form during gestation and until approximately 6 months of age. In adults, hemoglobin F makes up less than 1% of normal hemoglobin. One heme ring is accommodated within each of the four structural folds of the tetramer, allowing each molecule of hemoglobin to bind four oxygen molecules.

Hemoglobin accounts for approximately 95% of the dry weight of mature erythrocytes. Any significant changes in hemoglobin are often directly reflected in the way the erythrocytes look or behave grossly. Classically, laboratory analyses for anemia have reviewed erythrocyte size, shape, and color intensity. The size is determined by the mean corpuscular volume (MCV). The *normocytic,* or normal size, range is 80 to 100 fL/cell. Cells that are too small are termed *microcytic,* whereas cells that are too large are termed *macrocytic*. The shape of the red blood cells is also important in diagnosing the cause of anemia. Box 30-1 lists terms that describe various shapes found on a peripheral blood smear. The color intensity of the cell is reflected in the mean corpuscular hemoglobin (normally 26 to 34 pg/cell) and the mean corpuscular hemoglobin concentration (normally 31 to 36 g/dL). These two parameters, along with MCV, collectively referred to as the *red blood cell indices,* are extremely helpful in delineating the causes of a particular anemia.

The various kinds of anemia are classified by their typical effect on the erythrocytes (Table 30-1). When anemia results from a loss of blood (intrinsically from hemolysis or extrinsically from hemorrhage) or because of a decrease in production of normal erythrocytes, the cells are still normal, just fewer in quantity. These anemias are *normocytic* and *normochromic*. When anemia is caused by a decrease in the production of properly formed hemoglobin, the cells tend to be smaller (because hemoglobin comprises such a high percentage of erythrocyte content) and paler in color. These forms of anemia are known as *microcytic* and *hypochromic* and are usually the result of defective or inadequate iron absorption. Forms of anemia that cause the red blood cells to mature incompletely and retain some DNA content result in larger cells; these are known as *macrocytic* or *megaloblastic* anemia. They generally occur as a result of a deficiency in vitamin B_{12}, folic acid, or both nutrients. In these forms of anemia, the cells may also have a darker or *hyperchromic* color.

Iron and Iron Deficiency Anemia

Nutrition and physiologic characteristics

Iron deficiency anemia is the most common cause of anemia worldwide and may occur for many reasons: inadequate nutrition in relation to rate of growth (qualitative or quantitative); defective absorption, transport, or storage (e.g., congenital atransferrinemia or inability to release iron from transferrin to the red blood cells and their precursors); or blood loss from hemorrhage (most commonly gastrointestinal), menstruation, or blood donation. In the United States, iron deficiency

BOX **30-1**

Descriptive Terms of Red Blood Cell Morphologic Characteristics

TERM	DESCRIPTION
Poikilocytosis	Irregular erythrocyte shape
Anisocytosis	Irregular erythrocyte size
Polychromasia	Change in amount of hemoglobin
Sickling	Sickle cell disease and trait
Targeting	"Bull's-eye" look to the erythrocytes caused by hemoglobin C and liver disease
Leptocytes	Hemoglobin in the border with pigmentation in the center; found in thalassemia, obstructive jaundice, any hypochromic anemia, hemoglobinopathy, and after splenectomy
Spherocytes	Round erythrocytes (not biconcave), caused by hereditary spherocytosis or by immune or microangiopathic hemolysis
Schistocytes	Fragments of erythrocytes; found in hemolytic transfusion reactions, microangiopathic hemolysis, and other severe anemias
Acanthocytes	Distorted ("thorny") erythrocytes with protoplasmic projections; seen in severe liver disease and with high titers of bile, fats, or toxins
Howell-Jolly bodies	Smooth, round remnants of nuclear chromatin; seen in megaloblastic and hemolytic anemias and after splenectomy
Nucleated erythrocytes	Found in severe bone marrow stress (e.g., hemorrhage, hemolysis), marrow replacement by tumor, extramedullary hematopoiesis

TABLE **30-1**

Classification of Anemia by Cause and Presentation

	MICROCYTIC	MACROCYTIC	NORMOCYTIC
Decreased Production			
	Iron deficiency Thalassemia Anemia of chronic disease	Megaloblastic: vitamin B_{12} deficiency, folate deficiency Nonmegaloblastic: myelodysplasia, chemotherapy, hepatitis	Aplastic anemia Bone marrow infiltration Carcinoma Lymphoma
Increased Destruction			Intrinsic hemolysis Extrinsic hemolysis
Blood Loss			Acute hemorrhage Chronic hemorrhage

anemia is found in 7% of infants, 4% to 5% of children, and 9% to 16% of menstruating women.[5] Only 2% to 3% of men have iron deficiency anemia, and women taking oral contraceptives tend to have lower rates because progestins reduce menstrual blood loss. Children 6 months to 2 years old are particularly vulnerable because of their high growth rate coupled with weaning off breast milk and onto cow's milk. Cow's milk is low in absorbable iron and may irritate the intestines. Pregnancy may precipitate iron deficiency anemia by rapidly increasing the blood volume, sometimes requiring two to five times the normal intake of iron. According to a World Health Organization technical report,[17] women who have sufficient iron reserves to support the increase in hemoglobin production during pregnancy and who breastfeed their

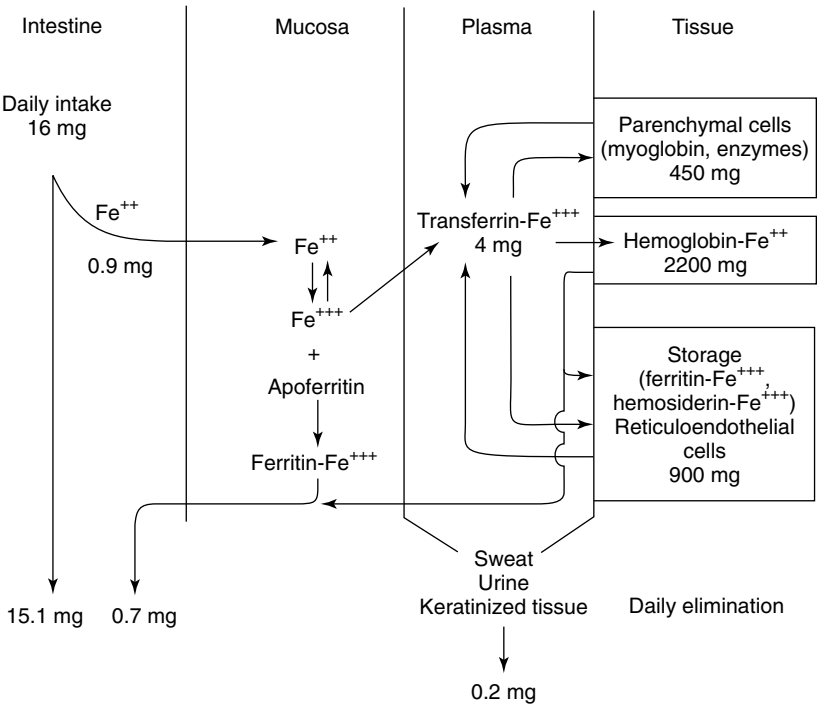

FIGURE **30-3** Absorption, excretion, and storage of iron within the body of a 70-kg man. The amounts of iron absorbed, excreted, and stored in the three major compartments are expressed in milligrams. Note the balance between daily absorption and excretion.

infants are generally capable of meeting their iron needs by diet alone, although supplementation is still recommended. In a nonpregnant, normal, healthy individual, iron reserves and recycling are so effective that even extreme reduction of iron intake may be insufficient to cause severe anemia.[12]

Men average 3.8 g total iron (50 mg/kg) and women average 2.3 g (35 to 42 mg/kg). Approximately 60% to 80% of the iron in the body is incorporated into hemoglobin (Figure 30-3). Anemia is the primary presenting sign of iron deficiency. Approximately 10% to 25% is sequestered in reticuloendothelial cells in the storage forms ferritin and hemosiderin (described later), and another 10% to 15% is associated in parenchymal cells with myoglobin. Less than 1% is used in various enzymes, most notably the cytochromes, and trace amounts are linked to the plasma transport protein transferrin. The amount of stored iron varies with intake and demand, averaging 400 mg in women and 1000 mg in men.

The average American ingests 10 to 20 mg of iron per day. Iron is obtained through the diet, most commonly by heme or iron complexed to various organic compounds. Foods considered high in iron (>0.5% by weight) are liver, heart, oysters, egg yolks, and yeast. Other meats and green vegetables have less iron. Absorption of iron from dietary sources is ordinarily 10% efficient or less, but it increases when iron stores are depleted. Therapeutic iron, generally in the form of inorganic salts or complexes, has an even poorer absorption profile than dietary iron because the Fe^{++} must be liberated from the salt before it can be absorbed across the intestinal mucosa.

Iron absorption occurs along the entire length of the intestine, but maximum absorption occurs in the duodenum and proximal jejunum because iron is absorbed primarily as Fe^{++}, and an acid medium favors the breakdown of salts to the ionic form. In the lower portions of the gastrointestinal tract there is a trend toward increasing alkalinity, which favors the formation of less soluble iron salts and complexes. Iron ingested as heme iron is absorbed five to seven times more efficiently than Fe^{++} salts. Iron absorption is hindered by coffee, tea, phosphates, and antacids, particularly calcium carbonate and aluminum or magnesium hydroxide. Absorption of nonheme iron is facilitated by vitamin C. How ethanol interacts with iron is not well elucidated, but approximately 50% of alcoholics exhibit some iron depletion or anemia.

Iron is absorbed by active transport across the intestinal mucosa, where it is converted intracellularly to ferric iron (Fe^{+++}). Depending on the body's acute need for iron, Fe^{+++} is either bound to transferrin or converted to ferritin or hemosiderin for storage in the intestinal mucosa. Transferrin is a transport glycoprotein electrophoretically migrating with the β globulins; it specifically binds two molecules of Fe^{+++}. It enters the plasma and carries Fe^{+++} to the bone marrow and developing erythroblasts. The erythroblasts present membrane transferrin receptors that bind diferric transferrin and then internalize the complex by endocytosis. Inside the cell, the transferrin receptor, transferrin, and Fe^{+++} are broken apart, with the iron being used in hemoglobin synthesis and the transferrin and transferrin receptor being carried back intact to the surface for recycling. The typical developing erythroblast can process 25,000 to 50,000 transferrin molecules per minute.

A test for transferrin is total iron-binding capacity (TIBC). In a normal adult, approximately 20% to 50% of transferrin is replete with Fe^{+++}. In an iron-deficient individual, transferrin saturation may decrease to 15% or less. The capacity to bind iron is considerably greater, and the TIBC value increases. Normal values are 250 to 450 μg/dL.

If the body is not in acute need of iron, most of the ingested iron is stored as ferritin. Twenty-four apoferritin monomers bind together to form a hollow spherical shell 130Å in diameter and fenestrated with small pores through which 4000 Fe^{++} atoms can enter. When inside, the Fe^{++} is oxidized to Fe^{+++} and stored in the form of hydrous ferric oxide phosphate. Ferritin, the resulting apoferritin-iron complex, is a very effective storage mechanism, allowing the binding and release of iron to occur rapidly and efficiently. Mature ferritin is found in virtually all cells of the body and in plasma. Although the amount in plasma is small, it reflects the total ferritin stores in the body and is measured to diagnose iron deficiency anemia. Normal values for serum ferritin are 16 to 300 mg/mL in men and 4 to 160 mg/mL in women.

The other minor storage component of iron is hemosiderin. It is found in the monocyte/macrophage system of the marrow and in the Kupffer cells of the liver. Hemosiderin is an insoluble compound that seems to be aggregated ferritin cores partially or completely stripped of the apoferritin protein shell. In pathologic conditions (hemosiderosis), it can be found in large quantities in most tissues of the body.

The concentration of iron in the plasma at any one time represents a balance between the absorption rate, storage capacity, rate of hemoglobin formation, and rate of iron excretion. Iron is remarkably well conserved in the body; less than 0.1% is excreted on a daily basis, or approximately 0.5 to 1 mg/day. The major pathway of iron excretion is through the feces by exfoliation of gastrointestinal cells and their intracellular stores of ferritin when the mucosal cells are replaced by new epithelium. Iron is also lost in considerably smaller amounts by excretion through urine, exfoliation of dermal cells, and perspiration. Menstruation causes the amount of lost iron roughly to double to 2 mg/day. Uncommon sources of iron loss include excessive blood loss or excessive destruction of erythrocytes. Hemorrhage depletes heme iron, whereas excessive turnover of erythrocytes releases it back into the circulation, where it can be recycled. A normal individual can lose a quarter to a third of the erythrocyte mass through hemorrhage without need for iron therapy. Because iron is so well conserved in the body and most people have large reserves, chronically insufficient intake of iron is almost always the cause of iron deficiency anemia.

Pathophysiologic characteristics

Iron deficiency is manifested as signs and symptoms of anemia (pale color, fatigue, tachycardia, tachypnea on exertion). Severe cases, which are rare in first-world nations, may show progressive skin and mucosal changes, such as angular cheilosis and brittle fingernails and toenails. Splenomegaly may be present if hemolysis is occurring. The classic intraoral finding is a red-appearing, sore, smooth tongue caused by atrophy of the dorsal filiform papillae. In very severe cases, Plummer-Vinson syndrome may occur, which is iron deficiency anemia coupled with the formation of esophageal webs and resultant dysphagia. This syndrome is also associated with pharyngeal or esophageal squamous cell carcinoma. Many iron-deficient patients develop pica, an unusual craving for specific foods or unnatural food items (e.g., ice cubes, soil, paint chips) that may or may not contain iron.

The laboratory findings of iron deficiency anemia reflect the severity of the loss. In the first stage, there is a normocytic anemia without changes in erythropoiesis. The ferritin stores are depleting, so the serum ferritin values decrease while the TIBC increases. As anemia progresses and the stores are depleted, the erythrocytes become affected, resulting in a decrease in the MCV, mean corpuscular hemoglobin, erythrocyte count, hemoglobin, and hematocrit.

Iron therapy

The intuitive treatment of any disease state that is accompanied by extreme fatigue, weakness, and loss of color includes increased dietary intake, and the ancient Greeks, Hindus, and other early peoples turned to iron in many forms simply because it represented "strength." Although Sydenham is generally credited with the first rational use of iron (iron filings in wine) for treating anemia in 1681, it was not known that iron was actually present in blood until 30 years later, when Lemery and Geoffry demonstrated its presence. Shortly thereafter, Menghini, an Italian physician, showed that foods with iron actually increase blood iron, but it was not until approximately 1830 that a pill containing iron (ferrous sulfate and potassium carbonate, 1:1) was introduced into medicine by Blaud,[3] an event that marked the beginning of modern treatment of iron deficiency anemia.

Iron therapy is indicated in iron deficiency anemia; it is contraindicated in anemia of any other cause. Iron is available in the form of Fe^{++} salts (sulfate, gluconate, and fumarate), which are reasonably well absorbed, and a Fe^{+++}-containing compound (iron polysaccharide), which is not as well absorbed. The most commonly used Fe^{++} preparation, and the agent of choice for uncomplicated iron deficiency anemia, is ferrous sulfate. It is normally given in doses (325 mg three times a day) much larger than should theoretically be needed because of its limited absorption (≤15%). The response to oral iron preparations is usually evident in 5 to 10 days and is first manifested by an increase in reticulocytes. Adverse effects associated with orally administered iron are gastrointestinal symptoms, chiefly nausea and vomiting, because of direct irritation of the stomach. The patient has black stools as a result of therapy, which may obscure the diagnosis of melena. The drug is unquestionably best absorbed when taken between meals, but gastrointestinal distress is reduced if the medication is taken with meals and if the dose is started at a lower level and slowly increased with time. In general, the hematocrit returns halfway to normal in approximately 3 weeks and is fully corrected in roughly 8 weeks. To replenish iron stores, a course of therapy of 3 to 6 months is generally required.

Although parenteral iron preparations are available, they are not generally used because of the simplicity of oral medication and the much greater risk of serious side effects and higher expense. Iron should be administered parenterally only if the oral preparations are inadequately absorbed or poorly tolerated, such as in patients with enteritis or colitis, or if it is absolutely necessary to replace a serious iron deficit quickly. The classic parenteral form is iron dextran, a sterile colloidal solution of ferric hydroxide and low-molecular-weight dextran, which is administered by intramuscular or intravenous injection. Adverse reactions include pain and straining at the site of injection (intramuscular), urticaria, fever, arthralgia, lymphadenopathy, nausea, and vomiting. Rarely, severe or fatal anaphylactic reactions have occurred after the use of this preparation. Another parenteral form, iron sucrose, is a polynuclear ferric hydroxide sucrose complex. It is believed that the antigenic potential of iron dextran lies in the Fe^{++} and dextran polysaccharides and that this preparation is less allergenic. Iron sucrose is commonly used in patients undergoing renal dialysis who are receiving erythropoietin (EPO) therapy.

Acute iron poisoning is uncommon, but can occur, particularly because many iron formulations are brightly colored and attractive to children. Ingestion of large doses of iron causes the transferrin to become saturated, and free iron enters the blood in excess. Unbound iron is toxic and has caused severe gastrointestinal disturbances and may lead to circulatory collapse. Chelating agents have been used in the treatment of acute iron toxicity; deferoxamine, a potent and specific iron-chelating compound, is capable of removing iron from ferritin and transferrin but not from hemoglobin. It is, however, no substitute for more immediate measures, such as inducing vomiting, gastric lavage, and fluid administration, that should be carried out in the event of iron poisoning.

Perhaps the most important consideration for the dental professional is the finding that people who are taking oral iron supplements may have altered absorption profiles of other drugs. The quinolone class of antibiotics, tetracyclines, and thyroid replacement hormones all form complexes with iron and result in significantly poorer (36% less) absorption profiles. Simply having the patient stagger the iron and the interacting competing medication by 2 or more hours is usually sufficient to avoid this difficulty.

OTHER MINERALS AND HEMATOPOIESIS

Copper deficiency, although extremely rare in humans, has been reported as the cause of anemia in patients undergoing intestinal bypass surgery. Copper is required for the operation of several copper-containing enzymes (e.g., cytochrome oxidase and monoamine oxidase) and may be essential for iron absorption. Too much zinc in the diet can result in copper deficiency.

Cobalt is not essential for hematopoiesis except in the form of vitamin B_{12}, as described later in this chapter. Elemental cobalt can stimulate red blood cell formation, however, to the point of polycythemia in humans. This effect is thought to be derived from the release of EPO by the kidneys. The toxic effects of cobalt limit its clinical application.

Lithium salts, used in the treatment of manic-depressive illness, frequently induce a selective leukocytosis involving neutrophils, eosinophils, and monocytes and may increase platelet formation. This effect is a true increase in blood cell proliferation, and lithium has been used in aplastic anemia, specific leukemias, and thrombocytopenia, albeit with limited success.

PORPHYRIA

Although iron deficiency anemia is the most commonly encountered form of anemia, it is not the only disorder in which insufficient functional heme is produced. The porphyrias, a cluster of disorders that involve decreased or disordered production of the porphyrin ring, can be associated with anemia depending on the variety and severity of the presentation of the diseases. Heme is a major component of hemoglobin, but it is also crucial to several enzyme systems, most notably the large family of cytochrome P450 enzymes involved in steroid synthesis and drug metabolism.

Porphyrin is produced in an eight-step process that occurs in the mitochondria and in the cytosol. The two principal cell types involved are the developing erythroblasts and reticulocytes of the bone marrow (mature erythrocytes lack mitochondria and are unable to synthesize porphyrin) and the liver hepatocytes. As a result, two general classifications of porphyria exist—erythropoietic and hepatic—that are divided further into nine varieties (Table 30-2), each corresponding to a particular enzyme deficiency in the synthetic pathway of porphyrin. These deficiencies may be genetic in nature or caused by medications.

Acute exacerbations usually occur when there is a significant demand for heme synthesis that cannot be met by the limited enzyme function. This deficiency in heme inhibits the negative feedback cycle on δ-aminolevulinic acid synthase, causing induction of this rate-limiting enzyme. Because the heme synthesis pathway is damaged, induction instead leads to the excessive production in the liver of the porphyrin precursors δ-aminolevulinic acid and porphobilinogen, which build up and cause the acute symptoms. This accumulation of protoporphyrin precursors results in neurologic disorders, photocutaneous disturbances, or both.

Probably the most common genetic form of porphyria is acute intermittent porphyria. Its mode of transmission is autosomally dominant and results from a partial enzymatic deficiency (<50% of normal) in the third step of porphyrin synthesis. Because synthetic activity is diminished but not lost, most patients remain asymptomatic throughout normal life. Acute exacerbations, which give rise to the name, have highly variable symptoms that last from days to months. The most common presentation is neurologic, including mental changes; seizures; and acute sensory neuropathies such as abdominal pain, chest and back pain, and limb pain. The severity of the pain can be great enough to mimic other acute disorders and result in unnecessary surgical intervention such as laparotomy. Motor neuropathies, especially in the cranial nerves, are often seen. Occasionally, motor paralysis of the respiratory diaphragm has resulted in death. Gastrointestinal disturbances—primarily nausea, vomiting, and diarrhea—are common.

Several events can precipitate an attack. Physiologic stressors, such as surgery, excessive alcohol intake, illnesses, and infections, may induce hepatic heme oxygenase, which breaks down heme. Endocrine changes, such as may occur around a woman's menses, or synthetic estrogens and progestins may also induce an attack. More than 1000 medications have been categorized with regard to their porphyrinogenicity,[32] of which a few reactions are well documented and many are still anecdotal. What is accepted is that endocrine properties of the drug, affinity for cytochrome P450, hepatic load, and capacity to modulate nuclear receptors affecting gene transcription (particularly 5-aminolevulinate synthase [ALAS1]) all play a role in how porphyrinogenic a drug might be.

Several medications commonly used in dentistry and medicine (Box 30-2) are steroid-based or metabolized by, and induce the synthesis of, the cytochrome P450 enzyme system, which leads to increased accumulation of porphyrin precursors.[22] The response of any individual to any of these medications can be highly variable; the proposed unsafe medications should be discussed with the physician on a case-by-case basis. In susceptible porphyric patients, which also includes individuals with hereditary coproporphyria and variegate porphyria, dose reductions or avoidance of specific medications

TABLE **30-2**

Classification of Porphyrias

PORPHYRIA	SITE OF EXPRESSION	PRINCIPAL CLINICAL FEATURE
Acute intermittent porphyria	Liver	Neurologic
δ-Aminolevulinic acid dehydratase deficiency porphyria (rare)	Liver	Neurologic
Hereditary coproporphyria	Liver	Neurologic, photosensitivity
Porphyria cutanea tarda	Liver	Photosensitivity
Variegate porphyria	Liver	Neurologic, photosensitivity
Hepatoerythropoietic porphyria	Liver, bone marrow	Photosensitivity
Congenital erythropoietic porphyria	Bone marrow	Photosensitivity
Erythropoietic protoporphyria	Bone marrow	Photosensitivity
X-linked sideroblastic anemia	Bone marrow	Hemolytic anemia

BOX **30-2**

Drugs Considered Safe or Unsafe for Use in Patients with Acute Intermittent Porphyria, Variegate Porphyria, and Hereditary Coproporphyria

SAFE	POSSIBLY UNSAFE
Acetaminophen	Alcohol
Amitriptyline	Alkylating agents
Aspirin	Barbiturates (severe)
Atropine	Carbamazepine
Chloral hydrate	Chlordiazepoxide
Clorazepate	Chlorpropamide
Diazepam	Chloroquine
Digoxin	Clonidine
Diphenhydramine	Dapsone
Glucocorticoids	Ergots
Guanethidine	Erythromycin
Hyoscine	Estrogens, synthetic
Ibuprofen	Food additives
Imipramine	Glutethimide
Insulin	Griseofulvin
Labetalol	Hydralazine
Lithium	Ketamine
Naproxen	Meprobamate
Nitrofurantoin	Methyldopa
Opioid analgesics	Metoclopramide
Penicillamine	Nortriptyline
Penicillin and derivatives	Pentazocine
Phenothiazines	Phenytoin
Procaine	Progestins
Propranolol	Pyrazinamide
Selective serotonin reuptake inhibitors	Rifampin
	Spironolactone
Streptomycin	Succinimides
Succinylcholine	Sulfonamides (severe)
Tetracycline	Theophylline
Thiouracil	Tolazamide
Vitamins B and C	Tolbutamide
	Valproic acid

may be necessary. Thunell and colleagues[32] have proposed a standardized method to determine a drug's probable porphyrinogenicity, and an Internet database is available at http://www.drugs-porphyria.org. Poor nutritional intake has also been associated with acute attacks.

Porphyria cutanea tarda is the most common porphyria and is representative of the erythropoietic porphyrias. Symptoms commonly include photosensitivity, which results from sequestration of protoporphyrins in the skin and subsequent deposition of iron in the integument. Porphyrin and its precursors undergo photoactivation at 400 nm in the presence of oxygen, causing cellular destruction by release of oxygen free radicals. In skin exposed to light, the porphyrins become photoexcited, and clinically evident cellular damage occurs. Porphyrin-laden erythrocytes also undergo phototoxicity when circulating through light-penetrated tissues. The damage may be sufficient to result in hemolytic anemia.

Management of acute intermittent porphyria has been primarily aimed at avoiding exacerbating conditions. Adequate caloric intake, prompt diagnosis and treatment of infections (including odontogenic and other orofacial infections), and care in not taking medications known to trigger attacks are strategies the patient can use to minimize the risk of developing a crisis. In patients who have photoreactive porphyria, avoidance of sunlight, wearing clothing to cover the skin, and generous use of sunscreen lotion are helpful. If an acute attack occurs that is not amenable to glucose infusion, a medication of choice is lyophilized hemin with sodium carbonate. Hemin is ferric heme that has a Cl^- on one of the two available coordination sites for Fe^{+++} (see Figure 30-2). On mixing with sterile water, hemin is converted in the resulting alkaline solution to hematin by replacement of the Cl^- with an OH^- group. Hematin serves as an enzymatic inhibitor of porphyrin synthesis by decreasing the concentration of the precursors porphobilinogen and δ-aminolevulinic acid. The reconstituted drug is unstable, however, and has been frequently associated with thrombophlebitis and increased coagulopathy. Palliative use of opioid analgesics is also often indicated during porphyric exacerbations.

THALASSEMIA

In addition to problems affecting iron and porphyrin, several disorders of the third component of hemoglobin—the globin chains—can lead to clinical anemia. Grouped together, these disorders are called the *thalassemias*. As discussed previously, normal hemoglobin A is composed of two α-globin and two β-globin chains. When there is a genetic defect in the production of the α chains, the patient has α-thalassemia. Similarly, a defect in the β chains results in β-thalassemia. Sickle cell anemia, although normally addressed as a separate entity, is a variant of β-thalassemia. Thalassemias generally result in a decreased production of their respective protein chains. As a result, hemoglobin synthesis is impaired, and a non–iron-deficient, hypochromic, microcytic anemia ensues.

There are two pairs of genes encoding the α-globin chains, both located on chromosome 16. When all four α-globin genes are defective, the fetus develops hydrops fetalis, a condition incompatible with life. If there is a defective mutation in one of the four genes, the individual is clinically normal but is called a *silent carrier*. If two genes are affected, the patient has *α-thalassemia minor*. The hematocrit is mildly depressed (32% to 40%), and there is a marked decrease in erythrocyte size (MCV 60 to 75 fL). All iron parameters are normal. If three genes are affected, the patient is diagnosed with *α-thalassemia intermedia*, also known as *hemoglobin H disease*. Hemoglobin H is composed of tetramers of β-globin (β_4), resulting from a relative excess of β-globin chains compared with the α chains. Hemoglobin H has a high affinity for oxygen and binds it too tightly for efficient tissue delivery. It is unstable, being prone to denaturation by oxidative medications (e.g., sulfonamides) and infectious conditions. The hematocrit in hemoglobin H disease is markedly depressed (22% to 32%), and the anemia is hypochromic and microcytic in nature (MCV 60 to 70 fL). Clinical signs of the disease include pallor and splenomegaly.

β-Thalassemias exhibit a similar variability in severity based on which mutations in the genome are present. Most β-thalassemias result from point mutations in the gene, which create premature stop codons or cause difficulties with RNA transcription. As a result, the affected β chain may be either reduced (β^+) or absent (β^0). Because the δ or γ forms of hemoglobin can substitute for the β form, β-thalassemias typically have decreased ratios of hemoglobin A ($\alpha_2\beta_2$) and increased ratios of hemoglobin A_2 ($\alpha_2\delta_2$) and hemoglobin F ($\alpha_2\gamma_2$). The total amount of useful hemoglobin is usually severely depressed, however, decreasing oxygen transport capability. Further clinical disease occurs because of a relative excess of α-globin chains, which precipitate and cause damage to the developing erythrocytes and the circulating peripheral

erythrocytes. The intramedullary destruction of reticulocytes triggers a hyperplastic response by the bone marrow, resulting in increased marrow spaces and subsequent pathologic fractures and osteopenia. Peripherally, the destruction of the red blood cells may lead to a potentially life-threatening hemolytic anemia, splenomegaly, hepatomegaly, and hyperbilirubinemia.

The correct diagnosis of thalassemia is crucial to proper treatment. Mild forms of the disease need no treatment. More severe forms typically require transfusion support and folate supplementation. Iron therapy should be avoided because there is often hemosiderosis/iron overload owing to insufficient complete hemoglobin production. Patients requiring chronic transfusions are particularly susceptible to iron overload. In these cases, deferoxamine can be used to chelate iron and suppress the progression of hemosiderosis. Splenectomy may be required if severe hemolysis is occurring. Finally, allogeneic bone marrow transplantation may be required to correct the defect in severe cases.

Sickle Cell Anemia

Sickle cell anemia is technically a variant of β-thalassemia. A point mutation in the number 6 position of the β-globin chain causes a valine to be substituted for glutamic acid. As an autosomal recessive disorder, *sickle cell anemia* occurs when both alleles are positive for the sickle variant. *Sickle cell trait* occurs in the heterozygous state, where partial penetrance ($\alpha_2\beta^s\beta$) can occur. The abnormal β chain is designated β^s, and the resulting tetramer of $\alpha_2\beta^s{}_2$ is known as *hemoglobin S*. The significance of hemoglobin S is that in the severely deoxygenated state the globin tetramers are capable of coalescing into long, straight, spiral polymers that act as deforming filaments within the red blood cell. The cell loses its typical biconcave disk shape and its inherent pliability that is so important for moving through the microvasculature. These deformed and hardened erythrocytes are much more prone to automembrane damage and hemolysis. Simultaneously, the sickled shape makes them likely to cause microvascular occlusion and endothelial vascular damage.

Sickle cell anemia generally first manifests in the homozygous patient by age 6 months, when hemoglobin F is downregulated and hemoglobin S becomes the dominant form of hemoglobin in the erythrocyte. Many patients with homozygous disease can have normal lives as long as they avoid situations in which moderate-severe hypoxic stress can develop. Acute crises of sickling occur when the globin tetramers are deoxygenated for a sufficient time to allow polymerization into the deforming filamentous form. Small infections, such as odontogenic infections, may or may not cause an acute crisis. Although acidosis can develop, unless the red blood cells are severely hypoxic, they reoxygenate at the lungs before developing significant polymers and distorted cells. If the hypoxic stress is great, such as with more severe infection acute sickling occurs. The episodes are extremely painful, often lasting several hours to days. Treatment for the acute crisis is aimed at hydration, oxygenation, and resolution of the underlying precipitating factor. Many patients require opioid analgesics to help them through a crisis.

A patient with sickle cell anemia who is prone to repeated acute crises experiences various chronic complications from the disease. The erythrocytes containing hemoglobin S have a shortened life span compared with the erythrocytes containing hemoglobin A, and episodes of sickling accelerate their demise, resulting in a chronic hemolytic-type anemia. The anemia predisposes the patient to diminished oxygen transport capability (furthering the likelihood of a sickling crisis), and the breakdown by-products of the erythrocytes can produce clinical jaundice, hepatomegaly, and splenomegaly. At the same time, chronic and repeated microvascular occlusive episodes can cause renal infarction, stroke, retinopathy, cardiomyopathy, and hepatic damage from occlusive ischemic necrosis. Many patients develop significant microvascular damage in the spleen because of its slow, tortuous microcirculation. In some cases, the spleen ultimately undergoes reactive fibrosis and becomes a small, scarred, essentially nonfunctional organ (autosplenectomy). In severe cases of sickle cell anemia, death can occur from multisystem organ failure.

Two strategies have been used in the long-term management of sickle cell anemia: bone marrow transplantation and pharmacotherapy. In one controlled study, definitive cure was shown in 36 (86%) of 42 cases by bone marrow transplantation from an antigen-matched sibling, with 5 of the 6 failures cured by subsequent engraftment.[14] Bone marrow transplantation replaces the pluripotent stem cells of the marrow with cells of a person without the genotype, erasing the genetic defect. Although bone marrow transplantation is significantly more predictable than in years past, there is still a significant (>10%) mortality rate associated with the procedure, and the implications of chronic graft-versus-host disease must be weighed. This approach is generally reserved for severe cases that exhibit recurrent sickle crises.

Although still experimental, pharmacologic therapy has shown at least partial success in β-thalassemia and sickle cell anemia. This approach is based on the premise that any measure that increases the quantity of β-like globin molecules in erythrocytes is beneficial.[21] Several antineoplastic agents—cytarabine, hydroxyurea, 5-azacytidine, interferon-γ, butyrates, and EPO with or without hydroxyurea—have been used to stimulate the formation of hemoglobin F. Hemoglobin F transports oxygen as effectively as hemoglobin A, and it circumvents the genetic abnormalities associated with defective β-globin synthesis. In addition, hemoglobin F suppresses the polymerization of hemoglobin S, helping further to reduce the effects of the disease. Although not a cure, this therapy has been recommended by the National Institutes of Health for adult patients, as long as they are closely monitored hematologically, to reduce the pain and organ damage of sickle cell anemia.[1]

VITAMIN B_{12}, FOLIC ACID, AND MEGALOBLASTIC ANEMIA

Deficiency Syndromes

Vitamin B_{12} and folic acid are two nutritional supplements that are crucial to normal DNA synthesis. When one or both of these are deficient, all rapidly dividing cells throughout the body, but especially cells of the bone marrow and gastrointestinal epithelium, begin to have difficulties with proliferation and differentiation caused by inhibition of mitosis and cytokinesis. Primarily, DNA synthesis is impaired; the resulting cells have large RNA-to-DNA ratios, increased cytoplasmic compartments, and unusual immature nuclear forms. In hematopoiesis, the deficiency causes the cells to assume a characteristic macrocytic and often oval or irregular shape that resembles the less mature blast forms—hence the term *megaloblastic anemia*. Protein synthesis is also adversely affected, resulting in substandard cell membranes and shortened life spans, causing the anemia to have a hemolytic component as well.

Although the diagnosis of megaloblastic anemia is most commonly made because of the characteristic changes in erythrocytes, all hematopoietic cell types are affected, which in rare cases can result in pancytopenia. The myeloid-derived cells released into the bloodstream may include macro-ovalocytes, hypersegmented polymorphonuclear leukocytes, and oversized platelets. Depending on which cell types

are adversely affected, there may be not only clinical fatigue caused by erythropoietic depression, but also leukopenia and thrombocytopenia, with an increased potential of infection (particularly in the urinary tract) and hemorrhage.

Although folic acid and vitamin B_{12} have similar effects on the developing erythrocytes, the overall clinical presentations of their respective deficiency states differ greatly. The similarity comes from the sharing of a common biochemical pathway. The major difference is that neurologic manifestations often occur with vitamin B_{12} deficiency but not with folic acid deficiency. Folate deficiency alone is characterized by pallor, anemia, fatigue, and glossitis. Vitamin B_{12} deficiency results in the same signs and symptoms as folate deficiency but also causes inadequate myelin synthesis and epithelial replacement in the gastrointestinal tract. Symptoms of vitamin B_{12} deficiency include gastrointestinal disturbances, weight loss, hepatomegaly, splenomegaly, and prominent neurologic disturbances related to inadequate myelin formation and maintenance. Paresthesias involving the peripheral nerves are the most common presenting symptoms. There is also decreased vibration and positional sense. Reflexes may be altered, and motor disturbances, including weakness and loss of sphincter tone, may occur. As the disease progresses, the posterior columns are affected, resulting in difficulty with balance.

In advanced cases, cerebral dysfunction may lead to memory loss, confusion, or dementia and other neuropsychiatric changes. It is crucial to diagnose correctly and treat a vitamin B_{12} deficiency early because most of these neurologic findings can be reversed in the early stages. Patients with more advanced cases have permanent neurologic damage. On occasion, neurologic changes occur without hematopoietic alterations.

Although any interruption in DNA synthesis, maturation, or division of marrow stem cells can give rise to a megaloblastic anemia, virtually all cases seen clinically result from vitamin B_{12} or folic acid deficiency. The cause may be insufficient dietary intake, decreased absorption, decreased utilization, or increased destruction of either or both of these two essential nutrients. Other, rarer causes include chemical agents that interfere with purine metabolism (e.g., chemotherapeutic drugs) and an intestinal parasite, the fish tapeworm (*Diphyllobothrium latum*), which competes successfully with the host for available vitamin B_{12}.

One particular form of vitamin B_{12} deficiency is *pernicious anemia*. Historically, some anemic patients did not respond to iron supplementation, and their disease was characterized as pernicious, meaning fatal. Although Addison and others described pernicious anemia in the early 1800s, it was not until 1926 that Minot and Murphy[25] showed the value of raw liver in treating the disease. Castle[4] showed in 1927 that a carrier glycoprotein secreted into the intestinal lumen by the gastroparietal cells plays a crucial role in reversing the lethal course of pernicious anemia. This finding led to the isolation of vitamin B_{12}.

Vitamin B_{12}

Nutrition and physiologic characteristics

Vitamin B_{12} is a generic term for cyanocobalamin and hydroxocobalamin, two stable forms of cobalamin. Cobalamins are unique because they are the only cobalt-containing organic compounds known to occur in nature, and they represent the only known biologic example of a metal-carbon bond. The cobalamins are composed of a nearly planar macrocyclic corrin ring (similar to porphyrin) covalently linked to a trivalent cobalt atom by four coordination bonds in a manner similar to iron binding in heme (Figure 30-4).[24] The nucleotide 5,6-dimethylbenzimidazole is bound perpendicularly below this ring structure to the corrin ring and the cobalt atom, whereas various R groups above the ring are bound solely to the cobalt atom. Four forms of the cobalamins have significant biochemical activity in vivo. Cyanocobalamin has a cyanide moiety as its R group; hydroxocobalamin has a hydroxyl. Hydroxocobalamin is converted endogenously to either deoxyadenosylcobalamin (5′-deoxyadenosyl R group) or methylcobalamin (methyl R group), the major form of cobalamin in plasma.

The cobalamins are essential cofactors in three human enzymatic processes. Deoxyadenosylcobalamin activates methylmalonyl coenzyme A (CoA) mutase, a mitochondrial enzyme that converts potentially toxic methylmalonyl CoA to the easily metabolized succinyl CoA. Methylmalonyl CoA is produced in the catabolism of propionate, which is formed during the breakdown of valine and isoleucine. In vitamin B_{12} deficiency, it is believed that accumulation of methylmalonyl CoA results in aberrant fatty acid synthesis and metabolism, causing nonphysiologic fatty acids to be incorporated into cell membranes of the central nervous system, leading to the neurologic symptoms already described.[2]

In a separate enzymatic pathway, methylcobalamin serves as a cofactor for methionine synthase, a cytoplasmic methyltransferase that converts homocysteine and 5-methyltetrahydrofolate to methionine and tetrahydrofolate. As discussed later, tetrahydrofolate is the precursor to many folate cofactors, several of which are crucial to DNA synthesis. When vitamin B_{12} is deficient, 5-methyltetrahydrofolate (derived from dietary folate) accumulates, and tetrahydrofolate (the metabolically useful product) declines, leading to megaloblastic anemia. Because of the common factor of folic acid, pharmacologic vitamin B_{12} can sometimes ameliorate a folic acid deficiency and vice versa. As stated previously, folic acid alone cannot correct the induced neurologic changes associated with decreased vitamin B_{12} activity. A deficiency of methionine, an essential amino acid whose daily utilization is approximately twice the normal dietary intake, may contribute to the degenerative nervous system changes that can occur in pernicious anemia.

The third vitamin B_{12}–dependent enzyme is leucine 2,3-aminomutase, which permits the interconversion of leucine and β-leucine. It is unknown at this time how interruption of this pathway may contribute to human disease.

The sole natural and commercial source of cobalamin is synthesis by microorganisms. Many animals can use vitamin B_{12} produced by their own enteric bacteria, but because microbial synthesis in humans is limited to the large intestine, a site too distal for effective absorption, humans must derive their vitamin B_{12} exogenously. Foods rich in vitamin B_{12} include shellfish, such as oysters and clams (>10 μg/100 g tissue), and mammalian organ meats (liver, kidney, and heart). The average daily diet contains 5 to 30 μg of vitamin B_{12}, of which 20% to 30% is absorbed. Daily intake of 1 to 3 μg does little more than compensate for daily loss, but normally more than 1000 times this amount (up to 4 mg) is stored in the liver.

Vitamin B_{12} is quite lipophobic and depends heavily on transfer mechanisms to be absorbed from the gastrointestinal tract. Cobalamin transport is mediated by several different proteins. When first ingested, the cobalamin liberated from food interacts with *R proteins* in the stomach. These proteins bind tightly to cobalamin and protect it from acidic degradation, but they do not have any ability to transport the cobalamin across the enteric mucosa. As the R protein–cobalamin complex moves into the duodenum and the pH increases, pancreatic proteases degrade the R protein from around the cobalamin. The cobalamin is next adsorbed onto *intrinsic factor,* a glycoprotein secreted by the stomach parietal cells

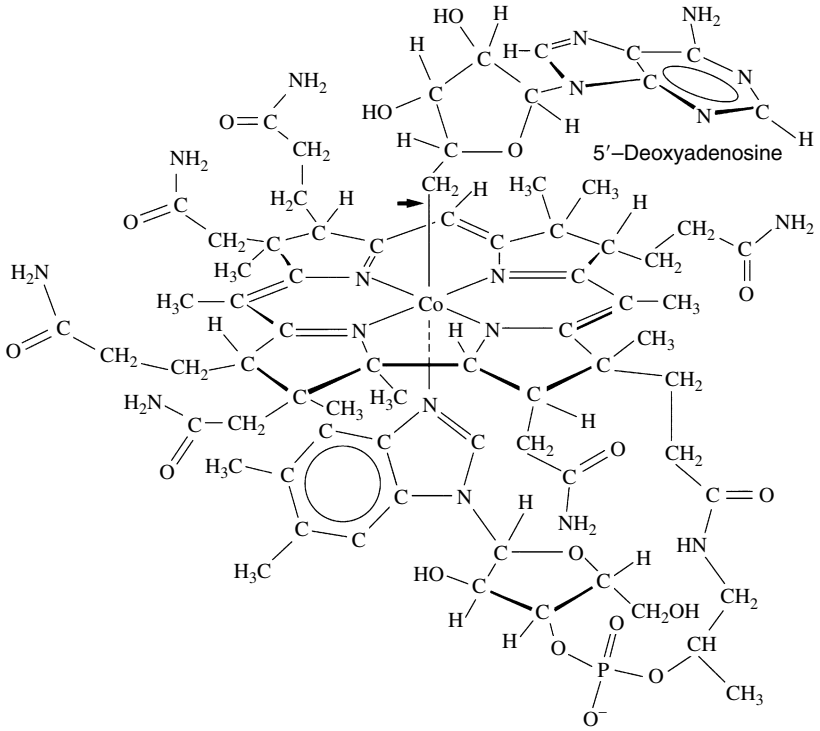

FIGURE **30-4** Hemelike corrin ring structure of deoxyadenosylcobalamin, one of the active coenzyme forms of vitamin B_{12}. Current therapeutic agents cyanocobalamin and hydroxocobalamin have CN or OH substituted for the 5′-deoxyadenosyl moiety at the bond indicated by the arrow. Methylcobalamin (CH_3 substituted) and deoxyadenosylcobalamin are active coenzyme forms. (Adapted from McGilvery RW, Goldstein GW: *Biochemistry: a functional approach*, ed 3, Philadelphia, 1983, Saunders.)

that has specific cobalamin-binding properties. The intrinsic factor–cobalamin complex is carried to the ileum, where highly specific receptors on cells of the ileal microvilli transport it across the cell membrane. In the enterocytes, the intrinsic factor is broken down, liberating the cobalamin. A plasma polypeptide, *transcobalamin II*, binds the cobalamin to carry the vitamin into the portal bloodstream.

Receptors for this protein-cobalamin complex are ubiquitous, but are especially rich in the liver. If the vitamin is needed in the tissues, it is taken up by the respective cells by endocytosis. If there is surplus, the cobalamin is moved to the hepatocytes for storage. Inside the cell, the cobalamin is freed by lysosomal enzymes, and the transcobalamin II is recycled back for reuse.

Transcobalamin II is the active transport protein, yet most of the circulating cobalamin is bound to two other transcobalamins—I and III—with transcobalamin I being the principal binding protein. Both proteins are also known to exist in saliva, bile, milk, and other fluids. It is unknown if transcobalamin I functions as a storage reserve of vitamin B_{12} or if it is involved in the excretion of nonuseful corrinoid moieties. Dietary foodstuffs do have other corrin-containing compounds, and it has been theorized that transcobalamin I binds all corrin compounds, not just vitamin B_{12}. The bound complexes are excreted into the intestine by the bile. In the intestine, vitamin B_{12} is reabsorbed with the assistance of intrinsic factor, whereas the other corrin compounds are excreted in the feces.

The enterohepatic cycling of cobalamin emphasizes the striking ability of the body to retain cobalamin. Normal hepatocyte turnover releases 3 to 4 μg of cobalamin into the bile each day, but the vitamin is essentially quickly rebound by intrinsic factor in the small intestine and reabsorbed. Very little new vitamin B_{12} is required in the diet each day. As long as the ability of the body to transport cobalamin across the intestinal wall and reabsorb the bile-secreted cobalamin is intact, a diet completely devoid of vitamin B_{12} may not produce clinical symptoms for many years.

Pathophysiologic characteristics

Vitamin B_{12} deficiency can be difficult to diagnose. Typically, the MCV of the erythrocytes is markedly increased (usually 110 to 140 fL). If there is a concurrent iron deficiency anemia, the combination of microcytic and macrocytic anemias may result in relatively normal-sized cells. Other times, the cells are normocytic for obscure reasons. The peripheral blood smear is abnormal, showing anisocytosis and poikilocytosis, along with the characteristic macro-ovalocytes. Multilobulated neutrophils are typical. Hemolytic changes, resulting in increased plasma bilirubin, lactate dehydrogenase, iron, and saturated transferrin, may also be found. Serum vitamin B_{12} concentrations, normally 150 to 350 pg/mL, are less than 100 pg/mL. Currently, interest has focused on measuring homocysteine and methylmalonic acid concentrations as good indicators of vitamin B_{12} deficiency, especially because a rise in homocysteine has been shown to be a significant risk factor for cardiovascular disease.[19]

It is rare to see an individual with dietary vitamin B_{12} insufficiency, especially in first-world nations. Only vegans, the strictest of vegetarians who eat no animal products whatsoever (including dairy products), may show dietary insufficiency. Even then, small amounts of vitamin B_{12} may be available in the diet from microorganisms of legumes or exogenous application of cobalamins to grain and cereal products. As previously mentioned, dietary deficiency may take decades to become clinically evident.

A more common difficulty is with malabsorption of dietary cobalamin. In these patients, the transport proteins are defective, so that not only is the primary absorptive capacity decreased or lost, but also the ability of the body to recycle enterohepatic cobalamin is impaired. These patients have a much more rapid onset of symptoms, usually 3 to 6 years. Three basic causes exist: (1) inadequate production of intrinsic factor in the stomach; (2) altered ileal ability to absorb the intrinsic factor–cobalamin complex; and (3) pancreatic disease, in which transfer of the cobalamin from the R proteins to intrinsic factor is interrupted.

Pernicious anemia is a hereditary autoimmune disease in which antibodies develop against intrinsic factor. Although the disorder is hereditary, the patient is usually middle-aged or older with age-related chronic atrophic gastritis. The antibodies (IgG or IgM) may bind to intrinsic factor and prevent cobalamin binding, or they may bind to the intrinsic factor–cobalamin complex to prevent the complex from binding to the ileal receptors. In the classic form, other problems such as IgA deficiency, polyglandular endocrine insufficiency, and predisposition to gastric carcinoma, are also found. Additional causes of decreased gastric secretion resulting in a condition similar to pernicious anemia include severe nonautoimmune gastritis, atrophic gastritis, and surgical resection. Surgical gastrectomy results in loss of intrinsic factor, usually in proportion to the amount of stomach removed. Total or near-total gastrectomy causes vitamin B_{12} deficiency and requires supplemental therapy.

Ileal problems may also lead to vitamin B_{12} deficiency. Luminal stasis may allow significant enteric bacterial overgrowth, leading to blind loop syndrome; the vitamin is "stolen" by the bacteria and is unavailable to the host. Other conditions such as surgical resection, carcinoma, Crohn's disease, and other inflammatory bowel disorders may similarly induce a vitamin B_{12} deficiency. Because vitamin B_{12} deficiency results in decreased DNA synthesis of rapidly dividing cells, the enterocytes themselves begin to experience inhibition of mitosis and cytokinesis as the availability of cobalamin declines. As the disease progresses, it becomes increasingly self-perpetuating because the enterocytes become defective and further lose their ability to absorb cobalamin. Pancreatic disease decreases the absorption of vitamin B_{12} by impairing the secretion of bicarbonate and pancreatic proteases necessary to degrade the R protein–cobalamin complex in the small intestine.

Finally, certain drugs such as *p*-aminosalicylic acid can reduce cobalamin absorption. Megadoses of vitamin C may cause vitamin B_{12} to be converted to nonuseful analogues, some of which may harbor anti–vitamin B_{12} activity.[12] Long-term exposure to nitrous oxide has been shown in pigs and humans to result in megaloblastic anemia by inhibiting methionine synthase activity. The nitrous oxide irreversibly oxidizes the exposed cobalt atom after the methylcobalamin cofactor of methionine synthase has transferred its methyl group to homocysteine. In so doing, nitrous oxide permanently inactivates the enzyme.

Therapeutic use

Various preparations are used for vitamin B_{12} therapy, most commonly cyanocobalamin and hydroxocobalamin. Both are given by intramuscular or deep subcutaneous injection. Hydroxocobalamin is more highly protein-bound and remains in circulation longer, but the more popular form is cyanocobalamin because hydroxocobalamin has been associated with the development of antibodies to the transcobalamin II–vitamin B_{12} complex. Neither cyanocobalamin nor hydroxocobalamin should be given intravenously.

Oral cobalamin is a relatively ineffective and expensive therapy because it relies on the same protein transport systems that have usually gone awry. In very high doses, sufficient vitamin B_{12} can be passively absorbed across the intestinal wall to correct some deficiencies. Although oral vitamin B_{12} is often formulated with intrinsic factor concentrate or liver extract to aid in the absorption process, these are not recommended over preparations of cobalamin only. The oral route is generally reserved for patients who cannot tolerate intramuscular injections.

Initial treatment of pernicious anemia involves twice-weekly intramuscular injections of vitamin B_{12} for several months. Such treatment brings about a rapid change in the bone marrow from megaloblastic to normoblastic erythropoiesis (usually in 2 to 3 days), with improving relief of glossitis, neuritis, and spinal cord degeneration in several months. As the blood picture improves, the interval between doses can be increased to 2 or 3 weeks. Because the hepatic stores are so great after they are replenished, the patient can eventually be put on maintenance therapy involving an injection every 1 or 2 months, but it must be continued for life. Neurologic damage that is not reversed after 12 to 18 months of therapy must be considered permanent.

Large doses of cobalamin are promptly excreted in the urine and to a lesser extent in the feces. There have been no reports of toxic effects from cyanocobalamin or hydroxocobalamin other than occasional allergic responses to impurities in the preparations. There is no evidence that large doses of cyanocobalamin result in cyanide poisoning.

Folic Acid

Nutrition and physiologic characteristics

In the course of an attempt to isolate vitamin B_{12} to treat another form of macrocytic anemia peculiar to Hindu women, a different hematopoietic factor, folic acid (folacin or pteroylglutamic acid), was recognized and isolated.[36] Because the hematologic picture produced by vitamin B_{12} deficiency is almost indistinguishable from that of folic acid deficiency, it is not surprising that the paths of discovery of these two essential antianemic factors were so entwined.

Although not usually referred to as such, folic acid fits the definition of a vitamin. It occurs widely in nature as polyglutamate conjugates, but is an essential nutrient in microgram quantities for humans. Folic acid itself is formed from glutamic acid, *p*-aminobenzoic acid, and pterin, as is shown in Figure 30-5. Fresh green vegetables (e.g., asparagus, broccoli, spinach, lettuce) are an excellent source of folic acid. Fruits such as bananas, lemons, and melons have high amounts, and liver, kidney, yeast, and mushrooms are also abundant in folate conjugates. Prolonged cooking destroys folic acid, especially when the conjugates are in dilute aqueous solution.

Absorption occurs primarily in the proximal jejunum, and it depends on specific mucosal membrane carboxypeptidases (conjugates) that hydrolyze the dietary polyglutamates to yield folic acid. In the mucosa, folic acid is reduced by dihydrofolate reductase and methylated to 5-methyltetrahydrofolate before entering the bloodstream. When in tissues, the compound is demethylated by vitamin B_{12}–dependent methionine synthase. The product, tetrahydrofolate, is conjugated with 1-carbon moieties to yield several active coenzyme forms that are essential for purine and thymidylate synthesis. Tetrahydrofolate is also involved in the conversion reactions of several amino acids. Figure 30-6 illustrates the major metabolic pathways and interactions of folate and vitamin B_{12}.

The minimum daily folate requirement for humans is approximately 50 μg, but because of incomplete absorption and special requirements for lactating women and certain other individuals, a daily intake of 400 μg of free folate is recommended. Folate is stored to some extent in cells as polyglutamates, primarily as the pentaglutamate, and is recycled through the enterohepatic pathway similarly to cobalamin. The resorptive process is far less efficient than with vitamin B_{12}, however, and deficient intake may manifest as megaloblastic anemia within a month.

Pathophysiologic characteristics

Folic acid deficiency has the same hematologic profile as cobalamin deficiency. As previously mentioned, folic acid deficiency causes a megaloblastic anemia essentially without neurologic manifestations. In patients who are folate-deficient, serum folate concentrations are less than 3 ng/mL, and erythrocyte folate is less than 150 ng/mL.

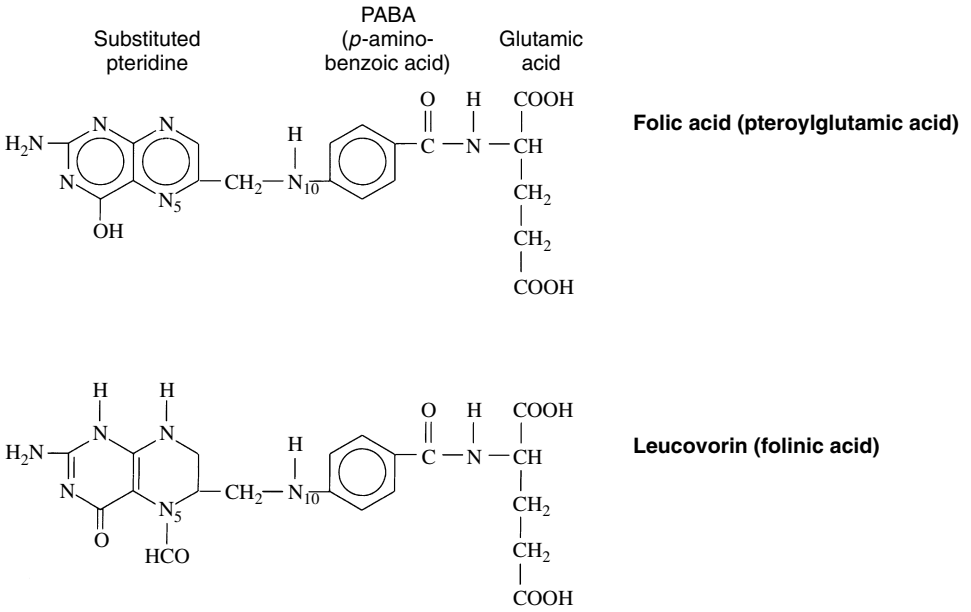

FIGURE **30-5** Structural formulas of folic acid and leucovorin.

Despite the fact that folates are abundant in many foods, deficiency still occurs from many different causes. Various malabsorption syndromes disturb the absorption of folic acid by the intestines. Phenytoin and other antiepileptic drugs, oral contraceptives, and antimalarial drugs may cause folate deficiency by inhibiting folate conjugates in the intestinal wall. The antimetabolites methotrexate and trimethoprim inhibit dihydrofolate reductase and lead to a megaloblastic anemia with prolonged use.

Elderly individuals and individuals of low socioeconomic status may have an inadequate intake of folate simply from poor nutrition. Overcooking of folate-containing foods, if consistently performed, can lead to folate deficiency. Pregnancy greatly increases the maternal requirement for folate, and a marginal diet can become inadequate to meet the growing demands of the fetus. Maternal folate deficiency, especially before conception, has been implicated in fetal neural tube defects such as spina bifida. Chronic debilitating disease, such as cancer and myeloproliferative disorders, may predispose a patient to folic acid deficiency. Alcoholism and other hepatic diseases are definitely correlated with folate deficiency caused by generally poor nutritional status, malabsorption difficulties across the intestinal wall, and depleted liver stores.

Folate therapy

Folate deficiency can often be treated with simple dietary supplements, such as an additional piece of fresh fruit daily. The vitamin is available in oral tablet form, is included in most multivitamin preparations, and is supplied for injection in the form of sodium folate or the calcium salt of folinic acid (citrovorum factor) under the nonproprietary name of leucovorin (see Figure 30-5). Leucovorin has been used to counteract the effects of folic acid antagonists (e.g., the dihydrofolate reductase inhibitors methotrexate and trimethoprim) used in cancer or malaria chemotherapy. A study showed that even simple use of folic acid or folinic acid greatly improved the side effects of methotrexate therapy in patients with rheumatoid arthritis, allowing better tolerance of the chemotherapeutic agent.[34] The response to oral folic acid therapy is rapid, and an improvement in the hematologic picture is seen 5 to 10 days after beginning daily administration of folic acid. Adverse effects directly attributable to folic acid have not been reported.

HEMATOPOIETIC GROWTH FACTORS

Perhaps the most exciting advance in the pharmacologic management of anemia and related disorders has been the introduction of hematopoietic growth factors to the therapeutic armamentarium. Numerous diseases and iatrogenic disorders can cause all or part of a patient's hematopoietic system to produce insufficient cells; the result is usually a pancytopenia with different degrees of individual cell line depression. Examples of causative conditions include the many varieties of leukemia, myeloproliferative disorders, lymphomas, aplastic anemia, and end-stage renal disease; therapies such as cytotoxic chemotherapy, ionizing radiation, stem cell transplants, and bone marrow transplantation also are causes. Other causes include side effects of medications such as the sulfonamides, phenytoin, zidovudine, and carbamazepine. In the past, the only recourse was to transfuse the patient with whole blood or appropriate replacement components of blood. In severe instances, a bone marrow transplant may have been necessary. Although not a panacea, the introduction of several hematopoietic growth factors has greatly reduced the need for transfusion therapy in many patients with various forms of hematopoietic depression. All these products are derived from their respective human genes that have been subcloned into mammalian, bacterial, or yeast expression systems so that large quantities can be obtained.

Erythropoietin/Darbepoetin

Background and physiologic characteristics

EPO was the first growth factor to be identified and successfully cloned into a recombinant vector. The gene is located on chromosome 7q11-22, and the final endogenous protein is a 165-amino acid glycoprotein with a molecular weight of 30,400 Da. Native EPO is formed primarily in the kidneys and, to a smaller degree, in the liver.[8] It is the major humoral regulator of red blood cell production and does not seem to have any effect on other cell lineages.

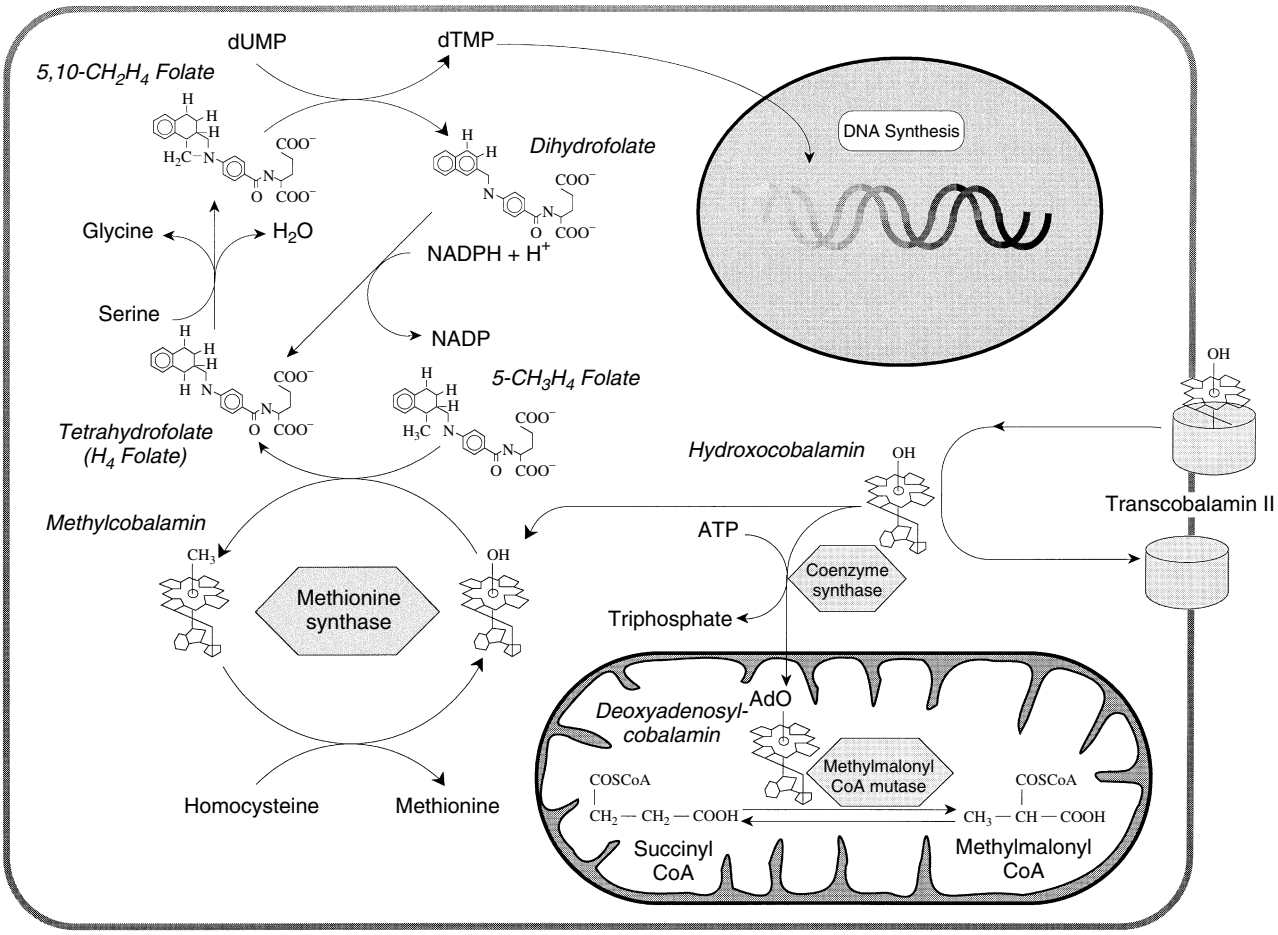

FIGURE **30-6** Major pathways of folate and vitamin B_{12} metabolism. Dietary folates are converted to 5-methyltetrahydrofolate (*5-CH_3H_4 folate*). Demethylation by the enzyme methionine synthase yields tetrahydrofolate, an acceptor of single-carbon units in the metabolism of histidine (not shown) and serine. The folate products of these reactions provide carbon units for the synthesis of purines and, as shown for 5,10-methylenetetrahydrofolate (*5,10-CH_2H_4 folate*), the conversion of deoxyuridylate (*dUMP*) to thymidylate (*dTMP*). Vitamin B_{12}, carried to the cell by transcobalamin II in the form of hydroxocobalamin, is converted to methylcobalamin and deoxyadenosylcobalamin, necessary cofactors for methionine synthase and methylmalonyl CoA mutase. *AdO,* Deoxyadenosyl moiety; *NADP,* nicotinamide adenine dinucleotide phosphate; *NADPH,* reduced nicotinamide adenine dinucleotide phosphate.

EPO expression is regulated in the kidney in response to the local oxygen tension by signaling mechanisms that are not well understood but are suspected to involve a membrane-bound, oxygen-sensitive heme protein.[11] The newly formed EPO moves to the bone marrow, where it attaches to EPO receptors on the cell membranes of myeloid stem cells, causing the cells in the presence of other regulatory factors to differentiate into erythroblasts and ultimately into erythrocytes. When committed to the erythrocytic line, these cells become dependent on continued EPO for their survival. If EPO is removed, the cells die within one or two cell cycles. As a result, it has been postulated that EPO may be an apoptosis inhibitor rather than a differentiation stimulator. Bone marrow sensitivity to EPO depends on the availability of iron; various inflammatory mediators suppress EPO secretion and stem cell stimulation.

Pathophysiologic characteristics

In disease states, EPO synthesis may be disrupted (as in end-stage renal disease), the protein may be prematurely cleared (as in the anemia associated with rheumatoid arthritis), or the target stem cells may not be responsive to it (as in some myeloproliferative disorders). In all cases of depressed synthesis or accelerated catabolism, the plasma EPO is low. If the problem is decreased tissue responsiveness, plasma EPO levels may be increased 100 times above normal.

Therapeutic use

Two forms of pharmacologic EPO are currently available. The recombinant form of the endogenous glycoprotein known as *epoetin alfa* has been available for several years and has been well tolerated. It generally requires intravenous or subcutaneous dosing three times a week. A newer form, darbepoetin alfa, has been approved for use and requires dosing only once a week. Darbepoetin contains five N-linked oligosaccharide chains instead of only three such chains in epoetin. Its pharmacologic profile is similar to that of epoetin alfa.

Both forms of EPO are currently approved for use in the anemia of chronic renal failure and cancer chemotherapy. Epoetin alfa has also been extensively studied for use in numerous other conditions that result in anemia or pancytopenia for which there is insufficient production of EPO in relation to the metabolic needs of the patient. One study showed that the use of EPO with supplemental iron significantly improved the health status of patients with congestive

heart failure and anemia. Treated patients experienced relative improvements in serum creatinine and left ventricular ejection fraction, resulting in better renal function and a reduced need for diuretics. The authors concluded that correction of anemia markedly enhanced cardiac function in these patients.[31]

Epoetin alfa has the most consistent effect when plasma EPO is low, but exogenous EPO has also been successful in treating some conditions in which endogenous titers are already high, and the target stem cells seem to be resistant to the effects of the protein. Epoetin alfa is also used in the treatment of chronic anemia associated with acquired immunodeficiency syndrome, but results have been inconsistent. On the positive side, epoetin alfa can often stabilize a patient's hematopoietic profile enough to resume zidovudine therapy. Zidovudine depresses the bone marrow, complicating the anemia to the point at which it may be necessary to discontinue the medication.

Epoetin alfa is sometimes used to prepare patients for autologous blood donation before nonemergency surgery. In these instances, the patient is phlebotomized normally and put on a course of epoetin alfa for a few weeks before surgery. Just before the surgery, patients can be phlebotomized again to maximize the available yield of autologous blood. Epoetin alfa has also been used in patients who require blood products but do not allow transfusions for religious reasons. Epoetin alfa solutions contain human albumin, a blood product. For this reason, these patients may still refuse the therapy unless the diluent can be changed.

Epoetin alfa can be given intravenously and is well absorbed, but the subcutaneous route is preferred because of a greater persistence of each dose in the plasma. (Epoetin alfa has a half-life of 6 to 9 hours after intravenous injection, but 24 to 30 hours after subcutaneous administration.) Less medication needs to be given, resulting in lower cost and fewer adverse effects. Contraindications for its use include uncontrolled hypertension and allergy to albumin or mammalian cell–derived products. Adverse reactions include aggravation of existing hypertension, seizures, headache, and nausea. Failure of epoetin alfa most commonly results from the development of a significant iron deficiency caused by the increased production of hemoglobin. For this reason, close monitoring of the iron stores (TIBC, iron, ferritin) should be performed routinely, with iron supplementation given as necessary. The rate of hematocrit increase should not exceed 4% per week to avoid depleting the iron stores. Clinically significant results are usually seen in 2 to 6 weeks.

Myeloid Growth Factors

Background and physiologic characteristics

Several additional growth factors are currently approved for use by the U.S. Food and Drug Administration. Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), are crucial to the early and intermediate development of the myeloid line of hematopoiesis. G-CSF is a lineage-specific growth factor for the neutrophil line, whereas GM-CSF is a stimulator for granulocytes and monocytes (with some erythrocyte and megakaryocyte effect as well; see Figure 30-1). In addition to increasing the numbers of neutrophils, both also activate the neutrophils and monocytes/macrophages in the tissues. Their names are derived from their ability to stimulate colony formation of hematopoietic stem cells when grown in semisolid media.

Recombinant human G-CSF, assigned the nonproprietary name of *filgrastim*, is synthesized in an *Escherichia coli* bacterial expression system. It is a 175-amino acid polypeptide. A pegylated derivative known as *pegfilgrastim* is produced by covalently linking a large polyethylene glycol moiety to the active polypeptide.

G-CSF binds to cell surface receptors present on the progranulocytes and stimulates them to proliferate and mature. The more differentiated cells are known to have two to three times more G-CSF receptors on their surface, which seems to correlate with increased functional activity in the presence of the drug. Exactly how the G-CSF upregulates transcription in the nucleus is currently unknown, but part of the therapeutic benefit of this medication is from enhanced neutrophilic activity and increased numbers.

The commercially available form of GM-CSF is a 127-amino acid glycopeptide with a leucine substitution at position 23; *sargramostim* is the nonproprietary name. Similar to G-CSF, GM-CSF stimulates terminal proliferation and differentiation of the granulocyte lineage. In contrast to G-CSF, it also stimulates the monocytic lineage. As with G-CSF, the mechanism by which the intracellular changes occur is unknown. It does seem, however, to require interleukin-3 (IL-3) stimulation to obtain a maximal differentiative response.[16]

Four additional growth factors have been cloned, purified, and made available for investigational laboratory and clinical use. They are stem cell factor (SCF), monocyte/macrophage-colony-stimulating factor (M-CSF), thrombopoietin (TPO), and IL-3. These four, coupled with G-CSF and GM-CSF, round out the six "classic" known hematopoietic stimulating agents.

SCF has been assigned the nonproprietary name of *ancestim*. As the name implies, SCF is crucial for the survival and proliferation of the early pluripotent/multipotent and myeloid/lymphoid stem cells. The immature stem cells produce and "autostimulate" themselves with their own SCF production to maintain a sufficient population of pluripotent/multipotent cells to keep the marrow supplied with adequate precursors for the various differentiation pathways. SCF alone does not push the stem cells toward maturation but maintains their immaturity. When coupled with other growth factors, SCF acts synergistically to "bump" the cells into a committed pathway, where most of these early intermediates begin to lose their need for this particular factor. As the cells continue to move toward maturation, SCF is no longer necessary.

M-CSF, as the name implies, promotes the growth and differentiation of monocyte progenitor cells, but only at high concentrations. More important, however, may be its ability to activate monocyte/macrophage cytotoxicity, as shown by its ability to increase the survival of patients with invasive fungal infections.[28] It remains to be seen how M-CSF may significantly differ in function from GM-CSF.

TPO has been tested in two forms. The first is a full-length, 332-amino acid recombinant human glycoprotein molecule known as *rhTPO*. The other is a pegylated truncated 163-amino acid form of the protein in which the receptor-binding N-terminal domain is intact. It is known as *pegylated megakaryocyte growth and development factor* (PEG-MGDF). TPO stimulates the megakaryocytic lineage, which results in increased platelet production by 10-fold. The medication so far has been used in cancer chemotherapy patients to hasten platelet recovery after thrombocytopenic nadirs are reached. The full-length and truncated versions seem to work equally well, but PEG-MGDF has caused neutralizing antibodies to develop in some patients.

IL-3 is encoded by a gene located near the gene for GM-CSF. Endogenous supply is essentially from activated T cells, mast cells, and natural killer cells.[10] IL-3 is a multilineage, broader-acting hematopoietic growth factor important in initiating early and intermediate stages of hematopoietic differentiation. It seems to be a crucial early trigger for the shift from pluripotent/multipotent stem cells down any of the myeloid differentiation pathways. IL-3 mediates its effects by the retinoic acid (vitamin A) receptors.[16] When "nudged" this

way, the cells show irreversible commitment and go on to become one of the myeloid stems that later differentiate into the granulocytic, erythroid, monocytic, or megakaryocytic lineages. IL-3 by itself has little differentiative activity, but it does seem to be involved in the crucial first step to bring stem cells out of the pluripotent/multipotent stage. As the cells mature, they become less dependent on its actions.

Interleukin-11 (IL-11), in the recombinant form of oprelvekin, is the first growth factor to gain approval for the management of thrombocytopenia. IL-11 is produced by fibroblasts and stromal cells in bone marrow. It binds to a specific receptor but acts with other growth factors to simulate the growth of myeloid and lymphoid cell lines. The primary therapeutic benefit is a significant decrease in the need for platelet transfusions in patients receiving chemotherapy for nonmyeloid cancers.

Pathophysiologic characteristics

Any of the diseases or therapeutic interventions that adversely affect the hematopoietic system may cause leukopenia, thrombocytopenia, or pancytopenia. Congenital or acquired bone marrow failure states, hematopoietic neoplasms, cancer chemotherapy, and total body ionizing radiation therapy are the most common causes for hematopoietic disruption.

Therapeutic use

Stimulating or accelerating the recovery of the bone marrow (especially the neutrophils) after disease or medical therapy is the primary indication for the myeloid growth factors G-CSF and GM-CSF. Similarly, TPO is being used to hasten the recovery of platelet counts in patients with thrombocytopenia. When so used, the window of immunosuppression and hemorrhagic vulnerability of leukopenic and thrombocytopenic patients has been significantly shortened, greatly improving chances for survival, while decreasing morbidity.

Filgrastim administered intravenously or subcutaneously is generally well tolerated, with the most common side effect being bone pain that clears on discontinuance of the medication. Rare serious reactions include anaphylaxis and splenic rupture. Pegfilgrastim is administered subcutaneously as a single dose after chemotherapy.

Sargramostim is administered intravenously. At normal doses, it does not significantly alter the megakaryocyte (and thrombocyte) or erythrocyte lineages. It does have significantly more severe side effects, however, especially at higher doses. The most common are fever, malaise, arthralgia, myalgia, and increased vascular permeability, which can lead to pleural and pericardial effusions.

SCF generally is given in conjunction with filgrastim and sargramostim. Its use is still limited; side effects associated with its administration include fever, chills, rash, myalgia, injection site irritation, and edema. In high doses, it can produce mast cell activation with associated symptoms.[35] IL-3 is usually given subcutaneously in daily doses in conjunction with GM-CSF and has been well tolerated.

Oprelvekin is injected daily for 3 weeks after a course of chemotherapy is completed. The therapeutic goal is to reach a platelet count of 50,000/μL. Impaired renal excretion of Na^+ may lead to fluid retention, hypokalemia, pulmonary edema, and atrial arrhythmias.

RED BLOOD CELL SUBSTITUTES AND PLASMA EXTENDERS

In recent years, considerable research has been focused on developing products that could substitute for blood on a temporary basis.[9] As the population ages and increases, and as surgeries become more sophisticated and therapies (e.g., for cancer) affect marrow function, more blood products are required for these procedures. Some patients have rare blood types that are simply unavailable at their hospital in significant quantities. In major trauma, large amounts of blood (≥20 U) might be required emergently, and careful screening, typing, and crossing is time-consuming. In times of war or natural disaster, urgent blood requirements can easily outstrip supplies. Testing blood for disease transmission risk is becoming increasingly complex (and costly) and remains problematic with some viruses; as a result, it is often not done in third-world nations. Finally, adherents of some religious groups do not accept blood product transfusions from another person.

As a result of these issues, several different products have been developed to serve as artificial blood capable of binding oxygen and supporting gaseous exchange in the lungs and peripheral tissues. Although *artificial blood* is technically a misnomer because these compounds do not have any of the cellular, immunologic, hemostatic, or hormonal constituents of whole blood, they do have the potential advantage that they could be manufactured in great quantities without the worry of viral contamination. Many of these compounds can be stored for long periods and can be administered in the field, and they serve as an emergency bridge to keep the patient alive until better solutions can be found. A less ambitious goal is to use artificial colloids to help maintain the normal volume and oncotic pressure of blood after acute hemorrhage. These products can be divided into hemoglobin preparations and plasma extenders.

Hemoglobin

The first approach to oxygen-transport compounds was to prepare solutions of hemoglobin tetramers ($\alpha_2\beta_2$). The rationale was to purify hemoglobin molecules to avoid the antigenic determinants (ABO) found in the erythrocyte membrane, while inactivating any viruses that may be present. It rapidly became clear, however, that after hemoglobin is removed from the erythrocyte, its properties change significantly.[29] Free tetrameric hemoglobin has a significantly higher affinity for oxygen (i.e., a leftward shift in the oxyhemoglobin desaturation curve) because of the lack of 2,3-diphosphoglycerate found in the erythrocyte, which allosterically reduces the affinity of hemoglobin for oxygen. In addition, the injected free hemoglobin rapidly dissociates into a dimeric or monomeric form that is cleared from the plasma by the kidneys, often with renal damage if sufficient dimers exist. Finally, the oncotic effect of the free hemoglobin molecules in the plasma greatly limits the amount that can be given safely. As a result, several modified hemoglobin products have been investigated in an attempt to circumvent these problems.[29]

The first modification was to polymerize the hemoglobin by cross-linking the α or β chains into polyhemoglobin. In this form, the normal hemoglobin tetramers are intramolecularly stabilized, preventing breakdown into dimers, while they are intermolecularly linked to other tetramers to form polymers, usually with three to six tetramers each. These approaches resulted in significantly larger molecules that were much more difficult to clear, giving significantly higher half-lives (30 hours). The hemoglobin was also modified to have a lower oxygen affinity by pyridoxylation of the β-globin chain. These modified hemoglobin solutions were shown to support life after near-complete transfusion in baboons and sheep.[30] In human clinical trials, the results were not as promising. Severe side effects, including renal failure and dyspnea, caused some trials to be discontinued. In the acidic ascending loop of Henle, the hemoglobin molecules precipitated, causing renal damage.

Further research indicated that most of the problems with polyhemoglobin preparations were caused by a significant per-

centage of intramolecularly cross-linked single tetramers existing among the polytetramers.[6] Removal of these single units gave much better results. Two formulations have been developed that essentially eliminate the single tetramers: glutaraldehyde cross-linked human pyridoxylated polyhemoglobin and *o*-raffinose cross-linked human polyhemoglobin. (Concern exists over the possible transmission of bovine spongiform encephalitis, or "mad cow" disease; however, the manufacturer obtains its hemoglobin from a single controlled herd, which is carefully screened for prions.[6,23]) These later generation polyhemoglobin products are promising in phase III trials. They are well tolerated, provide better plasma oxygenation in the microvasculature than erythrocytes, and are able to be stored for more than a year with good results.[6]

In a completely different approach, recombinant human hemoglobin ($\alpha_2\alpha_2$) tetramers have been synthesized in *E. coli*.[13] These tetramers effectively prevent breakdown to the dimer form and have a modified 2,3-diphosphoglycerate pocket yielding a more favorable oxygen dissociation curve. In clinical trials this product has shown significant vasoactivity because it scavenges free nitric oxide, a potent vasodilator. Normal ($\alpha_2\beta_2$) hemoglobin releases nitric oxide from its cysteine residues whenever it gives off oxygen, which causes capillary vasodilation and facilitates oxygenation. These recombinant tetramers apparently have nitric oxide–binding sites and end up causing the opposite effect. A second-generation recombinant human hemoglobin is being developed in an attempt to modify the nitric oxide–binding site on the molecule to reduce the hypertensive effect.[6]

Another approach has been to conjugate the individual hemoglobin tetramers to macromolecules such as polyethylene glycol, dextran, or polyoxyethylene derivatives.[17,29] Some products have been well tolerated in early clinical trials, but it remains to be seen how they will fare when more data are gathered. These formulations have also been tested in patients undergoing radiotherapy for cancer as a means to oxygenate hypoxic tumor tissue and increase its radiosensitivity.

Finally, much research is aimed at encapsulation methods to create an artificial red blood cell.[18] Free hemoglobin has a short half-life of about 24 hours and has to be ultrapure to avoid adverse reactions, problems that could be minimized by encapsulation. One way to encapsulate hemoglobin is with the use of liposomes, but to date many liposomal products have been phagocytized by the reticuloendothelial system. Polyactide membrane nanocapsules (about 150 nm in diameter) may be a potential solution to this problem. Polyactide is broken down into carbon and water, circumventing the need for lipid structures. Consideration is being given to include superoxide dismutase, catalase, carbonic anhydrase, and other enzymes with the nanocapsules to prevent the accumulation of methemoglobin.[18]

Synthetic Plasma Extenders

In applications in which support of oxygenation is not as crucial but blood volume needs supplementation to avoid hypotension, artificial colloids have been developed to serve as plasma extenders. These preparations help maintain the normal oncotic pressure of blood and can reduce, but not eliminate, the need for blood transfusion. There is no true substitute for lost whole blood except whole blood, but within fairly wide limits of total hemoglobin various colloidal solutions can be substituted to sustain an acceptable blood pressure. Whole plasma is the most effective replacement; however, individual units of plasma pose a risk of viral infection equal to that of individual units of whole blood. Suitable alternatives are 5% plasma protein solution (pooled plasma heated to 60° C for 10 hours to minimize the risk of cross-infection) and 5% human albumin. The former preparation may cause hypotension, and both are expensive and unacceptable to certain religious groups because of their human origins.

Theoretically, the development of a synthetic substitute to fulfill the oncotic functions of plasma proteins would be an ideal approach. To be of more value than isotonic saline solution as an oncotic substitute, a substance must be relatively inert, nontoxic, and nonallergenic and have a molecular size and weight greater than those that can be easily filtered across the glomerulus. Of the many materials that have been tested, the most suitable have proved to be polysaccharide derivatives—dextran and hetastarch.[27]

Dextran

A branched polysaccharide, dextran is produced by certain bacteria and consists of 200,000 glucose molecules interconnected by glucosidic linkages to produce a molecular weight of approximately 4×10^7 Da. Controlled hydrolysis of this material can yield a wide range of molecules that are then fractionated according to size. Available dextrans for injection include two forms: high-molecular-weight dextran, a 6% solution of dextran with a mean molecular weight of approximately 70,000 or 75,000 Da depending on manufacturer, and low-molecular-weight dextran, having a weight of approximately 40,000 Da. The main advantage of the smaller material, which can escape more readily across the glomerular membranes, is the fact that it seems to improve microcirculation by reducing the rouleaux formation and red blood cell sludging that usually accompanies hemorrhagic and other forms of shock.

Dextran can interfere with blood typing, which must precede dextran injection, and it impairs platelet function, resulting in an iatrogenic form of von Willebrand's disease. Fibrin formation is also impaired. The major disadvantage of dextrans is their antigenic potential. Enteric bacteria produce dextran, and a small percentage of the population has antibodies for dextran in the blood. When dextran is used as a plasma extender, a massive dose is usually given that overwhelms the immune response (immunologic paralysis), and anaphylactic risk is as low as or lower than the risk of blood transfusion. This risk can be reduced further by prophylactic administration of dextran 1, a monovalent hapten that binds to immunoglobulins without triggering an allergic response.

Hetastarch

Hetastarch is a hydroxyethylated derivative of amylopectin, with a mean molecular weight of 450,000 Da and a range of 10,000 to 1 million Da. The lower weight molecules (<50,000 Da) are excreted by glomerular filtration (33% within 24 hours); remaining molecules are metabolized slowly over 2 to 3 weeks to smaller products by plasma α-amylase activity.[15] The volume expansion produced by this agent lasts approximately 24 to 36 hours. Hematologically, there seems to be no obvious advantage of hetastarch over dextran; however, hetastarch is said to have a low incidence of anaphylaxis and may have less of an effect on blood clotting. Besides being effective as a volume expander, hetastarch has been found to be useful in leukapheresis (harvesting of granulocytes for patient use) and as a priming fluid for extracorporeal pumps used in coronary surgery.

IMPLICATIONS FOR DENTISTRY

The dentist is often in a unique position as the first health professional to observe manifestations of anemia in a patient. Because the oral signs frequently precede a decrease in hemoglobin below the normal range, the dentist may be able to diagnose the disease before it has caused symptoms warranting medical attention. Because anemia is a sign of an underly-

ing hematopoietic disorder, the blood cells are frequently the earliest biologic indicators of diseases such as cancer, malnutrition, or conditions of drug toxicity. The response may take the form of granulocytopenia, hemolytic or aplastic anemia, or thrombocytopenia with associated immunosuppression and defective hemostasis leading to spontaneous hemorrhage, internal bleeding, and purpura.

Patients with these difficulties may have oral mucositis, intraoral or circumoral viral outbreaks, fungal infections, and serious bacterial infections of odontogenic origin. The dentist should recognize these signs, understand the gravity of the situation, and attempt to ensure that the patient receives proper medical evaluation. Anemic conditions can run the gamut from easily corrected nutritional deficiency states to life-threatening disorders, and the sooner the patient is diagnosed, the better the chances are for correcting the underlying problem.

Patients who are undergoing therapy for these same diseases and taking many of the medications described in this chapter are increasingly encountered in dental practice. The dentist who knows how these medications function and why they are being given is better able to identify the presence or history of a particular disease and to make appropriate decisions about how to manage the patient's overall care.

As a final concern, dental professionals should know about the relationship between chronic nitrous oxide inhalation and pernicious anemia. Megaloblastic responses to nitrous oxide were first recognized in 1956 when the gas was used for sedation of patients with tetanus.[20] More recently, individuals habituated to inhaling nitrous oxide have been found to develop neuropathies similar to those seen with vitamin B_{12} deficiency.[7] It is now recognized that nitrous oxide readily interacts with the cobalt atom in cobalamin, which is oxidized and rendered inactive as a cofactor for methionine synthase. The potential implications for health care workers chronically exposed to nitrous oxide and for patients receiving nitrous oxide therapeutically are discussed in Chapters 17 and 18.

ANTIANEMIC DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Iron preparations	
Ferrous fumarate	Femiron, Feostat, Ferretts, Ferro-Sequels, Hemocyte, Ircon, Nephro-Fer
Ferrous gluconate	Fergon
Ferrous sulfate	Feosol, Fer-Gen-Sol, Fer-In-Sol, Fer-Iron, Feratab, Slow FE
Iron dextran	DexFerrum, INFeD
Iron sucrose	Venofer
Iron polysaccharide	Ferrex 150, Niferex, Nu-Iron 150, Poly-Iron 150, ProFe
Iron-chelating agent	
Deferoxamine	Desferal
Hematopoietic factors	
Darbepoetin alfa	Aranesp
Epoetin alfa	Epogen, Procrit
Filgrastim (G-CSF)	Neupogen
Oprelvekin	Neumega
Pegfilgrastim	Neulasta
Plerixafor	Mozobil
Sargramostim (GM-CSF)	Leukine
Vitamin B_{12} preparations	
Cyanocobalamin	CaloMist, Nascobal, Twelve Resin-K
Hydroxocobalamin	Cyanokit
Folic acid preparations	
Folate sodium	Folvite
Folic acid	—
Leucovorin (folinic acid)	—
Heme derivative	
Hemin	Panhematin
Plasma volume extenders	
Dextran	Gentran, LMD
Hetastarch	Hespan, Hextend, Voluven
Human albumin	Albumarc, Albuminar, AlubuRx, Albutein, Buminate, Flexbumin, Plasbumin
Plasbumin	
Plasma protein fraction	Plasmanate

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor.

CHAPTER 31

Procoagulant, Anticoagulant, and Thrombolytic Drugs

BARTON S. JOHNSON

The practice of dentistry frequently involves procedures that cause bleeding, and the dentist is often confronted with the need to achieve and maintain hemostasis. The dental practitioner must be familiar with the physiologic processes of hemostasis and the myriad conditions that cause abnormalities of these processes. Complicating matters, modern medicine has developed several therapies for systemic disease that use medications that purposefully alter normal hemostasis. When appropriate, the dentist needs to eliminate or make alterations in the dosage of these compounds before surgery. Only with a clear understanding of the complex process of hemostasis and the various drugs that affect it can the clinician manage patients with inherited or acquired bleeding disabilities safely.

HEMOSTASIS

Large or intermediate arteries and veins are generally not severed intentionally without prior ligation, but it is common during the extraction of teeth and other oral surgical procedures to sever small arteriolar, venous, and capillary vessels. Extensive blood loss may occur if hemostasis is delayed. The formation of a patent clot requires four distinct yet interdependent steps: (1) vessel constriction; (2) platelet adhesion, activation, and aggregation; (3) cross-linking of fibrin by the coagulation cascade; and (4) limitation of the blood clot to the area of damage only. Later, a fifth step becomes necessary: the controlled breakdown of the clot so that repair and remodeling can occur.

Vascular Constriction

In laboratory animals, transection of small arteries and arterioles has revealed several patterns of hemorrhagic flow. In general, after a sudden surge of blood, there is a moderate-severe reduction in flow, apparently caused by contraction of vascular smooth muscle initiated directly by the trauma. This initial hemostasis is independent of blood coagulation and platelet agglutination because it occurs in heparinized animals. It is maintained only for a short period (5 to 20 minutes). The vessel wall is lined with endothelial cells that constitutively secrete nitric oxide and prostacyclin, both of which are potent smooth muscle relaxing agents. Nitric oxide and prostacyclin diffuse to the vascular smooth muscle surrounding the endothelial cells, effect relaxation, and maintain luminal patency. On injury, this secretion is disrupted, and the now unopposed muscle layer reflexively and rapidly constricts, greatly narrowing the lumen. The effect is short-lived; after a few minutes the constriction wanes, and the muscle layers begin to relax again. This brief period of constriction provides a healthy individual sufficient time, for the platelets and coagulation cascade to seal the injured site.

Platelet Adhesion, Activation, and Aggregation

Adhesion

The next major event is the adhesion of platelets at the severed edges of the vessel. In normal untraumatized blood vessels, platelets show little tendency to adhere to the endothelium, partly because prostacyclin, again elaborated by the endothelial cells, induces cyclic adenosine 3′,5′-monophosphate (cAMP) synthesis in platelets and inhibits platelet adhesion. Endothelium-derived relaxing factor—now believed by most investigators to be largely or entirely nitric oxide—also normally secreted by the endothelial cells, is another natural inhibitor of platelet adhesion. Injury to the intima, even if the vessel wall remains intact, leads, however, to exposure of subendothelial extracellular matrix proteins such as collagen, fibronectin, von Willebrand factor (vWF), thrombospondin, and laminin.

The presence of these proteins, particularly vWF, stimulates a "catch and grab" response in the platelets, causing them to leave the laminar flow of the blood and adhere to the injured area. Platelets have a high density of surface receptors that respond to these proteins, and they undergo an extremely rapid localization to the site of injury, beginning the formation of a thrombus. Two main receptors are involved in adhesion: the glycoprotein (GP) Ia/IIa heterodimer, which binds to collagen directly but weakly, and the GP Ib/IX/V heterotrimer, which binds with high shear strength to connective tissue vWF associated with the collagen surface (Figure 31-1).[1] The GP Ib/IX/V–vWF linkage is more of a "tethering" of the platelet to the substrate; later, the adhesion is firmed up by GP IIb/IIIa activation. If vessels without a muscular sheath are severed, the immediate hemostatic action of platelet aggregation is especially important. The true significance of platelets in hemostasis is most evident in the management of patients with thrombocytopenia.

Activation

Activation of platelets is a crucial step in forming a proper thrombus. Activation can occur from various agonists, some of which are strong and some of which are weak. Examples include thrombin, adenosine diphosphate (ADP), thromboxane A_2 (TXA_2), 5-hydroxytryptamine (serotonin), epinephrine, vasopressin, fibrinogen, immune complexes, plasmin, and platelet-activating factor. Most plasma-derived agonists exert their effect by numerous G protein–linked membrane receptors. The strongest agonist for platelet activation is binding of vWF to the GP Ib/IX/V heterotrimeric receptors.[14] When one of these receptors is bound by its specific agonist,

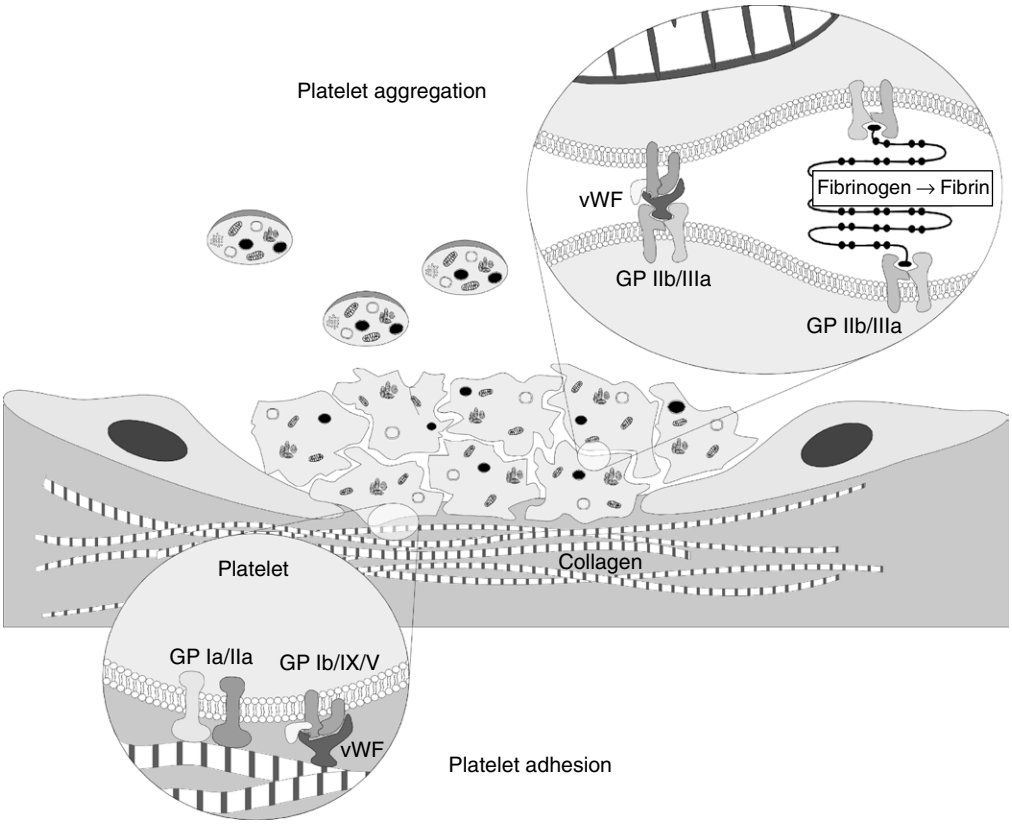

FIGURE **31-1** Platelet adhesion and aggregation. Exposed collagen at the site of injury stimulates initial weak platelet adhesion by the glycoprotein *(GP)* Ia/IIa receptors. Stronger adhesion follows by the GP Ib/IX/V/vWF complex. Platelet activation is triggered, which leads to initial aggregation by the GP IIb/IIIa receptors binding the GP Ib/IX/V complex. This low-shear bond is later supplanted by a pair of GP IIb/IIIa receptors interacting with fibrinogen to create high-strength mature fibrin "ropes" interconnecting the two, then cross-linking to others. *vWF,* von Willebrand factor.

an intraplatelet protein cascade begins that ultimately causes activation of Ca^{++} transporters and movement of Ca^{++} from stores in the platelet's dense tubular system to the general intracellular matrix.[26] The intracellular increase in Ca^{++} causes several other changes.

Platelets in the resting state have internal cytoskeletal actin that provides them with a smooth shape; as Ca^{++} increases, the actin is initially fragmented into smaller subunits, transforming the normal discoid shape of the platelet to a spherical conformation. These smaller actin subunits are rapidly reassembled into very-long-chain actin monomers, which cause the platelet to sprout filopods. The filopods are important in ultimate clot retraction. Meanwhile, as the filopods are developing, the increasing intracellular Ca^{++} concentrations act on cytoplasmic vesicles known as α and dense (or δ) granules (Figure 31-2), prompting them to rise to the cell surface and degranulate. The dense granules release ADP, adenosine triphosphate (ATP), the vasoconstrictor 5-hydroxytryptamine, Ca^{++}, and inorganic pyrophosphate.[18] The α granules contain numerous proteins involved in coagulation, adhesion, cellular mitogenicity, protease inhibition, and other functions (Box 31-1). Major proteins released include fibrinogen, coagulation factors, vWF, fibronectin, high-molecular-weight kininogen, plasminogen, plasminogen activator inhibitor-1 (PAI-1), platelet-derived growth factor, additional GP IIb/IIIa, and thrombospondin.[18]

Release of the dense granule ADP into the extracellular milieu has an autocatalytic effect on the platelet from which it came and also stimulates nearby platelets. The ADP binds to its own purinergic receptors, most notably $P2Y_1$ and $P2Y_{12}$.

BOX **31-1**

Contents of Platelet α Granules

α_2-Antiplasmin	Multimerin
α_2-Macroglobulin	P-selectin
Albumin	Plasminogen activator inhibitor 1
β-Thromboglobulin	Platelet factor
CD63	Platelet-derived growth factor
C1-inhibitor	Protein S
Endothelial cell growth factor	Thrombospondin
Epidermal growth factor	Tissue factor pathway inhibitor
Factors V, XI, XIII	Transforming growth factor-β
Fibrinogen	Vascular endothelial growth factor
Fibronectin	Vitronectin
GMP 33	von Willebrand factor
High-molecular-weight kininogen	
IgA, IgG, IgM	
Interleukin-1B	

Activation of both of these receptors is required for maximal aggregation of the platelets to one another. $P2Y_1$ stimulation acts to mobilize Ca^{++} further (an autocatalytic effect), which leads to further shape change and transient aggregation. $P2Y_{12}$ activation causes inhibition of adenylyl cyclase (blocking conversion of ATP to cAMP), potentiation of secretion by the α

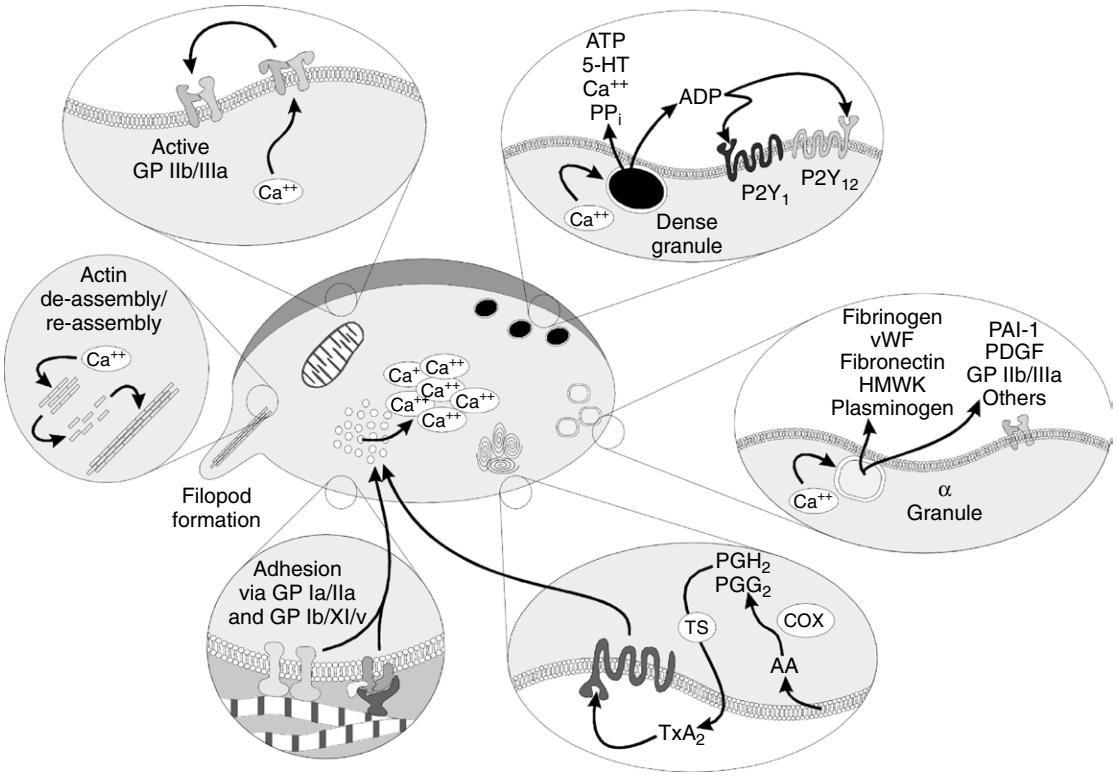

FIGURE **31-2** Platelet activation. *Lower left, moving clockwise,* Contact with the compromised vessel wall by platelet membrane GPs Ia/IIa and Ib/XI/V, stabilized by von Willebrand factor *(vWF)*, causes the platelets to become activated and begin moving Ca^{++} out of their tubular stores. The increased intracellular Ca^{++} causes actin to break down and reassemble in long chains, resulting in filopod formation. The increase in Ca^{++} causes conversion of the GP IIb/IIIa from its inactive form to the active form. The dense granules move to the surface and release many activating substances, one of which is adenosine diphosphate *(ADP)*. ADP stimulates purinergic receptors $P2Y_1$ and $P2Y_{12}$, both of which accelerate the activation process. The increase in Ca^{++} also causes a degranulation, resulting in the release of many substances important for further aggregation. Finally, platelet membrane phospholipids yield arachidonic acid (*AA*), which is converted by cyclooxygenase *(COX)* to prostaglandins G_2 *(PGG_2)* and H_2 *(PGH_2)*. Thromboxane synthase *(TS)* converts these to thromboxane A_2 *(TXA_2)*, which, acting on a G protein–linked receptor, is a potent catalyst of platelet aggregation by accelerating further release of stored platelet Ca^{++}. *5-HT*, 5-Hydroxytryptamine; *HMWK*, high-molecular-weight kininogen; *PAI-1*, plasminogen activator inhibitor-1; *PDGF*, platelet-derived growth factor; *PPi*, pyrophosphate.

and dense granules, and sustained aggregation. ADP also binds the transmembrane protein $P2X_1$, an ion channel receptor linked to influx of extracellular Ca^{++} into the platelet.

Aggregation

As the activated platelets interact with one another, they begin to aggregate. Aggregation is initiated by the Ca^{++}-mediated conformational activation of GP IIb/IIIa, a heterodimeric transmembrane protein. GP IIb/IIIa is a protein receptor complex unique to platelets and is expressed at extraordinarily high density on the surface of the platelets—some 80,000 to 100,000 per platelet—at an average distance of only 20 nm from one another. Another 20,000 to 40,000 units are stored in the α granules and are released onto the surface or within the local plasma milieu during degranulation. In the circulating, platelet, the resting GP IIb/IIIa receptor has little affinity for its ligands (primarily fibrinogen), so intravascular thrombus formation is minimized. On activation the GP undergoes a conformational change, however, which imparts high affinity for its ligands. Several proteins have the specific amino acid sequence necessary for binding to the GP IIb/IIIa receptor, including fibrinogen, fibronectin, vitronectin, and vWF.

As the α and dense granule contents are released extracellularly, nearby platelets become activated. The ligand proteins bind to the surface-associated GP IIb/IIIa of these adjacent platelets, forming bridges. At low shear rates, fibronectin and fibrinogen (stabilized by thrombospondin, another GP from the α granules) serve as the main adhesive proteins, whereas vWF is necessary for proper adhesion in areas of high shear. Microvascular video imaging studies show that thrombus formation initially is inefficient. Platelets bind quickly, but a significant percentage of them break free and float away. As a result, thrombus formation is much slower than would be the case if all the platelets that physically aggregate remained bound.[1]

Several other events occur simultaneously with activation and aggregation, but the two most important are generation of TXA_2 and platelet-assisted generation of thrombin. Both of these agents accelerate the platelet-activation response. TXA_2 is generated when platelet phospholipases are activated during platelet aggregation, which release arachidonic acid from glycerophospholipids of the platelet membrane. Arachidonic acid is a substrate for cyclooxygenase (COX), yielding the prostaglandin endoperoxides PGH_2 and PGG_2. These

prostaglandins are modified by thromboxane synthase to produce TXA_2, which acts at its own protein-linked receptor.

Perhaps the most remarkable effect of platelet activation is the procoagulant activity the platelets impart. In the normally resting platelet, the plasma membrane has negatively charged phospholipids, including phosphatidylserine, sequestered almost exclusively on the inner surface by processes that are not fully understood. When activating ligands bind to the platelet, the resultant increase in intracellular Ca^{++} causes a membrane enzyme termed *scramblase* to evert the phosphatidylserine to the outer surface, while simultaneously prompting the membrane to form small evaginated microvesicles. Factors Va and VIIIa (discussed subsequently) bind to the phosphatidylserine moieties and recruit factors Xa and IXa. The interaction of these complexes in toto accelerates the conversion of prothrombin to thrombin by a factor of 2.4×10^6. In addition, the binding of activated coagulation factors to the platelets seems to protect the factors from plasma inhibitors, while directing the bulk of the coagulation cascade to the site of injury. The α granules contain factors V and IX; factor V is apparently complexed with multimerin, a carrier protein (see Box 31-1).

As the thrombin is generated, it activates other platelets by stimulating G protein–linked receptors. The thrombin receptors seem to be unique "suicide" receptors, requiring proteolytic cleavage to transmit an activating signal. Thrombin is a serine protease, and it acts on the receptors by cleaving the protein at a serine residue near the amino terminus. The new amino terminus acts as a "tethered ligand" to double back and stimulate the transmembrane protein to activate—hence this receptor has been named a *protease-activated receptor (PAR)*. There are four such thrombin receptors, PAR-1 through PAR-4; only PAR-1 and PAR-4 are expressed by human platelets.[23] Thrombin-induced activation seems to upregulate GP IIb/IIIa activation while downregulating GP Ib/IX/V activity. The platelets apparently are converted from a mainly adhesive role to an aggregate role when thrombin is present.

Two other important activities of platelets warrant mention. First, the α granules contain P-selectin, a membrane protein that helps recruit and tether neutrophils and monocytes into the local area. This activity is believed to be crucial for generating a local inflammatory response at the site of injury, while promoting yet limiting thrombosis.[35] Second, platelets are also essential in clot retraction, an event that facilitates wound healing by bringing the severed ends of small blood vessels into closer apposition. Clot retraction, or syneresis, occurs when the filopodia expressed by platelets during activation attach to fibrin strands and contract. A number of actin-binding proteins are present in platelets.[4] On activation, phosphorylated myosin monomers polymerize into filaments next to the long-chain actin filaments, which slide past one another to generate a contractile force in the presence of ATP.

Coagulation Cascade

Although it is possible to separate the numerous events of hemostasis (e.g., platelet aggregation, formation of fibrin, retraction of the blood clot), the whole process occurs synergistically. Many of the factors involved are enzymatic cofactors, and most of the reaction occurs on cell and platelet membranes (Figure 31-3). Many refinements in the understanding of blood coagulation have come about through study of "experiments of nature," in which discrete defects of the clotting process have been identified in patients with bleeding diatheses, as illustrated by the factors and deficiency states listed in Table 31-1.

Initiation of coagulation after injury is a complex process involving an initial pathway of thrombin generation, which autocatalyzes a subsequent burst of additional thrombin generation sufficient to convert fibrinogen to fibrin (see Figure 31-3). Before the process is described, a brief review of the crucial factors and cofactors and how they function is warranted.

Vitamin K–dependent clotting factors

Synthesized in the liver, the vitamin K–dependent clotting factors comprise factors II (prothrombin), VII, IX, and X, and protein C. These five proteins are serine proteases and have similar structural elements (including a serine residue at their catalytic site). Molecular genetic evidence suggests they all are derived from a common ancestral precursor gene. They all have a preprotein leader that is cleaved away post-translationally, leaving an amino-terminal γ-carboxyglutamic acid (Gla) domain with 9 to 12 Gla residues. This sequence is followed by a hydrophobic domain and finally the serine protease domain, in which the carboxy-terminal region becomes activated by cleavage of key arginine residues.

The amino terminus Gla domain is crucial for the lipid binding of these proteases to their substrate membranes. In the presence of seven Ca^{++} ions intercalated within the three-dimensional structure of the Gla domain, the protein undergoes a conformational change that places its hydrophilic domain at one end of the three-dimensional protein structure, with the hydrophobic moieties facing outward. This arrangement is crucial because it allows the protein to settle into the lipid membrane and exert its effects locally rather than systemically in the vasculature. Before these events can occur, however, the Gla residues must be formed post-translationally by carboxylation of their precursor glutamate residues by a specific γ-glutamyl carboxylase that requires the uncleaved preprotein leader sequence of amino acids to bind to the protein. This carboxylase enzyme requires oxygen, carbon dioxide, and vitamin K to function (see Figure 31-8). For every glutamate residue carboxylated, one molecule of reduced vitamin K is converted to its epoxide form. A separate enzyme, vitamin K epoxide reductase, converts the vitamin K back to the reduced form. This reductase is the target of the warfarin-like anticoagulants and is discussed in greater detail later.

Each of the clotting factors mentioned is a protease with activity directed at substrate arginyl residues. Activated factors VII, IX, and X have specific cofactors associated with them—tissue factor (TF) with VIIa (*a* for activated), VIIIa with IXa, and Va with Xa. The cofactors bind the protease and its substrate in approximation to each other and modify the enzyme factor allosterically to have greater activity in the presence of substrate.

Enzymatic cofactors

TF is a unique protein normally constitutively expressed on the cell surfaces of many extravascular cell types. In contrast to the other coagulation cofactors, it is a transmembrane protein homologous to the receptors for interleukin-10 and interferons α, β, and γ. It seems to have procoagulant and signal transduction functions. It can be induced to become expressed on the cell surfaces of intravascular monocytes and endothelial cells in response to some bacterial products and inflammatory cytokines, perhaps as part of the body's immunologic defense system. P-selectin, secreted by platelet α granules, can also induce TF expression in monocytes adhering to activated platelets.

When injury occurs and the vasculature gains exposure to cells with TF on their surface, circulating factor VII rapidly binds to TF and undergoes proteolytic cleavage to factor VIIa by mechanisms that are not well understood. The TF/VIIa complex serves two crucial functions: it cleaves factor X to Xa and factor IX to IXa, both of which have distinct and separate activities. Newly formed factor Xa

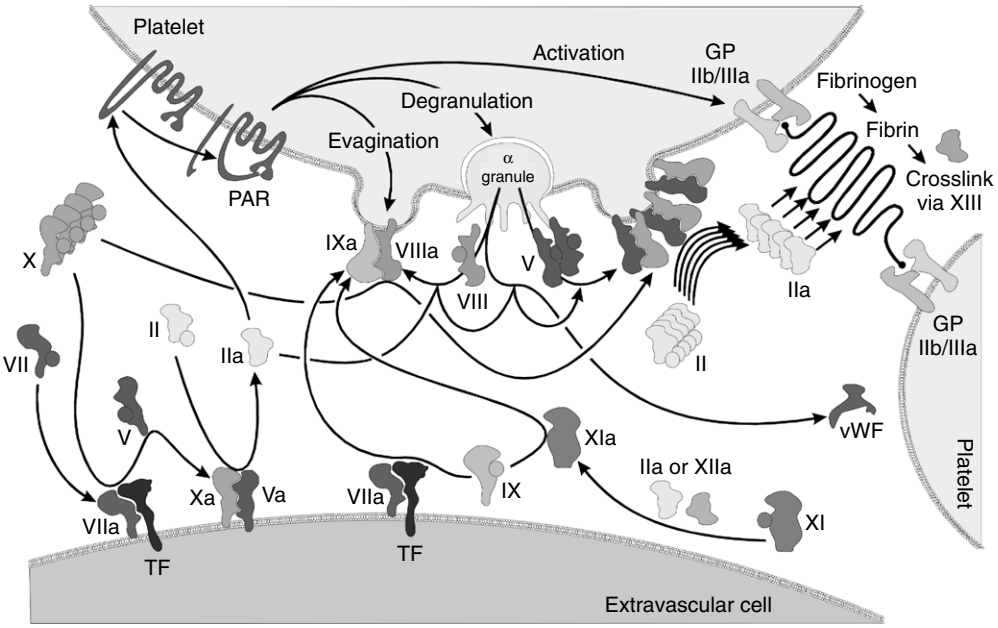

FIGURE **31-3** Blood coagulation cascade. Tissue factor *(TF)* (factor III) on cell membranes of exposed subendothelial matrix cells combines with circulating factor VIIa (activated by Ca^{++}) to form an activating complex for factor X and factor IX. Factor Xa, locally bound to the membrane by factor Va, converts prothrombin (factor II) to thrombin (factor IIa). Meanwhile, converted factor IXa diffuses to adjacent platelets, where it is bound to the platelet membrane by factor VIIIa. The complex acts to accelerate factor Xa conversion, leading to additional factor Va binding and ultimately vastly increased thrombin formation. Fibrin, after it is formed from fibrinogen by the proteolytic action of thrombin, is cross-linked and stabilized by factor XIIIa. Thrombin, a serine protease, accelerates the entire cascade by catalyzing cleavage of factor XI to factor XIa, stimulating platelets to activate by the transmembrane protease-activated receptor *(PAR)*, and stimulates conversion of factor XIII to factor XIIIa (not shown). *GP,* Glycoprotein; *vWF,* von Willebrand factor.

TABLE **31-1**

Blood Clotting Factors

INTERNATIONAL NUMBER OR TERM*	PLASMA FACTOR AND ALTERNATIVE NAMES†	CAUSE OR DESCRIPTION OF DEFICIENCY
I	Fibrinogen	Liver disease
II	Prothrombin	Liver disease or vitamin K deficiency
III	TF, thromboplastin	Deficiency of TF probably does not occur
IV	Ca^{++}	Never deficient without tetany
V	Proaccelerin	Parahemophilia, rare
VII	Proconvertin	Liver disease or vitamin K deficiency
VIII	Antihemophilic globulin, AHF A	Hemophilia A, 80% of hemophilics
IX	Christmas factor, AHF B	Hemophilia B (Christmas disease), depressed with vitamin K deficiency
X	Stuart-Prower factor	Liver disease or vitamin K deficiency
XI	Plasma thromboplastin antecedent, AHF C	Factor XI hemophilia (hemophilia C)
XII	Hageman factor	Generally no clinical symptoms but may have thromboses, rare
XIII	Fibrin-stabilizing factor, Laki-Lorand factor, fibrinase	Delayed bleeding, defective healing, rare
PF3	Platelet factor 3	Thrombocytopenia
—	Protein C	Liver disease or vitamin K deficiency
—	Protein S	Liver disease or vitamin K deficiency
—	Protein M	Liver disease or vitamin K deficiency
vWF	von Willebrand factor	vWD types I, IIa, IIb, IIc, III
Pre-K	Prekallikrein, Fletcher factor	
HMWK	High-molecular-weight kininogen	

*Roman numerals were assigned in 1958 by the International Committee on Blood Clotting Factors. Factor VI, originally assigned to prothrombin converting principle (prothrombinase), has since been abandoned.
†Most sources currently use factor numbers.
AHF, Antihemophilic factor; *TF,* tissue factor.

rapidly binds to circulating factor V and activates it to Va. The factor Xa/Va complex settles into the adjacent cellular membrane (using the hydrophobic Gla domain), where it acts on circulating prothrombin to generate a very small amount of thrombin. This tiny amount of thrombin is insufficient to cleave fibrinogen significantly but instead serves four crucial functions that set up the area for a much larger burst of thrombin formation: (1) nearby platelets are activated by their PAR receptors, which causes degranulation; (2) additional factor V liberated from the platelet α granules is activated (thrombin activates factor V much more efficiently than does factor Xa); (3) factor VIII is activated and dissociated from vWF; and (4) factor XI is activated. Factor Xa exerts its effect locally; any factor Xa that escapes the TF/VIIa complex area is rapidly destroyed by tissue factor pathway inhibitor (TFPI) or antithrombin III (ATIII), both of which are discussed later.

In contrast to the factor Xa/Va complex, activation of factor IXa by TF/VIIa results in an enzyme that is not restricted to the nearby cell surface because it is not inhibited by TFPI and is only slowly affected by ATIII. As a result, factor IXa diffuses through the plasma over to nearby activated platelets. As previously discussed, activated platelets rapidly place factors Va and VIIIa on their cell surfaces. The diffusing factor IXa binds tightly to the factor VIIIa cofactor, and this IXa/VIIIa complex efficiently activates additional factor X to Xa. As before, factor Xa then binds to adjacent factor Va, and this time a much larger burst of prothrombin conversion to thrombin occurs. This much larger amount of thrombin formation is sufficient to begin cleaving fibrinogen and start clot formation and continue to perform the activating functions listed previously.

Fibrinogen and factor XIII

The final phase of blood clotting consists of the thrombin-mediated proteolytic cleavage of fibrinogen to fibrin. Fibrinogen consists of a mirror image dimer in which each monomer is composed of three intertwined and disulfide bond–linked polypeptide chains. In the dimer, the amino terminus of all six polypeptides meet in the middle of the linear molecule to form the N-terminal disulfide knot, or *E domain*. The carboxy termini of the three polypeptides at each opposite end form a globular protein cluster known as the *D domain*. Between the E and D domains, the polypeptide chains form a helical structure.

Thrombin binds to the central E domain and cleaves off peptides from the knot to expose binding sites in the E domain that match the corresponding D domains of two neighboring fibrinogen molecules. The monomers begin to form a staggered "ladder" protofibril. As the monomers continue to associate, branch points occur that allow the fibrin meshwork to become more like a net and thicken. The initial clot is unstable, being held together primarily by hydrogen bonds. With time, however, the fibrin strands become cross-linked with covalent bonds by the action of a transglutaminase, fibrin-stabilizing factor XIII. This factor cross-links proteins between the γ-carbon of glutamine in one fibrin strand and the ε-amino group of lysine in the other.

Entrapped in this coagulum are red and white blood cells and intact platelets; the latter promote clot retraction as previously described. These events are followed by the inflammatory processes of organization and wound healing, which require, among other things, an effective proteolytic (fibrinolytic) mechanism described later in this chapter.

Other coagulation cascade proteins

It has long been known that patients with factor XI deficiency do not have severe bleeding profiles. Activated by thrombin, factor XIa cleaves factor IX to IXa. It is thought that this factor boosts the levels of factor IXa, but is not crucial to its function. Factor XII, prekallikrein, and high-molecular-weight kininogen all have been implicated in the activation of platelets when exposed to a negatively charged surface such as glass or kaolin. It is believed that these proteins work together to yield factor XIIa, which activates factor XI to XIa and ultimately factor IX to IXa. This method of "surface activation" is used to initiate the activated partial thromboplastin time (aPTT) test to determine how well the factor IXa system is functioning.

Regulation of Coagulation

When discussing hemostatic mechanisms, consideration should be given to the natural inhibitors of blood clotting. As important as the procoagulant process is, it is equally important to ensure that inappropriate clotting does not occur. The intent of the clotting system is to seal a site of vascular compromise; powerful antithrombotic mechanisms must come into play to ensure that clotting remains limited to the injured area. Several mechanisms of antithrombosis have been elucidated; they are discussed in detail subsequently and summarized in Figure 31-4. At the heart of the matter is how to control the extremely efficient clotting cascade after it is initiated.

Strict control of the coagulation cascade is mediated by several proteins that act as natural anticoagulants, all of which rely on the first traces of thrombin from the nearby wound site to activate them. In general, the theory is simple: bind or degrade any activated procoagulant proteins if they escape the site of injury. At the same time, the site of injury must be protected from invasion or inclusion of these same inhibitory proteins.

Because thrombin is the major procoagulant protein, it makes sense that inactivation of it is a high priority. An elegant mechanism exists that, instead of destroying thrombin, uses thrombin to catalyze an important set of anticoagulant proteins, the protein C/protein S system. In the microcirculation, where there is a high cell surface-to-volume ratio, the protein C/protein S system predominates. Vascular endothelial cells normally express thrombomodulin on their membranes. Thrombomodulin is a transmembrane cofactor protein with no known enzymatic activity. It binds the thrombin that escapes from the surface of nearby platelets but is not carried off in the vascular flow.

Thrombomodulin, as the name implies, alters the conformation of the thrombin and effectively removes its ability to cleave fibrinogen, activate platelets, and activate factors V and VIII. Instead, the new conformation of thrombin imparts a 2000 times greater affinity for activation of the vitamin K–dependent protein C.[12] Activated protein C (aPC) has considerable homologous characteristics with the other vitamin K–dependent factors, complete with a Gla domain, hydrophobic domain, and active serine protease domain. The cofactor for aPC is protein S, a membrane-bound protein that has no inherent activity. When aPC is bound, the complex efficiently cleaves and destroys any factors Va and VIIIa that might have been liberated from the platelet surfaces, however, slowing coagulation and protecting the normal individual against random intravascular coagulation.

Another protein, ATIII, is a serine protease inhibitor ("serpin") found in the plasma. It inhibits clotting by covalently binding 1:1 to the active sites of thrombin and certain other serine proteases (factors IXa, Xa, and XIIa). This reaction is normally slow but is accelerated 1000-fold in the presence of heparan sulfate, a proteoglycan synthesized on the surfaces by endothelial cells. (A similar effect is achieved therapeutically by administration of the closely related agent heparin sulfate.) Although ATIII binds to these factors only without destroying them, reactivation by unbinding

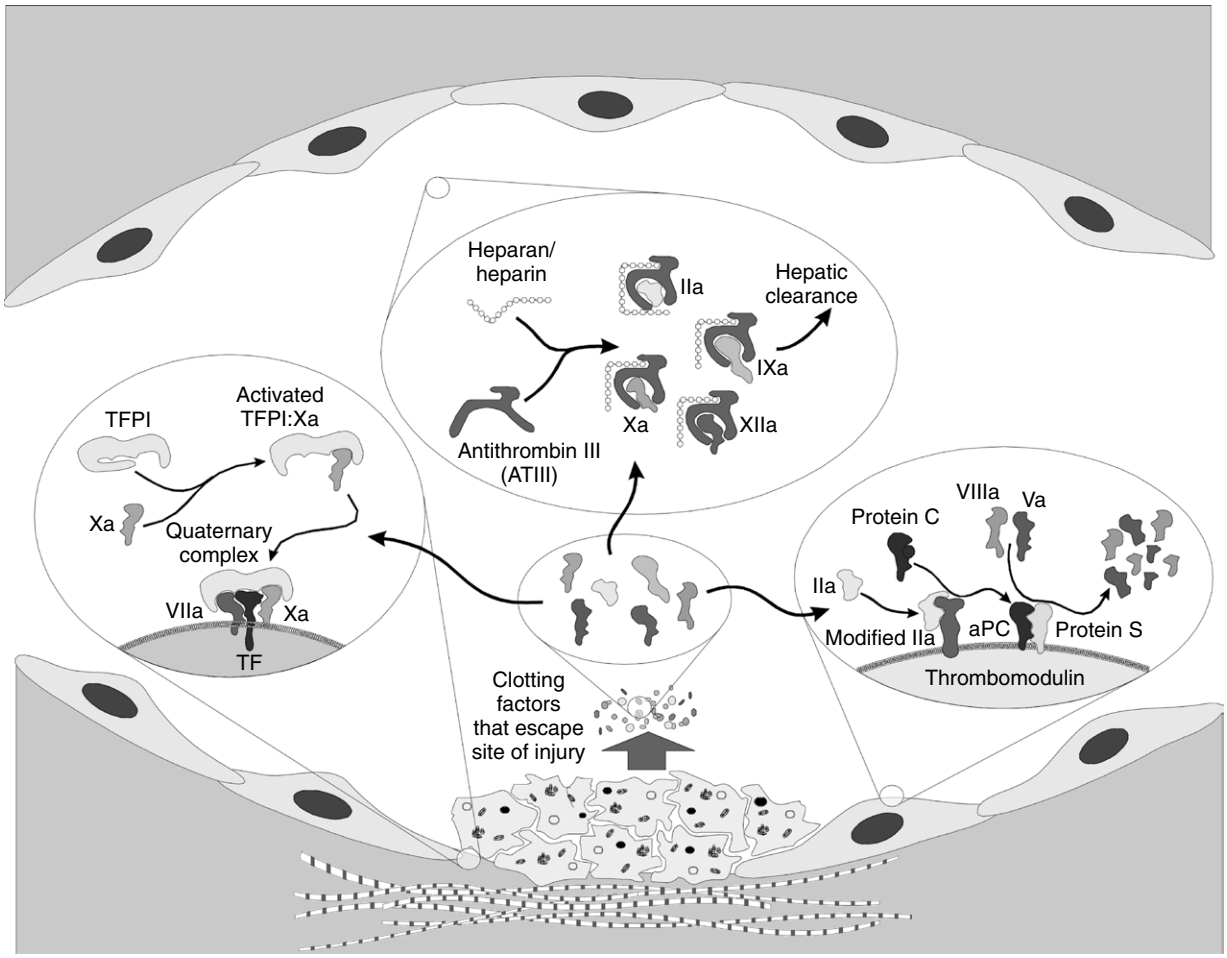

FIGURE **31-4** The clotting inhibition system: examples of proteins that help limit fibrin formation to the site of the vascular injury by inactivating clotting factors. Antithrombin III *(ATIII)* undergoes conformational change in the presence of heparin/heparan, which allows it to bind and sequester factors IIa (thrombin), IXa, Xa, and XIIa. It is later cleared in the liver. When trace amounts of thrombin bind to thrombomodulin on intact endothelial cell membranes, the thrombin-thrombomodulin dimer undergoes a conformational change that allows it to activate protein C, which is bound to the membrane by protein S to form a protease complex specific for factors Va and VIIIa. Loss of these two factors disrupts the coagulation cascade sufficiently to prevent disseminated intravascular coagulation. A final inhibitor, tissue factor pathway inhibitor *(TFPI)*, is first activated by factor Xa and then binds to the tissue factor *(TF)*/VIIa complex to interrupt conversion of additional factor X. *aPC*, Activated protein C.

probably does not occur physiologically. The ATIII-protease complexes are cleared in the liver. It is believed that ATIII is responsible for complexing with proteases that escape into the circulation.

Finally, as mentioned earlier, TFPI is a protease inhibitor found in low concentrations in the plasma, mostly bound to circulating lipoproteins or to endothelial cell membrane heparans. It is capable of inactivating factor Xa and the TF/VIIa complex; it must first bind factor Xa before it can bind to the TF/VIIa complex. TFPI seems to be the major inhibitor of free-floating factor Xa, and it may be responsible for shifting the activation of factor IX from the TF/VIIa complex to thrombin-activated factor XI. The inhibitor is found in high concentrations in patients with hemophilia A and B, presumably because fewer substrates are available for TFPI binding. This finding offers one explanation for why hemophilics bleed despite normal concentrations of TF, factor VIIa, and factor Xa at the site of injury. TFPI is synthesized in liver and endothelial cells.

PROCOAGULANT AGENTS

In medical and dental practice it is essential to take appropriate precautions to avoid serious hemorrhage. This admonition is particularly true for patients with hemophilia, patients with hematopoietic disease, and patients receiving therapies known to affect hemostasis. Precautions, which may include the administration of clotting factors or hospitalization or both, are prudent in these cases. In contrast, normal patients usually require no more than temporary hemostatic assistance (e.g., pressure packs, hemostatic forceps, ligation, or other locally active measures) to facilitate normal hemostasis and allow clotting to occur. Table 31-2 outlines various methods for controlling bleeding.

Local Measures

A perplexing hemostatic problem may arise from continued, slow oozing of blood from small arterioles, veins, and capillaries. These vessels cannot be ligated, and measures such as

TABLE **31-2**

Methods of Controlling Bleeding

DESIRED RESULT	PHYSIOLOGIC METHODS	PHYSICAL METHODS	CHEMICAL AGENTS
Hemostasis	Vasoconstriction, platelet plugs, clot retraction	Pressure, electrocautery, cooling, sutures	Epinephrine, astringents-styptics*
Clotting	Procoagulants: thrombin, platelets, other clotting factors	Physical matrixes: gelatin, cellulose, collagen	Topical thrombin, fibrin sealant, antifibrinolytics

*Chemicals that denature protein include aluminum, zinc, iron, and silver salts; alcohol; tannic acid; and cellulosic acid.

pressure packs and intrasocket preparations, vasoconstrictor agents, and procoagulants must be used. Styptics or astringents, extensively used in the past, are no longer viewed as rational procedures for routine hemostasis in most applications; however, some astringents are commonly used during gingival retraction to aid in controlling the tissue for impressions.

Bleeding caused by dentoalveolar surgery is most often controlled by applying direct pressure with sterile cotton gauze. If this treatment is inadequate, the clinician must localize the source of bleeding as originating either within the soft tissues or within the bony structures. Soft tissue bleeding may be controlled by hemostats, ligation, electrocautery, or application of microfibrillar collagen or collagen sheets (on broad bleeding surfaces). Microfibrillar collagen, made from purified bovine skin collagen, is used topically to arrest certain hemorrhagic conditions that do not respond to conventional methods of hemostasis. Collagen accelerates the aggregation of platelets and may have limited effectiveness in patients with platelet disorders or hemophilia.

Intrasocket Preparations

Bleeding from bony structures, especially from extraction sockets, can be controlled by various means. If initial attempts to achieve hemostasis with sterile cotton gauze and pressure do not succeed, a gelatin sponge, denatured cellulose sponge, or collagen plug may be inserted within the bony crypt.

Gelatin sponges are intended to be a matrix in which platelets and red blood cells can be trapped. In so doing, the sponges facilitate platelet disruption and can absorb 40 to 50 times their own weight in blood, both of which aid in coagulation. They typically resorb in 4 to 6 weeks. Because they are made of gelatin, they must be applied dry; when moistened, they become difficult to handle. For this reason, many practitioners prefer to use either denatured cellulose preparations or collagen sponge.

Denatured cellulose sponge or gauze serves as a physical plug and a chemical hemostatic. The apparent coagulation-promoting action stems from the release of cellulosic acid, which denatures hemoglobin, and these breakdown products help plug the site of injury. Cellulosic acid, similar to tannic acid, inactivates thrombin; the use of cellulose sponge in conjunction with this procoagulant is ineffective. Two forms of cellulose sponge, oxidized cellulose and oxidized regenerated cellulose, are available. Both these materials cause delayed healing, particularly oxidized cellulose, which notably interferes with bone regeneration and epithelialization. Although regenerated cellulose is said to have less inhibitory action, neither dressing should be left permanently in the wound if it can be removed.

The collagen plug, similar to microfibrillar collagen, serves to accelerate the aggregation of platelets and form a physical barrier. Because it also is usually made from bovine collagen sources, occasional foreign body responses can occur. Overall, the collagen plug generally activates platelets more completely and is the preferred intrasocket product.

Topically Applied Clotting Factors

The most physiologic hemostatic aids are the blood clotting factors themselves. Assuming an otherwise normal clotting system, topical thrombin is often used clinically. It must remain topically applied; if given intravenously, thrombin causes extensive thrombosis and possibly death. Topically applied thrombin (particularly in conjunction with a compatible matrix such as gelatin sponge) operates as a hemostatic, particularly if the patient has a coagulation deficiency or is receiving oral anticoagulants, because all that is required for clotting is a normal supply of platelets, fibrinogen, and factor XIII in the plasma. If blood flows too freely, temporary physical hemostasis must be attained before topical thrombin can be of practical value. The use of thrombin is not without problems. Currently available thrombin, especially the bovine products, may be relatively crude preparations that still contain plasmin, a fibrinolytic agent (discussed subsequently). Antibodies may also be generated to the bovine thrombin or bovine factor V; the latter can cross-react with human factor V and lead to an acquired inhibition and bleeding.

Fibrin sealant, also sometimes referred to as *fibrin glue,* is one of the more promising hemostatic aids to appear in recent years.[5] With this agent, the concept of the application of topical thrombin is taken one step further. Bovine or human thrombin and calcium chloride are mixed in one of two syringes; purified human fibrinogen with factor XIII, aprotinin, and other plasma proteins (fibronectin and plasminogen) are in the second syringe. The two solutions are mixed in a single delivery barrel, where the thrombin cleaves the fibrinogen to fibrin monomers. Initially, they are gelled by hydrogen bond formation, but in 3 to 5 minutes the factor XIII in the presence of Ca^{++} initiates cross-linking and increases the tensile strength of the clot.[5] As the clot solidifies, the sealant becomes milky white.

The rate of fibrin clot formation depends on the concentration of the thrombin; 4 IU/mL produces a clot in approximately 1 minute, whereas 500 IU/mL requires only a few seconds. The strength of the clot depends on the concentration of the fibrinogen. If used in an area where the clot is likely to break down too soon, or in patients with compromised hemostasis, a protease inhibitor such as aprotinin can be added to delay fibrinolysis. Aprotinin functions by inhibiting plasmin, which is generally carried along with the thrombin. The term *glue* arises from the fact that in many medical applications this material has been literally used to adhere tissues together naturally.

Fibrin sealant is commercially available in the United States. The protein fractions are lyophilized and require careful reconstitution at 37° C under sterile conditions; proper mixing of the materials requires approximately 30 minutes to perform. As a result, the emergent use of this material is

difficult; typically, it is used more in planned surgeries in patients with known bleeding disorders. It is also an expensive medication; 1 mL of the material costs several hundred dollars. Fibrin sealant works well, however, in stopping the microbleeding and oozing that often accompany dental procedures.[27]

Astringents and Styptics

The terms *astringents* and *styptics* are interchangeable, referring to different concentrations of the same drugs. Many chemicals have vasoconstrictive or protein-denaturing ability, but relatively few are appropriate for dentistry. The suitable preparations are primarily salts of several metals, particularly zinc, silver, iron, and aluminum. Aluminum and iron salts are quite acidic (pH 1.3 to 3.1) and irritating.[36] Iron causes annoying, although temporary, surface staining of the enamel, whereas silver stains may be permanent.

Currently, astringents are generally used in dentistry only to aid hemostasis while retracting gingival tissue. Other applications, such as controlling bleeding after surgery, are not looked on as favorably as in the past, when 20% ferric subsulfate (Monsel's solution) and 8% zinc chloride were among the most popular agents used. Aluminum and iron salts function by denaturing blood and tissue proteins, which agglutinate and form plugs that occlude the capillary orifices. In a rabbit mandible model, when ferric sulfate salts were left in an osseous wound, there was an intense foreign body reaction and delayed healing in many of the experimental sites compared with the control sites.[24] When the salts were irrigated, and the coagulum was curetted away, this response was markedly diminished with no persistent inflammation or delay of osseous repair.

It is imperative that if these compounds are used in dentistry, they are used briefly and with copious irrigation and debridement to remove the breakdown products. They should not be applied to areas of exposed osseous material so as to avoid inflammation or complications of retarded healing such as the distressful dry socket. Tannic acid (0.5% to 1%) is an effective astringent; it also precipitates proteins, including thrombin, but is often incompatible with other drugs and metal salts used therapeutically. Finally, the use of an astringent in a patient with even a mild bleeding tendency may provide temporary hemostasis, but subsequently lead to a larger area of delayed oozing after the chemically affected tissue sloughs.

Vasoconstrictors

Temporary hemostasis may be obtained with adrenergic vasoconstrictor agents, generally epinephrine. Such vasoconstrictors should be applied topically or just under the mucosa only for restricted local effects and for very short periods to avoid prolonged ischemia and tissue necrosis. Because some of the drug is absorbed systemically, particularly in inflamed and abraded tissue, cardiovascular responses may occur. Epinephrine solutions and dry cotton pellets impregnated with racemic epinephrine are available for topical application, but other methods to control bleeding are generally preferred.

Systemic Measures

Patients with acquired or genetic bleeding disorders usually have deficiencies in platelet number, platelet function, or faulty or missing clotting factors. Bleeding may develop several hours after trauma or surgery. Uncontrolled bleeding does not generally appear with superficial abrasions, but hemarthrosis and hemorrhage are common with deeper injuries. Thrombocytopenia is frequently drug-induced or associated with other myelogenous diseases; hemophilia disorders are generally inherited. With proper evaluation and supportive therapy (Table 31-3), extensive surgery can usually be accomplished without serious incident.

Platelet disorders

Patients with a platelet count of less than 50,000/mm^3 are at risk for surgical or other trauma, but generally do not exhibit spontaneous hemorrhage until the count becomes less than 20,000/mm^3. Platelet transfusion should be reserved for acute situations because alloimmunization to injected platelets can occur. One unit of platelet concentrate (equal to the platelets derived from 1 U of whole blood) increases the platelet count in adults from 4000/mm^3 to 10,000/mm^3. Platelet recovery is low in patients with hypersplenism and may be undetectable in patients with immune thrombocytopenia. Idiopathic forms may benefit from corticosteroid administration, splenectomy, use of immunosuppressive agents, or (acutely) high doses of intravenous immunoglobulin. Drug-induced disease generally is alleviated by withdrawal of the offending drug. In the case of aspirin or a thienopyridine such as clopidrogel prescribed deliberately to alter platelet function, the relative risks of hemorrhage versus thromboembolism must be considered in relation to the planned procedure.

Hemophilia

All forms of hemophilia are genetically based disorders of coagulation. They may range in severity from mild to moderate to severe; this designation greatly affects what dental interventions can occur. The most common forms of hemophilia result from deficiencies in factors VIII and IX (hemophilia A and B). Although the transmission of hemophilia A or B is hereditary and X-linked, nearly half of all cases arise spontaneously as new mutations.[32] Any child or adult with newly discovered hemophilia should have counseling with the family as provided by hemophilia treatment centers. Bleeding disorders (especially of the mild variety) are often first discovered after dental procedures, such as extractions or periodontal surgery.

Hemophilia A occurs when there is a deficiency in circulating factor VIII activity. Factor VIII accelerates blood coagulation by serving as a cofactor in the platelet membrane in the enzymatic activation of factor X by the factor IXa/VIIIa complex (see Figure 31-3). In the inactive state, factor VIII is an asymmetric protein molecule. The normal amount of factor VIII antigen averages 100 U/dL (range 50 to 180 U/dL). Mild hemophilia occurs when the patient's blood has 5% to 30% of normal factor VIII activity. Moderate disease is defined as showing 1% to 4% factor VIII, and severe hemophilia shows less than 1% factor VIII. Individuals with more than 40% normal factor VIII antigen clot normally.

The gene for factor VIII resides on the long arm of the X chromosome (Xq28),[32] resulting in an X-linked pattern of inheritance. In severe factor VIII hemophilia, gene inversions account for 45% of mutations, whereas other patients have point mutations that often cause a premature stop codon to be inserted, resulting in incomplete mRNA transcription. In general, only males with a faulty factor VIII gene on their only X chromosome show phenotypic expression of severe disease, at a rate of 1 in 10,000. Females who carry an affected X chromosome typically do not show phenotypic disease because the unaffected factor VIII gene on the other X chromosome provides sufficient protein to allow normal clotting. Expression of the normal gene may become depressed during development, however, if key progenitor cells favor the chromosome with the defective gene. The result is that some carrier females are phenotypically mild (or, rarely, moderate) hemophilics, with factor VIII concentrations 15% to 25% of normal. Referred to as *symptomatic carriers*, their bleeding tendency is often not discovered until they encounter a significant insult, such as extraction of teeth, orthognathic

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAMES	CONTENT	THERAPEUTIC USE
Factor VIII Products			
Antihemophilic factor, plasma derived	Humate-P	250, 500, and 1000 IU/vial; contains albumin vWF and small amounts of other proteins	Hemophilia A, vWD
Antihemophilic factor, plasma derived, purified	Alphanate, Hemofil M, Koate DVI, Monarc-M, Monoclate-P	250, 500, 1000, and 1500 IU/vial; contains albumin	Hemophilia A
Antihemophilic factor, recombinant	Bioclate, Helixate, FS, Recombinate	250, 500, and 1000 IU/vial; contains albumin and trace amounts of animal protein	Hemophilia A; patients without HIV or viral hepatitis
Antihemophilic factor, recombinant, albumin-free	Advate, Kogenate FS, ReFacto, Xyntha		
Factor IX Products			
Factor IX complex	Bebulin VH, Profilnine SD, Proplex T	500, 1000, and 1500 IU/vial; also contains significant amounts of factors II, VII, and X	Hemophilia B
Factor IX human complex, purified	AlphaNine SD, Mononine	500, 1000, and 1500 IU/vial; contains small amounts of factors II, VII, and X	Hemophilia B
Factor IX, recombinant	BeneFIX	250, 500, and 1000 IU/vial	Hemophilia B; patients without HIV or viral hepatitis
Factor VIIa Product			
Factor VIIa, recombinant	NovoSeven RT	1, 2, and 5 mg/vial	Hemophilia A or B; patients with inhibitors for factors VIII or IX
Mixed Factor Products			
Anti-inhibitor coagulant complex (factor VIII inhibitor bypassing activity)	Autoplex T, FEIBA VH	≥80 IU/bag; contains other clotting factors; prepared from single donors	Hemophilia A, vWD, hypofibrinogenemia, DIC, Kasabach-Merritt syndrome
Antihemophilic factor, cryoprecipitated	—	≥80 IU/bag; contains other clotting factors; prepared from single donors	Hemophilia A, vWD, hypofibrinogenemia, DIC, Kasabach-Merritt syndrome

Unless otherwise noted, all products are derived from human plasma or, in the case of recombinant products, based on human genes.
DIC, Disseminated intravascular coagulopathy; *HIV,* human immunodeficiency virus; *vWD,* von Willebrand's disease; *vWF,* von Willebrand factor.

surgery, or extensive periodontal surgery. For this reason, female relatives of hemophilics should have interviews, and possibly blood tests, to determine their carrier status and their factor VIII activity.

Hemophilia B was discovered when it was noted that combining plasma from different hemophilics sometimes allowed normal clotting; it was deduced that the second sample corrected the defect in the first. It was later determined that deficiencies in factor IX were responsible for approximately one fifth of the forms of hemophilia. Older literature refers to factor IX deficiency as C*hristmas disease,* named after the surname of the first family studied with this variant of hemophilia.

Similar to hemophilia A, the gene for factor IX is on the X chromosome (Xq27.3)[32] and shows the same familial pattern of expression: affected males and carrier females. Because this gene is considerably smaller than the factor VIII gene (34 kDa versus 186 kDa), most of the genetic variations have been identified in kindreds. Similar to factor VIII deficiency, partial or whole gene deletions or insertions lead to severe hemophilia B, as do nonsense point and some missense mutations. Also similar to hemophilia A, there are mild, moderate, and severe forms of the disease, and female symptomatic carriers occur. Hemophilia A and B are clinically indistinguishable.

von Willebrand's disease

Originally described by von Willebrand in 1926, von Willebrand's disease (vWD) is an autosomal dominant hemorrhagic disorder resulting from a quantitative or qualitative deficiency of the vWF GP. Males and females are affected equally; the defect is in an autosomal dominant gene located on chromosome 12.[15] vWD may be the most common inherited bleeding disorder, with many cases remaining undiagnosed.

The vWF GP is produced in vascular endothelial cells and megakaryocytes and is stored intracellularly in the α granules of platelets and circulated in the plasma as multimeric polymers. The high-molecular-weight multimers are necessary for normal biologic activity, presumably because of their greater number of ligand-binding domains. vWF has three important functions. The first is to form a tight but noncovalent complex with factor VIII protein (in a ratio of approximately 1 factor VIII to 100 vWF), stabilizing factor VIII and slowing its

clearance from the circulation. Second, vWF promotes normal, high-shear platelet adhesion to the subendothelium on injury and exposure of subendothelial matrix proteins. The latter function is mediated by the GP Ib/IX/V tetramer found on the platelets, and the vWF involved is bound to the subendothelial matrix proteins. Third, vWF is one of the proteins that binds to the multiple platelet membrane GP IIb/IIIa receptors, along with fibrinogen, to help stabilize the aggregating platelets.

As an aside, ristocetin, one of the first antistaphylococcal antibiotics, was found to cause thrombocytopenia in many patients because of binding to the platelet membrane, which enhanced the binding of vWF, resulting in platelet aggregation, thrombus formation, and depletion thrombocytopenia. Although the antibiotic was removed from clinical use as a result, it is now used in an assay for vWD. By mixing ristocetin, washed platelets, and plasma from the affected patient, an inverse correlation occurs between the amount of functional vWF present in the plasma (originally called *ristocetin cofactor*) and the amount of ristocetin necessary to induce platelet aggregation. When the ristocetin cofactor assay is compared with tests that show the amount of vWF protein present in the plasma, diagnosis of the type of vWD can be made.

The hematologic disorder in vWD can manifest as either structural or quantitative changes in vWF. Three basic types of disease exist. Type 1 vWD is associated with a mild quantitative defect in the amount of vWF produced. Titers of vWF antigen (total vWF protein) and ristocetin cofactor activity (functional vWF protein) are comparable. This is the most common type (80%) and is most often manifested by mucocutaneous bleeding. Type 2 vWD is a defect in the amount of high-molecular-weight multimers present in the plasma, causing a marked decrease in platelet adhesion, but little change in total vWF antigen. There is a high ratio of antigen to ristocetin cofactor activity. Type 3 vWD is characterized by severe bleeding disorders from an essential lack of any vWF, with concomitantly low concentrations of factor VIII and decreased platelet adhesion. This third type is rare, mostly occurring in homozygous or compound heterozygous offspring of parents with mild or asymptomatic variants of vWD.

Treatment

Treatment of either variety of hemophilia or vWD requires the restoration of the appropriate factor so that factor complex IXa/VIIIa activity is sufficient. For the treatment of hemophilia A, various factor VIII replacement products are available (see Table 31-3).[32] Because the half-life of factor VIII is 8 to 12 hours, the patient must be reinfused with at least half the original dose at approximately 12-hour intervals to prevent late bleeding from surgical wounds.

Until more recently, the only way to obtain factor VIII was by pooled human blood products. Initially, the most common method was to use cryoprecipitate. Cryoprecipitate is the cold-insoluble (precipitated) protein fraction derived when fresh frozen plasma is thawed at 4° C. It is primarily composed of factor VIII, fibrinogen, and vWF. Classically, it was one of the mainstays of factor VIII hemophilia treatment, but has virtually disappeared from this use with the development of methods to manufacture recombinant factor VIII. Similar to plasma, cryoprecipitate is not virally inactivated. The most common current use of cryoprecipitate is as a source of fibrinogen for the treatment of disseminated intravascular coagulopathy.[3] Cryoprecipitate is still occasionally used for the treatment of vWD, particularly if it is obtained from a single donor after desmopressin stimulation, but this use is waning.

Modern plasma-derived factor VIII products have greatly reduced the risk of viral transmission by donor screening and viral inactivation protocols. Two methods are currently being used to inactivate viruses—heat and solvent detergent. All viruses that have lipid envelopes are readily destroyed, including human immunodeficiency virus (HIV), hepatitis B virus, and hepatitis C virus. Viruses that do not have lipid envelopes, such as the B19 parvovirus and hepatitis A virus, can still be transmitted in the solvent detergent or heat-inactivated products. A vaccination for hepatitis A is now available, and patients with hemophilia or vWD are encouraged to receive it early in life.

Some manufacturers additionally purify their factor VIII protein products from the pooled factor VIII proteins on affinity columns, increasing the specific activity of the preparation and decreasing further the risk of viral transmission. Those products are more expensive. One of the factor VIII products, Humate-P, is purified with a process that retains a considerable amount of vWF. Although still occasionally used for factor VIII hemophilics, this product has become the favored way to treat bleeds or potential bleeds in patients with moderate-severe vWD and is used mostly for this reason. It has the advantage that it can be manufactured on a large scale, lyophilized for stability and storage, and reconstituted when necessary. It is considered very safe from viral contamination.

Most factor VIII hemophilics are now receiving recombinant factor VIII products, particularly if they are HIV and hepatitis virus negative. These proteins are derived from stable transfection of the human factor VIII cDNA into Chinese hamster ovary (CHO) or baby hamster kidney (BHK) cells, with resultant transcription and protein production. The first-generation products required human albumin to be added to provide stabilization through the purification process; the second-generation and third-generation products are now being made albumin-free. The distinction is important because the albumin adds a small risk for viral contamination. The new products are considered virus-free, have high specific activities, and have been successful in transiently correcting the bleeding disorder. The main difficulty is that in a patient with severe hemophilia with essentially no endogenous protein, the use of this "foreign antigen" product may cause the development of anti–factor VIII antibodies, known in hematology as *inhibitors* and discussed in greater detail subsequently. In most patients who develop them, the inhibitors are low titer and controllable with low-dose daily infusions of factor VIII protein to build immune tolerance over time.

Another approach to the treatment of mild hemophilia A and type 1 vWD was introduced when it was discovered that desmopressin, the synthetic 1-desamino-8-D-arginine analogue of vasopressin (antidiuretic hormone), could prevent bleeding in many of these patients. This medication causes endogenous factor VIII, vWF, and plasminogen activator to be released from storage sites on the vascular endothelium. In many patients with mild hemophilia or type 1 vWD, the protein structures are normal, but concentrations are low. With desmopressin, transient increases of two to three times the patient's baseline concentrations can be achieved, which may be sufficient to allow adequate hemostasis during minor surgery. For hemophilics who use single donors (usually a parent or sibling) as their sole source of factor product to decrease the risk of viral transmission, desmopressin can be given to the donor before donation to double or triple the amount of factor VIII recovered.

The advantage of desmopressin over vasopressin is that it retains the factor VIII–releasing activity but lacks the vasoconstrictor action of vasopressin. Most importantly, desmopressin is devoid of the risk of viral transmission inherent in the blood-derived products. Desmopressin is subject to peptic hydrolysis and is injected or insufflated intranasally. Mild facial flushing is normal during the infusion, with headache, nausea, and lightheadedness as common side effects. Because of its antidi-

uretic properties, water intake must be restricted for 12 hours to avoid volume overload. (The drug is also used in lower doses as an aid for children with bed-wetting difficulties.)

Historically, factor IX concentrates have been difficult to purify. The most common factor IX preparations are known as *factor IX complex* because, although they have high amounts of factor IX protein, they also contain factors II and X and some factor VII (see Table 31-3).[31] Because of the presence of the excessive extra clotting factors (some partially activated), disseminated intravascular coagulopathy is occasionally a problem, so in some preparations heparin has been added to reduce thrombin generation during storage. These concentrates are still in use simply because of cost considerations. Similar to factor VIII concentrates, they are subjected to various forms of viral inactivation to reduce the transmission of HIV, hepatitis B, and hepatitis C.

A recombinant factor IX preparation was licensed in 1997. Similar to all recombinant products, it is essentially virus-free. It is produced in CHO cells. A major difficulty in developing this product is the extensive post-translational modifications the natural protein undergoes. Eleven disulfide bonds, 1 β-hydroxylation, 1 sulfation, 1 phosphorylation, and 12 γ-carboxylations all must occur to activate the protein. The recombinant product has several differences from the native protein: only approximately 60% is fully carboxylated, 15% gets sulfated, and only 1% is phosphorylated. As a result, the protein is not as efficacious as the natural factor, so patients typically require an average of 1.5 times more protein than the highly purified plasma-derived protein to get sufficient increases in plasma factor IX. The cost is also substantially higher on a per-unit basis.[33]

One aspect of blood product replacement therapy that is often overlooked is cost. On average, a patient with severe hemophilia A uses $10,000 to $90,000 worth of factor per year depending on the type of product used and the dose required. Younger hemophilics, to avoid potential viral exposure, generally use the recombinant products.

As a hope for the future, correction of hemophilia by gene transfer is actively being pursued. Gene therapy is in its infancy, but hemophilia is considered one of the more ideal targets for early trials because the active proteins are found in the bloodstream and can be made in just about any tissue as long as they can be released to the blood. It will be interesting to see which hemophilia gene transfer succeeds first. The factor VIII gene is larger and more difficult to transfer, but the resultant protein undergoes much less post-translational modification than occurs with factor IX.

Inhibitors

A confounding problem in treating hemophilics is the development of antibody inhibitors against the deficient factor.[25] Approximately 10% of patients with severe hemophilia A express a high titer of inhibitor, usually within the first few years of being treated with factor VIII concentrates. Multiple approaches must be used to protect these patients against bleeding crises. The most crucial task is to determine whether the patient carries low-titer or high-titer antibodies. Patients with low-titer antibodies can often be given excessive amounts of factor replacement, depleting the inhibitor antibody sufficiently to allow the remaining factor to promote hemostasis. Although low-titer inhibitors may persist for years, they do not show the typical alloantibody boost response after exposure to human factor VIII concentrates. Care must be exercised in using this method for elective procedures because there is the risk that in some patients the additional factor challenge will boost the titer from a low-titer to a high-titer inhibitor, making future crisis intervention more difficult.

In patients who have high-titer inhibitors, preventing or reducing hemorrhage risk is crucial. Daily infusion of high-dose, medium-dose, or low-dose factor replacement to induce immune tolerance has been shown to be successful. Concomitant administration of immunosuppressant medications may depress antibody formation further. This approach is much more effective with autoantibody inhibitors than with alloimmune responses. A short course of daily intravenous infusion of IgG has sometimes reduced titers as well. After immune tolerance is achieved, most patients require continued low-dose prophylactic factor infusions at least weekly.

In an acute hemorrhagic situation, or in an emergent dental crisis, porcine factor VIII is sometimes useful. Although not readily available in the United States, a recombinant version is being developed. The protein is fully functional in humans, but inhibitor antibodies directed against the human form tend not to be strongly cross-reactive. Side effects include fever, chills, headache, vomiting, and rarely anaphylaxis. Continued use can result in development of species-specific antibody or, occasionally, immune tolerance to the human antigen.

When hemophilics with high-titer inhibitors require coagulation support, but factor VIII replacement therapy cannot be used, two products may be effective. Factor VIIa is a recombinant protein derived in BHK cells transfected with factor VII cDNA and has no risk of transmission of human pathogenic viruses. During processing, it spontaneously activates to factor VIIa. The protein as a therapeutic agent functions similar to its endogenous counterpart: by combining with TF present at all sites of injury to stimulate conversion of factors IX and X to their respective activated analogues. Because TF is found only at the site of injury, disseminated coagulation has not been a problem. Also, factor VIIa is not rapidly inactivated by ATIII, giving it a sufficient half-life to allow hemostasis. It has a much shorter half-life (only 2 to 3 hours) than either factor VIII or factor IX and requires high doses every 2 hours in the dental setting. The drug has the limitation that its mechanism is to achieve sufficient thrombin formation via the part of the coagulation cascade that is intended for only small amounts of thrombin generation. It seems to work well for initial hemostasis, but there have been difficulties with breakthrough bleeding 48 hours or so after surgery (unpublished data). The use of topical fibrin sealant in conjunction with this product seems to be a wise choice. The current cost of this medication is several thousand dollars per dose.

The other medication that can be used is a procoagulant complex known as FEIBA VH (factor eight inhibitor bypassing activity). The VH form is a vapor-heated concentrate of plasma-derived factors II, VII, IX, and X (the vitamin K–dependent clotting factors) in their inactive and active forms. How this medication corrects the bleeding disorder is unknown, but it is believed the extra factors II and X complex with endogenous factor V and reconstruct the common pathway, eliminating the need for factor VIII. The main difficulty with this medication is that the extra clotting factors can overshoot and cause thrombosis elsewhere in the body. Which product, FEIBA versus factor VIIa, works best in any given patient is unpredictable. Some patients clearly do better with one over the other, but the reason for this is elusive.

AGENTS THAT PROMOTE OR INHIBIT FIBRINOLYSIS

Fibrinolytics

Achieving hemostasis is a crucial aspect of the coagulation system, and limiting its spread is another; remodeling or breaking down clots when they are no longer necessary is a third crucial facet of vascular repair. As healing occurs, it is necessary to remove part or all of the fibrin that has been

deposited so that normal blood flow can be restored to the affected tissue. This process is mediated by the protease plasmin (Figure 31-5). When fibrin is initially deposited, thrombin stimulates adjacent endothelial cells to release tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA).

A serine protease with a fibrin-binding domain, t-PA must adhere to the fibrin molecules to function. This binding occurs on lysine residues of the fibrin. When adhered, t-PA binds plasminogen (also at a lysine residue) and cleaves the plasminogen to liberate plasmin, another serine protease. Plasmin has the ability to bind directly to fibrin. u-PA acts independently of fibrin and instead activates plasminogen to plasmin in the circulation. Plasmin associated with t-PA lyses the fibrin, releasing fibrin degradation products, and degrades factors V and VIII, inhibiting further clotting. t-PA can associate with circulating plasminogen, but does not effectively activate it unless both become bound to the fibrin, which is an important consideration in the therapeutic use of this compound.[9]

As expected, strict control mechanisms for plasmin activity exist. Without such control, circulating plasmin would cause systemic fibrinolysis and oozing of previously clotted sites. Three proteins are intimately involved. The first, α_2-antiplasmin (α_2-AP), is a serpin (serine protease inhibitor) that is synthesized in the liver and is efficient at neutralizing

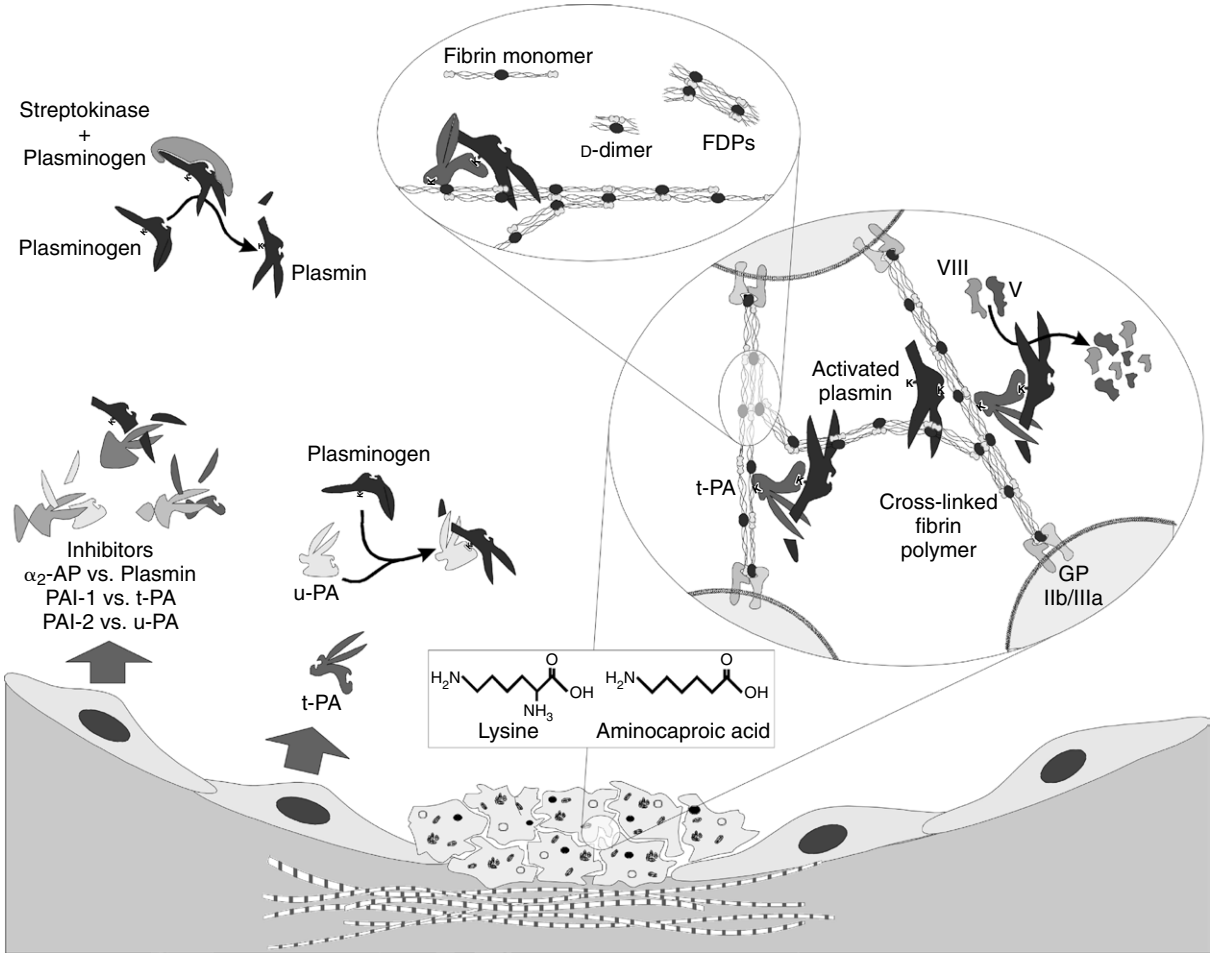

FIGURE **31-5** Fibrinolysis. Thrombin formation causes adjacent endothelial cells to release tissue plasminogen activator *(t-PA)* and urokinase plasminogen activator *(u-PA)*. t-PA adheres to lysine residues on the fibrin molecules and adsorbs plasminogen onto it, also by lysine binding. The proteolytic action of t-PA converts the plasminogen to plasmin at the wound site, whereas u-PA converts it in the free circulation. Plasmin acts to degrade factors V and VIII and proteolytically cleave the fibrin. Various fibrin degradation products *(FDPs)* are liberated, including the D-dimer formed from two fibrin molecule "ends" linked to one fibrin molecule "middle." Aminocaproic acid interferes with plasminogen conversion by occupying lysine-binding sites on t-PA and plasminogen, resulting in antifibrinolysis. The endothelial cells also release several inhibitors: plasminogen activator inhibitor-1 *(PAI-1)*, which destroys any free circulating t-PA, and plasminogen activator inhibitor-2 *(PAI-2)*, which inhibits u-PA. Both serve to limit the plasminogen activation primarily to the clot site. Another protein, circulating α_2-antiplasmin *(α_2-AP)*, neutralizes any free plasmin in the bloodstream, also restricting activity of plasmin to the wound site. Exogenous t-PA functions similarly to endogenous t-PA. Streptokinase combines with plasminogen to create a complex that cleaves other plasminogen molecules to free circulating plasmin. As a result, systemic fibrinolysis is more common with this medication. Not shown is streptokinase formulated with exogenous acylated plasminogen, which spontaneously deacylates on mixing with the plasma to form the same streptokinase-plasminogen complex. *GP*, Glycoprotein.

any free plasmin circulating in the blood. Conversely, binding of the plasmin to fibrin (independently or by t-PA) protects it from attack by α_2-AP, which appropriately restricts the activity of plasmin to the wound site. The second control protein, PAI-1, is a serpin synthesized by the endothelial cells in response to thrombin stimulation, with specificity for t-PA as its substrate. PAI-1 is in molar excess in the plasma compared with t-PA, effectively inhibiting systemic conversion of plasminogen to plasmin by t-PA, unless (as with α_2-AP and plasmin) the t-PA can "hide" from it by binding to fibrin. The third control protein is PAI-2, which functions similar to PAI-1, only with specificity for u-PA. The liver also functions to clear the bloodstream of any free active plasmin, further helping to prevent systemic fibrinolysis.

Therapeutic measures designed to induce or facilitate fibrinolysis are available for use in relieving certain types of thromboses, most notably in the event of acute myocardial infarction. These agents may also be valuable in patients with life-threatening pulmonary emboli, infarctive stroke, or deep venous thrombosis. All these agents function by activating the conversion of plasminogen to plasmin with subsequent natural fibrinolysis. One of the medications used is the natural activator, u-PA. The parent compound is cleaved twice, first to high-molecular-weight u-PA and second to low-molecular-weight u-PA. As with the endogenous form, low-molecular-weight u-PA loses its fibrin-binding domain, causing it to be effective at activating circulating plasminogen to plasmin. In pharmacologic doses, this activity results in systemic fibrinolysis.

t-PA is produced by recombinant DNA techniques. It is marketed under the nonproprietary name of alteplase. Because t-PA is naturally more fibrin specific than are preparations containing streptokinase or u-PA, it is the first thrombolytic agent recommended by the American Heart Association in the management of myocardial thrombosis.[19] At pharmacologic doses, it imparts some circulating plasminogen conversion, however. A deletion mutation variant of t-PA is available by the nonproprietary name of reteplase. It is similar in activity and side effects to t-PA.

Streptokinase, an exotoxin from certain β-hemolytic streptococci, also serves as an activator of plasminogen. It is different from t-PA and u-PA because it is not an enzyme and does not proteolytically cleave plasminogen to plasmin. Instead, it binds noncovalently to plasminogen and confers plasmin-like proteolytic activity on the plasminogen-streptokinase complex. The complex cleaves other molecules of plasminogen, liberating active plasmin. Because streptokinase is an exogenous protein originating in bacteria, there is a higher incidence of adverse and allergic reactions with this medication. Similar to u-PA, streptokinase is efficient at converting circulating plasminogen to plasmin, causing systemic fibrinolysis. It has been shown, however, that there is no greater mortality rate with this product than with t-PA when used for the treatment of acute myocardial infarction.[19]

A similar medication, anistreplase (anisoylated streptokinase plasminogen activator complex), is a combination of streptokinase with an acylated plasminogen, forming an inactive complex that spontaneously deacylates in plasma. The deacylated form is the same as the streptokinase-plasminogen complex previously discussed. Anistreplase has the advantage that it does not seem to be inhibited by endogenous serpins because of the acylated plasminogen protein, but its disadvantage is that it still causes systemic fibrinolysis.

The many available plasminogen activators have made effective treatment possible in reducing ischemic myocardial necrosis if given within 30 to 60 minutes after the onset of chest pain.[19] There is a 47% success rate in thrombolysis if the products are given 1 hour from onset of symptoms. Results are poor if given after a 3- to 6-hour delay.

Antifibrinolytics

In some circumstances it is advantageous to limit fibrinolytic activity (e.g., after surgery in a hemophilic who may be prone to breakthrough bleeding as the wound heals). The drug used for this purpose is aminocaproic acid (sometimes referred to as ε-aminocaproic acid), which competitively inhibits plasminogen and plasminogen activators from binding to fibrin. Aminocaproic acid is a lysine analogue that binds to plasminogen and plasmin, masking their ability to adhere to fibrin. The usual dose of aminocaproic acid is 50 mg/kg every 6 hours for 10 days. In its tablet form (500 mg) this dosage requires the average adult patient to take approximately seven tablets every 6 hours. As a result, compliance can be difficult. A concentrated syrup form exists for pediatric use (250 mg/mL), and experience indicates that adult patients generally are more compliant with taking the liquid form of the medication, especially after oral surgical procedures.

Side effects of this medication include unwanted thrombosis in patients who are prone to deep venous thrombosis and cardiovascular disease. Careful consideration and consultation with the physician is important before using this medication in such patients.

ANTICOAGULANTS

Although dentists are unlikely ever to prescribe an anticoagulant agent, it is essential that they be aware of any hemostatic deficiency in the patient, whether pathologic or therapeutic in origin. Anticoagulants are being used with ever-increasing frequency by physicians, and dentists commonly encounter patients who are taking these medications. There are now three classes of anticoagulants in clinical use: direct-acting agents, which are capable of acting in vitro and in vivo; indirect-acting agents, which interfere with the synthesis of coagulation system proteins; and platelet inhibitors, of which three subclasses exist: COX inhibitors, GP IIb/IIIa antagonists, and ADP receptor antagonists. Dentists should be familiar with the pharmacologic features of each class and understand if, how, and, more important, when their effects should be modified.

Direct-Acting Anticoagulants: Heparins

First extracted by McLean in 1916, heparin is a powerful, systemically effective direct-acting anticoagulant. Heparin is a linear mucopolysaccharide primarily composed of repeating units of D-glucosamine in 1,4 glucosidic linkage with D-glucuronic and L-iduronic acids. These disaccharide residues, which are partially esterified (≤40%) with sulfuric acid, make heparin the strongest organic acid normally occurring in the body. About 10 to 15 of these chains, each with 200 to 300 monosaccharide units, are attached to a core protein to give the final proteoglycan as the storage form of heparin in mast cells. Because the polysaccharide chains differ in length, and the sulfation reactions vary, endogenous heparin is a heterogeneous mixture of molecules, with molecular weights ranging from 4000 to 40,000, none of which has been completely characterized. Commercial preparations are made primarily from recombinant DNA techniques. Figure 31-6 depicts 1 of 40 to 50 repetitive sequences found in commercial preparations, a pentasaccharide segment of heparin that is believed to include an essential binding site for anticoagulant activity.

Heparin is produced endogenously in mast cells, where it is stored in a large macromolecular form complexed with histamine. Heparin and histamine are released together, providing a physiologic example of a fixed-drug combination, the significance of which is not yet fully understood. Many investigators have attempted to explain the in vivo maintenance of blood fluidity by the presence of heparin in plasma.

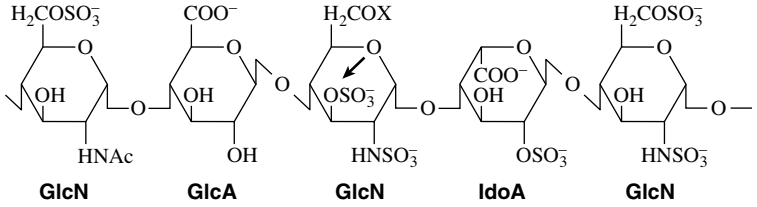

FIGURE **31-6** Pentasaccharide sequence of heparin. This sequence, unique in its high affinity for antithrombin III (binding site indicated by *arrow*), also reflects the general structure of heparin: repeating units of sulfate-substituted glucosamine *(GlcN)*, glucuronic acid *(GlcA)*, and iduronic acid *(IdoA)* residues. *Ac,* Acetyl group; *X,* H or SO_3^-.

Historically, such attempts have been frustrated by methodologic limitations and by the strong tendency of heparin to bind with proteins. An important feature of heparin's activities, and one that is obscured by a narrow focus on plasma heparin concentrations, is the fact that the vascular epithelium can concentrate heparin against a gradient of 100:1. It has been proposed that adsorbed heparin-like mucopolysaccharides (termed *heparans*) are major contributors to the normally strong electronegative charge maintained by the vascular epithelium. This property is made use of in the manufacture of prosthetic devices such as heart valves, in which ionizable heparin is incorporated into the surface plastic to inhibit thrombus generation.

Mechanism of action

Heparin interferes with blood coagulation in several ways. Heparin functions by binding tightly to the plasma protease inhibitor ATIII, causing a conformational change in the inhibitor that exposes its active site and accelerates its activity 1000-fold. ATIII is a "suicide" serine protease inhibitor that covalently binds to several serine proteases (factors IXa, Xa, and XIIa), resulting in the permanent inactivation of the protease and the ATIII protein. As a result, factor Xa–mediated conversion of prothrombin to thrombin does not occur, and because thrombin is unavailable, factors V, VIII, and XIII are also not activated. In the form of a true catalyst, heparin is not destroyed in this process. The heparin-ATIII complex dissociates on binding of a protease to ATIII, releasing intact heparin for renewed binding to another ATIII molecule.

At higher concentrations, the heparin-ATIII complex binds to and inactivates thrombin itself (also a serine protease), inhibiting its proteolytic action on fibrinogen. This occurs when the heparin-ATIII dimer forms a ternary complex with thrombin by the heparin binding to one site on the thrombin protein and ATIII binding the active site on the other side. These two sites are a significant distance from one another, and only the higher molecular weight moieties of heparin are capable of producing the effect. Molecules of less than 18 monosaccharides are incapable of reaching far enough across the protein to allow ATIII to bind and inhibit thrombin.

The effects of heparin on platelets are likewise complex. In part, because thrombin is not formed or is rendered inactive, platelet activation is usually reduced. More troubling, heparin may also sometimes induce independently of other aggregating agents a transient, anomalous platelet aggregation and significant thrombocytopenia in 1% to 5% of patients. Two varieties of heparin-induced thrombocytopenia (HIT) exist: a relatively benign nonimmune process and an immune-mediated process. The latter, known as type II, can be fatal in 30% of cases. It is believed that complexing of the heparin to platelet factor 4 results in antibody formation and subsequent activation of platelets. In this syndrome, the difficulty is not with bleeding, but with runaway thrombosis. As the platelets activate, they form thrombi, which account for much of the clinical presentation. As the platelets are used up, thrombocytopenia and bleeding occur. Patients with a history of HIT are far more likely to have a repeat problem, as would be expected with immunologic phenomena.[17]

Heparin also exhibits an ability to promote lipid clearance from the bloodstream. In this capacity it releases and stabilizes lipoprotein lipase, which hydrolyzes the triglycerides of chylomicrons and very-low-density lipoproteins to free fatty acids, which can be rapidly absorbed by tissue cells. This effect occurs at low physiologic blood concentrations, and it has been shown that all heparin molecules are capable of activating lipoprotein lipase. Because the anticoagulant property of heparin and its antilipemic action depend on the presence of ATIII in the plasma, heparin cannot act as an anticoagulant in a system composed of isolated clotting factors alone, and it cannot function as a lipemia-clearing agent in the absence of cofactor.

Low-molecular-weight heparins

Much research activity has focused on the use of low-molecular-weight heparin (LMWH) fractions for the prevention of thrombosis.[13] Unfractionated heparin consists of heterogeneous combinations of various-sized sulfated mucopolysaccharides. Because only high-molecular-weight heparins (heparins with ≥18 specific saccharide sequences) can bind thrombin and inactivate it, attention has turned to LMWHs. They are poor inhibitors of thrombin, but they retain the ability to catalyze ATIII to inhibit other serine proteases, most notably factor Xa. As a result, they have at least some advantage in that they exert antithrombotic activity without completely destroying the coagulant activity thrombin imparts on factors V, VIII, XII, and XIII. A problem with LMWHs is that they all are prepared by fractionating heparin, and different methods impart different ratios of anticoagulant and antithrombotic activity. Enoxaparin and dalteparin currently are the most commonly used medications in this class; the one selected by the physician depends on the degree of anticoagulation desired for the patient.

A synthetic pentasaccharide, fondaparinux, similar to LMWHs, has been marketed. This medication is a selective factor Xa inhibitor, and studies have shown that it is more effective than enoxaparin in preventing deep venous thrombosis after hip and knee surgery.[11] More specific products are likely to be developed that mimic the basic actions of heparin.

Absorption, fate, and excretion

All available forms of heparin must be administered parenterally because they are highly charged and rapidly hydrolyzed in the gastrointestinal tract. Unfractionated heparin is usually infused intravenously but may be given by deep subcutaneous or fat depot injection. It should not be injected intramuscularly because of the risk of deep muscle hematoma. Heparin has a dose-dependent biologic half-life of 1 to 5 hours when given intravenously, and it is removed primarily by the liver. Two distinct advantages of LMWHs are that they are generally administered subcutaneously, and their effects are prolonged compared with unfractionated heparin because they are less readily neutralized by platelet factor 4 (platelet antiheparin), which permits once-daily or

twice-daily dosing. LMWHs cause more release of t-PA and have less lipoprotein lipase-activating capacity than the unfractionated drug.

Heparin activity is best monitored by the partial thromboplastin time or the aPTT, both of which measure drug effects on the intrinsic pathway and are sensitive to low doses of heparin. The partial thromboplastin time is much less sensitive (and often completely normal) to LMWHs. Standardized doses of LMWHs achieve a more consistent anticoagulant effect, reducing the need for monitoring. The prothrombin time (PT), routinely used to monitor oral (indirect-acting) anticoagulants, is also of little value because it does not respond to inhibition of the thrombin-catalyzed part of the coagulation cascade, and heparin is diluted out in the procedure.

Antidotes

The action of heparin can be readily terminated by intravenous injection of one of several highly positively charged compounds, including protamine sulfate, toluidine blue dye, or hexadimethrine bromide. Only protamine is currently recommended for this purpose, however. Protamine is a highly basic compound that combines with heparin as an ion pair to form a stable complex that can no longer bind to ATIII. Because protamine may itself have anticoagulant (antithromboplastic) effects, only enough drug should be given to neutralize the heparin (approximately 1 mg protamine/100 U unfractionated heparin). The drug should be given slowly intravenously (5 mg/min) to avoid depression of the myocardium and vascular smooth muscle. Anticoagulant rebound is often seen after protamine administration because of more rapid clearance of protamine compared with heparin.

Other Direct-Acting Anticoagulants

Direct thrombin inhibitors

It has long been known that leeches secrete a potent anticoagulant in their saliva. In many centers, medicinal leeches (*Hirudo medicinalis*) are still used to help patients combat venous thromboembolic events. The active component has been isolated and identified as hirudin, a 65-amino acid polypeptide chain that is a specific direct thrombin inhibitor. It works by stoichiometrically binding to thrombin at two sites, the fibrinogen-binding site and the active protease site. It is the most powerful naturally occurring anticoagulant known.

Hirudin has many advantages over heparin. As a direct thrombin inhibitor, it is able to inhibit clot-bound thrombin that the heparin-ATIII complex cannot reach. As would be expected with a direct inhibitor, it also has caused more severe bleeds. A recombinant analogue, lepirudin, has been approved for the treatment of thrombosis associated with HIT. Because 50% of patients develop IgG antibodies against the hirudins, aPTT must be monitored closely.

Perhaps the most widely used direct thrombin inhibitor is bivalirudin, a semisynthetic analogue of hirudin consisting of 20 amino acids. It competes for the fibrinogen-binding site and the proteolytic site, effectively stopping all cleavage of fibrinogen to fibrin. Bivalirudin differs from hirudin in that it produces only transient inactivation of the thrombin protease site because the thrombin itself slowly acts on the bivalirudin to cleave it, and when cleaved it "falls off" the thrombin molecule, allowing fibrinogen to bind. This net effect means that it has a relatively short clinical half-life of 1 to 2 hours, but that is advantageous because it can be infused to prevent thrombosis before cardiac surgery and turned off shortly before the case to allow full clotting to occur in a predictable fashion. Bivalirudin was shown more recently to prevent blood clots better than heparin in patients undergoing angioplasty.[28] The drug is primarily cleared via intravascular proteolysis and renal elimination in the urine; it has a significantly longer clinical half-life in patients with moderate-severe renal failure.

Several low-molecular-weight thrombin inhibitors have been developed. They bind to the active protease site of thrombin and inhibit its action. Argatroban is the only currently approved medication in this class. Argatroban has been associated with an increased mortality rate when treating patients with HIT type II.

Miscellaneous agents

Danaparoid functions similarly to heparin, but it is composed of a mixture of glycosaminoglycans, including heparan sulfate, dermatan sulfate, and chondroitin sulfate. It works primarily by binding with ATIII to diminish factor Xa activity and has been used to treat HIT type II.

Aprotinin is a broad-spectrum protease inhibitor. It selectively blocks the activation of the major thrombin receptor PAR-1. As discussed earlier, this platelet receptor is activated by thrombin cleaving a portion away, allowing the "new" N-terminus to autostimulate signal transduction. Aprotinin blocks this proteolytic cleavage, inhibiting the receptor from thrombin activation. It does not stop ADP-induced, collagen-induced, or epinephrine-induced activation of platelets because the receptors for those ligands do not require proteolytic cleavage, and it does not fully inhibit clot formation. The medication is often used during cardiopulmonary bypass surgery because it helps protect platelets from forming thrombi under the influence of thrombin liberated from platelets while in the bypass circuit.[23]

Indirect-Acting Anticoagulants: Coumarin-Indanediones

Discovery of the prothrombin-depressant action of spoiled sweet clover by Roderick in 1929 led to the isolation and synthesis of dicumarol (bishydroxycoumarin) by Campbell and Link in the 1940s. These advances introduced a new era of relatively inexpensive, self-administered oral anticoagulant therapy. Since then, several other coumarin compounds have been introduced, as have drugs of a related group, the indanediones. Because there is little qualitative difference in the action of any of these agents, they are referred to here as a single group, the coumarin-indanediones. Indanediones are generally more toxic, however.

Mechanism of action

Indirect anticoagulants act by competitively inhibiting vitamin K epoxide reductase, an enzyme essential for the synthesis of many coagulation factors by the liver. (The structural similarity between these drugs and vitamin K is shown in Figure 31-7.) Vitamin K serves as a cofactor with oxygen and carbon dioxide in the γ-carboxylation of glutamic acid residues of several proteins, including the clotting factors II, VII, IX, and X and proteins C and S. The carboxyglutamic acid moieties formed are able to chelate Ca^{++}, which promotes conformational change and eversion of hydrophobic domains, allowing the factors to settle into the platelet or endothelial cell membrane and bind cofactors. Vitamin K is oxidized in the carboxylation process and must be reduced enzymatically to regain cofactor activity. Coumarin-indanediones inhibit this reduction (Figure 31-8).

The most sensitive indicator of vitamin K deficiency, or of dicumarol anticoagulation, is the depression of factor VII. Prothrombin (factor II) is the most resistant of the factors affected. This apparent ordering of sensitivity is a reflection of the plasma half-lives of the clotting factors. Factor VII is initially depressed because its half-life is only 4 to 8 hours. Prothrombin, with a half-life of 2 to 3 days, is the last to be diminished.

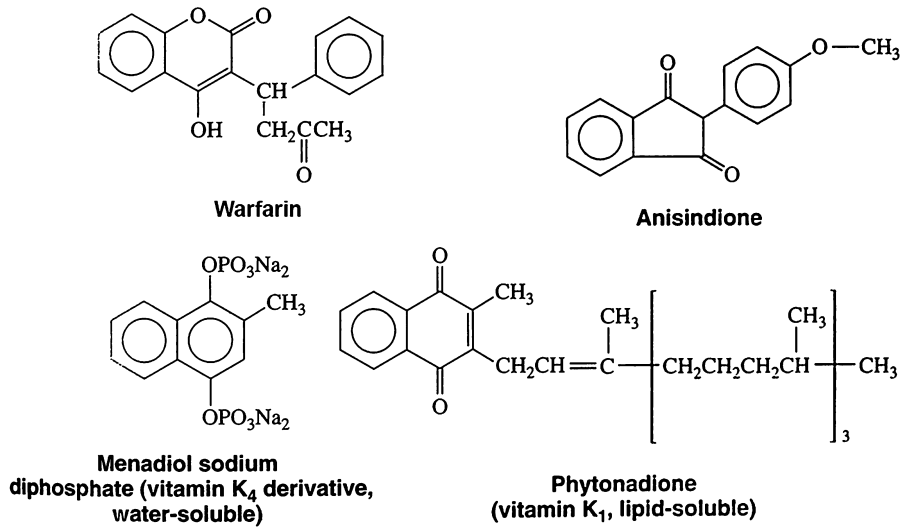

FIGURE **31-7** Structural formulas of several indirect-acting anticoagulants and analogues of vitamin K.

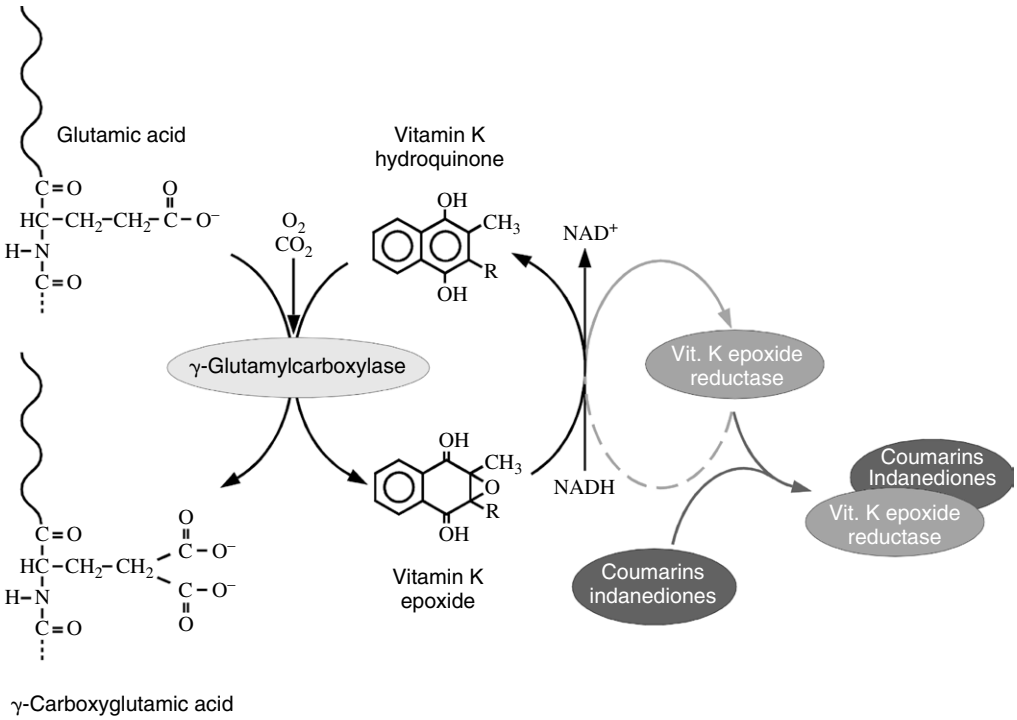

FIGURE **31-8** Inhibition of synthesis of vitamin K–dependent clotting factors by coumarin-indanedione anticoagulants. In the final post-translational modification of prothrombin (factor II), factor VII, factor IX, factor X, protein C, and protein S, vitamin K is oxidized to the epoxide in the process of carboxylating glutamic acid residues on the amino end of each protein. The resultant γ-carboxyglutamic acid groups serve to chelate Ca^{++} ions and conformationally change to expose a hydrophobic domain that settles into phospholipid membranes, anchoring the factors for normal hemostasis. The indirect-acting anticoagulants prevent the restoration of vitamin K by competitively inhibiting vitamin K epoxide reductase, the enzyme responsible for reducing vitamin K epoxide by nicotinamide adenine dinucleotide *(NADH)*. *R*, Hydrocarbon side chain of vitamin K.

Because of the close relationship between hypovitaminosis K and spontaneous hemorrhaging in patients and animals receiving coumarin-indanedione drugs, it is generally assumed that there is a direct causal relationship between coagulation impairment and hemorrhage. This has never been proved, however, and there is reason to doubt that the incoagulability of blood per se is sufficient to cause spontaneously leaky vessels. Vitamin K may have physiologic functions not yet fully realized, including an important role in carboxylation of bone proteins necessary for Ca^{++} binding.

Adverse effects

Indirect anticoagulants notably produce adverse reactions in the presence of certain drugs and medical conditions. These effects most often arise from interference with vitamin K absorption or metabolism, competition for the drug-binding sites of proteins, or competition for or activation of the hepatic microsomal enzymes responsible for biotransformation. The most important toxic effect of coumarin-indanediones is hemorrhage.

Any change in the absorption or availability of vitamin K from the intestine affects the balance between the anticoagulant and vitamin K in the liver and is reflected in the PT. A decrease in vitamin K uptake may result from a disease such as sprue (biliary stasis with concomitant loss of fat-emulsifying bile salts) or from the use of mineral oil as a laxative. In patients with marginal amounts of vitamin K in the diet, it can reflect the depressed bacterial synthesis of vitamin K in the intestine resulting from administration of a wide range of antimicrobial agents. A great deal of attention has been directed in recent years to the effects of oral contraceptive agents on the blood coagulation mechanism. In this regard, oral estrogen, such as that used in contraceptive preparations, greatly increases vitamin K_1 absorption in experimental animals.[21]

Coumarin compounds are highly protein-bound in the plasma (warfarin approximately 99%). This association creates a tremendous reserve of drug in the bloodstream, a very small displacement of which could easily double the concentration of active free drug. Many unrelated compounds that are highly protein-bound theoretically may compete for this protein binding by coumarins and potentiate their action. Examples of drugs reported to compete successfully with indirect anticoagulants for albumin binding sites are some anti-inflammatory drugs; the antiepileptic agent phenytoin; and clofibrate, a drug capable of lowering blood cholesterol. It has been suggested that part of the salicylate potentiation of dicumarol may also result from this kind of mechanism.

Only trace amounts (approximately 1%) of coumarin-type anticoagulants are excreted unchanged; hepatic biotransformation serves as the principal route of elimination. Warfarin is a racemic mixture of an R-enantiomer and S-enantiomer. The R-enantiomer, a weak anticoagulant, is metabolized primarily by CYP1A2, with CYP2C19 and CYP3A4 providing minor pathways. The S-enantiomer, a potent anticoagulant, is metabolized by CYP2C9. Medications that either inhibit or induce these various hepatic microsomal enzymes may affect the patient's response to warfarin. Certain agents, particularly rifampin, phenytoin, and the barbiturates (including phenobarbital, which is only partially metabolized), are capable of hepatic microsomal enzyme induction, which tends to decrease plasma concentrations of coumarin compounds. Microsomal enzyme induction may also occur with chloral hydrate, ethanol, and other drugs. In some instances, a reverse sensitization may be shown in which coumarin compounds potentiate these and other drugs by inhibiting their metabolism through competition for microsomal enzymes or, more important, are potentiated, leading to overaccumulation of anticoagulant and generalized hemorrhaging. Drug-warfarin interactions are listed in Box 31-2.

Many other drug interactions regarding oral anticoagulant agents do not involve vitamin K absorption, carrier protein displacement, or biotransformation. Aspirin, ibuprofen, and clopidogrel are representative drugs that inhibit platelet function. When administered concurrently with warfarin, their combined influences on the coagulation cascade may result in uncontrolled bleeding. Finally, there are many still unexplained interactions, such as the lethal hemorrhagic effects of adrenocorticotropin, reserpine, and various stress situations.

Antidotes

Except in situations in which an emergency demands the replacement of whole blood or plasma, the usual antidote for coumarin-indanedione toxicity is vitamin K administered parenterally in high concentrations. Because coumarin-indanediones inhibit recycling of vitamin K, simple administration of more "fresh" vitamin K obviates the need for recycling the epoxide form immediately. This therapy depends on the temporal synthesis of clotting factors, and significant shortening of PT cannot be expected to occur for several hours. Of the two major congeners, vitamin K_1 (naturally occurring, lipid-soluble phytonadione) and vitamin K_4 (as water-soluble menadiol salts), the more efficient drug is vitamin K_1. Natural vitamin K_1 is not water-soluble, but it is now available in solubilized form (with a polyoxyethylated fatty acid derivative), reducing the hazard of injecting an emulsion intravenously and the added delay of oral administration. Subcutaneous or intramuscular administration provides obvious improvement in coagulation in 1 to 3 hours, but normal hemostasis may not be achieved for 24 hours.

Similarly, minor correction in an anticoagulated PT is seen if patients ingest significant amounts of vitamin K via their diet. Liver, broccoli, Brussels sprouts, spinach, Swiss chard, collards, and other green leafy vegetables that are high in vitamin K can add enough vitamin K to shift the patient's anticoagulation profile in a few hours after ingestion. This technique is often used by anticoagulation clinics to "fine-tune" a patient before dental surgery if they are close to, but not quite under, their target PT international normalized ratio (INR).

Anticoagulants: General Pharmacologic Characteristics and Therapeutic Uses

The principal pharmacologic actions of direct-acting and indirect-acting anticoagulants interfere with some step in the blood coagulation process. Beyond this, neither direct-acting nor indirect-acting anticoagulants have outstanding effects on the cardiovascular, respiratory, or other systems except in the case of coumarin-type agents through competition with other drugs for protein binding sites and drug-metabolizing enzymes.

There are many indications in medicine for the use of anticoagulants, including myocardial infarction, cerebrovascular thrombosis, pulmonary embolism, venous thrombosis, rheumatic heart disease, mechanical cardiac valves, and renal dialysis. Cardiovascular compromise, such as that seen in atrial fibrillation or congestive heart failure, causes decreased flow of blood and presents a greater risk for thrombosis in areas of stasis. Atherosclerotic plaques, especially in hypertensive patients, are risks for intimal tears, with resultant thrombus formation. Heparin and oral anticoagulants are useful in the prevention and treatment of these disorders. Heparin, although it is costly and requires parenteral administration, acts immediately and is more effective than coumarin-indanediones in arterial thrombosis. Oral anticoagulants, most commonly warfarin, provide a less expensive, more easily administered, and more readily controlled form of sustained therapy. It has become commonplace to see patients treated with anticoagulants for long periods for these various reasons, and anticoagulation clinics are a staple in most medical centers. The dentist must be able to manage such patients appropriately without causing undue harm either from excessive bleeding or from increased thrombosis risk.

PLATELET INHIBITORS

As is discussed in Chapter 21, drugs that interfere with platelet function are increasingly being recommended for prophylaxis of arterial and venous thrombosis. In recent years, many different agents have been developed and marketed successfully. These agents can be divided into three essential groups: COX inhibitors, ADP receptor inhibitors, and GP IIb/IIIa inhibitors. Each has unique characteristics in managing thrombosis, and the dentist is likely to find patients with one or more of these medications in their drug profiles.

Cyclooxygenase Inhibitors

Aspirin (acetylsalicylic acid) is the prototypic and most commonly recognized COX inhibitor. Inexpensive and readily available, it is prescribed in doses of 81 to 325 mg/day to reduce the risk of myocardial infarction, particularly in men with a history of unstable angina, or in any patient at risk for myocardial infarction or ischemic stroke or both. The antihemostatic effect of aspirin is ascribed to irreversible acetylation of COX-1 isozyme. (The COX-2 isozyme is also inhibited, but is involved in inflammatory and pain pathways; aspirin is a more potent inhibitor of COX-1 than

COX-2, which explains its ability to impart antithrombotic activity at much lower doses than pain control requires.) COX-1 is required to synthesize platelet TXA_2 from arachidonic acid. Disruption of this pathway results in decreased platelet ADP release and aggregation. Because platelets are incapable of synthesizing new COX, the inhibition by aspirin lasts for the life of the platelet. The seemingly fortuitous effect on TXA_2 may be offset theoretically by a similar inhibition of prostacyclin synthesis in the vascular endothelium, which could facilitate thrombotic activity. The nonreversible nature of this inhibition and the relative insensitivity of COX-2–dependent prostacyclin synthesis to aspirin remove this concern, however.

When aspirin therapy is used in combination with thrombolytic therapy after acute myocardial infarction, there are significant reductions in mortality rate and in the incidence of major complications.[29] Ibuprofen has been shown to prevent the platelet inhibition of aspirin. In one study, aspirin was given either 2 hours before or 2 hours after acetaminophen, ibuprofen, or diclofenac. When ibuprofen was given before the aspirin, a 54% decrease in the TXB_2 (a stable metabolite of TXA_2) effect was seen. In all other arms of the study, no change was noted.[8]

Adenosine Diphosphate Receptor Inhibitors

As described earlier, ADP binds to its own receptor proteins $P2Y_1$ and $P2Y_{12}$, which results in maximal aggregation of the platelets to one another. The thienopyridine compounds ticlopidine and clopidogrel are two medications currently available that irreversibly inhibit the $P2Y_{12}$ receptor by what is believed to be a covalent bond to the receptor. Ticlopidine is more toxic and infrequently administered, leaving clopidogrel as the clear favorite in this drug class. Both are inactive until metabolized in the liver to their active forms. Because they bind only to the $P2Y_{12}$ receptor, the $P2Y_1$-mediated ADP effects still occur. This results in the platelets still undergoing shape change and transient aggregation, but sustained aggregation and potentiation of granule secretion are inhibited. Clinically, patients are likely to have sustained bleeding as a result of the action of these drugs. No reversal agents are available. Because the inhibition lasts the lifetime of the platelet, stopping antiplatelet therapy for 3 to 7 days before invasive surgery may be necessary to synthesize sufficient unaffected platelets.[15]

A new thienopyridine drug, prasugrel, is undergoing final approval by the U.S. Food and Drug Administration, but has been delayed several times from entering the market. It is pharmacologically similar to clopidogrel. Another drug, cangrelor, is a nonthienopyridine drug that inhibits the $P2Y_{12}$ receptor in a similar manner to the thienopyridines but has a much shorter half-life. It would theoretically have a unique position in hospital environments when more precise control over platelet aggregation is desired.

Glycoprotein IIb/IIIa Receptor Inhibitors

Activation of GP IIb/IIIa receptors is a crucial near-final step in platelet aggregation, and platelets genetically deficient in these receptors (i.e., Glanzmann thrombasthenia) display a much more profound inhibition to aggregation than platelets altered by the limited effects of aspirin or thienopyridines. As a result, attention has been focused on developing agents that can antagonize the GP IIb/IIIa receptors. The first agent, abciximab, is a mouse-human chimeric monoclonal antibody protein. The highly variable region of the antibody is from the mouse and is directed against the human GP IIb/IIIa protein complex. The Fc region is human, however, so as to not engender an immunogenic response. The medication has also been shown to bind to the vitronectin receptor on the endothelial cells, contributing further to its antithrombotic activity. No allergic or anaphylactic reactions have been reported, but the medication can result in severe thrombocytopenia.

Molecular analysis of the GP IIb/IIIa receptors indicates that they recognize a specific arginine-glycine-aspartic acid (RGD) sequence found in many of the adhesive molecules to which they bind (e.g., vWF). As a result, peptide analogues have been developed to bind at this RGD sequence and compete for the active sites. (Similarly, the venom of several species of viper contains peptides with similar RGD homologic features; these peptides are referred to as *disintegrins* and are known to bind to the GP IIb/IIIa receptors in an antagonistic fashion.[30]) Cyclic peptides bind better than linear ones, and one that is currently available is the peptide eptifibatide. Rather than an RGD sequence, it has a lysine-glycine-aspartic acid (KGD) sequence that imparts improved specificity for the GP IIb/IIIa receptor.

Finally, various nonpeptide agents that can compete for binding with the GP IIb/IIIa receptor have been developed. Similar to eptifibatide, they have structure and charge characteristics that mimic the RGD sequence and compete for the receptor's docking. Not being peptides, they have the advantage that they might be engineered to be orally acting. Currently, tirofiban (a tyrosine derivative) and lamifiban have been approved. In addition, lotrafiban is currently undergoing evaluation.

Herbal and Dietary Supplements

There is great academic interest in the surging herbal and dietary supplement use in current society and whether these agents may have pharmacologic action. Many of these agents have been implicated in directly modifying the coagulation status of patients or indirectly interacting with Western medications to increase or decrease their pharmacokinetic profiles (see Box 31-2). Chapter 56 discusses in detail the current knowledge about many of these compounds. As more data become available, it will be necessary for the dentist to be knowledgeable about what these medications might do in a patient who requires dentoalveolar or other oral surgery.

IMPLICATIONS FOR DENTISTRY

Anticoagulants

There are no accepted indications for the use of anticoagulants in the practice of dentistry. Many patients requiring dental treatment receive some form of medical anticoagulation therapy, however, for the reasons previously cited. These patients present three kinds of problems to the dentist: (1) their therapeutic regimen may result in excessive bleeding after oral or periodontal surgery, unless there is appropriate prior modification; (2) modification of their therapeutic regimen in preparation for surgery may predispose them to thromboembolic events; and (3) they may present a real danger of drug interaction between their anticoagulants and agents commonly used in dental practice, such as some analgesics, antibiotics, and sedatives. It is essential for the dentist to have a complete and thorough knowledge of the patient's drug history and what options are available when treating patients in whom anticoagulant therapy is involved.

Any intended oral surgical therapy in anticoagulated patients requires preliminary planning and consultation with the patient's physician or anticoagulation clinic. Coumarin-indanedione anticoagulants are monitored by the PT, which is now expressed in INR units. The PT test is performed by adding a source of TF and Ca^{++} to a patient's citrated blood sample and measuring the time necessary to coagulate the

sample. Previously, this value has been expressed in seconds or as a ratio of the patient's value to a laboratory-specific control. Because various laboratories use TF from different sources (human, rabbit, recombinant), there have been wide variations in the reported values and the resulting amount of anticoagulation. In an effort to normalize the activity of the various forms of TF, a formula has been developed that accounts for the inherent sensitivities of TF and individual laboratory methods. The resultant ratio, the INR, can be compared with any other INR value with high accuracy.[2] The test should not be called "the INR" because the assay is the PT, with the results reported as an INR. Other tests, such as aPTT, are likely to have INR units attached to them soon.

Because the PT INR is derived from an exponential formula, small changes in anticoagulation result in large changes in the PT INR value as the anticoagulation progresses. It is generally agreed that for coumarin-indanediones a PT INR value of 2.0 to 3.0 is considered ideal for most medical conditions. Prosthetic heart valves and other instances in which more anticoagulation is required generally have a target value of 2.5 to 3.5. Although there are no official recommendations from the American Dental Association on the topic of PT INR and dental treatment, one report recommends that a PT INR of 4.0 be used as the upper limit for simple oral surgical procedures and that a maximum of 3.0 be targeted for procedures likely to result in significant blood loss, such as multiple extractions with alveoloplasty.[7] The authors state, and others have agreed,[7,10,20,22] that it is unusual to have significant clinical bleeding when the PT INR is less than 3.0.

If a patient is anticoagulated to a high PT INR value, the dentist should consult with the physician about the possibility of reducing the anticoagulation to an acceptable PT INR, as shown in Figure 31-9. A unilateral request by a dentist for a patient to discontinue or decrease coumarin without consulting the physician is at best poor medical practice because medicolegally, even if the coumarin is ultimately decreased, the physician is the appropriate individual to alter and follow the dosages perioperatively. This adjustment may take several days to a week to accomplish. Current medical practice often places the responsibility of the anticoagulation management with an anticoagulation clinic that tracks the PT INR on a consistent basis, and such a clinic is a reliable resource to help guide the dentist and patient in making therapeutic decisions. Some patients have erratic responses to the coumarin class of anticoagulants, with unpredictable highs and lows in the PT INR despite the best efforts of the medical team to stabilize it. In these patients, the prudent dentist obtains a PT INR on the day of surgery and is prepared to reschedule the appointment if the value is too high to be safe. In the emergent patient, reversal with vitamin K and use of local hemostatic measures (collagen plugs, suturing, topical thrombin, fibrin sealant) may be indicated; in severe cases, the administration of fresh frozen plasma may be necessary.

If the anticoagulant is intravenous heparin, the drug may be withheld by the physician for 1 to 6 hours. This time interval is dose-dependent. If the heparin is to be restarted after surgery, typically waiting at least 1 hour is advisable to allow time for the clot to form fully. The use of local hemostatic agents may be considered for further hemorrhage control; in rare cases, protamine infusion may be necessary. Note that subcutaneous "maintenance" heparin absorbs into the bloodstream at such a slow rate that it can be effectively ignored in terms of dental bleeding issues.

Patients who are taking a LMWH such as enoxaparin present a dilemma. Because LMWHs stimulate ATIII to be active against factor Xa but are not very effective against thrombin (factor IIa), the PT and aPTT in these patients are usually normal. A special factor Xa assay (costly and not

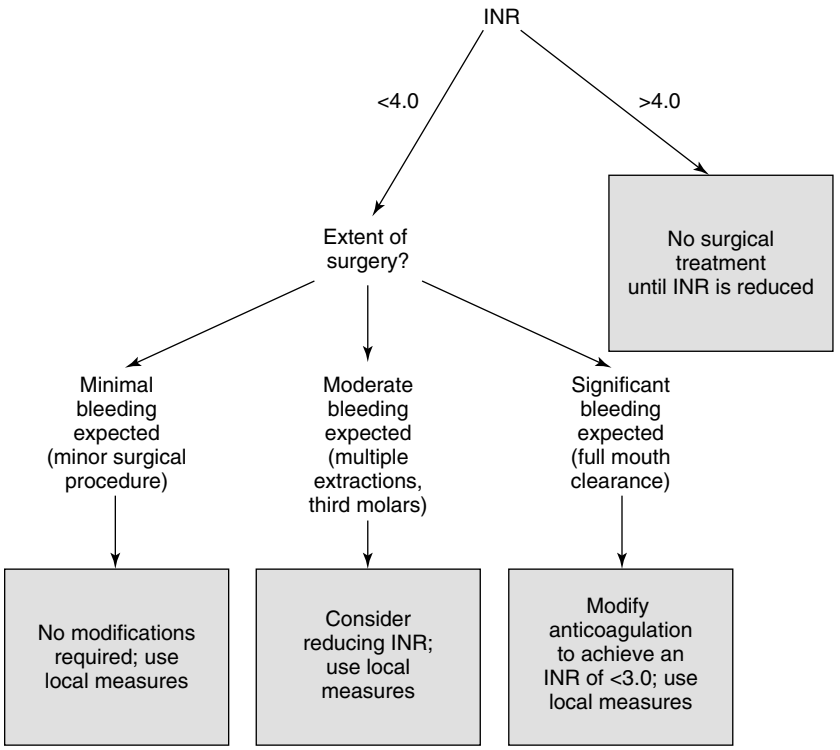

FIGURE **31-9** Flow chart for determining the appropriateness of dental therapy based on the prothrombin time. *INR*, International normalized ratio. (From Beirne OR, Koehler JR: Surgical management of patients on warfarin sodium, *J Oral Maxillofac Surg* 54:1115-1118, 1996.)

always available in every medical center) is used to monitor these medications when needed. The question arises as to what a dentist should do when patients are using these agents on a daily basis. Data are limited; one author suggests that the LMWH should be discontinued for 12 hours before the surgical event.[34] It can be argued, however, that for simple surgical procedures (e.g., dentoalveolar surgery, periodontal surgery), if there is sufficient thrombin generation to maintain the aPTT at a normal value, perhaps no adjustment to the regimen needs to be made. Anecdotal evidence supports this latter concept. Until proper research data become available, it is advisable to discuss each situation with the physician and arrive at a consensus decision.

Several studies have shown that postoperative bleeding after minor oral surgery, including tooth extraction, is not significantly affected by long-term aspirin therapy.[6] Although such studies are not currently available with respect to thienopyridines such as clopidrogel—either taken alone or with aspirin—an advisory report regarding patients with coronary artery stents states "there is little or no indication to interrupt antiplatelet drugs for dental procedures."[16] This conclusion is based on a paucity of reported bleeding problems after dental procedures, easy access to the affected tissues, and the high effectiveness of local measures in controlling oral bleeding. Should unusual circumstances dictate the need to restore platelet function to normal before treatment, withholding antiplatelet drugs for 3 to 7 days may be necessary because of the irreversible nature of the antiplatelet actions of aspirin and clopidogrel. The patient's physician should be involved in any plan to limit antiplatelet therapy. Local measures coupled with platelet transfusion as required may be necessary if the clinical situation is emergent or too risky to have the patient off these medications for several days.

Hemophilics

Managing a patient with hemophilia and other coagulopathies has become significantly easier in recent years, but many issues require careful consideration before proceeding. Patients who were previously believed to be unable to undergo operative procedures are now being treated routinely in many hospitals and dental offices. The most difficult problem a hemophilic faces is not the threat of exsanguination from a small laceration, but rather the problems encountered from a massive muscle bleed or chronic joint disease resulting from hemarthroses. In dentistry, there are many procedures that potentially can cause significant bleeding in a hemophilic. Surgical procedures must be planned so that replacement factor can be given preoperatively and postoperatively.

An important issue involves prediction of where an uncontrolled hematoma might develop in the head and neck region. Any potential space that might support the movement of blood through fascial planes toward crucial structures (e.g., the airway or major blood vessels) needs to be considered for "vented" wound management. In these areas, suturing to a tight, primary closure is contraindicated to allow any accumulation of blood to drain preferentially into the oral cavity and be identified rather than fill crucial spaces. Conversely, whenever the wound site is sufficiently removed from worrisome dissection paths (e.g., an anterior frenectomy), closure can be sutured tightly to help control localized bleeding. For similar reasons, the dentist must take care that inferior alveolar or posterior superior alveolar nerve block injections of local anesthetic are adequately covered by factor replacement to reduce the risk of hemorrhage into muscle or one of the parapharyngeal areas or both. The use of a commercial intraosseous anesthetic delivery system is indicated for patients in whom block anesthesia is contraindicated. Profound anesthesia usually can be easily obtained with minimal hemorrhage risk when these systems are used in hemophilics.

Associated disorders that commonly occur with hemophilics also may affect the delivery of dental care. Hemophilics often have joint disorders resulting from hemarthrosis. Any spontaneous or trauma-induced bleeding into the synovial space of a joint may cause permanent damage if inflammatory by-products, produced as the blood breaks down, damage the surrounding cartilaginous and bony structures. Knees, ankles, and elbows are most commonly affected, and many hemophilics have permanent limitation of motion in their joints by the time they reach adulthood. Joint replacement surgery is common in patients with severe hemophilia. As a result, mobility in and out of the operatory and positioning in the chair itself may be compromised.

Because of the historic necessity of transfusing hemophilics with pooled human blood products before recombinant factor replacements were available or the products were treated with heat or solvent detergent to inactivate viruses, many hemophilic patients were infected with HIV, hepatitis B virus, and hepatitis C virus. Seroconversion to HIV began around 1979 and accelerated rapidly until the mid-1980s. Many of these patients have since died. Screening donors began in the 1970s for hepatitis B, in 1985 for HIV, and in 1990 for hepatitis C. This screening has significantly reduced, but not eliminated, the viral risk. Noninfected hemophilics (primarily children and teens) are now being given recombinant factor replacements, whereas infected hemophilics more often select pooled human-derived, virally inactivated products. In uninfected patients for whom no recombinant factor replacement is available, and especially in families with vWD that is not responsive to desmopressin, the use of single-donor cryoprecipitate (usually a family member) for all necessary transfusions has proved effective in reducing the risk for viral transmission.

When surgical procedures are required in hemophilics, it is imperative that the dentist work closely with a hematologist well versed in the care of these patients. The dentist should describe the nature of the proposed surgery, the expected amount of bleeding, and the normal postoperative course after the procedure. In this way, the hemophilia treatment center can best plan how much and which kinds of factor replacement (or other pharmacologic intervention, such as desmopressin) are most appropriate. Depending on the training, location (office versus hospital), and experience of the treating dentist, the blood product or factor replacement may be given in the dental office, the medical office, or perhaps at home by the patient. Most of the products have an in vivo half-life of several hours, allowing the patient to receive the product at another site and go to the dental office for treatment with no reduction in hemostatic ability.

The normal healing mechanism of a wound site involves breakdown and re-establishment of newer fibrin matrices as the tissue heals. In a patient with a coagulopathy, the normal breakdown of fibrin can result in a rebleeding episode a few days later. Stabilization of the clot with an antifibrinolytic medication such as aminocaproic acid helps reduce the incidence of bleeding episodes for several days postoperatively. In many cases, the use of aminocaproic acid can greatly reduce or eliminate the need for additional blood or factor replacement. Adjunctive measures, such as the use of local hemostatic agents (microfibrillar collagen, suturing, or fibrin sealant), may also be helpful.

AGENTS THAT AFFECT COAGULATION AND HEMOSTASIS

Nonproprietary (generic) name	*Proprietary (trade) name*
Astringents-styptics	
Aluminum chloride	Hemodent
Tannic acid	In tea bags
Vasoconstrictor	
Epinephrine	Adrenalin
Topical procoagulants	
Absorbable gelatin film	Gelfilm
Absorbable gelatin powder	Gelfoam
Absorbable gelatin sponge	Gelfoam, Surgifoam
Absorbable gelatin sponge with thrombin (human)	Gelfoam Plus
Carboxymethylcellulose	In Orabase
Fibrin sealant (human)	Artiss, Tisseel
Gelatin matrix with thrombin (human)	FloSeal
Microfibrillar collagen	Avitene
Oxidized cellulose	Oxycel
Oxidized regenerated cellulose	Surgicel
Thrombin (bovine)	Thrombin-JMI
Thrombin (recombinant)	RECOTHROM
Systemic procoagulants	See Table 31-3
Fibrinolytics	
Alteplase (t-PA)	Activase
Anistreplase*	Eminase
Fibrinolysin, human*	In Elase
Reteplase	Retavase
Streptokinase	Streptase
Tenecteplase	TNKase
Urokinase (u-PA)	Abbokinase
Fibrinolysis inhibitors	
Aminocaproic acid	Amicar
Aprotinin	Trasylol
Tranexamic acid*	Cyklokapron
Direct-acting anticoagulants	
Unfractionated heparin, heparinoids	
Danaparoid*	Orgaran
Heparin†	—
Low-molecular-weight heparins	
Ardeparin	Normiflo
Dalteparin	Fragmin
Enoxaparin	Lovenox
Fondaparinux	Arixtra
Tinzaparin	Innohep
Direct thrombin inhibitors	
Argatroban	Novastan
Bivalirudin	Angiomax
Hirudin	*Hirudo medicinalis*‡
Lepirudin	Refludan
Indirect-acting anticoagulants	
Anisindione*	Miradon
Dicumarol* (bishydroxycoumarin)	—
Phenindione*	Hedulin
Warfarin	Coumadin, Jantoven
Antidotes for anticoagulants	
Menadiol* (vitamin K_4)	Synkayvite
Menadione (vitamin K_3)	—
Phytonadione (vitamin K_1)	Mephyton
Protamine sulfate	—
Platelet inhibitors	
Abciximab	ReoPro
Aspirin	—
Clopidogrel	Plavix
Cangrelor*	—
Dipyridamole	Persantine
Eptifibatide	Integrilin
Ticlopidine	Ticlid
Tirofiban	Aggrastat

*Not currently available in the United States.
†Available in calcium and sodium salts.
‡Organism of origin.

CHAPTER 32

Drugs Acting on the Respiratory System

KAREN S. GREGSON, BRUNO KREINER, AND JEFFREY D. BENNETT

Worldwide interest and concern continue to increase as a result of the escalating morbidity of inflammatory lung disease. According to the Centers for Disease Control and Prevention, the prevalence of asthma among U.S. children increased from 3.8% in 1980 to 5.8% in 2003.[27] Globally, it is estimated that 300 million people have asthma.[32] The World Health Organization in the Global Burden of Disease Study ranked chronic obstructive pulmonary disease (COPD) as the 12th leading contributor to the burden of disease in 1990; by 2020, it is estimated that COPD will be ranked 5th.[45] COPD is currently the fourth leading cause of death in the United States.[55]

In response to the alarming increase in inflammatory lung disease, a global network of physicians and scientists founded the Global Initiative for Asthma (GINA) in 1989. In 1998, the Global Initiative for Chronic Obstructive Lung Disease (GOLD) was founded. The goals of both assemblies are to increase awareness of asthma and COPD as global health problems, present guidelines for the diagnosis and treatment of disease, and stimulate research in each area. Asthma is defined by GINA as a chronic inflammatory disorder of the airways associated with airway hyperresponsiveness, with episodes of wheezing, breathlessness, chest tightness, and coughing and with a widespread, variable, and often reversible airflow limitation. The severity of disease is measured with spirometry as mild, moderate, or severe and defined by the percentage decrease of forced expiratory volume in 1 second (FEV_1) after a methacholine or histamine challenge.

COPD is defined by GOLD as a progressive airflow-limiting disease that is irreversible with a component of abnormal inflammatory responsiveness to noxious stimuli. Some significant extrapulmonary effects are also seen in many individuals with COPD. Classification of severity of COPD is measured with spirometry. The degree by which FEV_1 differs from predicted indicates mild, moderate, or severe disease. Treatment guidelines are based on measurements of severity of disease.

Many of the drugs recommended by the aforementioned assemblies are discussed in this chapter, including corticosteroids, bronchodilators, and leukotriene modifiers. The information presented here is intended to give the dentist an overview of why and how the drugs are used and how they may influence the choice of dental treatment or drug therapy for a patient with inflammatory lung disease.

PATHOPHYSIOLOGY OF ASTHMA

Asthma is a chronic inflammatory disease of the airways associated with acute symptoms, exacerbations, and airway remodeling.[14] The acute symptoms, bronchospasm and wheezing, can be reversed by bronchodilators. Exacerbations and airway remodeling are caused by chronic inflammation. Exacerbations can be controlled with anti-inflammatory drugs. There is no defined treatment for airway remodeling. Airway obstruction follows an acute bronchoconstrictor response to the spasmogenic stimulus, peaking within 10 to 20 minutes.[15] This early-phase reaction is characterized by the release of IgE and the activation of cells bearing allergen-specific IgE receptors, especially airway mast cells. The activated cells produce proinflammatory mediators such as histamine, eicosanoids, and reactive oxygen species (ROS).

Proinflammatory mediators induce contraction of airway smooth muscle, mucus secretion, and vasodilation. Airflow obstruction is caused by inflammatory mediators that induce microvascular leakage and exudation of plasma into the airways. Plasma protein leakage induces a thickened, engorged, and edematous airway wall and a narrowing of the airway lumen. The late-phase reaction occurs 6 to 9 hours after the early-phase reaction and is characterized by recruitment and activation of eosinophils, $CD4^+$ cells, basophils, neutrophils, and macrophages. Adhesive interactions occur among the various cell types. T cells are recruited 24 hours after the early-phase reaction and are thought to play a role in the chronic phase of the response and the enhancement of nonspecific bronchial hyperresponsiveness.

The chronic inflammation seen in the airways in patients with asthma is a complex process in which the whole mucosal immune system seems to be involved. Cell survival in airway tissues plays a role in chronic inflammation. The tissue load in inflammatory sites is controlled by apoptosis. In asthma, the persistence of inflammation is thought to be an alteration of the regulation of apoptosis. Characteristics of chronic inflammation include epithelial cell shedding and activation and the presence of mixed inflammatory infiltrates, lymphocytes, and many other cell types. There is also an increase of inflammatory mediators, including endothelins and nitric oxide. The end result of chronic inflammation is remodeling of the airways.

Activation of epithelial cells may be important in the regulation of airway remodeling and fibrosis because these cells release fibrogenic growth factors. The airway structural changes include thickening of the airway wall, increased muscle mass, and proliferation of mucous glands. Some clinical consequences of airway remodeling are increased resistance to airflow, bronchial contraction and bronchial hyperresponsiveness, production of mucous and exudate, and increased surface tension favoring airway closure. Although drug therapy does not reverse the effects of airway remodeling, it does decrease the chronic inflammation that plays an important role in this serious complication of asthma.

PATHOPHYSIOLOGY OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is a progressive condition characterized by irreversible airflow limitation.[41] The major etiologic factor is cigarette smoking. Cigarette smoke is a complex mixture of approximately 4700 compounds, including high concentrations of free radicals and other oxidants. Inflammation of the lungs as a reaction to cigarette smoke is characteristic of the disease and is thought to produce lung injury. Symptoms of COPD include chronic cough with sputum production and breathlessness on exertion. There is also a systemic component to the disease involving various organs, including skeletal muscle, the central nervous system (CNS), and the cardiovascular system. Systemic inflammation intensifies with progression of COPD and has been linked to cardiovascular events, muscle wasting, and colon cancer.

Chronic bronchitis, emphysema, and small airway disease are present in variable degrees in patients with COPD. Chronic bronchitis is an innate immune response to the inhaled toxic particles in cigarette smoke. Emphysema is defined as enlargement of the distal airspaces beyond the terminal bronchioles caused by destruction of the airway walls. Airway obstruction in the smaller conducting airways is caused by inflammatory mucus exudates.

The presence of $CD8^+$ lymphocytes and $CD4^+$ cells suggests chronic immunostimulation of the airway epithelium. Neutrophils and macrophages are found in the sputum, lung parenchyma, and bronchoalveolar lavage fluid from patients with COPD. Each cell type is activated by cigarette smoke. Activation causes the release of ROS and proteases by neutrophils. Macrophage activation induces the synthesis and secretion of inflammatory mediators, such as tumor necrosis factor-α, interleukin-8, monocyte chemotactic peptide-1, and leukotriene B_4 (LTB_4). Inflammation in the lungs may be intensified further by an imbalance between histone acetylation and deacetylation. Oxidants are believed to interact with histone deacetylase. Nitrosylation of tyrosine residues in histone deacetylase decreases enzymatic activity and leads to enhancement of inflammatory gene expression through chromatin remodeling.

DRUGS USED TO TREAT ASTHMA

Corticosteroids

Mechanism of action

Corticosteroids diffuse readily across plasma membranes to enter cells where they encounter the glucocorticoid receptor, a cytosolic protein. When the steroid binds the receptor, the receptor undergoes a conformational change.[8] Chaperone proteins dissociate from the receptor, and nuclear receptor localization regions on the receptor are exposed. The receptor-steroid complex dimerizes and is transported to the nucleus, where it binds to DNA in promoter sequences termed *glucocorticoid response elements* (GREs). Repression of genes activated by inflammatory diseases is the predominate effect of corticosteroids. These genes encode cytokines; chemokines; adhesion molecules; and inflammatory enzymes, proteins, and receptors. Repression of these genes by corticosteroids occurs at concentrations easily achieved clinical practice. There are no recognizable GRE sites within these genes, however. This response seems to be a result of corticosteroid effects on chromatin remodeling.[6]

Chronic inflammation involves activation of the proinflammatory transcription cofactors nuclear factor-κB (NF-κB) and activating protein-1 (AP-1). NF-κB and AP-1 bind to large coactivator molecules, such as cyclic adenosine 3′,5′-monophosphate (cAMP) response element–binding protein, which possess intrinsic histone acetyltransferase activity. Acetylation of core histones on specific lysine residues reduces their charge and changes the electrostatic attraction between the histone protein and DNA; this allows the histone-DNA complex to undergo a conformational change from the closed structure to the activated open form. DNA unwinds and is accessible to RNA polymerases, which initiate transcription of inflammatory genes. Histone deacetylases (HDACs) act as corepressors along with other proteins, such as nuclear receptor corepressor, to silence gene expression. Deacetylation of histone proteins on lysine residues returns the DNA to the closed basal state, countering the activity of the histone acetyltransferases.[1]

Corticosteroids have multiple effects on chromatin remodeling proteins. Anti-inflammatory genes are activated by selective acetylation of histone H_4 by coactivator molecules, such as steroid receptor coactivator-1 (SRC-1) and glucocorticoid receptor interacting protein-1 (GRIP-1). Corticosteroids also repress gene activity by reversal of histone acetylation of proinflammatory sequences; this can occur in two pathways. First, activated glucocorticoid receptor can bind directly to cAMP response element–binding protein and other coactivators and inhibit their histone acetyltransferase activity. Second, and more important, activated glucocorticoid receptor can recruit HDACs to the transcriptional complex, which results in deacetylation of histones associated with inflammatory gene expression.[2]

Given the effects that corticosteroids have on chromatin remodeling pathways, it is now apparent why low doses are effective in the treatment of asthma. The pathophysiology of asthma involves the increased expression of multiple inflammatory genes activated by the proinflammatory transcription factors AP-1 and NF-κB. In bronchial biopsy specimens from patients with asthma, there is an increase of histone acetyltransferase and a small decrease of HDAC activity compared with airways of patients without asthma, indicating an increase of inflammatory gene expression.

Steroids can also reduce chronic inflammation by transactivation.[8] Transactivation requires higher concentrations of steroids, however, than those concentrations required for chromatin remodeling. Transactivation involves the monomeric glucocorticoid receptor complex, which can interact directly with AP-1 and NF-κB through protein-protein interactions. This interaction decreases their transcription factor–mediated proinflammatory actions. Corticosteroids also increase the expression of two proteins that affect these inflammatory signal transduction pathways: glucocorticoid-induced leucine zipper protein (GILZ) and mitogen-activated protein kinase phosphatase-1 (MKP-1). GILZ inhibits AP-1 and NF-κB. MKP-1 inhibits p38 mitogen-activated protein kinase, which is activated by AP-1.

Pharmacologic effects

The pharmacologic effects of steroids on inflammatory lung diseases indicate that they are very effective at controlling symptoms of the disease, but they do not cure the disease. When the steroid dose is reduced, or the steroid is discontinued, the symptoms eventually return. In asthma, corticosteroids reduce airway inflammation and hyperresponsiveness, improve lung function, and decrease the incidence and severity of acute asthma exacerbations. Treatment of COPD with corticosteroids is controversial.[42] Experimental data indicate that the inflammatory processes in COPD may be resistant to the effects of corticosteroids because of oxidation and nitrosylation of proteins involved in chromatin remodeling by the oxidants found in cigarette smoke. Clinical data show inhaled corticosteroids improve the health of patients with COPD, however.[50] The pharmacologic effects seen with corticosteroids in COPD are largely the same as those

seen with asthma, but they also reduce systemic inflammation and reduce the rate of decline of health in patients with COPD.

Efficacy and safety

The optimal route of administration of corticosteroids for inflammatory lung disease is inhalation. Inhalation delivers the drug directly to the lungs. The corticosteroid acts locally, which minimizes the systemic adverse effects encountered with oral or parenteral administration. Receptor-binding affinity is the only pharmacodynamic parameter that differs among the corticosteroids that are available for inhalation.[24] High binding affinity can be considered a desirable trait providing for better efficacy in the lung. High binding affinity can also be detrimental because it can lead to increased systemic adverse effects.

The differences between the inhaled products depend on factors such as formulation, pulmonary and systemic bioavailability, and excretion.[23] Characteristics that enhance the efficacy of inhaled corticosteroids include small particle size and long pulmonary residence time. Solution aerosols formulated with hydrofluoroalkane, such as ciclesonide and beclomethasone dipropionate, have a small mass median aerodynamic diameter (MMAD) <2 μm. A small MMAD can have effects on efficacy because the smallest airways have an internal perimeter ≤2 μm. MMAD can also have an impact on local adverse effects because larger particles are more likely to be deposited in the oropharyngeal cavity.

Pulmonary residence time depends on two factors, lipophilicity and lipid conjugation. Lipophilic side chains on the D-ring of the steroid portion of the drug (see Figure 35-2) slow the dissolution in aqueous bronchial fluid. Lipophilic groups also aid the passage of the drug through the phospholipid bilayer of cell membranes to reach the receptors in the cell. Lipid conjugation to fatty acids in the pulmonary cells occurs via a reversible ester bond. Esterification provides a slow-release reservoir of the corticosteroid, prolonging residence time. This prolonged residence time allows a once-a-day dosing schedule for budesonide and ciclesonide.

Adverse effects

The most common adverse effects of inhaled corticosteroids are oropharyngeal candidiasis and dysphonia.[36] Although they can be easily managed, these localized adverse effects diminish compliance leading to uncontrolled disease and reduced quality of life. Less common adverse effects of inhaled corticosteroids are systemic in nature, including adrenal suppression, bone loss, skin thinning, metabolic changes, behavioral abnormalities, weight gain, and decreased linear growth in children. The concentration of the corticosteroid in the blood is a combination of the portion that is swallowed and the portion that is delivered to and absorbed from the lungs.

The safety of inhaled corticosteroids depends on factors such as activation in the lungs, low oral bioavailability, high protein binding, and rapid systemic clearance. Although most corticosteroids are inhaled in their pharmacologically active form, beclomethasone dipropionate undergoes activation in the human lung.[30] Beclomethasone dipropionate is metabolized to beclomethasone 17-monopropionate, which has a relative receptor affinity about 30 times greater than the parent compound. Metabolism in human plasma is quite different from metabolism in human lung. Human lung metabolism involves a simple hydrolysis reaction to the active form. Metabolism in human plasma involves hydrolysis, transesterification, and loss of hydrogen chloride. Metabolism in human plasma results in beclomethasone 21-monopropionate, which has no binding affinity for the glucocorticoid receptor. This differential metabolism in lung and plasma leads to fewer systemic effects of beclomethasone.

Ciclesonide is metabolized to desisobutyryl-ciclesonide by esterases located in human lung. This metabolite has a relative receptor binding affinity 120 times that of ciclesonide. Metabolism of ciclesonide in the oropharynx region is very low, resulting in low amounts of active drug entering the systemic circulation by swallowing. Activation in the lung can improve the safety profile of an inhaled corticosteroid. The degree of protein binding can also affect the safety of an inhaled corticosteroid. Protein binding to albumin in the blood controls the systemic unbound concentrations and limits adverse effects.

β_2-Adrenergic Receptor Agonists

β_2-adrenergic receptor agonists are structurally modified catecholamines. The useful structural modifications result in increased β_2 receptor selectivity, enhanced oral activity, and an extended duration of action after inhalation.[12] Susceptibility to degradation by catechol-O-methyltransferase (COMT) and reuptake mechanisms in neurons are decreased by structural modifications. There are two types of β_2 adrenergic receptor agonists. The short-acting drugs have bronchodilatory effects that last 4 to 6 hours and are exemplified by albuterol. The long-acting drugs have bronchodilatory effects that last 12 hours and bronchoprotective effects lasting 6 to 12 hours.

Short-acting and long-acting drugs were designed along the same structure-activity principles. Albuterol and salmeterol have a nearly identical active moiety, (Figure 32-1). Salmeterol has an extended aliphatic side chain, however, which was designed to anchor the drug in or near the receptor. There are currently two long-acting β_2 agonists on the market: salmeterol and formoterol.[3] Formoterol is a formanilide-substituted phenylethanolamine. Formoterol has a higher intrinsic efficacy and a faster onset of action than salmeterol.

Two theories have been proposed to explain the increased duration of action of salmeterol and formoterol. Using site-directed mutagenesis of the β_2 receptor, Green and coworkers[34] proposed that the aliphatic side chain of salmeterol binds in a second locus of the receptor that is separate from the active site, termed the *exosite*. These investigators used β receptor antagonists to determine activity kinetics. An exosite would explain how activity is so quickly restored after washout with the β receptor antagonist. In the second theory, termed the *diffusion microkinetic theory*, which applies to salmeterol and formoterol, the high membrane partition affinity of the two drugs creates a microdepot of the drug near the receptor.[3] The exact nature of the sustained duration of action is likely to relate to aspects of the clinical pharmacology and tolerability of salmeterol and formoterol.

Mechanism of action

The β_2-adrenergic receptor is a member of the seven-transmembrane receptor superfamily of G protein–coupled receptors.[2] The ligand-binding pocket open to the extracellular space is formed when the seven α helices of the receptor cluster together in a ring. When a receptor is moved to its active state by binding of ligand, its associated G protein dissociates into a G_α subunit and a β/γ dimer. As illustrated in Figure 5-7, the $G_{\alpha s}$ subunit activates adenylyl cyclase, which increases the concentration of cAMP in the cell. cAMP activates protein kinase A. Protein kinase A phosphorylates protein substrates that control Ca^{++} availability in the cell. With decreased Ca^{++} availability, the myosin light chain is ineffective in sustaining active tone in airway smooth muscle. The tissue relaxes passively.

The mechanism previously described is the traditional cAMP/cAMP-dependent protein kinase A cascade. Studies

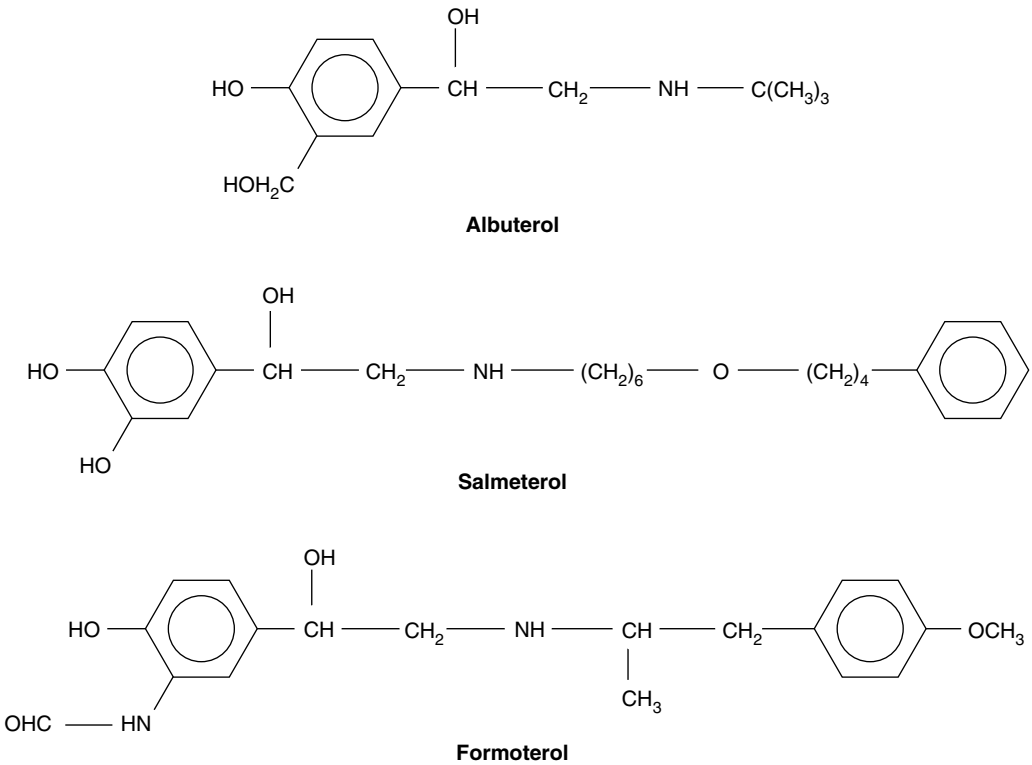

FIGURE **32-1** Structural formulas of several β_2-adrenergic receptor agonists.

since the 1990s suggest that there are other mechanisms involved with β-adrenergic signaling in the airways.[31] In addition to $G_{\alpha s}$, the β_2-adrenergic receptor can also couple to $G_{\alpha i}$ and inhibit adenylyl cyclase. β_2 Receptors are found on proinflammatory and immune cells, including mast cells, macrophages, neutrophils, lymphocytes, eosinophils, epithelial and endothelial cells, and types 1 and 2 alveolar cells. Inhibition of adenylyl cyclase may be involved in decreasing the reactivity of these proinflammatory cells.

Membrane hyperpolarization is another significant effect of β_2 agonists. Activation of K^+ channels by β_2-adrenergic receptor agonists in the plasma membrane decreases electrical excitation. This decrease in electrical excitation inhibits extracellular Ca^{++} from entering the cell and decreases the available Ca^{++} for smooth muscle contraction. The effect of β_2 agonists on K^+ channels is thought to occur by direct coupling of the big-conductance K^+ channel and the $G_{\alpha s}$ subunit of the receptor.

Pharmacologic effects

Bronchodilation is not the sole pharmacologic effect of β_2 receptor activation. Other effects include reduction of inflammatory cytokine production, suppression of plasma exudation secondary to receptor presence on postcapillary venules, regulation of fluid balance in alveolar epithelial cells, and reduction of cholinergic neurotransmission. In asthma and COPD, β_2-adrenergic agonists not only cause bronchodilation but also offer bronchoprotection, or reduced responsiveness, to noxious stimuli.

Adverse effects

The most serious adverse effect of β_2 agonist use is an increase in sensitivity of the smooth muscle in the lungs to noxious stimuli. Paradoxically, an increased incidence of asthma exacerbations and morbidity and mortality is seen after long-term use of β_2 agonists[44]; this is attributable to the loss of bronchoprotection and bronchodilation effects of the drugs. This effect is called *tolerance*, a state of refractoriness that occurs after prolonged exposure to an agonist. The mechanistic basis for tolerance involving β-adrenergic receptors is currently unclear. Factors that can contribute to tolerance include receptor downregulation, due to receptor internalization, and receptor desensitization (see Figure 1-12) which can be due in part to receptor uncoupling from adenylyl cyclase.[15] It is not the use of intermittent short-acting β_2 agonists, such as albuterol, that leads to tolerance, but rather the continued use of long-acting β_2 agonists.

The U.S. Food and Drug Administration (FDA) has required manufacturers of long-acting β_2 agonists to place a "black box" warning on the physician information for salmeterol and formoterol. Data for the advisory labeling came from the Salmeterol Multi-Center Asthma Research Trial (SMART),[18] which examined the safety of salmeterol when added to usual asthma therapy. Study subjects who were on salmeterol showed a small but significant increase in asthma-related death compared with subjects receiving placebo.

Upregulation of phosphodiesterase-4, the enzyme responsible for degradation of cAMP, is also thought to play a role in the loss of effect of β_2 agonists. This hypothesis led to the development of phosphodiesterase-4 inhibitors, roflumilast and cilomilast. Currently available in Europe, phosphodiesterase-4 inhibitors seem to improve FEV_1 in COPD patients.

With the exception of levalbuterol, all β_2 agonists are racemic mixtures of R-enantiomers and S-enantiomers.[39] Although the R-enantiomer of albuterol, levalbuterol, is 100 times more potent at the receptor, the S-enantiomer of albuterol is metabolized much more slowly and is retained in the lung. Preclinical data indicate that S-albuterol is associated with proinflammatory activity that can lead to bronchial hyperresponsiveness. These activities include an increase in intracellular Ca^{++}, an increase in inflammatory stimuli, an increase in eosinophil activation and recruitment, and an increase in mucin

production. These proinflammatory activities have led to speculation that the S-enantiomer of salmeterol is responsible for the loss of effect seen with long-term use of this drug. Formoterol has two chiral centers, and there is evidence to suggest that S-formoterol accumulates in bronchial tissue relative to the R-enantiomer because of different rates of metabolism. Many new long-acting β_2 agonists in clinical development are pure active enantiomers.

Clinical trial retrospective analyses of genetic polymorphisms of the β_2 receptor in individual patients seem to suggest that individuals who are homozygous for arginine at position 16 on the β_2 receptor (about 15% of the population) show greater rates of asthma exacerbations than patients who have glycine at this position, or patients who are heterozygous. It is unclear what role the arginine substitution at position 16 on the β_2 receptor plays in the mechanism of β_2 agonists. More data are needed to determine if genotype is another factor contributing to receptor desensitization.

Specific agents

Albuterol. Albuterol, the most commonly prescribed β_2-adrenergic bronchodilator, is available in tablet form, as a sustained-release tablet, and as a metered-dose pressurized aerosol. Pulmonary β_2 specificity is greater with aerosol delivery than it is with an oral dose.[40] Adverse reactions to albuterol are similar to adverse reactions of other β_2-adrenergic receptor agonists.

Levalbuterol. The R-enantiomer of albuterol, levalbuterol is available currently on the in form of a metered-dose inhaler and as an inhalation solution for nebulizers. As mentioned previously, the potential advantage of levalbuterol over the racemic form of the drug is that S-albuterol may have some bronchoconstrictive activity mediated through nonadrenergic mechanisms. The bronchoconstrictive action is not observed in humans acutely after single doses of albuterol compared with levalbuterol, but the much slower metabolism of the S-enantiomer causes it to predominate over time with repeated doses. This selective build-up may explain the paradoxical bronchoconstrictive responses that occasionally occur with albuterol (and with other racemic β_2 agonists). Additional studies will be required to access accurately the relative merits of levalbuterol versus albuterol in the clinical setting.

Salmeterol. Salmeterol is a long-acting, highly selective β_2-adrenergic agent structurally related to albuterol. Compared with albuterol, salmeterol has greater β_2 receptor selectivity, but decreased intrinsic efficacy. The receptor selectivity and the intrinsic efficacy differences of the drug minimize cardiac side effects. Salmeterol provides bronchodilation usually lasting at least 12 hours. Salmeterol is slow in onset (approximately 10 minutes), and maximal bronchodilation takes hours. It is not indicated for the symptomatic relief of acute asthma. Side effects, such as tachycardia, tremor, hypokalemia, and hyperglycemia, are minimal at standard doses.

Incorporating a long-acting β_2 agonist into the therapeutic regimen has several advantages. Clinical trials have shown salmeterol to be more efficacious than albuterol in (1) reducing variation in diurnal peak expiratory flow rates; (2) decreasing nocturnal symptoms, asthma exacerbations, and the need for rescue medications; and (3) increasing overall lung function.[20,49] The combination of salmeterol with an inhaled corticosteroid has been shown to be beneficial. Several studies have indicated that the administration of salmeterol with a lower dose of corticosteroid results in improved pulmonary function compared with a larger dose of corticosteroid administered alone.[29,61] In addition to the improved physiologic response, the administration of salmeterol decreases the potential of systemic effects of corticosteroids.

Metaproterenol. Metaproterenol is a derivative of the nonselective β-adrenergic blocker isoproterenol in which the hydroxyl group is moved from C_4 to C_5 of the benzene nucleus in the molecule. This structural change produces a predominantly β_2-stimulant action. It also protects metaproterenol from enzymatic degradation by COMT, prolonging the drug's duration of action.

An effective clinical response is obtained after inhalation or oral administration of metaproterenol. As with all the β_2-selective sympathomimetic drugs, however, selectivity of action is less apparent when the drug is given orally. Inhalation produces a peak effect in 30 to 60 minutes, and there is sustained improvement in pulmonary function tests for 5 hours. Tachycardia and tremor are two common side effects, but the incidence and severity of cardiac reactions are less than with isoproterenol.

Terbutaline. Terbutaline, a congener of metaproterenol, is of clinical interest because of its long duration of action (3 to 6 hours), its availability in an injectable form, and a side-effect profile equivalent to metaproterenol.[4] For patients with spontaneous asthma, terbutaline is reported to provide greater protection against bronchoconstriction than an equivalent dose of metaproterenol. Terbutaline from the aerosol metered-dose inhaler stimulates bronchial β_2 receptors more selectively than oral or parenteral forms of the drug. Tolerance to the aerosol does not seem to develop with continued use over several months. The most common side effect of therapeutic doses is a slight tremor, which may be particularly noticeable in elderly patients. Other side effects, typically seen with nonselective β blockers, are infrequent. Terbutaline is the only drug used as a bronchodilator that has good safety data supporting its use during pregnancy.

Interaction between corticosteroids and β_2-adrenergic receptor agonists

Corticosteroids and β_2 agonists have different mechanisms of action and in the treatment of patients with asthma and COPD. Coadministration of the two classes of drugs results in a synergistic effect as each drug enhances the activity of the other.[28,46] In addition, corticosteroids can protect against receptor desensitization.[54] The β_2 receptor gene contains several GRE sites in the promoter region, enabling corticosteroids to increase the rate of transcription of β_2 receptors. This effect can offset one of the mechanisms for tolerance—receptor downregulation seen in long-term use of β_2 agonists. The efficiency of coupling is increased between the β_2 receptor and $G_{\alpha s}$ after administration of corticosteroids with the resulting increase in the concentration of cAMP in the cell.

Long-acting β_2-adrenergic receptor agonists can promote the translocation of the corticosteroid receptor to the nucleus with no corticosteroid present.[34] When a corticosteroid is added, the translocation of the receptor is accelerated, and the rate of GRE-dependent expression of corticosteroid-inducible genes is enhanced. An increase in smooth muscle bulk is a pathologic feature of asthma that leads to bronchial hyperplasia and bronchial hyperactivity. Coadministration of β_2 agonists and corticosteroids induces p21, a kinase inhibitor that restrains smooth muscle hyperphsia.[53]

Other Adrenergic Receptor Agonists

Epinephrine

Epinephrine may be administered by oral inhalations from a nebulizer or metered-dose inhaler. The inhaler is generally favored because it is effective, less expensive, and more portable. The therapeutic effect is weak and transient compared with longer acting β_2 agonists immune to metabolism by COMT. Signs of overdose include nervousness, restlessness, sleeplessness, bronchial irritation, and tachycardia. Inhalation

of recommended dosages may minimize reactions other than bronchodilation. Patients frequently have palpitation and tremors, however, which increase with increased use. The occurrence of these signs and symptoms usually limits the use of this drug because patients tend not to tolerate these effects.

Parenteral epinephrine is reserved for acute episodes of asthma requiring immediate relief when inhaled β_2-selective agonists have proved ineffective or could not be effectively administered. In such cases, 0.2 to 0.5 mg may be injected subcutaneously or intramuscularly to produce bronchodilation. Because epinephrine produces α-adrenergic and β-adrenergic receptor stimulation, it can also improve respiration by relieving congestion of the bronchial mucosa.

Ephedrine

Ephedrine stimulates α-adrenergic and β-adrenergic receptors by a direct action and through the release of endogenous catecholamines. Its pharmacologic effects are similar to the effects of epinephrine. Ephedrine was previously widely used in treating mild-moderate asthma because of its oral efficacy and longer duration of action. It is not as effective as epinephrine in severe attack because its bronchodilator action is weaker. Ephedrine may be administered at bedtime to prevent nocturnal wheezing. The tendency of ephedrine to produce tolerance when taken for long periods has limited its use in chronic asthma.

Ephedrine is marketed as a single-entity drug and as a component in fixed-dose combination products. It was often combined with theophylline, sedatives, or expectorants. Until the FDA banned its sale, ephedrine was widely used in the form of ephedra and related herb products.

The adverse reactions are similar to those of epinephrine. In addition, there may be CNS stimulation, the most common signs of which are nervousness, excitability, and insomnia. There is little reason to recommend ephedrine over the more recently developed β_2-selective bronchodilators.

Isoproterenol

Isoproterenol is the prototypic nonselective β-adrenergic receptor agonist. It acts on β_1 receptors to increase the rate and force of cardiac contractions and on β_2 receptors located in the smooth muscle of the bronchi, blood vessels, and other locations. Oral inhalation is still used to treat asthmatic attacks, but has been largely superseded by the more selective β_2 agonists. Isoproterenol has a rapid onset but a short duration of action. Excessive administration of the drug can produce adverse effects, such as nervousness, headaches, and severe arrhythmias (including ventricular fibrillation), and tolerance and refractoriness.

Theophylline

Mechanism of action

Theophylline is a naturally occurring plant alkaloid (a methylxanthine) related to caffeine and theobromine.[10] Theophylline causes an increase in the concentration of cAMP in the cell through inhibition of phosphodiesterase-3 and phosphodiesterase-4. As with the β_2 agonists, an increase in cAMP concentration leads ultimately to a decrease in available Ca^{++} in the cell and smooth muscle relaxation. In addition to bronchodilation, theophylline has anti-inflammatory effects, which are exerted through action on HDACs. The exact mechanism of action of theophylline on HDACs is not completely understood. This action differs from that of the corticosteroids in that the steroids recruit HDACs to the active transcription site with no direct effect on HDAC activation. There is evidence to suggest that the action of theophylline on HDACs is more direct.[38] In immunoprecipitation studies, theophylline, HDACs, and several other nuclear proteins are coprecipitated with antibodies to HDAC.[2] This mechanism suggests that theophylline and corticosteroids may have synergistic effects on inflammatory processes. In vitro, theophylline and dexamethasone increase the repression of inflammatory cytokine release in macrophages and epithelial cells to a greater extent than either drug alone.

TABLE **32-1**

Anti-inflammatory Effects of Theophylline

TARGET	EFFECT
In Vitro	
Mast cells	Decreased mediator release
Macrophages	Decreased release of reactive oxygen species
Monocytes	Decreased cytokine release
Eosinophils	Decreased basic protein release, decreased release of reactive oxygen species
T lymphocytes	Decreased proliferation, decreased cytokine release
Neutrophils	Decreased release of reactive oxygen species
In Vivo	
Experimental animals	Decreased late response to allergen, decreased plasma exudation (guinea pigs), decreased airway responsiveness to allergen and platelet-activating factor (guinea pigs, sheep), decreased airway inflammation after endotoxin and allergen (guinea pigs, rats)
Asthmatic patients	Inhibition of late response to allergen, increased $CD8^+$ cells in peripheral blood, decreased T lymphocytes in airways

From Barnes PJ, Pauwels RA: Theophylline in the management of asthma: time for reappraisal?, *Eur Respir J* 7:583, 1994.

Pharmacologic effects

Theophylline has been used since the early 1920s for its bronchodilatory effects. Anti-inflammatory effects of theophylline include inhibition of the late response to allergen, reduced infiltration of eosinophils and $CD4^+$ lymphocytes into the airways, and a decrease in the concentration of interleukin-8 and neutrophil chemotactic responses.[9] In vitro, theophylline inhibits mediator release from mast cells, inhibits ROS release from macrophages and eosinophils, and inhibits cytokine release from monocytes and T lymphocytes (Table 32-1).

Adverse effects

Theophylline has a narrow therapeutic window with therapeutic plasma concentrations of 10 to 20 mg/L.[51] At concentrations >20 mg/L, serious effects, such as ventricular arrhythmias, seizures, and death, can occur. These serious adverse effects may be preceded by headache, abdominal discomfort, increased acid secretion, gastroesophageal reflux, diuresis, repetitive vomiting, and restlessness. Proper dosing of theophylline depends on many patient factors, including smoking history, cardiac disease, and hepatic disease. Serum concentration monitoring is often necessary because of the narrow therapeutic window.

Theophylline is not effective when administered by inhalation. Theophylline is administered orally. Theophylline is metabolized by the cytochrome P450 isoenzyme CYP1A2. Many drug interactions with theophylline involve the inhibition or induction of the enzyme that metabolizes theophylline (Box 32-1). Inhibition of CYP1A2 would increase theophylline plasma concentrations, possibly causing toxicity. Induction would decrease theophylline plasma concentrations, rendering them subtherapeutic. The clinical use of theophyl-

line has declined because of the potential for toxicity, difficulty in dosing, and numerous drug interactions.

Anticholinergics

Muscarinic acetylcholine receptors are physiologically important, but medications directed to these receptors are not commonly used because of the difficulty in targeting a specific organ or tissue. The advantage of targeting the respiratory system is in the route of administration, inhalation. The mechanism of action of anticholinergic drugs in respiratory disease is competitive antagonism of acetylcholine at M_3 muscarinic receptors in the smooth muscle cells of the lungs.[35] The result is bronchodilation.

There are currently two anticholinergic bronchodilators on the market, ipratropium and tiotropium.[25] These agents are synthetic quaternary ammonium congeners of atropine, and they are poorly absorbed into the bloodstream when given by inhalation. The differences in the two drugs are in their pharmacokinetics. The dissociation half-life of ipratropium from human M_3 muscarinic receptors is approximately 20 minutes. The dissociation half-life of tiotropium at M_3 muscarinic receptors is approximately 35 hours. Ipratropium is marketed in a combination inhaler with albuterol, which is indicated for use in patients with COPD. It is used four times a day. Tiotropium is also used in patients with COPD, but because of its long half-life it can be administered once a day. Adverse effects for both drugs include mild dry mouth, altered taste, and coughing after administration.

Leukotriene Modifiers

Cysteinyl leukotrienes (cysLTs) are a class of lipid molecules that produce smooth muscle contraction and mucus secretion, induce allergic inflammatory cells, modulate cytokine production, influence neural transmission, and alter structure in the airway.[48] Administration of cysLTs to experimental animals and humans produces symptoms that resemble allergic reactions and asthma.

The cysLTs are produced in mast cells, eosinophils, and macrophages from arachidonic acid. Arachidonic acid is cleaved from membrane phospholipids and metabolized through the 5-lipoxygenase pathway. Arachidonic acid is oxidized to LTA_4, which on conjugation to glutathione is converted to LTC_4. LTC_4 is transported to the extracellular space and cleaved to LTD_4 and LTE_4. LTC_4, LTD_4, and LTE_4 all contain a cysteine residue and are collectively called cysLTs. Previously known as the slow-reacting substance of anaphylaxis, they stimulate airway smooth muscle by interacting with cysLT receptor type 1. It has been shown that they play a role in the inflammatory responses seen in asthma. LTA_4 can also be converted to LTB_4 by epoxide hydrolase in neutrophils and other inflammatory cells. LTB_4 is a neutrophil and eosinophil chemoattractant.

Bronchoalveolar lavage fluid shows an increase in cysLTs in asthmatic subjects after administration of allergen. The increases in cysLTs are not reduced by treatment with inhaled corticosteroids. Increases in cysLTs in the bronchi are not limited to noxious stimuli. Drying of the airway and exercise can also stimulate cysLT production. The cysLTs also interact with inflammatory pathways. Release of cysLTs from mast cells is seen in response to IgE ligation. Hyperosmolarity in exercise-induced asthma and cyclooxygenase-1 (COX-1) inhibition in nonsteroidal anti-inflammatory drug (NSAID)–intolerant asthma also cause release of cysLTs. cysLTs also promote the generation of chemokines and cytokines from airway smooth muscle, increase the expression of histamine receptors, amplify the effects of tachykinins in the airway, and have a role in the structural changes in the airway seen in asthma. Two classes of drugs are used to decrease the effects of the leukotriene pathway in asthma: leukotriene formation inhibitors and leukotriene receptor antagonists.[22]

Zileuton, an N-hydroxyurea derivative, chelates the iron in the active site of 5-lipoxygenase, blocking the redox potential of the enzyme.[19] Zileuton is able not only to block the formation of the cysLTs, but also that of LTB_4. Zileuton is not used as extensively as leukotriene receptor antagonists probably because of its short half-life and potential liver toxicity. Zileuton is orally bioavailable, with a half-life of 2 hours, and must be administered three to four times a day. This frequent administration can cause problems with patient compliance, and only an extended release form of the drug is still in use. Zileuton is contraindicated in liver disease, and liver enzymes must be monitored during therapy.

Montelukast and zafirlukast are selective antagonists for the cell surface cysLT 1 receptor.[22] They reduce airway hyperresponsiveness, eosinophils, and exhaled nitric oxide. They are orally active and are administered once daily and are generally well tolerated. Elevated concentrations of cysLTs are found in chronic asthma with concomitant allergic rhinitis, exercise-induced asthma, and aspirin-sensitive asthma. It has been suggested that leukotriene antagonists may have a specific role in these conditions.

Cromolyn

Cromolyn is a nonbronchodilating, nonsteroidal drug used for prophylactic treatment of asthma. It is a synthetic deriv-

ative of khellin, the agent in extracts of the *Ammi visnoga* plant that produces smooth muscle relaxation. It is administered by inhalation. Although the mechanism of action is not fully understood, it is known that cromolyn inhibits the release of mediators from mast cells and other inflammatory cells, probably by inhibiting the inflow of Ca^{++} into the mast cells.[16,58] The drug inhibits early and late asthmatic responses and is effective in the long-term treatment of chronic asthma. Other biologic effects, including inhibition of afferent pulmonary nerve fiber receptors that contribute to reflex bronchoconstriction, may also be relevant to its therapeutic action.

Clinically, cromolyn is ineffective in the treatment of acute attacks of asthma, including status asthmaticus. It functions exclusively as a prophylactic agent in the management of chronic symptoms. Maximum benefit is obtained only after 4 weeks of treatment. Cromolyn has also been shown to be useful as a premedication before a challenge-like exercise, where the drug, similarly to steroids and leukotriene inhibitors, reduces airway hyperactivity. Long-term and short-term studies have documented clinical improvement in patients taking cromolyn, with a low incidence of adverse effects. Cromolyn is one of the least toxic medications used for asthma. Most adverse reactions have been mild and have consisted mainly of wheezing, coughing, and dryness of the throat. There have been rare reports, however, of eosinophilia with pulmonary infiltration, pulmonary granulomatosis, and the development of subacute and acute allergic reactions. In general, cromolyn therapy is stopped in any patient who shows a reaction other than a transitory irritative response.

During cromolyn treatment, patients are maintained on regular medication, such as oral bronchodilators. In cromolyn-treated patients receiving corticosteroids, there have been reports of a decreased corticosteroid requirement, which permits many patients to convert from a daily steroid schedule to an alternate-day program or to discontinue steroids completely. A decreased requirement for sympathomimetic and xanthine bronchodilators has also been noted. This medication-sparing effect is one of the major advantages of cromolyn therapy. Cromolyn is generally available in a metered dose aerosol unit and in a nebulizer solution. The availability of liquid cromolyn has been beneficial to many asthmatics, especially young children.

Nedocromil

Nedocromil is a novel and potent anti-inflammatory drug with many properties and effects similar to cromolyn.[17] It inhibits the immediate bronchoconstrictor response to allergen challenge, probably as a result of preventing the release of mast cell mediators. It also inhibits the late-phase asthmatic response. Nedocromil, similar to cromolyn, is essentially free from systemic toxicity. Both drugs are highly ionized (>99%) at physiologic pH, and their inability to penetrate cells, coupled with the lack of an extracellular route of metabolism, results in their being excreted unchanged in the urine (approximately 80%) and feces (approximately 20%). Clinical experience has shown that nedocromil is well tolerated by most patients, but a bitter taste and, less frequently, headache and nausea have been reported.

Ketotifen

Ketotifen, an oral agent with cromolyn-like activity, has been tested in the management of mild-moderate bronchial asthma and allergic disorders.[33] It has strong antihistaminic (H_1) actions and powerful antianaphylactic properties. Inhibition of the release or activity of proinflammatory mediators may contribute to the prophylactic effect of ketotifen. Some evidence suggests that ketotifen also interferes with Ca^{++} flux. It does not seem to affect smooth muscle contraction.

In asthmatic patients, the clinical benefit of ketotifen is usually detectable only after 6 to 12 weeks of treatment. The delayed onset has not been satisfactorily explained. Comparative clinical trials have shown that the oral administration of ketotifen and the inhalation of cromolyn have a similar prophylactic efficacy. As with cromolyn, an important benefit of ketotifen treatment is that dosages of bronchodilators and corticosteroids can be reduced during therapy.

The major side effect of ketotifen is sedation, which is experienced by 10% to 15% of patients during the first week of treatment. Drowsiness diminishes with time. The drug is well tolerated, and the oral route of administration promotes patient compliance. Currently, ketotifen is approved for topical use in the treatment of allergic conjunctivitis.

Methotrexate

Methotrexate is a well-known immunosuppressive chemotherapeutic drug used for the treatment of various diseases. Methotrexate inhibits the enzyme dihydrofolate reductase, preventing folate-dependent nucleic acid synthesis. The drug is used as an adjuvant for the treatment of severe glucocorticoid-dependent asthma. The low doses used do not significantly inhibit nucleic acid synthesis, but they have an anti-inflammatory action. There is often a decrease in white blood cell count, and the patient should be monitored to detect this change. The rationale for methotrexate in the treatment of asthma came from the observation that corticosteroid doses can be reduced when combination therapy with methotrexate is prescribed. Some studies have found a reduction of steroid dosages by 25%, but others have been unable to show this effect.[43] Because methotrexate produces no direct effect on pulmonary function, it is added to the treatment of asthma patients only for its steroid-sparing effect in patient unresponsive to steroids or taking high doses with severe side effects. The objective is to reach the lowest possible oral steroid dose. Low doses of methotrexate are not free of side effects. Liver toxicity, pneumonitis, and *Pneumocystis carinii* pneumonia have been observed.[60] There is also a small possibility for delayed malignancy.

Omalizumab

IgE is produced by B cells after sensitization to an allergen. IgE plays a central role in the pathophysiology of allergic responses in patients with asthma.[21] Epidemiologic studies suggest that 60% to 80% of patients with asthma have rhinitis, and 20% to 40% of patients with rhinitis have asthma. Although the plasma concentration of IgE is low, it is highly active because of the large number of high-affinity receptors on mast cells and basophils. The binding of allergen to IgE on these cells initiates the inflammatory cascade that results in the release of many mediators, including histamine, leukotrienes, and platelet-activating factor. The release of these mediators results in airway obstruction by smooth muscle contraction, vascular leakage, and secretion of mucus.

Omalizumab is a humanized murine monoclonal anti-IgE antibody directed against an epitope on the fragment of IgE that binds to the high-affinity and low-affinity receptor regions.[47] This activity prevents free IgE from interacting with receptors on cellular targets. The antibody binds only to free IgE, not receptor-bound IgE. The antibody does not cause receptor cross-linking and cell degranulation, which leads to anaphylaxis. The antibody causes a 99% reduction of free IgE. Omalizumab also downregulates receptor expression on basophils. The reduction in free IgE and IgE receptors results in inhibition of IgE-mediated inflammation.

The most frequent adverse reactions to omalizumab include nasopharyngitis, upper respiratory tract infection,

headache, and sinusitis. About 0.1% of patients experience urticaria, bronchospasm, hypotension, syncope, angioedema of the throat or tongue, and other symptoms of anaphylaxis. The onset of anaphylaxis can occur 2 to 24 hours after the administration of omalizumab. In 2007 the FDA required the manufacturer of omalizumab to place a boxed warning on the packaging to alert physicians of the possibility of anaphylactic reaction in patients after administration of omalizumab.

PHARMACOTHERAPY FOR ASTHMA

GINA defines controlled asthma as two or fewer daytime symptoms in 1 week, no limitations of activities, no nocturnal symptoms, the need for reliever treatment two or fewer times in 1 week, normal lung function as measured by FEV_1, and no exacerbations (Table 32-2). Although this definition of controlled asthma seems idealized, studies have shown that it is achievable. The Gaining Optimal Asthma control (GOAL) study enrolled 3421 patients in a 1-year prospective trial that compared the efficacy of two therapies.[11] The therapies compared were an increasing dose of fluticasone alone or combined with salmeterol to achieve asthma control as defined in the GINA guidelines. Most of the patients (80%) were able to achieve asthma control as defined by the guidelines with the combination therapy.

Asthma treatment is progressive in steps and is based on the severity of the disease.[7] Step 1 is the use, as-needed, of a rapidly acting β_2 agonist. If the patient has exacerbations, step 2 involves the addition of either a low-dose inhaled corticosteroid or a leukotriene modifier drug. If the asthma is not controlled at step 2, one more therapy is indicated based on the therapy choice in step 2. The choice in step 3 includes a long-acting inhaled β_2 agonist or a medium-dose or high-dose inhaled corticosteroid, or if a low-dose inhaled corticosteroid was used in step 2, a leukotriene modifier or sustained-release theophylline is recommended. Step 4 involves the addition of a drug or drugs not already in use, such as the addition of a leukotriene modifier or sustained-release theophylline or an increase in the dose of the inhaled corticosteroid. Step 5 is the addition of either the lowest dose of an oral corticosteroid or anti-IgE treatment (Table 32-3).

Regardless of the severity of asthma, other therapeutic measures may also be used. The prompt administration of antibiotics is indicated for respiratory infections of nonviral origin. Sedatives many be used to minimize emotional stress; expectorants may aid in the removal of secretions. Finally, avoidance of tobacco and environmental irritants or allergens may help prevent episodes of asthma. Table 32-4 lists properties of common drugs used in asthma.

ASPIRIN-INDUCED ASTHMA

The incidence of aspirin-induced asthma among adult patients with asthma is estimated oral provocation testing to be 21%.[57] Aspirin hypersensitivity is underreported probably because of either lack of routine aspirin challenge or lack of recognition by patients of a mild NSAID-induced reaction. Aspirin-induced asthma is more frequent in women than in men. It

Selective β_2-adrenergic agonists	Short-acting: Albuterol (Proventil HFA) Long-acting: Salmeterol (Serevent Diskus)	Stimulation of β_2 receptors in the lung	Bronchodilation	Tachycardia, tremor, potential for overuse Airway hyperresponsiveness
Antimuscarinic agents	Ipratropium (Atrovent)	Blockade of M_3 receptors	Bronchodilation, decreased secretions	Tachycardia, xerostomia
Methylxanthines	Theophylline (Theo-24)	Phosphodiesterase inhibition, adenosine receptor blockade	Bronchodilation, anti-inflammatory effects	Nausea and vomiting, arrhythmias, tachycardia
Inhaled glucocorticoids	Fluticasone (Flovent HFA)	Modulation of gene expression	Reduced airway inflammation, prophylactic control	Oropharyngeal candidiasis
Leukotriene synthesis inhibitors	Zileuton (Zyflo CR)	Inhibition of 5-lipoxygenase	Decreased inflammation	Hepatotoxicity
Leukotriene antagonists	Montelukast (Singulair)	Blockade of cys-LT1 receptor	Decreased inflammation	Slight increase in gastrointestinal symptoms
Khellin derivative	Cromolyn (Intal)	Unknown	Inhibition of mast cell degranulation	Sneezing, burning

usually begins in adulthood, at an average age of 30 years. Rhinorrhea and nasal congestion are the first symptoms, with complications of nasal polyposis developing in response to chronic inflammation. Approximately 80% of patients with aspirin-induced asthma have sinusitis. This syndrome is characterized by asthma, nasal polyps, aspirin reactions, and chronic hyperplastic eosinophilic sinusitis.

The prostaglandin PGE_2 plays a role in aspirin-induced asthma.[56] PGE_2 is proinflammatory in many diseases, but in the lung it protects against bronchoconstriction during aspirin challenge. This prostaglandin exerts its activity through the binding of the prostanoid receptor EP_3. This receptor is expressed on bronchial epithelia and mast cells. Through the EP_3 receptor, PGE_2 inhibits synthesis of cysLTs, inhibits release of mediators from mast cells, and diminishes inflammatory cell influx. PGE_2 is synthesized by COX-1 and COX-2 in the lung. In the lungs of individuals with aspirin-induced asthma, the expression of COX-2 is diminished. When COX-1 is inhibited by aspirin or NSAIDs, the concentration of the protective prostaglandin PGE_2 is decreased. COX-2 biosynthesis of PGE_2 is insufficient to compensate.

Another biochemical difference between patients with asthma who are aspirin-tolerant and those who are not is the expression of 5-lipoxygenase. In aspirin-intolerant patients, 5-lipoxygenase is upregulated, and the synthesis of cysLTs is increased. Aspirin-intolerant patients also express more cysLT receptors on nasal inflammatory cells. Although treatment of asthma in aspirin-intolerant patients is essentially the same as treatment in aspirin-tolerant patients, leukotriene modifiers, either inhibitors or antagonists, have been reported to be effective in long-term therapy in individuals with aspirin hypersensitivity.

PHARMACOTHERAPY FOR CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Recognizing that there is no cure for COPD, the goals of therapy are to prevent disease progression, relieve symptoms, improve health status, prevent exacerbations, reduce morbidity, and minimize adverse effects from treatment.[26] Anticholinergics and β_2-adrenergic receptor agonists cause bronchodilation through different mechanisms. There is a long history of therapy with a combination of these two drug classes. Combination therapy also allows for smaller doses to be administered and minimizes adverse effects from treatment. The American Thoracic Society, the European Respiratory Society, and GOLD recommend that as COPD symptoms progress, the patient should receive treatment with one or more long-acting bronchodilators. If the patient has repeated exacerbations, an inhaled corticosteroid should be added as regular therapy.[59] Drug therapy is combined with smoking cessation and pulmonary rehabilitation exercises. As the disease progresses, the patient requires supplemental oxygen therapy.

IMPLICATIONS FOR DENTISTRY

To provide the most effective and safest dental care for a patient with respiratory disease, the dentist must be aware of the patient's history, medication usage, and how the medical problem is being managed. Factors that are important in the patient interview include past history of sudden severe exacerbations, previous intubation, previous admission to an intensive care unit, two or more hospitalizations or three or more emergency department visits in the past year, comorbidity from cardiovascular disease, frequency of use of a rapidly acting β_2-adrenergic receptor agonist inhaler, and current use of steroids or recent withdrawal from corticosteroids.[37] The use of two or more canisters per month of a rapid-acting β_2 agonist inhaler is an indication that the respiratory disease is not well controlled.

The dentist must also be aware that patient factors, such as dementia, psychiatric disease, or psychosocial problems, can have an impact on the perception of airflow obstruction. Low socioeconomic status, urban residence, and illicit drug use also put the patient at risk for exacerbation of asthma or COPD. Inhaled steroids can contribute to slower healing in

the oral cavity and make the patient more susceptible to oral fungal infections. The patient should be asked to bring all medications for the respiratory condition to the dental appointment.

Another consideration is how the patient reacts to dental appointments. Many individuals become apprehensive and anxious about impending visits to the dental office. Emotional factors play an active role in precipitating or exacerbating respiratory symptoms. Dental materials that contain powder or the powder in latex gloves can increase the patient's airway obstruction if the particles are inhaled. Some patients may be unable to tolerate a horizontal position in the dental chair for a long time.

Analgesic therapy for a patient with asthma must be chosen with care. Aspirin should be avoided if there is a question of patient intolerance or nasal polyps because asthmatic episodes can be precipitated in some patients in minutes to hours after ingestion of these drugs. Patients with asthma who are unable to tolerate aspirin may also react adversely to other NSAIDs. The analgesic of choice for patients with asthma and aspirin allergy is acetaminophen. Large doses of morphine can produce bronchial obstruction by causing histamine release from mast cells. Opioids also decrease the respiratory drive, which is a dangerous liability to a patient whose airway resistance may be greater than normal.

The hypoxic state seen in patients with COPD can cause oral complications such as difficulty in healing after surgery and difficulty in fighting infection. Difficulty in breathing often forces patients to breathe through the mouth, which can cause xerostomia and the oral problems associated with a dry mouth. Also, many medications commonly used in COPD can inhibit salivation, such as β-agonist inhalers. Patients with advanced emphysema might use portable oxygen with a nasal cannula.

Long-term exposure to cigarettes places a patient with COPD at a greater risk for oral cancer. The dentist can encourage the patient to stop smoking. In 2003, the American Dental Association provided guidelines to assist the dentist in approaching patients who want to stop smoking.

It is important for the dentist and dental practice employees to be prepared for emergency exacerbations that may occur during a dental appointment. The National Asthma Education and Prevention Program of the National Heart, Lung and Blood Institute has written guidelines for such situations.[13] The dentist should encourage patients with respiratory disease to bring their inhalers to all dental appointments. Initial recommended treatment for acute exacerbations is the administration of a short-acting β_2 agonist (2 to 4 puffs) by a metered dose inhaler at 20-minute intervals. After initial treatment, the response should be assessed as good, incomplete, or poor. If the response is incomplete or poor, patients might require further treatment in the emergency department. Additional therapy may include an oral corticosteroid and inhaled anticholinergic inhaled short-acting β_2 agonist. For severe episodes, administration of subcutaneous epinephrine, 0.2 to 0.5 mg, may be required.

DRUGS FOR MILD RESPIRATORY ILLNESSES

Numerous drugs are used to provide symptomatic relief of some uncomfortable symptoms of respiratory infection or mild allergies with respiratory symptoms. These include bronchodilators, antitussives, nasal decongestants, intranasal steroids, expectorants, and mucolytic agents.

Antitussives

Coughing is a protective reflex that clears the respiratory tract of accumulated secretions or noxious substances. A productive cough, with the elimination of excessive secretions, is beneficial, but nonproductive cough may impair rest and increase discomfort. An ideal antitussive agent should decrease the frequency and intensity of coughing but still allow adequate elimination of excessive secretions from the respiratory tract.

Opioid analgesics

In addition to their analgesic effect, most opioids suppress cough. Because of their side effects and addiction liability, more potent drugs, such as morphine and hydromorphone, are not commonly used as antitussives.

Codeine is the most useful opioid for cough suppression, by acting centrally on the medullary cough center. At therapeutic doses and for short-term use, its addiction potential is minimal, and depressed ventilation is infrequent. Overdosage can result in respiratory depression, convulsions, hypotension, and tachycardia.

Hydrocodone, similar to codeine, acts centrally on the medullary cough center. Hydrocodone apparently is three times more potent in antitussive activity than codeine. It also has a greater abuse potential. At therapeutic doses, the most common side effects include nausea, constipation, and dizziness. Long-term use should be accompanied by a plan for supporting bowel function. Lactulose may be prescribed to minimize constipation.

Other drugs for cough

Other drugs that act centrally on the medullary cough center include benzonatate, dextromethorphan, and noscapine. These agents generally produce fewer adverse reactions than the traditional opioid drugs.

Benzonatate is an antitussive structurally related to tetracaine. Although the primary action of benzonatate is apparently depression of the central cough mechanism, it may also act by inhibiting the stretch receptors of the respiratory mucosa. The most common adverse reactions include nausea, constipation, headache, drowsiness, and vertigo. Nasal congestion and numbness of the tongue, mouth, and pharynx have been noted if the capsules are chewed before swallowing.

Dextromethorphan, the methyl ester of the dextroisomer of the opioid levorphanol, seems to be the most popular cough suppressant. In one clinical study, the antitussive effects of 60 mg of dextromethorphan did not differ significantly from the antitussive effects of 30 mg of codeine phosphate.[5] In over-the-counter mixtures, dextromethorphan is often used in combination with other agents, such as bronchodilators, antihistamines, and expectorants. It has no addiction liability or analgesic properties. Side effects are minimal at recommended doses.

Noscapine is one of the isoquinoline series of opium alkaloids. It has no analgesic activity or abuse potential but is an effective antitussive with few adverse reactions. At high doses, nausea, headache, and drowsiness have been reported. Noscapine is occasionally included in multientity over-the-counter preparations.

Nasal Decongestants

The most commonly used nasal decongestants are adrenergic agents. These drugs act by stimulating excitatory α-adrenergic receptors of vascular smooth muscles, constricting the dilated arterioles within the nasal mucosa. This constriction reduces blood flow in the edematous area and opens obstructed nasal passages.

Most of these drugs are used topically. Topical application may cause temporary stinging, burning, or drying of the mucosa. Rebound congestion occurs after the use of many of these agents, often causing misuse of the drugs. Prolonged topical use may be irritating enough to induce a chronic swell-

ing of the nasal mucosa; discontinuing the drug remedies this situation.

Phenylephrine, a selective α_1-adrenergic receptor agonist, is a widely used decongestant. It is less potent than the catecholamines but its duration of action is longer. Pseudoephedrine is a closely related drug.

Ephedrine and epinephrine are effective decongestants, but they are seldom used in this capacity. Ephedrine can produce swelling of the nasal mucosa, tachyphylaxis, CNS stimulation, palpitation, and transient hypertension. Epinephrine frequently produces rebound nasal congestion and the typical symptoms of CNS and cardiovascular stimulation, such as anxiety, palpitation, restlessness, dizziness, and headache. The adverse reactions produced by either drug disappear rapidly after the medication is discontinued.

Propylhexedrine is administered by nasal inhalation. Although local burning and stinging may occasionally occur, it has few adverse effects when used clinically. It can even be used for patients in whom the pressor effect of ephedrine is to be avoided.

Oxymetazoline is an effective decongestant with a long duration of action. It is a selective α_2-adrenergic receptor agonist. (Nasal vessels contain numerous α_2-adrenergic receptors.) It is available as a solution and as a spray. The adverse reactions associated with its use are mild and include stinging or drying of the nasal mucosa, headache, palpitation, and insomnia. Rebound nasal congestion may occur with use. Similar drugs include naphazoline, tetrahydrozoline, and xylometazoline.

Intranasal Steroids

Adrenal corticosteroids administered by nasal spray are effective for the relief of seasonal and perennial rhinitis. In this use, these drugs share many of the characteristics of steroids given by inhalation for the management of asthma. Drugs that are used for both purposes include beclomethasone, flunisolide, triamcinolone, budesonide, and fluticasone. Therapeutic benefits normally begin after several days of continuous use (one to three times per day, depending on the drug) but may be delayed for 3 weeks.

When intranasal steroids are used appropriately, systemic effects are minimal. Local candidiasis of the mouth and pharynx has occasionally been reported. Rinsing the mouth after use helps prevent such occurrences.

Expectorants and Mucolytics

Agents administered to stimulate the flow of respiratory tract secretions are termed *expectorants*. Mucolytic agents are used to reduce the viscosity of respiratory tract secretions. Both drug groups enhance the movement of secretions upward and outward by ciliary movement and coughing.

Expectorants are believed to act by stimulating receptors in the gastric mucosa, initiating reflex secretion of respiratory tract fluid. This action is assumed to increase the volume and decrease the viscosity of the secretions. There is little clinical evidence supporting the efficacy of these agents.

Potassium iodide is an example of a drug used traditionally as an expectorant and for which there is little proof of effectiveness. It is readily absorbed and produces untoward reactions on prolonged use. Iodism, characterized by skin rash, fever, parotitis, and lacrimal gland enlargement, can be produced. Thyroid enlargement or decreased thyroid function can also occur. Sensitivity reactions can develop, and anaphylaxis has occasionally been reported.

Ammonium chloride is another example of a drug used traditionally to stimulate the flow of respiratory secretions. It is used most frequently in multientity mixtures. It is readily absorbed and can produce metabolic acidosis if large doses are administered.

Guaifenesin (glyceryl guaiacolate) is available as an ingredient in various tablets and syrups. In clinical evaluations when compared with a matching vehicle, guaifenesin reportedly increased sputum volume; facilitated removal of sputum; and reduced cough frequency, cough intensity, and chest discomfort.[52] Nausea and gastrointestinal upset may occasionally occur, but no serious adverse effects are associated with guaifenesin.

DRUGS ACTING ON THE RESPIRATORY SYSTEM

Nonproprietary (generic) name	*Proprietary (trade) name*
Emergency drugs	
Aromatic ammonia spirit	Aromatic Ammonia Aspirols
Doxapram	Dopram
Oxygen	—
Corticosteroids (inhalation or intranasal or both)	
Beclomethasone	Beclovent, Beconase AQ, QVAR
Budesonide	Pulmicort, Rhinocort
Dexamethasone	Decadron
Flunisolide	AeroBid, Nasalide
Fluticasone	Flonase, Flovent, in Advair
Mometasone	Nasonex
Triamcinolone	Nasacort AQ
Adrenergic bronchodilators	
Albuterol	Proventil HFA, Ventolin HFA
Bitolterol*	Tornalate
Ephedrine	—
Epinephrine	Nephron, Primatene Mist
Ethylnorepinephrine	Bronkephrine
Formoterol	Foradil
Isoetharine	—
Isoproterenol	Isuprel
Levalbuterol	Xopenex
Metaproterenol	Alupent
Pirbuterol	Maxair
Procaterol*	Pro-Air
Salmeterol	Serevent, in Advair
Terbutaline	Brethine
Xanthines	
Aminophylline (theophylline ethylenediamine)	Phyllocontin, Truphylline
Oxtriphylline	Brondecon, Choledyl
Theophylline	Elixophyllin, Slo-Phyllin
Theophylline, extended-release	Slo-Phyllin Gyrocaps, Theo-Dur
Agents limited to prophylaxis or long-term treatment of asthma	
Cromolyn	Intal, Nasalcrom
Ketotifen*	Zaditen

DRUGS ACTING ON THE RESPIRATORY SYSTEM—cont'd

Nonproprietary (generic) name	*Proprietary (trade) name*
Montelukast	Singulair
Nedocromil	Tilade
Zafirlukast	Accolate
Zileuton	Zyflo CR
Anticholinergic bronchodilators	
Atropine	Day-Dose Atropine Sulfate
Ipratropium	Atrovent
Antitussives	
Benzonatate	Tessalon Perles
Caramiphen	In Rescaps-D S.R.
Codeine	—
Dextromethorphan	Pertussin, Vicks Formula 44
Diphenhydramine	Bydramine, Diphen Cough
Hydrocodone	In Hycodan
Hydromorphone	In Dilaudid Cough Syrup
Noscapine	—
Nasal decongestants	
Ephedrine	Pretz-D, Vicks Vatronol
Epinephrine	Adrenalin Chloride
Naphazoline	Privine
Oxymetazoline	Afrin, Dristan Long Acting
Phenylephrine	Alconefrin, Neo-Synephrine
Phenylpropanolamine*	Propagest
Propylhexedrine	Benzedrex
Pseudoephedrine	Novafed, Sudafed
Tetrahydrozoline	Tyzine
Xylometazoline	Otrivin
Expectorants and mucolytics	
Acetylcysteine	Mucomyst, Mucosil
Ammonium chloride	In Efricon Expectorant Liquid
Guaifenesin	In Halotussin, in Robitussin
Iodinated glycerol	Iophen NR, Organidin NR
Potassium iodide	Pima
Syrup of ipecac	—
Terpin hydrate	—

CHAPTER 33

Drugs Acting on the Gastrointestinal Tract

DAVID H. SHAW

Drugs that exert an effect on the gastrointestinal tract are among the most frequently used drugs. Digestive diseases are estimated to affect 60 to 70 million people in the United States each year with an annual direct cost of more than $85 billion.[23] There is a high likelihood that a patient coming into the dental office may be on a regimen of one or more of these agents. Included in this group of drugs are anticholinergics, antihistamines, antacids, proton pump inhibitors (PPIs), antiemetics, laxatives, antidiarrheal or antispasmodic drugs, and gastrointestinal stimulants. Some of these drugs are available over-the-counter (OTC) without prescription and may be used at the discretion of the patient.

Dentists are likely to prescribe these some of these drugs to modify salivary gland function or reduce nausea and vomiting. Knowledge that the patient is taking these drugs helps the dental provider to understand the patient's medical situation better, guides treatment decisions such as chair position, and may influence the choice of a dental therapeutic agent. A gastrointestinal disturbance arising during the course of dental treatment may be attributable to, or managed by, one of these agents.

Many of the drugs discussed here are described in detail in other parts of the book. This chapter focuses on drugs used exclusively for their effect on the gastrointestinal tract and drugs with a wider spectrum of activity that have application to gastrointestinal disorders. Drugs that act on the gastrointestinal tract and are commonly used in dentistry to modify salivary gland activity or to reduce drug-induced nausea and vomiting are listed in Table 33-1.

GASTRIC HYPERACIDITY, GASTROESOPHAGEAL REFLUX DISEASE, AND PEPTIC ULCER DISEASE

Acid-peptic conditions such as heartburn (pyrosis), dyspepsia (indigestion), gastroesophageal reflux, and peptic ulcer disease (PUD) (gastric and duodenal) are often treated with drugs that either reduce intragastric acidity or promote gastrointestinal mucosal defense. In all these conditions, patient discomfort primarily results from the caustic effects of the gastric acid on the esophagus or from overcoming the gastrointestinal mucosal defense system or both. In the United States, heartburn has been reported to occur at least once a month by 44% of adults, at least weekly by 14%, and at least daily by 7%.[12] *Heartburn* is a common term to describe a burning sensation that usually arises from the lower chest area (substernal) and moves upward toward the neck. It most commonly occurs within 2 hours after eating or when lying down or bending over. The symptoms are caused by the abnormal reflux of gastric contents or vapors retrograde into the esophagus. Heartburn that is frequent and persistent is the most common symptom of gastroesophageal reflux disease (GERD). GERD is one of the most prevalent digestive diseases among adults in the United States with more than 19 million cases annually.[25] Symptoms arising from GERD, such as heartburn, are among the most common reasons for visits to primary care physicians.

PUD is a common malady affecting 10% to 15% of the population at some time in life. In a given year, nearly 15 million people in the United States have PUD.[23] Although PUD is a painful condition that can seriously affect the quality of life, it is rarely fatal. Economically it is a major illness, with annual direct costs in the United States of greater than $3 billion, not including dollars lost in decreased wages and work productivity.[25] Peptic ulcers are characterized by spontaneous healing and recurrence. The primary complication is hemorrhage, which may be life-threatening if undetected or ignored. Perforation of the gastrointestinal wall, which occurs much less frequently, accounts for most of the more than 4000 deaths from this disease each year in the United States.[10]

Throughout most of the twentieth century, therapy for PUD was directed at suppression of acid secretion or neutralization of secreted acid. This approach was based on the erroneous assumption that ulcers develop only because of increased gastric acid secretion. The primary causes of PUD are now known to be related to mucosal exposure to gastric acid and pepsin with a very strong association with *Helicobacter pylori* infection or the breakdown of normal mucosal defenses from the use of nonsteroidal anti-inflammatory drugs (NSAIDs).[10] *H. pylori* infects more than half of the U.S. population older than 50 years and accounts for 80% of all stomach ulcers and greater than 90% of all duodenal ulcers.[3] Because only a relatively small percentage of *H. pylori*–infected patients develop PUD in their lifetime, other factors must play a role in the development of this disease. Although *H. pylori* is found in saliva, the relationship between its presence in the mouth and infection in the stomach is unknown. The oral cavity may be a permanent reservoir for *H. pylori*, and a person-to-person route is the most probable mode of transmission.[26]

DRUGS USED TO REDUCE GASTRIC ACID AND TREAT PEPTIC ULCER DISEASE

Proton Pump Inhibitors

PPIs are drugs that irreversibly inhibit H^+/K^+-activated adenosine triphosphatase (H^+,K^+-ATPase, commonly called the *proton pump*) in the gastric parietal cell (Figure 33-1), the final common pathway for acid secretion. PPIs have become the drug class of choice for treating acid-related gastrointestinal diseases such as PUD and GERD. PPIs are among the most

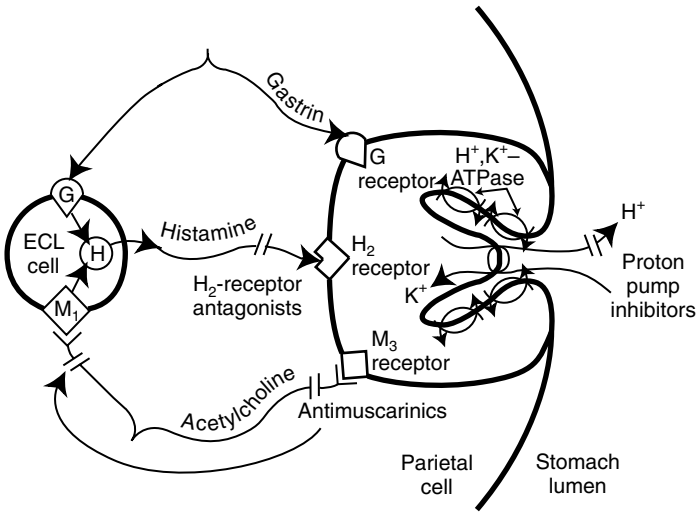

FIGURE **33-1** The physiologic control of H^+ secretion by the gastric parietal cell, with the site of action of the major antisecretory drugs. Included is an endocrine cell that secretes histamine (enterochromaffin-like *[ECL]* cell) and an acid-secreting parietal cell.

TABLE **33-1**

Drugs Useful in Dentistry That Affect the Gastrointestinal Tract

THERAPEUTIC USE	DRUG	DOSE (mg)*
Sialagogue	Pilocarpine hydrochloride (Salagen)	5†
	Cevimeline hydrochloride (Evoxac)	30†
Antisialagogue	Atropine sulfate (Sal-Tropine)	0.3-1.2
	Scopolamine hydrobromide (Scopace)	0.4-0.8
	Glycopyrrolate (Robinul)	1-2
	Propantheline bromide	7.5-30
Antiemetic	Dimenhydrinate (Dramamine)	50-100
	Meclizine hydrochloride (Antivert)	25-50
	Promethazine hydrochloride (Phenergan)	25

*Adult, oral route.
†Discussed in Chapter 8.

widely selling drugs because of their outstanding efficacy and safety. Currently, five members of the PPI class are available by prescription in the United States: esomeprazole, lansoprazole, omeprazole, pantoprazole, and rabeprazole (Table 33-2). Omeprazole is available OTC. When taken orally, all five agents effectively reduce basal and stimulated acid secretion considerably. They are longer lasting and substantially more potent than histamine H_2-receptor antagonists in the short-term treatment of PUD and GERD and relief of heartburn.

PPIs are administered as inactive prodrugs that accumulate selectively in the acid environment of the secretory canaliculus of the gastric parietal cell. The PPI is rapidly protonated and converted to the active form of the drug. Because PPIs bind covalently to active proton pumps, synthesis of new pumps or activation of resting pumps is required to restore activity. This irreversible inhibition of the pump explains why the duration of action of this class extends beyond the elimination half-life of 0.5 to 2 hours (see Table 33-2). PPIs are best taken on an empty stomach (food can decrease bioavailability up to 50%) once daily 1 hour before a meal so that the peak serum concentration coincides with the maximum activation of the proton pumps.

The most common adverse effects reported with PPIs are headache, diarrhea, and nausea, but the frequency is only slightly greater than placebo. Long-term use of PPIs may cause a slight increase in serum gastrin. This information led to concerns regarding gastrin-induced neoplasms that have been reported in animal models. PPIs have been available for more than 20 years and, to date, none have been associated with an increased risk of gastric cancers in patients receiving long-term therapy. Of more recent concern are reports that PPIs, particularly at high doses, are associated with an increased risk of hip fracture by interfering with Ca^{++} absorption through induction of hypochlorhydria[31] and with an increased risk to develop community-acquired *Clostridium difficile*–associated disease (CDAD).[22]

All PPIs increase gastric pH and may alter the absorption of drugs that are weak bases or acids or formulated as pH-dependent, controlled-release products. Absorption of aspirin, digoxin, and midazolam may be increased, and ketoconazole absorption may be decreased when administered with a PPI. The clinical significance of the alterations is unclear. PPIs can also alter the hepatic metabolism of other medications. All PPIs are metabolized to varying degrees by hepatic P450 cytochromes, including CYP2C19 and CYP3A4, and may interfere with the medications metabolized by these same enzymes. Omeprazole has been shown to progressively inhibit CYP2C19 activity with repeated administration and may inhibit the metabolism of diazepam, warfarin (Coumadin), and phenytoin.[24] Despite these concerns, few clinically significant drug interactions have been reported given the enormous popularity of PPIs.

H_2 Receptor Antihistamines

Histamine is one of the primary mediators of gastric acid secretion, along with acetylcholine and gastrin. The final common pathway is through the proton pump (see Figure 33-1). As discussed in Chapter 22, H_2 receptors are located on the membranes of acid-secreting parietal cells of the stomach. H_2 receptor antihistamines (commonly called *H_2 blockers*) are reversible, competitive antagonists of histamine at the H_2 receptors. The duration and the degree of acid suppression are dose-dependent. These are highly selective agents in that they do not affect the H_1 receptors and are not

TABLE **33-2**

Comparison of Proton Pump Inhibitors

DRUG	BIOAVAILABILITY (%)	PEAK PLASMA TIME (hr)	ELIMINATION HALF-LIFE (hr)	ORAL DOSE INTERVAL (hr)
Esomeprazole (Nexium)	>50	1.5	1.7	24
Lansoprazole (Prevacid)	>80	1.7	1.5	24
Omeprazole (Prilosec)	35	0.5-3.5	0.5-1	24
Pantoprazole (Protonix)	>77	2.4	1	24
Rabeprazole (Aciphex)	52	2-5	1-2	24

Comparison of H_2 Antihistamines

DRUG	BIOAVAILABILITY (%)	PEAK PLASMA TIME (hr)	ELIMINATION HALF-LIFE (hr)	ORAL DOSE INTERVAL (hr)*
Cimetidine (Tagamet)	60-70	0.75-1.5	2	6-24
Famotidine (Pepcid)	40-45	1-3	3	12-24
Nizatidine (Axid)	>90	0.5-3	1.5	12-24
Ranitidine (Zantac)	50-60	1-3	2.5	12-24

*For treatment of duodenal or gastric ulcer.

anticholinergic. Cimetidine, the first of these drugs to be used widely, revolutionized the treatment of duodenal ulcers. With the recognition of the role of *H. pylori* in PUD and the introduction of PPIs, the use of H_2 antagonists has markedly declined.

A usual single dose of any of the H_2 antagonists currently available for prescription or nonprescription use in the United States, including cimetidine, famotidine, nizatidine, and ranitidine (Table 33-3), inhibits 60% to 70% of total 24-hour acid secretion. These agents are particularly effective in inhibiting nocturnal acid secretion, which is stimulated more by histamine. Food-induced gastric acid secretion is stimulated more by gastrin and acetylcholine and is less inhibited by the H_2 blockers.

H_2 antagonists, in addition to their antisecretory actions, also accelerate ulcer healing by the induction of endogenous prostanoid synthesis. Patients with untreated duodenal ulcers have significantly lower gastric prostanoid synthesis than occurs in normal subjects, and patients on long-term NSAID therapy show almost complete inhibition of prostanoid synthesis by gastric mucosa. These findings suggest that decreased endogenous prostanoid synthesis may contribute to the pathogenesis of mucosal damage.

H_2 blockers are commonly administered orally. The antisecretory activity usually begins within 1 hour of administration and persists for 6 to 12 hours. They have an oral bioavailability of 40% to greater than 90%, achieve peak plasma concentrations in 0.5 to 3 hours, and are eliminated with a terminal half-life of 1.5 to 3 hours (see Table 33-3). The drugs undergo partial metabolism in the liver; the remainder of the parent drug is eliminated unchanged by the kidney. The duration of effectiveness varies with the drug, dose, and medical condition being treated, ranging from 4 hours for a low dose of cimetidine for hypersecretory disorders to 24 hours for all these agents when used to treat duodenal and gastric ulcers.

Comparative studies of H_2 blockers show that the four drugs in this class are essentially equal in clinical effectiveness regarding ulcer treatment even though they express varying potencies in their ability to block pentagastrin-stimulated gastric acid secretion in the research laboratory. Cimetidine seems unique among H_2 blockers in exerting biologic effects that are unrelated to gastric H_2 occupancy. Cimetidine therapy, particularly when prolonged and at high doses, can cause antiandrogenic effects. These reversible effects result from the ability of cimetidine to compete with dihydrotestosterone at androgen-binding sites and to inhibit the CYP metabolism of estradiol.[13] Men treated with high doses of cimetidine for long periods may experience impotence and development of gynecomastia, whereas women may develop galactorrhea. Substitution of ranitidine for cimetidine reverses these effects; no antiandrogenic effects have been reported after therapeutic doses of famotidine or nizatidine.

Of importance to the dentist is the ability of cimetidine to decrease the hepatic oxidative biotransformation of many other drugs, including lidocaine and diazepam. Cimetidine and ranitidine are ligands for multiple CYP enzymes (see Table 2-3), with cimetidine exhibiting a much higher affinity and inhibiting hepatic microsomal enzyme activity to a much greater extent. The clinical use of ranitidine, famotidine, and nizatidine does not seem to have a significant effect on the metabolism and elimination of other drugs.

The widespread use of cimetidine has revealed various central nervous system (CNS) manifestations (e.g., headache, lethargy, confusion, forgetfulness), especially in elderly patients. Impaired renal function in an older patient may contribute to these reactions. Similar effects have been reported for ranitidine and famotidine but seem to be less common.

Antibiotics

The evidence that PUD (and gastritis and possibly gastric adenocarcinoma) is directly linked to infection by the gram-negative organism *H. pylori* is now well established. Cultures taken from biopsy material are positive for *H. pylori* in approximately 95% of duodenal ulcer specimens and 75% of biopsy specimens taken from gastric ulcers compared with a roughly 25% incidence in asymptomatic control subjects.[5]

These findings have led to the routine use of antibiotic therapy for the eradication of gastric and duodenal ulcers. Significant reductions in clinical symptoms and histologic evidence of ulcers have been achieved. The current cornerstone

of therapy for *H. pylori*–associated peptic ulcers involves a triple regimen of a PPI (e.g., lansoprazole) with dual antibiotics clarithromycin and amoxicillin. This treatment regimen results in eradication of the organism in greater than 80% of patients,[9] although the success rate has been declining because of increasing clarithromycin resistance.[6] PPIs not only add antisecretory properties, but may also enhance healing through direct anti–*H. pylori* properties. Other therapeutic approaches include adding bismuth subsalicylate to the regimen (quadruple therapy) or substituting a different antibiotic such as levofloxacin or metronidazole.[9] For patients with NSAID-induced PUD, rapid healing is often initiated with the use of a PPI and discontinuation of the NSAID. Future studies are required to determine the exact interaction between bacterial infection and other prognostic factors (e.g., smoking, alcohol, NSAIDs) implicated in ulcer formation.

Gastric Antacids

Gastric antacids are weak bases that buffer or neutralize gastric hydrochloric acid (HCl) to form a salt and water and reduce gastric acidity. They are useful in the treatment of PUD, heartburn, GERD, and dyspepsia caused by overeating or eating certain foods. Through acid neutralization, antacids also secondarily reduce the proteolytic activity of pepsin, which is completely inactivated at a pH greater than 4. Overuse of antacids is discouraged because excessive neutralization may stimulate acid rebound; this response may be of little clinical significance because the added acid load likely is compensated by the buffers in the antacid. All antacids may affect the absorption of other medications by directly binding to the drug or increasing the intragastric pH, altering the drug's dissolution/solubility. In particular, antacids should not be given within 2 hours of a dose of a tetracycline or fluoroquinolone antibiotic.

Antacids may also enhance ulcer healing independent of their acid-neutralizing property by enhancing the gastric mucosal defense mechanisms. They may stimulate prostaglandin production or bind unidentified substances that may be injurious to the mucosa, or both. Prostaglandins are known to inhibit gastric acid secretion and exert cytoprotective properties. Taken together, the overall effect of antacid therapy is far more complex than simple acid neutralization.

Antacids have a rapid onset of action that depends on how fast the product dissolves in gastric acid. In general, antacid suspensions dissolve more easily than tablets or powders for a faster response. The duration of action of an antacid in the stomach is influenced by the gastric emptying time, which is slowed by food in the stomach and patient variability in gastric secretory capacity. In general, antacids taken on an empty stomach have a duration of action of approximately 30 minutes, whereas antacids taken after a full meal may neutralize acid for 3 hours. Four primary compounds are currently used, alone or in combination, in antacid products: sodium bicarbonate, Mg^{++} salts, aluminum salts, and calcium carbonate. Following is a discussion of these commonly used antacid preparations:

Sodium bicarbonate

Sodium bicarbonate is widely available in the form of baking soda and combination products. It reacts almost instantaneously to neutralize HCl to produce CO_2 and NaCl. The formation of CO_2 results in belching and gastric distention. Sodium bicarbonate is referred to as a "systemic" antacid because the unreacted fraction is readily absorbed into the general circulation and may alter systemic pH. The potential for Na^+ overload and systemic alkalosis limits its use to short-term relief of indigestion. Na^+ overload resulting from repeated use of large doses may contribute to fluid retention, edema, hypertension, congestive heart failure, and renal failure. Sodium bicarbonate is contraindicated in patients on a low-salt diet.

Mg^{++} salts

Several Mg^{++} salts (carbonate, hydroxide, oxide, trisilicate) have antacid properties. Magnesium hydroxide (milk of magnesia) is used most often and has a more rapid onset of action and high neutralizing capacity. It reacts slowly with HCl to form $MgCl_2$ and water. No CO_2 is generated. The risk of Mg^{++} overload is low and significant only in patients with impaired renal function. A disadvantage is its laxative effect, and few ulcer patients can tolerate it as the sole antacid for any length of time.

Magnesium trisilicate is much weaker than magnesium hydroxide, and substantially more of the drug is required for the same degree of neutralization. Its onset of action is slow, and it reacts with gastric acid to form silicon dioxide in the stomach. Silicate kidney stones have been reported after its prolonged use. It is generally used in combination with other antacids, such as aluminum hydroxide, calcium carbonate, and magnesium carbonate.

Aluminum salts

Aluminum may be administered in several salt forms (aminoacetate, carbonate, hydroxide, phosphate), but aluminum hydroxide gel is the most potent buffer and most frequently used. Aluminum hydroxide dissolves slowly, is poorly absorbed, and reacts with HCl to form $AlCl_3$ and water. As with the Mg^{++} salts, no CO_2 is generated. Liquid formulations provide a more rapid response than solid forms. Other than occasional nausea and vomiting, toxicity is rare. The formation of insoluble salts limits its absorption. Patients with impaired renal function who take aluminum antacids long-term may not clear the Al^{+++} resulting in hyperalbuminemia and accumulation of Al^{+++} in other tissues. The most common side effect is constipation, which may lead to intestinal obstruction. The constipating effect of aluminum-containing antacids is dose-related and can be managed with stool softeners or laxatives or minimized when the drug is taken with magnesium hydroxide. Because Al^{+++} can combine with phosphate in the gut to form insoluble aluminum phosphate, which is then excreted in the feces, prolonged use of large doses of aluminum hydroxide may result in phosphate depletion, particularly when phosphate intake is low. Anorexia, malaise, and muscle weakness are characteristic of phosphate depletion.

Calcium carbonate

Calcium carbonate produces a potent and prolonged neutralization of HCl forming CO_2 and $CaCl_2$. Approximately 90% of the ingested Ca^{++} forms insoluble salts in the gut and is excreted in the feces. The remaining Ca^{++} is absorbed into the systemic circulation. Extensive use of Ca^{++}-containing antacids may cause or exacerbate hypercalcemia, which is characterized by neurologic symptoms and reduced renal function. This effect is rare in healthy patients with normal renal function. Ca^{++}-containing antacids are associated with acid rebound and increased serum gastrin concentrations. These effects have not been shown to delay ulcer healing and may be caused by a direct effect of Ca^{++} on the gastric mucosa.[25] Calcium carbonate has a chalky taste and may produce constipation, which reduces its desirability as an antacid. Because some Ca^{++} is absorbed, Ca^{++}-containing antacids may be marketed as a source of dietary Ca^{++}.

Alginic Acid

Alginic acid is not an antacid, but because of its unique mechanism of action it is added to various antacid preparations to increase their effectiveness in the treatment and relief

of the symptoms of GERD. In the presence of saliva, alginic acid reacts with sodium bicarbonate to form sodium alginate. Gastric acid causes this alginate to precipitate, forming a foaming, viscous gel that floats on the surface of the gastric contents. This provides a relatively pH-neutral barrier during episodes of acid reflux and enhances the efficacy of drugs used to treat GERD. These effects are considered to be of questionable value to the U.S. Food and Drug Administration (FDA). Alginic acid products are not indicated for the treatment of PUD.

Simethicone

Simethicone is a defoaming agent used to relieve gas discomfort in the stomach and intestine. It does not have antacid properties, but may be included in antacid products. Its action is to reduce the surface tension of gas bubbles in the gastrointestinal tract, which allows the gas bubbles to break up and coalesce, facilitating the elimination of the gas by belching or passing through the rectum. The FDA considers simethicone to be safe and effective as an antiflatulent agent.

Sucralfate

Sucralfate, a complex of aluminum hydroxide and sulfated sucrose, is a cytoprotective agent that provides a physical barrier over the surface of a gastric ulcer and enhances the gastric mucosal protective system. It is employed in clinical practice to treat several gastrointestinal diseases, including PUD, GERD, and dyspepsia. After oral administration the drug disperses in the stomach and, in the presence of acid, forms a viscous suspension that binds with high affinity at the ulcer site. An adherent, physical cytoprotective barrier is produced that covers the ulcer and protects it from further attack by damaging agents such as acid, pepsin, and bile salts.

Although sucralfate has multiple actions, it possesses no meaningful antacid properties. A key element in the acute gastroprotective actions of sucralfate is its ability to maintain mucosal vascular integrity and blood flow. It enhances bicarbonate and mucus secretion, increases mucosal hydrophobicity, and induces an increase in mucosal concentration of prostaglandin—all factors considered important in tissue healing. An increase in local fibroblast growth factors and possibly other growth factors has also been proposed to explain the powerful ulcer-healing actions of sucralfate, which occur independently of a decreased gastric acid concentration in the stomach and duodenum.[7]

Because it is minimally absorbed from the gastrointestinal tract, sucralfate is considered a remarkably safe agent. For this reason, sucralfate is a first-choice therapy in the management of acid-related diseases during pregnancy.[8] It requires an acid pH to be activated and so should not be administered concomitantly with antacids, H_2 antagonists, or PPIs. The most common side effect is constipation (15%). Other reactions include dry mouth, nausea, vomiting, headache, and rashes.

Sucralfate may reduce the absorption of many other drugs, including the fluoroquinolone and tetracycline antibiotics. The use of a topical sucralfate suspension has also been advocated in the prevention or treatment of stomatitis caused by chemotherapy or radiation, despite studies that showed no substantial benefits from this drug in inhibiting radiation-induced esophagitis.[21]

Antimuscarinic Drugs

The use of antimuscarinic drugs (muscarinic receptor antagonists) for the treatment of PUD declined dramatically after the introduction of the H_2 blocker cimetidine. As discussed in Chapter 9, antimuscarinic agents (e.g., atropine) are not selective inhibitors of gastric acid secretion, and therapeutic benefits for the treatment of gastrointestinal disease accrue only at doses that cause sufficient side effects to impair patient compliance. Antimuscarinic drugs with a higher relative affinity for gastric M_1 muscarinic receptors have been developed, however. Pirenzepine and telenzepine, selective M_1-receptor antagonists, are currently available in other countries for the treatment of PUD, but they are still investigational in the United States. Pirenzepine and telenzepine block gastric acid secretion more selectively because the M_1 receptor is not the major muscarinic receptor in most smooth muscle, cardiac muscle, or salivary glands. In those tissues, M_2 and M_3 muscarinic receptors predominate. Pirenzepine and telenzepine have a low incidence of side effects because of their selective inhibition of gastric acid secretion; this may make them a valuable addition to current agents used in the treatment of PUD.

Prostaglandins

Misoprostol, a synthetic prostaglandin E_1 analogue, is the best studied of the prostaglandin derivatives. Although the prostaglandins are crucial in creating the alkaline mucus layer that provides cytoprotective effects on the gastroduodenal mucosa, the ulcer-healing effect of misoprostol and other prostaglandin analogues seems to be caused mainly by the inhibition of acid secretion.[13] These agents interact with a basolateral receptor of the parietal cell that causes the inhibition of adenylyl cyclase. This inhibition results in reduced production of cyclic adenosine 3′,5′-monophosphate, the major second messenger for histamine-induced acid secretion. Misoprostol is approved for prevention of NSAID-induced ulcers in high-risk patients, although PPIs may be as effective and better tolerated. The most common side effects are abdominal pain (7% to 20%) and diarrhea (13% to 40%); both are dose-related. Misoprostol stimulates contraction of the uterus, which contraindicates its use during pregnancy or in women of childbearing potential. This property makes it effective, however, in women undergoing elective termination of pregnancy by facilitating expulsion of the uterine contents.

Implications for Dentistry

The diagnosis of GERD may be a very important finding when considering if a patient should be reclined in the dental chair. Although it is safe to place most GERD patients supine, some with severe GERD need to be kept at a 45-degree angle for their visit. Asking patients how they sleep can help elucidate what should be done. Similarly, if general anesthesia is being considered in a patient with GERD, a rapid-induction sequence with cricothyroid pressure may be indicated.

A patient history of a gastric or duodenal ulcer provides important information for the dentist because this can influence the choice of a therapeutic agent or time of drug administration. The use of aspirin as an analgesic is contraindicated because of its irritating effect on gastric mucosa; this is particularly true for elderly patients. All NSAIDs share the ulcerogenic property of the salicylates, with the risk of developing NSAID-induced peptic ulcer disease. The risk is affected with increased drug dosage and duration of use. Acetaminophen may be used as an alternative analgesic because it produces minimal damage to gastric mucosa compared with aspirin and other NSAIDs. For acute dental pain in high-risk patients, the cyclooxygenase-2–selective inhibitor celecoxib may also be used. It is efficacious and significantly less ulcerogenic than either aspirin or ibuprofen (see Chapter 21).

As previously mentioned, PPIs may cause sufficient inhibition of gastric acid secretion to reduce the absorption of drugs in which gastric pH influences bioavailability (e.g., ketoconazole, ampicillin). The clinical significance of this interaction has yet to be determined. Likewise, the theoretic risk of

increasing the response to diazepam when coadministered with PPIs, especially omeprazole, has shown little clinical significance to date.

Systemic corticosteroids, as used after oral surgical procedures, are potentially ulcerogenic. Even topical steroids used in the management of oral lesions should be avoided in patients with an ulcer because of the possibility that absorption through the mucosa would occur. The choice of a preoperative or postoperative sedative is particularly important for ulcer patients. Chloral hydrate is quite irritating, and gastrointestinal side effects such as nausea and vomiting can occur. Diazepam is appropriate for selected patients because, in addition to producing sedation, it can suppress the nocturnal secretion of gastric acid. Absorption of orally administered diazepam is increased by the use of aluminum hydroxide, whereas Mg^{++} salts retard its absorption. For a patient being treated with cimetidine or omeprazole, a prudent choice might be lorazepam or oxazepam; these are antianxiety drugs not dependent on hepatic oxidative biotransformation. They are eliminated in the urine as glucuronide conjugates, the formation of which is not impaired by either drug.

Treatment with cimetidine for a day or more may cause much higher plasma concentrations of diazepam taken on a regular basis, a more pronounced sedative effect, and slowed elimination of the drug. The significance of such cimetidine-induced drug interactions is likely to depend on the patient, however. The manifestations of the diazepam-cimetidine interaction may be clinically insignificant in young adults, but the interaction could be important in elderly patients or in patients on multiple medications. If a course of diazepam therapy is prescribed for a dental patient on cimetidine, dosage reduction should be considered.

As previously mentioned, cimetidine inhibits the hepatic metabolism of lidocaine and presumably other amide local anesthetics. This interaction is of little practical concern in view of the low dosages of lidocaine typically required for intraoral anesthesia and the extrahepatic metabolism in the vascular endothelial lining.

Aluminum hydroxide gels, Ca^{++} and Mg^{++} antacids, and sodium bicarbonate impair the absorption of tetracyclines and fluoroquinolones. This action is shared by milk and milk products and seems to result from chelation and an increased gastric pH. Sucralfate can also reduce the absorption of several drugs, including tetracycline, when administered concomitantly. A reasonable general approach for prescribing these vulnerable drugs to a dental patient receiving antacid or sucralfate therapy, or both, would be to separate the administration of each drug by several hours. This approach results in a negligible effect on absorption of the antibiotic.

ANTISIALAGOGUES

The short-term control of salivary flow is often helpful in dental procedures (e.g., occlusal adjustment and impression taking), but is not an approved indication for antisialagogues. A dramatic reduction of the secretory function of the salivary glands can be achieved by blockade of acetylcholine at muscarinic receptor sites. The pharmacologic characteristics of the antimuscarinic drugs are presented in detail in Chapter 9, but in summary, these drugs block the action of acetylcholine on the muscarinic receptor sites of effector cells innervated by postganglionic parasympathetic cholinergic nerves. They are used in dentistry to control excessive salivation and as a preanesthetic medication. In medicine, they are used as antispasmodics. The recommended oral doses for blocking excessive salivation are low and free of side effects (see Table 33-1).[30]

The prototypic drugs for this class are the belladonna alkaloids atropine and scopolamine. Many patients experience unpleasant side effects such as difficulty in swallowing because of excessive dryness in the mouth and throat and a reduction in sweating. Scopolamine in particular may impair psychomotor activity and is not the drug of choice to reduce salivary secretion in the typical dental setting. The decision to use an antisialagogue depends partly on the patient's medical history. Atropine is contraindicated in patients with prostatic hypertrophy or narrow-angle glaucoma, and the topical use of atropine is absolutely contraindicated in all forms of glaucoma. Atropine should be administered with caution in patients with cardiovascular disease because it can increase the pulse rate and cardiac workload. It may also antagonize the vagal effects of digitalis. Toxic effects are common, particularly in children, who have increased susceptibility to heat prostration from inhibition of sweating.

The synthetic anticholinergic drugs propantheline and glycopyrrolate have also been used in dental procedures to control excessive salivation. Because they are quaternary amines, they are ionized at body pH and are unable to cross the blood-brain barrier. The resultant freedom from CNS effects constitutes a distinct advantage over atropine and scopolamine. Both drugs are also less well absorbed, however, and propantheline is less selective in controlling salivation. Precautions for their use in dentistry are similar to the precautions for atropine and scopolamine.

EMETICS AND ADSORBENTS

Emetics such as syrup of ipecac have been used in emergent cases of poisoning because they induce forceful emptying of the stomach. The efficacy of emesis in the management of acute poisoning episodes declines when treatment is initiated more than 1 hour after ingestion of a toxic substance. The amount of substance removed from the stomach is inversely related to the duration of time from ingestion to emesis. For these reasons, the American Academy of Pediatrics and the American Academy of Clinical Toxicology no longer support the use of ipecac to treat accidental poisonings in the home.[1] Instead, the administration of activated charcoal as an adsorbent is preferred because it has been shown to reduce the bioavailability of ingested substances effectively. Routine use of activated charcoal for poison management in the home cannot yet be recommended, however, because its efficacy and safety have not been clearly shown.[2] In all cases in which poisoning is suspected, consultation with the local poison control center should be the first action taken for information needed to determine the appropriate treatment approach.

Despite the previous discussion, if an emetic is recommended, syrup of ipecac is available OTC. Syrup of ipecac is a mixture of plant alkaloids (principally emetine) that act centrally on the medullary chemoreceptor trigger zone (CTZ) and locally by irritation of the stomach and duodenum. Vomiting occurs 15 to 30 minutes after oral administration. Because emesis may not occur if the stomach is empty, the drug should be followed by a drink of water. Adverse reactions to ipecac syrup include diarrhea, lethargy, and prolonged vomiting; such responses are rare if the recommended dose is not exceeded.[1] The oral dose is 15 mL in children 1 to 12 years old and 15 to 30 mL in adolescents and adults.

Apomorphine, a potent dopamine receptor agonist derived chemically from morphine, has been used as an emetic in a supervised medical setting. Because excessive dosages may cause significant respiratory depression, apomorphine is now considered too dangerous for this use and is employed infrequently as an emetic.

ANTIEMETICS

Numerous drugs are available that have shown antiemetic action (see Table 33-1). Nausea and vomiting are complex processes that are not yet fully elucidated. The brainstem vomiting center, located in the lateral medullary reticular formation, apparently coordinates the associated motor activities after input from the CTZ, cerebral cortex, gastrointestinal tract, and vestibular apparatus. The identification of the neurotransmitters and their receptors within these sites has provided a likely target for the disruption of the emetic process. Cancer chemotherapeutic agents and other chemical stimuli activate the CTZ, an area rich in dopamine D_2 receptors, serotonin 5-HT_3 receptors, and neurokinin 1 and opioid receptors. Motion sickness results from muscarinic and histamine H_1 receptor–mediated response from vestibulocochlear disturbances via cranial nerve VIII. Drugs or drug classes useful as antiemetics include antipsychotics (phenothiazines and butyrophenones), metoclopramide, H_1 antihistamines, anticholinergics, serotonin 5-HT_3 antagonists, neurokinin antagonists, cannabinoids, and corticosteroids.

The pharmacologic features of antipsychotics are discussed in Chapter 12. The phenothiazines and butyrophenomes are central dopamine antagonists and inhibit stimulation of the CTZ. Inhibition of muscarinic receptors may also play a role in this activity. Most antipsychotics are not effective for motion sickness, but they are often used successfully for the nausea of pregnancy, postoperative emesis, or vomiting induced by radiation or cancer chemotherapy. Among the most commonly used agents are promethazine, prochlorperazine, and droperidol. Trimethobenzamide, a substituted benzamide, also inhibits the CTZ through dopamine-receptor blockade and has the same range of action as antipsychotic antiemetic agents.

Nausea and vomiting, sometimes very marked, are almost universal sequelae of cancer chemotherapy. The protracted bouts of severe drug-induced vomiting, which may be only slightly relieved by standard antiemetic therapy, have led to the inability of some patients to complete courses of potentially curative treatment. Chemotherapy-induced nausea and vomiting were found to respond to high doses of the dopaminergic D_2 receptor antagonist metoclopramide. Approximately 40% to 60% of cancer patients treated with cisplatin (a highly emetogenic drug) responded to the antiemetic effect of metoclopramide in well-controlled clinical trials. Metoclopramide acts peripherally and centrally. Peripherally, it stimulates the release of acetylcholine and sensitizes smooth muscle to acetylcholine. Centrally, it blocks D_2 receptors in the CTZ. In addition, metoclopramide inhibits 5-HT_3 receptors, which may be more responsible for its antiemetic effect. High-dose metoclopramide, similar to other dopamine antagonists, may cause extrapyramidal symptoms and sedation, particularly in young and elderly patients. Prolonged use has been associated with tardive dyskinesia. Droperidol, an anti-D_2 dopamine receptor neuroleptic, is an antiemetic used in anesthesia for the prophylactic management of postoperative nausea and vomiting.

As pointed out in Chapter 22, certain H_1 histamine antagonists are effective antiemetics. All possess significant anticholinergic actions that contribute to their antiemetic efficacy. Diphenhydramine, dimenhydrinate, meclizine, and cyclizine are especially useful in treating the nausea and vomiting associated with motion sickness, pregnancy, and the postoperative state. These drugs should not be used during pregnancy, however, unless absolutely necessary. The antihistamines are not of significant value in relieving nausea associated with the administration of cytotoxic drugs. Promethazine, a phenothiazine antihistamine without significant dopamine-blocking activity, is effective in vertigo and motion sickness. Its sedative action is advantageous in the treatment of postoperative nausea and vomiting. Nonsedating H_1 antihistamines such as loratadine are ineffective against motion sickness because they penetrate poorly into the CNS.

The anticholinergic scopolamine is effective in the prevention and treatment of motion sickness, but its oral use is limited by its sedative and antimuscarinic actions. A transdermal sustained-release preparation of scopolamine, when applied to the postauricular area for several hours before need, effectively prevents motion sickness for 72 hours with minimal side effects.

The recognition that 5-HT_3 receptor blockade by high-dose metoclopramide provides antiemetic activity led to the development of ondansetron. It is a potent, highly selective competitive 5-HT_3 antagonist. 5-HT_3 receptors are found in the gastrointestinal tract and the CNS. Ondansetron is more effective than high-dose metoclopramide in the first 24 hours after chemotherapy, and there is evidence that it maintains efficacy for at least the following 4 days. It is generally well tolerated, although during clinical trials, constipation, abdominal discomfort, headache, sedation, dry mouth, blurred vision, and anxiety were noted in some patients. Extrapyramidal effects have not been reported. At this time, the relative efficacy and safety of ondansetron and its congeners granisetron and dolasetron have made them drugs of first choice for the management of chemically induced nausea.

Cannabinoids are indicated when conventional antiemetics fail to relieve the nausea and vomiting associated with cancer chemotherapy. Dronabinol, or Δ-9-tetrahydrocannabinol, is the main psychoactive constituent in marijuana (see Chapter 51). Investigation of its use as an antiemetic was undertaken after anecdotal reports that marijuana smokers had less nausea and vomiting in association with cytotoxic agents than other patients. Dronabinol given orally has been shown to be significantly better than placebo and comparable to metoclopramide in reducing chemotherapy-induced vomiting in selected patients. The use of dronabinol is limited by its tendency to produce acute, and often intolerable, mental disturbances, particularly in older patients who are unaccustomed to marijuana-like side effects.

Corticosteroids, such as dexamethasone and methylprednisolone, have been reported to be effective for cancer chemotherapy–induced nausea and vomiting. The mechanism of this effect is unknown, but it may be related to a reduced synthesis of prostaglandins; prostaglandin E has been shown to induce nausea and vomiting (see Chapter 21). Sedative-hypnotics such as the benzodiazepines may also help prevent anticipated nausea and vomiting associated with chemotherapy; lorazepam is most commonly used.

Aprepitant is a highly selective neurokinin 1 receptor antagonist employed in combination with 5-HT_3 antagonists and corticosteroids for the prevention of chemotherapy-induced nausea and vomiting. Adding aprepitant greatly improves antiemetic outcomes. This drug is metabolized by CYP enzymes (CYP3A4), and its use may influence the metabolism of other drugs sharing this pathway.

Just as combinations of antineoplastic drugs with different modes of action are used in cancer chemotherapy (see Chapter 42), combinations of different antiemetic drugs are being used to treat the nausea and vomiting associated with the use of antineoplastics. Combinations of antiemetics are often more effective than single-agent therapy because of multiple sites of emetic action by antineoplastic agents and the potential for additive or even synergistic effects of several antiemetics with different mechanisms of action.

Droperidol, metoclopramide, dexamethasone, and 5-HT_3 blockers are useful as antiemetics when used prophylactically to reduce the incidence of postoperative nausea and vomiting. In a comparison of the first three antiemetics, the choice was

not a significant predictor of postoperative nausea and vomiting. The choice of antiemetic drug given for prophylaxis had little effect on clinical outcome or patient satisfaction.[11] Ondansetron and granisetron are now widely used when there is expectation of postoperative nausea and vomiting.

Alternative treatments, including acupuncture, hypnosis, ginger, and pyridoxine (vitamin B_6), have shown efficacy in several conditions with nausea and vomiting.[18,19,29] Widespread acceptance of these alternative therapies awaits confirmation of efficacy from additional studies.

LAXATIVES

Constipation is a common gastrointestinal complaint, affecting more than 65 million Americans.[15] Laxatives are used to relieve acute and chronic constipation, treat anorectal disorders (hemorrhoids), and prepare the bowel for examination (colonoscopy). Constipation occurs in all age groups, but is especially common in pregnant women and elderly individuals. Most cases are self-limiting or are self-treated with diet. Laxatives are well-known, highly advertised, and the most overused OTC drugs having a therapeutic effect on the gastrointestinal tract. Traditionally, these drugs have been generally classified as stimulants/irritants, saline and osmotic cathartics, bulk-forming agents, stool softeners, and lubricants (Figure 33-2). Although that taxonomy is used in this chapter, these categories are arbitrary and not reflective of either the pathophysiologic principles or the multiplicity of effects generated by laxatives.

Stimulants

Numerous laxatives belong to the stimulant category. As a group, these drugs are thought to act as a local irritant of the intestinal mucosa that increases propulsive activity. The exact mechanism is not completely understood, but they may increase motility by a selective action on the intramural nerve plexus of intestinal smooth muscle. All the stimulant laxatives increase mucosal permeability, resulting in movement of fluid and electrolytes into the intestinal lumen.

Castor oil is obtained from the seeds of *Ricinus communis* and is hydrolyzed in the small intestine by pancreatic lipase to glycerol and ricinoleic acid, an unsaturated hydroxy fatty acid. Castor oil evokes the secretion of water and electrolytes in the colon and small intestine and increases small bowel peristaltic activity to produce a very prompt cathartic effect in 2 to 6 hours. It is of historic interest but rarely used today.

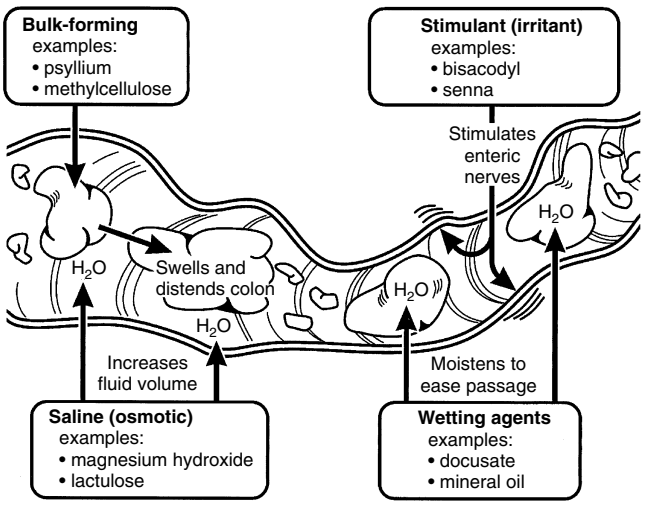

FIGURE **33-2** The site of action of the major categories of laxatives.

Phenolphthalein was a widely used stimulant OTC laxative until the FDA banned its use because of reports of its association with carcinogenic tumors in laboratory rats. Bisacodyl is structurally related to phenolphthalein and has similar pharmacologic actions. After oral administration, approximately 5% of a therapeutic dose is absorbed from the digestive tract with no apparent systemic effects. The laxative effect is obtained in 6 to 8 hours, but can be accelerated by administration in suppository form. The major toxicity is diarrhea with overdosage.

Some of the most extensively used stimulant laxatives are in the anthraquinone group, which includes senna and cascara sagrada. These preparations contain emodin (or anthracene) alkaloids in an inactive glycoside form. The glycosides are hydrolyzed within the colon by the action of bacteria to liberate the active principle. A small percentage of the active form may be absorbed and excreted in the bile and other body fluids. The laxative action is limited primarily to the colon and is produced in 6 to 8 hours. Cascara sagrada is considered to be milder than senna. In general, adverse reactions to these agents relate to excessive catharsis and may include severe abdominal pain.

Stool Softeners and Lubricants

Docusate sodium (dioctyl sodium sulfosuccinate) and docusate calcium (dioctyl calcium sulfosuccinate) act like detergents and are used to soften the stool when it is desirable to lessen the discomfort or the strain of defecation. These drugs are anionic surfactants that produce their effect by reducing the surface tension and allowing intestinal fluids and fatty substances to penetrate the fecal mass. They usually require 1 to 3 days to exert their full effect if used alone, but they may be combined with other laxatives in OTC preparations. These agents are not believed to interfere with the absorption of nutrients from the intestinal tract, and they are not appreciably absorbed. Docusate is frequently recommended for elderly patients because it is associated with so few side effects. Diarrhea and mild abdominal cramps are the only adverse effects reported.

Mineral oil (liquid petrolatum) may be considered with the surface-active agents because it also softens the stool. Mineral oil acts as a lubricant and coats the intestinal contents, preventing the absorption of fecal water. It produces a cathartic action in 6 to 8 hours after oral administration and 5 to 15 minutes if given rectally. Its use is attended by several potential hazards not associated with the other agents. Prolonged oral use or administration with meals can reduce the absorption of the fat-soluble vitamins (A, D, E, and K). Lipid pneumonia can result from the accidental aspiration of the oil. Mineral oil is absorbed to a limited extent from the intestinal tract; its use with a wetting agent (docusate), which could increase its absorption, is contraindicated. Significant absorption of mineral oil may occur if used repeatedly. The seepage of oil through the anal sphincter may occur and produce pruritus ani or other perianal conditions.

Saline and Osmotic Cathartics

Saline cathartics are salt solutions containing one or more ions that are poorly absorbed from the gastrointestinal tract. Available preparations include Mg^{++} salts (hydroxide, sulfate, or citrate), sodium phosphate (monobasic or dibasic), and sodium biphosphate. The salt solutions osmotically increase the water content of feces and fluid volume in the intestinal lumen; this increases the intraluminal pressure, which exerts a mechanical force to stimulate peristalsis. It has also been postulated that Mg^{++} salts increase colonic motility by causing the release of cholecystokinin. Oral administration of these

agents generally results in the production of a fluid to semifluid stool within 30 minutes to 3 hours. If given rectally, laxation occurs in 2 to 5 minutes.

Some absorption of saline cathartics does occur, and consequently systemic effects may be noted. For this reason, Na^+ salts are contraindicated in patients on a low-salt diet and in patients with edema or congestive heart failure. Mg^{++} and K^+ salts are contraindicated in patients with impaired renal function. Magnesium sulfate (Epsom salt), which is an effective and frequently used cathartic, may cause serious loss of body water with repeated use. Milk of magnesia, a suspension of magnesium hydroxide, is a widely used OTC preparation. Abdominal cramps and dehydration are reported adverse reactions from saline laxatives.

Several preparations, notably glycerin, lactulose, and polyethylene glycol (PEG), contain large poorly absorbable or nonabsorbable molecules that produce an osmotic effect resulting in distention and catharsis. Glycerin is used in suppository form to promote defecation. It osmotically dehydrates exposed rectal tissue; the resultant irritation promotes evacuation of the lower bowel within 30 minutes. Lactulose is a semisynthetic disaccharide. In the large intestine, lactulose is metabolized by enteric bacteria to various acids and carbon dioxide. The acidification and increased osmolarity of the bowel contents cause fecal softening and a more normal bowel movement. Two days may be required for a therapeutic effect to occur. Lactulose is also used in patients with liver failure who have developed too much ammonia in their bodies. Lactulose is given orally and rectally to scavenge ammonia ions from the gut lumen and inhibit their absorption. As expected, a side effect is loose stools.

Although PEG acts osmotically to retain water in the gut to produce laxation, it is not metabolized by bowel flora and is not significantly absorbed. In contrast to lactulose, PEG does not produce significant cramps or flatus. These osmotic agents are often the mainstay of therapy for individuals with chronic constipation.

Bulk-Forming Agents

Bulk-forming agents include synthetic fibers (polycarbophil) and natural plant products (psyllium and methylcellulose). They possess the property of absorbing water and expanding, increasing the bulk of the intestinal contents. The elevated luminal pressure stimulates reflex peristalsis, and the increased water content softens the stool. These agents are not absorbed and do not interfere with the absorption of nutrients from the gastrointestinal tract. Several days of medication may be required to achieve the full therapeutic benefit, although the usual onset of action is 12 to 24 hours. Some patients prefer to add foods such as bran or dried fruit (e.g., prunes and figs) to their diet that exert the same effect rather than use a bulk-forming laxative. These laxatives have the advantage of having few systemic effects and are unlikely to produce laxative abuse. Cellulose agents may physically bind with other drugs if administered concurrently (e.g., salicylates, warfarin, digitalis glycosides) and hinder their absorption. Patients should not take a calcium polycarbophil laxative within 2 hours of taking tetracycline for the same reason.

Laxatives with psyllium come in a powdered mixture containing approximately 50% powdered psyllium seeds and 50% dextrose or sucrose. Sugar-free products are also available. Psyllium seeds are rich in a hemicellulose that forms a gelatinous mass with water. The refined hydrophilic colloid from the seeds is the most widely used form of this agent. Methylcellulose is indigestible and not absorbed systemically. Bloating and flatus have been reported after the use of psyllium products because of bacterial digestion of the plant fibers within the colon.

ANTIDIARRHEAL AGENTS

One out of every six illnesses of adults and children involves the digestive system, and diarrhea is one of the most common complaints. Diarrhea occurs when not enough water is removed from the stool during transit, making the stool loose and poorly formed. Commonly used antidiarrheal agents act in one of two ways. They either soak up excess water or decrease intestinal motility, which provides the body more time to absorb the luminal water. Antidiarrheal agents may be used to treat acute diarrhea, although they should be discontinued if the diarrhea worsens despite therapy. They may also be used to control chronic diarrhea associated with conditions such as irritable bowel syndrome (IBS) or inflammatory bowel disease. The following agents have been determined by the FDA to be safe and effective in the treatment of acute nonspecific diarrhea.[4]

Kaolin

Kaolin is a hydrated aluminum silicate with a crystalline structure that allows for a large surface area that adsorbs many times its weight in water. Its use in the treatment of diarrhea is based on its purported ability to absorb fluid, bacteria, toxins, and various noxious materials in the gastrointestinal tract, decreasing stool liquidity and frequency. In the colon, it may act as an adsorbent or protectant, but the adsorption is not selective, and it should not be used in children younger than 12 years without physician approval. If taken together, kaolin may adsorb other medications and reduce their systemic absorption. Few controlled clinical studies showing the efficacy of kaolin have been published, and no major product containing kaolin as the sole active ingredient is presently available in the United States.[4]

Bismuth Subsalicylate

Bismuth subsalicylate (Pepto-Bismol) is a commonly used OTC agent in the treatment of various gastrointestinal symptoms and diseases, including dyspepsia and acute diarrhea, and in the prevention of traveler's diarrhea. It is the only OTC bismuth compound available in the United States and is estimated to be used by most American households. It is a crystal complex of bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the stomach, the bismuth subsalicylate reacts with the hydrochloric acid to form bismuth oxychloride and salicylic acid. The salicylate is readily absorbed into the body, whereas the bismuth passes unaltered and unabsorbed into the feces. Caution is advised if patients are taking aspirin or other salicylate-containing drugs concurrently because toxic levels of salicylate may be reached. Bismuth subsalicylate products are not recommended for patients younger than 12 years because of a lack of studies to prove efficacy in young children.

Bismuth is thought to produce its therapeutic actions in part by stimulating prostaglandin, mucus formation, and bicarbonate secretion. It also has direct antimicrobial effects and may bind to enterotoxins, which accounts for its use in the prevention of traveler's diarrhea. In addition, bismuth has been used in the home treatment of gastric ulcers because of its ability to coat the ulcer and other gastric erosions, shielding them from the stomach acid and pepsin. In the treatment of acute diarrhea, the salicylate moiety is thought to inhibit intestinal prostaglandin and Cl^- secretion, leading to a reduction in stool frequency and liquidity. Bismuth subsalicylate has an excellent safety record, and side effects are minor. Bismuth may cause blackening of the stool or harmless black staining of the tongue, which is thought to be caused by the formation of bismuth sulfide from the reaction between the drug and the bacterial sulfides in the gastrointestinal tract. As noted previously, salicylate-induced adverse reactions may

occur after the administration of bismuth subsalicylate (see Chapter 21).

Opioid Preparations

Opioids are effective and prompt-acting antidiarrheal agents. As discussed in Chapter 20, opioids enhance tone in the anal sphincter and in segments of the longitudinal muscle of the gastrointestinal tract, while inhibiting propulsive contraction of circular and longitudinal muscle. Opioids cause a marked slowing of fluid movement through the jejunum, but produce a minimal effect on the movement of fluid through the ileum or colon. By increasing the contact time of luminal fluid with mucosal cells, therapeutic doses of an opioid increase net intestinal absorption of water and electrolytes, reducing stool volume. Commonly used opioid diarrheals include diphenoxylate and loperamide, which act primarily via peripheral μ-opioid receptors (see Chapter 20).

Diphenoxylate

Diphenoxylate, a Drug Enforcement Administration (DEA) Schedule V (C-V) prescription drug, is a congener of meperidine and was originally synthesized during the search for compounds similar to the opioid analgesics in actions on the gastrointestinal tract but devoid of their CNS effects. The efficacy of diphenoxylate was found to be approximately equal to that of camphorated tincture of opium in patients with diarrhea of various causes. Because diphenoxylate is structurally related to meperidine, there was concern about its abuse potential, but in the several decades of experience with it, diphenoxylate has emerged as having an addiction liability comparable to that of codeine, which is diminished further by the incorporation of atropine (as in Lomotil) and by the low water solubility of diphenoxylate salts, both of which prevent inappropriate parenteral administration.

Various minor side effects have been reported, including abdominal cramps, nausea, weakness, drowsiness, xerostomia, gingival swelling, partial intestinal obstruction, and urinary retention. In patients with inflammatory bowel disease, diphenoxylate has caused toxic megacolon, and it has caused hepatic coma in patients with severe liver disease. Toxic doses have produced respiratory depression and unconsciousness, which can be effectively reversed by the opioid antagonists. Although clinical studies have indicated only minimal, if any, drug interactions during diphenoxylate therapy, the drug may potentially augment the actions of barbiturates, alcohol, opioids, and antianxiety and antipsychotic drugs.

Difenoxin, the principal active metabolite of diphenoxylate, is a DEA Schedule IV (C-IV) prescription antidiarrheal drug that is effective at one fifth the dosage of diphenoxylate. Atropine is added to the formulation to discourage deliberate misuse of the drug.

Loperamide

Loperamide, a long-acting derivative of haloperidol and diphenoxylate, is the most selective antidiarrheal opioid currently available for clinical use because it has a distribution within the body different from other opioids. Although drugs such as meperidine penetrate the blood-brain barrier and interact with CNS opioid receptors to modify intestinal motor function, only small concentrations of loperamide reach the brain. Its antidiarrheal effect is thought to result mainly from interactions with intestinal μ-opioid receptors. When loperamide is administered orally at therapeutic doses, the effect on the gastrointestinal tract is not accompanied by any significant CNS opioid effect. Large amounts of the drug become concentrated in target tissues along the gastrointestinal tract. One hour after oral administration, 85% of the drug is distributed to the gastrointestinal tract, 5% is distributed to the liver, and less than 0.04% is distributed to the brain.

Loperamide exerts its antidiarrheal effect by altering motor function in the intestine, which results in increased capacitance of the intestine and slowing of intestinal motility; this permits greater absorption of electrolytes and water through the intestine. This action is analogous to that of morphine and codeine. The stimulation of μ-opioid receptors also decreases gastrointestinal secretions, which contributes further to its antidiarrheal effects. Despite differences in distribution and other pharmacologic properties, the action of the traditional opioid antidiarrheal drugs and loperamide seems to be the same inhibition of propulsion through the intestine.

Adverse effects of loperamide occur infrequently but include abdominal pain and distention, constipation, nausea and vomiting, dry mouth, and drowsiness or dizziness. Allergic reactions, including skin rash, have been reported. In contrast to diphenoxylate and difenoxin, loperamide is available OTC. After years of extensive use, there has been no evidence of drug abuse or physical dependence. It is a safe and effective antidiarrheal agent.

Agents Used for the Prevention and Treatment of Traveler's Diarrhea

Nearly 50% of travelers from the United States acquire a diarrheal illness while visiting developing countries.[16] Worldwide, approximately 20 million episodes of diarrhea occur annually in people traveling from industrial regions to developing countries.[14] The most common infecting organism is enterotoxigenic *Escherichia coli*, which is primarily acquired through fecal contamination of food (e.g., raw vegetables) and water, including ice. The ingested bacteria produce enterotoxins that cause the sudden onset of loose stools, commonly referred to as traveler's diarrhea. This is usually a self-limiting illness lasting only several days. Less common pathogens that may cause this disorder include *Shigella*, *Campylobacter*, *Giardia*, and nontyphoid *Salmonella*.

Several approaches to the prevention of traveler's diarrhea have been evaluated. Because of the potential for drug resistance and adverse reactions, the Centers for Disease Control and Prevention does not recommend prescription of drugs prophylactically; instead, they recommend the traveler begin treatment promptly only when symptoms occur. When prophylaxis is used, once-daily dosing with a fluoroquinolone antibiotic (see Chapter 39) is the recommended treatment of choice. Antibiotics recommended from this group include ciprofloxacin (500 mg), levofloxacin (500 mg), ofloxacin (300 mg), and norfloxacin (400 mg). Rifaximin is a nonabsorbed antibiotic approved for prevention and treatment of traveler's diarrhea caused by noninvasive strains of *E. coli* because the action of this drug is limited to the gut.[28] Azithromycin has been recommended for treatment of traveler's diarrhea in countries where antibiotic resistance is prevalent.

Bismuth subsalicylate has also been shown to be particularly active against mild-moderate traveler's diarrhea, although it is considered less effective than antibiotics. A regimen of 520 mg (2 fluid oz [60 mL] of the liquid suspension or two 260-mg tablets) taken four times a day is effective for the prevention of traveler's diarrhea.[32] If started after the onset of diarrhea, it diminishes the number of loose bowel movements and relieves abdominal cramps. The preparation is well tolerated, and constipation is not a problem. As described previously, the mechanisms of action of bismuth subsalicylate are complex and incompletely understood. Bismuth subsalicylate possesses an antibacterial effect, but this may not be its major action. Salicylate is absorbed, but its exact role is undetermined. Patients on anticoagulants should seek medical advice before using this medication because they may get an additional antiplatelet effect from the salicylate. Travelers taking doxycycline for malaria prophylaxis should not take bismuth

subsalicylate because it interferes with the absorption of the doxycycline.

An effective treatment for traveler's diarrhea in most parts of the world consists of loperamide (4 mg loading dose, then 2 mg orally after each loose stool, to a maximum of 16 mg/day) plus a single dose of a fluoroquinolone antibiotic. This regimen usually relieves symptoms within 24 hours. If diarrhea persists after 1 day of therapy, treatment should be continued for 1 or 2 more days. The antimicrobial combination product trimethoprim-sulfamethoxazole has also been used successfully in the past, but resistance to it has become common in many areas, and its use is no longer recommended.[32]

In countries where traveler's diarrhea is prevalent, what one ingests or avoids ingesting may be as important as chemoprophylaxis in reducing the risk. Common sense is an important preventive measure. Helpful maxims to keep in mind include "boil it, cook it, peel it, or forget it" and the "rule of P's": food is safe if it is peelable, packaged, purified, or piping hot.[20]

GASTROINTESTINAL STIMULANTS

Drugs that stimulate smooth muscle of the gastrointestinal and urinary tracts are used in the treatment of nonobstructive urinary retention, paralytic ileus, gastrointestinal atony, and postoperative abdominal distention. Cholinomimetic agents such as bethanechol are effective in these situations by promoting gastrointestinal motility (see Chapter 8). Bethanechol is a useful agent because it is resistant to metabolism by cholinesterase enzymes, its actions are essentially stimulatory to the muscarinic M_3 receptors, and its effects on the gastrointestinal tract are much more pronounced than its effects on the cardiovascular system. Previously used for the treatment of GERD and gastroparesis, it is now seldom used because of the introduction of less toxic agents. The side effects of bethanechol are those typical of other cholinergic drugs, but serious adverse reactions are rare with therapeutic doses. This drug is contraindicated in patients with obstructive ileus, obstructive urinary retention, peptic ulcer, bronchial asthma, hyperthyroidism, or serious cardiac disease.

Gastroparesis (gastric stasis) is a clinical syndrome characterized by delayed gastric emptying that leads to debilitation. It is most commonly seen in patients with diabetes mellitus and is characterized by intractable nausea, vomiting, early satiety, abdominal pain, and bloating.[17] Therapeutic success is often elusive. The use of a prokinetic agent is the best option for acute exacerbations and long-term maintenance therapy. Metoclopramide, the dopamine D_2 receptor antagonist cited earlier for its antiemetic action, and the macrolide antibiotic erythromycin both have prokinetic actions that are commonly used in the management of gastroparesis. Erythromycin acts as a motilin receptor agonist to stimulate gastrointestinal activity (see Chapter 39). Metoclopramide, possessing cholinomimetic and dopamine antagonist properties, is also useful in this syndrome because the drug stimulates the motility of the upper gastrointestinal tract. Metoclopramide augments esophageal peristalsis, gastric antral contractions, and the rate of intestinal transit. In addition, metoclopramide increases the resting pressure of the lower esophageal sphincter but reduces the resting pressure of the pyloric sphincter. It does not stimulate gastric, biliary, or pancreatic secretions and has little effect on colonic motor activity.

Oral administration of metoclopramide is indicated for relief of symptoms associated with diabetic gastroparesis. The usual duration of therapy is 2 to 8 weeks, depending on the response. An injectable form of metoclopramide is also approved for use in facilitating intubation of the small intestine and the passage of barium into the intestine for radiographic procedures. Of particular concern to the dentist is that the use of opioids or anticholinergic drugs antagonizes the gastrointestinal effects of metoclopramide.

IRRITABLE BOWEL SYNDROME

IBS is the most common disorder diagnosed by gastroenterologists and one of the most common gastrointestinal conditions encountered by family practice physicians. It is characterized by abdominal pain and discomfort in association with altered bowel habits (diarrhea, constipation, or both). IBS is reported to affect 5% to 11% of the population worldwide.[27] Pharmacologic treatment of IBS differs from patient to patient and is directed at relieving abdominal discomfort and improving bowel function. Antidiarrheal agents, especially loperamide, are helpful for patients with predominant diarrhea. Increasing dietary fiber is often helpful for IBS patients presenting with constipation. Increasing dietary fiber (e.g., psyllium) may increase gas production and exacerbate abdominal discomfort, however. For that reason, an osmotic cathartic agent such as milk of magnesia is commonly used to soften stools and increase stool frequency.

Anticholinergic drugs such as dicyclomine, inhibitors of muscarinic cholinergic receptors in the enteric plexus and on smooth muscle, previously were commonly used to provide relief of abdominal discomfort through antispasmodic actions. These drugs are now infrequently used because of the significant anticholinergic effects they produce (e.g., xerostomia, urinary retention). Newer therapeutic modalities for IBS include serotonin 5-HT_3 receptor antagonists (alosetron) and serotonin 5-HT_4 receptor agonists (tegaserod).

ADVERSE REACTIONS OF THE GASTROINTESTINAL SYSTEM TO DRUGS

The gastrointestinal tract must be considered a target for the adverse side effects of many drug groups, some important to dentistry. Opioid analgesics may produce constipation, nausea, and vomiting. Aspirin-containing analgesic compounds are associated with gastric distress, fecal blood loss, and ulceration. All nonselective cyclooxygenase-inhibiting NSAIDs share the gastric irritation and ulcerogenic action of aspirin. The sedative-hypnotic alcohol chloral hydrate may be prescribed by the dentist for children or elderly patients. A major complaint against its use is the gastric irritation it produces.

Antibiotic agents are often associated with gastrointestinal distress, especially diarrhea. Antibiotics, especially agents with a broad spectrum of activity, affect the bacteria that normally exist in the large intestine. As a consequence, antibiotic-associated diarrhea develops. Typically, this diarrhea is caused from an overgrowth of C. *difficile* (C. *difficile*–associated diarrhea). Most antibiotics can cause C. *difficile*–associated diarrhea, but it is most commonly associated with clindamycin, amoxicillin, and the cephalosporins. Many drugs not directly related to dentistry cause a wide spectrum of gastrointestinal effects, including adverse effects on the oral cavity. Taste disturbances, especially in elderly patients, are often drug-induced. Xerostomia can be produced from numerous drug classes, including anticholinergics, antispasmodics, psychotropic agents, antihistamines, drugs for parkinsonism, and antihyperlipidemics. Drugs may also induce various oral lesions (e.g., erythema multiforme) in all age groups. Gingival hyperplasia is a well-known side effect from phenytoin, Ca^{++} channel blocker, and cyclosporine therapy.

DRUGS ACTING ON THE GASTROINTESTINAL TRACT

Nonproprietary (generic) name	*Proprietary (trade) name (selected)*
Antacids	
Algenic acid, sodium bicarbonate, magnesium carbonate	Gaviscon
Aluminum carbonate gel	Basaljel
Aluminum hydroxide gel	Amphojel
Calcium carbonate	Tums, Alka-Mints
Magaldrate (aluminum magnesium hydroxide sulfate)	Riopan
Magnesium hydroxide	Milk of Magnesia
Magnesium hydroxide/aluminum hydroxide	Maalox, Gelusil, Mylanta
Magnesium oxide	Mag-Ox 400, Uro-Mag
Sodium bicarbonate	Bell/ans
Sodium bicarbonate/aspirin	Alka-Seltzer
Sodium citrate	Citra pH
H_2 antagonists	
Cimetidine	Tagamet, Tagamet HB
Famotidine	Pepcid, Pepcid AC
Nizatidine	Axid, Axid AR
Ranitidine	Zantac, Zantac 75
***H. pylori* agents (combination packages)**	
Bismuth subsalicylate, metronidazole, tetracycline	Helidac
Lansoprazole, amoxicillin, clarithromycin	Prevpac
Prostaglandin analogue	
Misoprostol	Cytotec
Proton pump inhibitors	
Esomeprazole	Nexium
Lansoprazole	Prevacid
Omeprazole	Prilosec, Prilosec OTC
Pantoprazole	Protonix
Rabeprazole	Aciphex
Ulcer-adherent complex	
Sucralfate	Carafate
Antisialagogue*	
See Tables 9-5 and 33-1	
Emetic	
Ipecac syrup	Ipecac

CHAPTER 34

Pituitary, Thyroid, and Parathyroid Pharmacology

GAIL T. GALASKO

HYPOTHALAMIC AND PITUITARY HORMONES

The pituitary gland consists of an anterior lobe (adenohypophysis) and a posterior lobe (neurohypophysis). It is connected to the hypothalamus, which lies above it, by the stalk that contains neurosecretory fibers and capillaries. The hypophyseal portal system drains the hypothalamus and perfuses the anterior pituitary. Numerous releasing factors or regulating hormones that are produced by the hypothalamus are carried to the anterior pituitary by this portal system. These hypothalamic releasing factors stimulate the anterior pituitary to produce and secrete numerous tropic hormones, which stimulate target glands to produce hormones. The hypothalamic releasing factors, anterior pituitary hormones produced, target glands, and target gland hormones are presented in Table 34-1. Pituitary hormone secretion is regulated by negative feedback. For anterior pituitary hormones, secretion of releasing factors from the hypothalamus is decreased when the concentration of target gland hormones is high and increased when it is low.

POSTERIOR PITUITARY HORMONES

The posterior lobe of the pituitary secretes two homologous peptide hormones, vasopressin and oxytocin. These hormones are synthesized in the hypothalamus and transported via the neurosecretory fibers of the stalk to the posterior pituitary, where they are stored and released. Both of these hormones are nonapeptides, and their structures are similar.

Vasopressin

Vasopressin (antidiuretic hormone [ADH]) acts on the kidney to increase water reabsorption. It increases total peripheral resistance and has an important role in the long-term control of blood pressure. Vasopressin also has a vasoconstrictor action that plays a role in the short-term regulation of arterial pressure. There are two subtypes of vasopressin receptors. V_1 receptors, which are $G_{q/11}$ protein–linked, produce their action by stimulation of phospholipase C and formation of inositol triphosphate. This is the pathway responsible for the vasoconstrictor action of vasopressin. V_2 receptors, which are G_s protein–linked, cause stimulation of adenylyl cyclase and increase cyclic adenosine 3′,5′-monophosphate (cAMP) formation. Stimulation of V_2 receptors by vasopressin leads to its antidiuretic effect. Lack of ADH leads to diabetes insipidus, resulting in polyuria and polydipsia.

Pharmacokinetics

Vasopressin may be given intravenously, intramuscularly, or intranasally. Because the drug is rapidly metabolized in the liver and kidney, the half-life is approximately 20 minutes.

Therapeutic uses

Vasopressin and desmopressin acetate, a long-acting synthetic analogue that acts predominantly at V_2 receptors, are used to treat diabetes insipidus. The receptors mediating this effect are located on the cells of the collecting duct in the kidney. Vasopressin is also used to control bleeding in certain conditions (e.g., colonic diverticular bleeding). Vasopressin stimulates the release of von Willebrand factor and clotting factor VIII and is used to treat deficiencies of these factors in certain types of hemophilia. Desmopressin is also used to decrease nocturnal enuresis. Felypressin, a synthetic analogue of vasopressin, is a vasoconstrictor that is used outside the United States with local anesthetics as an alternative to epinephrine.

Oxytocin

Oxytocin receptors are $G_{q/11}$ protein–linked receptors that, when stimulated, lead to an increase in intracellular Ca^{++} and muscle contraction. Oxytocin causes contraction of uterine smooth muscle and may play a role in the initiation of labor. Oxytocin also stimulates milk ejection in lactating mothers by stimulating myoepithelial cells around the alveoli of the mammary glands. Recent data suggests that oxytocin is a neuropeptide involved in a wide array of social behaviors in diverse species. Maternal bonding, social decision making, and processing of social stimuli and social memory are enhanced by increased levels of oxytocin.

Pharmacokinetics

Oxytocin has a circulating half-life of 5 minutes. It is not bound to plasma protein and is metabolized in the liver and kidneys.

Therapeutic uses

Oxytocin is used intravenously for stimulation of labor and to induce postpartum lactation in cases of breast engorgement. Investigations are underway for its use in therapeutic interventions in a variety of conditions, especially those characterized by anxiety and aberrations in social function, such as autism.[12]

ANTERIOR PITUITARY HORMONES

Growth Hormone

Growth hormone (GH), also known as somatotropin, is the most abundant of the anterior pituitary hormones. The principal form of GH is a 191-amino acid single-peptide chain with two sulfhydryl bridges. GH for pharmacologic use is

TABLE **34-1**

Hypothalamic Stimulatory Releasing Factors, Corresponding Anterior Pituitary Tropic Hormones, Target Glands, and Target Gland Hormones

HYPOTHALAMIC HORMONE	PITUITARY HORMONE	TARGET ORGAN	HORMONE PRODUCED
Corticotropin-releasing hormone	Adrenocorticotropin	Adrenal cortex	Glucocorticosteroids, mineralocorticosteroids, androgens
GH-releasing hormone	GH (somatropin)	Liver, bone, other tissues	IGFs
Gonadotropin-releasing hormone	Follicle-stimulating hormone, luteinizing hormone	Gonads	Estrogen, progesterone, testosterone
Thyrotropin-releasing hormone	Thyroid-stimulating hormone	Thyroid	T_4, T_3

GH, Growth hormone; *IGFs,* insulin-like growth factors; T_3, triiodothyronine; T_4, thyroxine.

produced by recombinant DNA techniques and contains the 191-amino acid sequence of somatotropin, recombinant human GH, or 192 amino acids consisting of somatotropin plus an extra methionine at the amino terminal end. These preparations are equipotent.

Actions

GH has direct and indirect effects. Its action is through cell surface receptors (JAK/STAT family). The direct actions of GH include lipolysis in fat cells and stimulation of hepatic glucose output. These effects are opposite to those of insulin. The anabolic and growth-promoting effects of GH are indirect and are mediated by insulin-like growth factor type I (IGF-I). IGF-I stimulates chondrogenesis and skeletal and soft tissue growth. IGF-I increases mitogenesis, increasing cell number rather than cell size. GH-releasing hormone from the hypothalamus stimulates GH release. Somatostatin from the hypothalamus inhibits GH release and release of gastrointestinal secretions.

In contrast to the direct effects of GH, the effects mediated by IGF-I are insulin-like. IGF-I acts through cell membrane receptors that resemble those of insulin. Insulin at high doses may act at IGF-I receptors and vice versa (see Chapter 36). In pharmacologic doses, GH causes an initial insulin-like effect followed by an effect antagonistic to that of insulin.

Pharmacokinetics

Circulating endogenous GH has a half-life of 20 to 25 minutes, although slow-release forms are available allowing injections once or twice a month. Human GH can be given subcutaneously, with peak plasma levels reached in 2 to 4 hours. Metabolism occurs in the liver and the kidney.

Therapeutic uses

GH (somatrem, somatropin) is used in the treatment of growth failure in children (pituitary dwarfism), wasting in acquired immunodeficiency syndrome (AIDS), and somatotropin deficiency syndrome. Short-term treatment of GH-deficient adults results in increased lean body mass, decreased fat mass, increased exercise tolerance, and improved psychological well-being. It is sometimes abused by athletes[6] or used for its antiaging effect. GH is a potent anabolic agent and may have a role in clinical management of burn injuries. The GH-releasing hormone analogue sermorelin is used to treat GH deficiency in children who have growth retardation and diagnostically to determine the GH-releasing capacity of the pituitary. Octreotide, a somatostatin analogue that inhibits GH release, is approved for use in treating symptoms of vasoactive intestinal tumors, metastatic carcinoid tumors, and acromegaly. Other uses include AIDS-associated diarrhea and esophageal varices. Pegvisomant, a competitive antagonist of GH, is used to treat acromegaly.

TABLE **34-2**

Hypothalamic Inhibitory Releasing Factors, Anterior Pituitary Hormones Inhibited, and Target Glands

HYPOTHALAMIC HORMONE	PITUITARY HORMONE INHIBITED	TARGET ORGAN
Dopamine	Prolactin	Breast
Somatostatin	Growth hormone	Liver, bone, other

Adverse effects

GH may induce relative insulin resistance. It has been documented to cause diabetes in AIDS patients[16] and decreased insulin sensitivity that is dose-dependent, with a possible increase in type 2 diabetes in children.[5] It may cause scoliosis in children. Arthralgia, especially in the hands and wrist, may occur. Patients may have headaches, especially in the first few months of therapy, and should be carefully observed (monitored) because of the possibility of intracranial hypertension.

Prolactin

Prolactin is an anterior pituitary hormone that is similar in structure to GH. Prolactin increases the growth of the secretory epithelium in the breast and stimulates the production of milk. Although prolactin is not used clinically, the secretion of prolactin can be altered by certain drugs. Because dopamine inhibits prolactin release (Table 34-2), drugs that affect dopamine levels or dopamine receptors in the pituitary affect prolactin release. Bromocriptine and cabergoline are dopamine-receptor agonists that are used to inhibit prolactin release and reduce the size of pituitary prolactin-releasing tumors.

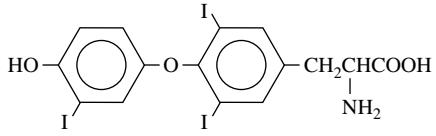
Thyrotropin (Thyroid-Stimulating Hormone)

Thyrotropin (thyroid-stimulating hormone [TSH]) is a glycoprotein hormone consisting of two subunits (α and β). Secretion is pulsatile and follows a circadian rhythm, with levels of TSH being highest during sleep at night. TSH secretion is controlled by thyrotropin-releasing hormone (TRH), which is inhibited by thyroid hormone negative feedback. Because TRH is stimulated by cold and decreased by severe stress, TSH is also affected by these conditions. TSH stimulates the thyroid to synthesize thyroglobulin and the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3). An increase in the amount of free thyroid hormone in the circulation results in decreased TSH gene transcription and decreased TSH secretion.

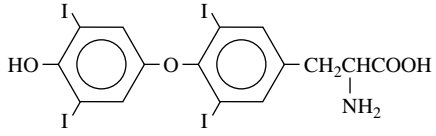
The TSH receptor is G protein–coupled. The effects of TSH are mediated by stimulation of adenylyl cyclase and increased cAMP (G_s–adenylyl cyclase–cAMP) in the thyroid cell. TSH also causes activation of phospholipase C (G_q-PLC). TSH is used for diagnostic purposes and to stimulate iodine (^{131}I) uptake in some patients with thyroid cancer (see later).

THYROID HORMONES

The active principles of the thyroid gland are iodine-containing amino acid derivatives of thyronine. They are formed from iodinated tyrosine residues. The structures are shown in Figure 34-1.



Triiodothyronine (T_3)



Thyroxine (T_4)

FIGURE **34-1** Structure of thyroid hormones.

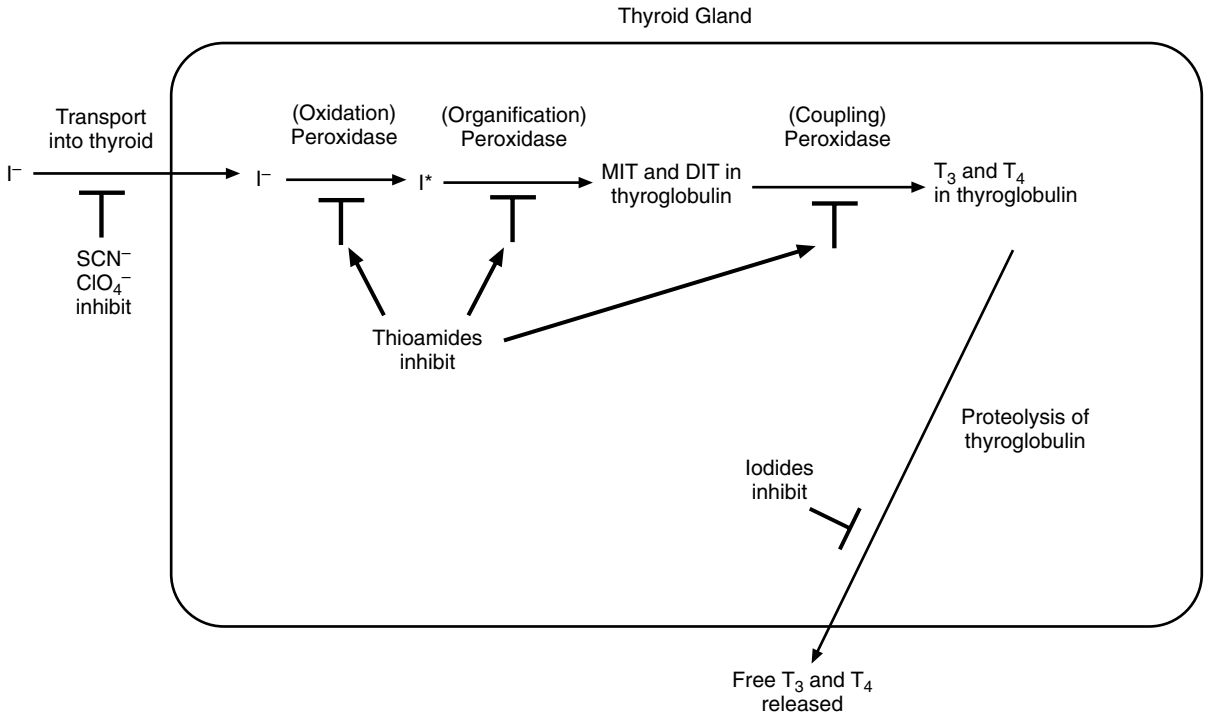
Synthesis of Thyroid Hormones

The synthesis of thyroid hormones is shown schematically in Figure 34-2. The first step is uptake of iodide by the thyroid gland. This step may be inhibited by ions of similar size and charge such as perchlorate. Iodide uptake is followed by oxidation of iodide to hypoiodite and iodination of tyrosyl groups of thyroglobulin to form iodotyrosyl groups. Tyrosine residues within the thyroglobulin molecule may be monoiodinated to monoiodotyrosine (MIT) or diiodinated to form diiodotyrosine (DIT). This step is catalyzed by thyroperoxidase and is rapid. Iodotyrosyl residues are coupled to form iodothyronyl residues within thyroglobulin. This may be either MIT plus DIT to form T_3 or DIT plus DIT to form T_4. The ratio of T_4 to T_3 formed is approximately 4:1. The coupling of iodotyrosyl groups is also catalyzed by peroxidase enzyme. Thyroid hormones are released by proteolysis of thyroglobulin. Most of the hormone released is T_4, which is converted to T_3 in peripheral tissues by iodothyronine deiodinases. T_3 is about four times more potent than T_4.

Control of Thyroid Hormone Secretion

The effect of TSH on the thyroid gland is to stimulate the synthesis and secretion of thyroid hormones T_4 and T_3 (see previous discussion). In addition to TSH, the iodine concentration in the blood plays an important role in regulating the uptake of iodide and formation of thyroid hormones in the thyroid gland. Iodination and thyroid hormone release can be inhibited by larger doses of iodides.

The hypothalamic-pituitary-thyroid axis is stimulated by cold and decreased in severe stress. It is under negative feedback control of the thyroid hormones, which act on the hypothalamus to decrease TRH synthesis and secretion, and on the pituitary to block the action of TRH.



*= Iodine in hypoiodate form

FIGURE **34-2** Synthesis of thyroid hormones and sites of action of various antithyroid drugs. *DIT,* Diiodotyrosine; *MIT,* monoiodotyrosine; *T_3,* triiodothyronine; *T_4,* thyroxine.

Actions of Thyroid Hormones

Thyroid hormones act by diffusing across the cell membrane and binding to intracellular receptors in target tissues. T_4 is converted to T_3 inside the cell. T_3 has greater affinity than T_4 for the receptors. The action of thyroid hormones leads to an increase in transcription, resulting in synthesis of proteins that produce many of the actions of thyroid hormones. Thyroid hormones are crucial in normal development and metabolism. They have a critical effect on growth, partly by direct action and partly by potentiating GH. Thyroid hormones are important for a normal response to parathyroid hormone (PTH) and calcitonin. They are crucial for nervous and skeletal tissues. Thyroid deficiency during development causes cretinism, characterized by mental retardation and dwarfism.

In addition, thyroid hormones are regulators of metabolism in most tissues. They increase basal metabolic rate and resting respiratory rate. Thyroid hormones stimulate the heart, resulting in the heart beating more rapidly and with greater force and an increase in cardiac output. Energy use in skeletal muscle, liver, and kidney is also markedly stimulated. T_3 sensitizes the heart to the effects of circulating endogenous catecholamines by a direct effect on Ca^{++} channels,[8] and thyroid hormones cause an increase in myocardial β-adrenergic receptors.[17]

Pharmacokinetics

The thyroid hormones are highly protein-bound; the major plasma-binding protein is thyroxine-binding globulin. They are also bound by thyroxine-binding prealbumin and albumin. The half-life of T_4 is normally 6 to 7 days; this is shortened to 3 to 4 days in hyperthyroidism. T_3 binds more loosely to plasma proteins and has a half-life of approximately 2 days.

THYROID DISORDERS

Worldwide, the most common cause of thyroid disorders is iodine deficiency. In the United States, the leading cause of hypothyroidism is Hashimoto's thyroiditis, an autoimmune disease. Graves' disease (diffuse toxic goiter), also an autoimmune disorder, is the most common cause of hyperthyroidism in the United States.

Hypothyroidism

Thyroid deficiency during development causes cretinism, which is characterized by gross retardation of growth and mental deficiency. In an adult, thyroid deficiency results in hypothyroidism and, in more severe cases, myxedema. Hypothyroidism is a common endocrine disorder affecting 1.4% to 2% of women and 0.1% to 0.2% of men. The prevalence of overt and subclinical hypothyroidism is significantly greater in women than in men and increases dramatically in women after age 40 years, affecting 5% to 10% of women older than 50 years.[2] Subclinical hypothyroidism is common, especially among older women.[15] It has been suggested that this condition may be associated with an increased mortality rate, particularly from cardiovascular disease and a subtle decrease in myocardial contractility.[11] Subclinical hypothyroidism is associated with a small increase in low-density lipoprotein cholesterol and a decrease in high-density lipoprotein cholesterol, changes that increase risk of atherosclerosis and coronary artery disease.[10] Cognitive impairment occurs in hypothyroidism, and attention, motor speed, memory, and visual spatial organization all are significantly impaired.[4] In addition, hypothyroidism is an important risk factor for carpal tunnel syndrome.[14]

Signs and Symptoms of Hypothyroidism

Typical symptoms of hypothyroidism include lethargy; fatigue; loss of energy and ambition; slowing of intellectual and motor activity; decreased appetite; increased weight; and skin that is dry, cold, and coarse. Hair loss, including loss of the outer third of eyebrows, occurs. Hypothyroid patients have cold intolerance, bradycardia, hypotension, and increased capillary fragility. They also show an exaggerated response to central nervous system depressants such as sedatives and narcotic analgesics.

Replacement Therapy

Animal products include desiccated thyroid, which is composed of animal thyroid glands. Numerous preparations of levothyroxine sodium (T_4) are available. Liothyronine sodium (T_3) and liotrix, a mixture of T_4 and T_3 in a 4:1 ratio, are also available. Synthetic T_4 has a uniform content and a long half-life and is the preferred and most widely used thyroid replacement medication. Because of its greater potential for cardiotoxicity and its shorter half-life, the use of T_3 is controversial and much less frequent. Nevertheless, for some patients, the combination of T_3 and T_4 is better than T_4 alone.[3] Animal experiments have shown that in rats, only replacement of T_3 and T_4 ensures euthyroidism in all tissues.

The thyroid hormones are well absorbed after oral administration. Absorption of T_4 may be decreased, however, by food, Ca^{++} preparations, and aluminum-containing antacids. Absorption of T_4 is best if it is taken on an empty stomach in the morning. Absorption of T_3, which is almost completely absorbed, is not affected by food.

Levothyroxine has a half-life of approximately 7 days. It takes about 1 month to reach steady state. The half-life of liothyronine is shorter (<2 days), as is its duration of action.

Hyperthyroidism

Hyperthyroidism may be caused by Graves' disease (diffuse toxic goiter), an autoimmune disorder, or toxic nodular goiter. Graves' disease is the most common cause of hyperthyroidism in the United States. In hyperthyroidism (thyrotoxicosis), there is an excess of thyroid hormones, resulting in a high metabolic rate, increased heart rate and contractility, and increased sensitivity to catecholamines. Other signs and symptoms include increased appetite but decreased weight, weakened skeletal muscles or muscle wasting, increased body temperature, sensitivity to heat, nervousness, and tremor. Exophthalmus may be present in Graves' disease.

Hyperthyroidism may be treated surgically or pharmacologically. The most common treatments are described subsequently.

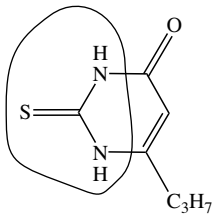
DRUGS USED IN THE TREATMENT OF HYPERTHYROIDISM

The major drugs used to inhibit production of thyroid hormones are radioactive iodine (^{131}I), thioamides, and iodide.

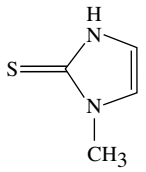
Radioactive Iodine

The ^{131}I isotope has a half-life of 8 days and emits γ radiation and β particles. Given orally, it is concentrated in the thyroid, where the β particles destroy the gland. Symptoms of hyperthyroidism begin to improve in a few days to a few weeks, but 2 to 3 months are often required for a complete effect.

^{131}I is selective for the thyroid gland. Advantages of the use of ^{131}I include the comparative low cost because surgery is not required and the fact that no deaths have been reported resulting from this treatment. The disadvantage of this treat-



Propylthiouracil



Methimazole

FIGURE **34-3** Chemical structure of propylthiouracil and methimazole. The thiocarbamide group is circled in propylthiouracil.

ment is that hypothyroidism frequently occurs as a delayed effect. It is now believed, however, that hypothyroidism may represent the end stage of hyperthyroidism rather than overtreatment with ^{131}I. ^{131}I should be avoided in children and pregnant patients. Uptake of low-dose ^{131}I may be used as a test of thyroid function.

Thioamides

Propylthiouracil and methimazole are the most important antithyroid drugs used in the United States within the thioamides (Figure 34-3). These drugs are related to thiourea and contain a thiocarbamide group that is essential for their antithyroid activity.

Mechanism of action

Thioamides inhibit thyroid peroxidase, decreasing iodide oxidation, iodination of tyrosines, and coupling of iodotyrosyl and iodothyronyl residues (see Figure 34-2). As a result, less thyroid hormone is synthesized. Propylthiouracil also inhibits the peripheral conversion of T_4 to T_3.

Pharmacokinetics

Thioamides are given orally. Methimazole is distributed throughout body water and has a plasma half-life of 6 to 15 hours. An average dose produces more than 90% inhibition of thyroid incorporation of iodide within 12 hours, but the clinical response takes weeks to manifest because of the long half-life of T_4 and because there may be stores of hormone in the thyroid that need to be depleted. The actions of propylthiouracil may be seen more quickly because of the inhibition of peripheral conversion of T_4 to T_3.

Adverse effects

Adverse effects include occasional, reversible, yet rapidly developing agranulocytosis; rashes; pain; stiffness in joints; paresthesias; and loss or depigmentation of hair.

Therapeutic uses

Thioamides are used to control hyperthyroidism in anticipation of spontaneous remission, before surgery, or together with ^{131}I to hasten recovery from hyperthyroidism.

Ionic Inhibitors

Ionic inhibitors interfere with the concentration of iodide by the thyroid gland. They are monovalent anions that resemble iodide. Examples include thiocyanate and perchlorate. Their effects may be overcome by large doses of iodides. Thiocyanate, which is not used therapeutically, may be formed during the digestion of certain foods such as cabbage and has an antithyroid effect.

Iodide

Iodide is the oldest remedy for thyroid disorders. Iodine/iodides are required for thyroid hormone synthesis (see Figure 34-2); however, high concentrations of iodide limit its own transport. In addition, high concentrations of iodide inhibit synthesis of iodotyrosines and iodothyronines (organification) and inhibit thyroid hormone release. These effects, which depend on intracellular concentrations of iodide, are transient. High plasma iodide concentrations also inhibit release of thyroid hormones. Iodide has been used preoperatively in preparation for thyroidectomy because it makes the gland less vascular. Iodide is also used together with antithyroid drugs and propranolol to treat thyrotoxic crisis.

Hypersensitivity to iodides is the major adverse effect. Iodism, which is chronic iodine toxicity, has many adverse effects, including unpleasant taste, burning in the mouth and throat, soreness of teeth and gingiva, and increased salivation. Symptoms similar to those of a head cold commonly occur, as do skin eruptions, gastric irritation, and diarrhea. Inflammation of the larynx, tonsils, and lungs and enlargement of the parotid and submandibular glands may occur. Iodide concentrates in salivary glands.

IMPLICATIONS FOR DENTISTRY

Subclinical hypothyroidism and hyperthyroidism are common, well-defined conditions that often progress to overt disease. The clinical presentation of thyroid disorders is often subtle in older adults and may be confused with normal aging.

Hypothyroidism

Hypothyroidism is five to six times more common than hyperthyroidism. Hypothyroidism affects 7 to 10 times as many women as men, and the incidence of the disease increases sharply with age in women after age 40 years, affecting 5% to 10% of women older than 50 years.[2,15] Subclinical states may contribute to hyperlipidemia, cardiac dysfunction, and osteoporosis.[15]

The dentist may be in a position to detect signs and symptoms of subclinical thyroid disease and refer the patient for medical evaluation and treatment; this is very important in hypothyroidism, in which signs and symptoms are subtle and similar to those of depression (Box 34-1). As a result, the disease may not be diagnosed. Subclinical hypothyroidism in younger individuals may manifest as delayed eruption of teeth, malocclusion, and skeletal growth retardation. Other oral manifestations of hypothyroidism include tongue enlargement and scalloping. Hypothyroid patients have increased capillary fragility and show an exaggerated response to central nervous system depressants such as sedatives and opioids.

Clinical hypothyroidism or myxedema may be recognized by a patient's dull expression; puffy eyelids; alopecia of the outer third of the eyebrows; dry, rough skin; dry, brittle, coarse hair; increased size of the tongue; slowing of physical and mental activity; anemia; constipation; and increased sensitivity to cold. In patients with myxedema, stressful situations such as surgery, trauma, or infections may precipitate myx-

Depressed mood
Decreased interests
Weight gain
Disturbed sleep
Muscle weakness/slow speech
Disturbed concentration and cognition
Feelings or guilt or inadequacy/inability to cope

edematous coma. Myxedematous coma is very rare and occurs predominantly in elderly women and has a greater than 50% mortality rate.[1]

Hyperthyroidism

Thyrotoxicosis is characterized by warm, moist skin; a rosy complexion; weight loss; fine, friable hair; and nail softening. Profuse sweating is common in these patients. Achlorhydria may occur, and approximately 3% of individuals affected develop pernicious anemia. Hyperthyroid individuals are nervous, emotionally labile, and always moving. They display tremor of the hands and tongue and muscle weakness. In thyrotoxicosis there is increased bone loss. In these patients there is also increased stroke volume and heart rate and palpitations. Supraventricular arrhythmias may occur. Graves' ophthalmopathy may be recognized by eyelid retraction, proptosis, and a bright-eyed stare. Patients who are hyperthyroid are highly sensitive to epinephrine. Propranolol alleviates adrenergic symptoms such as sweating, tremor, and tachycardia.

Oral complications of thyrotoxicosis include osteoporosis of the alveolar bone. Dental caries and periodontal disease appear more frequently. In children, teeth and jaws develop more rapidly, and there is early loss of deciduous teeth and early eruption of permanent teeth. Changes in the gingiva resulting from hyperthyroidism may lead to ill-fitting dentures.

HORMONES OF Ca^{++} HOMEOSTASIS

Parathyroid Hormone

The parathyroid glands (there are usually four) are embedded within the posterior surface of the thyroid. The principal cells secrete PTH, which is formed by proteolysis of a larger precursor. PTH is a single-chain polypeptide containing 84 amino acids and has a molecular weight of approximately 9500 Da. Loss of the first two amino acids eliminates most biologic activity.

Regulation of secretion

The principal factor in control of PTH secretion is plasma Ca^{++} concentration. High plasma Ca^{++} concentration decreases PTH secretion; low Ca^{++} concentration stimulates it. Ca^{++} regulates PTH secretion by a G protein–coupled, cell surface Ca^{++}-sensing receptor. Phosphate regulates PTH secretion indirectly by forming complexes with Ca^{++}. Increases in phosphate concentration reduce Ca^{++} levels and increase PTH secretion. Calcitriol (1,25-dihydroxyvitamin D_3) directly inhibits PTH secretion by affecting gene transcription.

Pharmacologic effects

PTH regulates Ca^{++} and phosphate, causing an increase in plasma Ca^{++} and a decrease in plasma phosphate concentrations. The primary function of PTH is to maintain a constant extracellular Ca^{++} concentration.

The most important target tissues for PTH are bone and kidney. In bone, PTH increases Ca^{++} and phosphate release by increasing bone resorption. It acts on the osteoblast to induce RANK ligand (RANKL), which stimulates osteoclast activity, resulting in increased bone turnover. Bone formation and bone resorption are enhanced by PTH. With constant dosing, PTH increases bone resorption. When PTH is given intermittently at low doses, it stimulates cortical and trabecular bone growth.[13] Teriparatide (recombinant human PTH1-34) has been approved for the treatment of osteoporosis. In the kidney, PTH increases reabsorption of Ca^{++} and Mg^{++} and decreases reabsorption of phosphate. PTH also increases conversion of vitamin D to its active form, 1,25-dihydroxyvitamin D_3 (calcitriol), which is secreted into the circulation and acts in the gastrointestinal tract to increase the absorption of Ca^{++}.

Pharmacokinetics

PTH has a half-life of minutes, with clearance occurring mostly in the liver and kidney.

Calcitonin

Calcitonin is secreted by the parafollicular cells of the thyroid gland. Calcitonin is synthesized as a prohormone and processed to the hormone. There is considerable species variation in calcitonin. Human calcitonin is a single-chain peptide composed of 32 amino acids and has a molecular weight of 3600 Da. A disulfide bridge between positions 1 and 7 is essential for biologic activity.

Control of secretion

Elevated extracellular Ca^{++} concentration is the most important stimulator of calcitonin secretion. Calcitonin release is also stimulated by gastrointestinal tract hormones, including cholecystokinin and gastrin.

Actions

Calcitonin acts on G protein–linked cell surface receptors located on target tissues. It reduces plasma Ca^{++} and phosphate concentrations mainly by acting on bone to inhibit osteoclast activity and bone resorption. Calcitonin also acts on the kidney to increase urinary excretion of Ca^{++} and phosphate.

Therapeutic uses

Calcitonin is used in the treatment of Paget's disease, in which there is excessive, disorganized bone remodeling, and in some patients with osteoporosis. Salmon calcitonin, which is more potent and has a longer half-life than mammalian calcitonin, is typically used in therapy. It is given by injection or nasal spray.

Adverse effects

Nausea and gastrointestinal tract effects are the most common adverse effects. Rash with itching and swelling may also occur.

Vitamin D

Vitamin D is the name given to two related substances, cholecalciferol (vitamin D_3) and ergocalciferol (vitamin D_2). Both substances are active in humans and are able to prevent or cure rickets. Cholecalciferol is formed in the skin from 7-dehydrocholesterol by the action of ultraviolet irradiation; ergocalciferol comes from plants. Vitamin D is also found in dietary products.

The major action of vitamin D is control of Ca^{++} homeostasis. Vitamin D facilitates absorption of Ca^{++} and phosphate from the small intestine, interacts with PTH to enhance

TABLE **34-3**

Effects of Parathyroid Hormone and Vitamin D on Bone, Gastrointestinal Tract, and Kidney

ORGAN	PARATHYROID HORMONE	VITAMIN D
Bone	Low doses increase bone formation; high doses increase bone resorption	Secalcifediol may increase bone formation; calcitriol increases bone resorption
Gastrointestinal tract	Increases Ca^{++} and phosphate absorption (by increased calcitriol production)	Calcitriol increases Ca^{++} and phosphate absorption
Kidney	Decreases Ca^{++}, increases phosphate excretion	Decreases Ca^{++} and phosphate excretion
Overall effect	Increases plasma Ca^{++}, decreases plasma phosphate	Increases plasma Ca^{++} and plasma phosphate

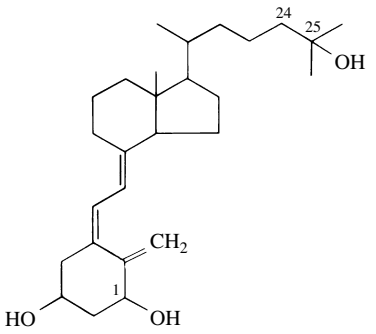

FIGURE **34-4** Structural formula of the primary active form of vitamin D: 1,25-dihydroxycholecalciferol (calcitriol).

mobilization of Ca^{++} and phosphate from bone, and decreases excretion of Ca^{++} and phosphate by the kidney. In addition, vitamin D has effects on bone remodeling. More recent studies suggest that vitamin D may have several other actions, including anti-inflammatory properties (downregulation of tumor necrosis factor-α, interleukin-6, interleukin-1, and interleukin-8). Vitamin D is used to treat secondary hypoparathyroidism.

The net effect of vitamin D is to increase serum Ca^{++} and serum phosphate. This is different from the net effect of PTH, which is to increase serum Ca^{++} and reduce serum phosphate. The effects of PTH and vitamin D are shown in Table 34-3.

Vitamin D is a prohormone that is a precursor to numerous biologically active metabolites. Cholecalciferol is biotransformed to 25-hydroxycholecalciferol (calcifediol) in the liver and converted further to 1,25-dihydroxyvitamin D_3 (calcitriol) and 24,25-dihydroxyvitamin D_3 (secalcifediol) in the kidney.

Calcitriol is biologically the most active metabolite of vitamin D (Figure 34-4).[20] It stimulates Ca^{++} and phosphate absorption from the gastrointestinal tract. Calcitriol is required for bone mineralization, although it directly stimulates bone resorption.[7] In the kidney, it slightly increases Ca^{++} and phosphate reabsorption. Receptors for calcitriol are found in various tissues, including bone, gut, and kidney. These are intracellular receptors, as are typical of other steroid hormone receptors. Calcitriol binding to its receptors leads to a selective increase in transcription and production of proteins such as Ca^{++}-binding proteins in the gastrointestinal tract. Calcitriol may also act directly on the membrane to alter Ca^{++} flux. In addition to its classic effects (discussed earlier), calcitriol has many other actions, including regulation of PTH secretion, cytokine production, and proliferation and differentiation of numerous cells. Secalcifediol stimulates bone formation and is essential for fracture healing.

Calcifediol (25-hydroxycholecalciferol) is more potent than calcitriol in stimulating renal reabsorption of Ca^{++} and phosphate. Calcifediol may be the major metabolite involved in the regulation of Ca^{++} flux and contractility in muscle.

High levels of Ca^{++} and phosphate reduce the amount of 1,25-dihydroxyvitamin D_3 produced by the kidney and decrease the amount of 24,25-dihydroxyvitamin D_3. Calcitriol directly inhibits PTH secretion by a direct action on PTH gene transcription.

Vitamin D is usually given orally. After absorption, vitamin D and its metabolites circulate in plasma bound to vitamin D–binding protein, which is an α globulin. Vitamin D (cholecalciferol) has a plasma half-life of 19 to 25 hours but is stored in fat for prolonged periods. The major circulating form is calcifediol, which has a half-life of 19 days. The half-life of calcitriol is 3 to 5 days.

Calcifediol and calcitriol are available for clinical use as vitamin D. In addition, doxercalciferol and paricalcitol have been approved for treatment of secondary hyperparathyroidism in patients with renal failure.

Bisphosphonates

Bisphosphonates are analogues of pyrophosphate (Figures 34-5 through 34-8). There are three distinct classes: non-nitrogen-containing bisphosphonates (etidronate, clodronate, tiludronate), linear nitrogen-containing bisphosphonates (pamidronate, alendronate, ibandronate), and ringed nitrogen-containing bisphosphonates (risedronate, zoledronic acid). Non-nitrogen drugs are very low potency, linear nitrogen drugs are moderate potency, and ringed nitrogen drugs are high potency.

The major action of bisphosphonates is inhibition of osteoclast-mediated bone resorption. Because osteoblasts require cytokines released from osteoclasts to differentiate them from their precursors, osteoblastic bone formation is coupled to osteoclastic bone resorption. By inhibiting the osteoclasts, a secondary, indirect decrease in bone formation occurs. This process is believed to be responsible for delaying healing and creating bisphosphonate osteonecrosis of the jaw.

The mechanisms of action of bisphosphonates are not completely understood. It is believed that bisphosphonates are incorporated into bone matrix and taken into the osteoclast during resorption, incapacitating it. Non-nitrogen-containing drugs apparently replace the distal phosphate in adenosine 5′-triphosphate (ATP), rendering it useless for energy production. Nitrogen-containing bisphosphonates have been shown to inhibit farnesyl diphosphate synthase, a crucial enzyme in the cholesterol biosynthesis pathway and in the isoprenylation of several regulatory proteins, including GTPases, Ras, Rac, Rho, and Cdc. The latter proteins play a rate-limiting role in the activity of the osteoclast.[18]

Pharmacokinetics

It is crucial to understand that there is a vast clinical difference between how orally administered bisphosphonates work versus intravenously administered preparations. Oral bisphos-

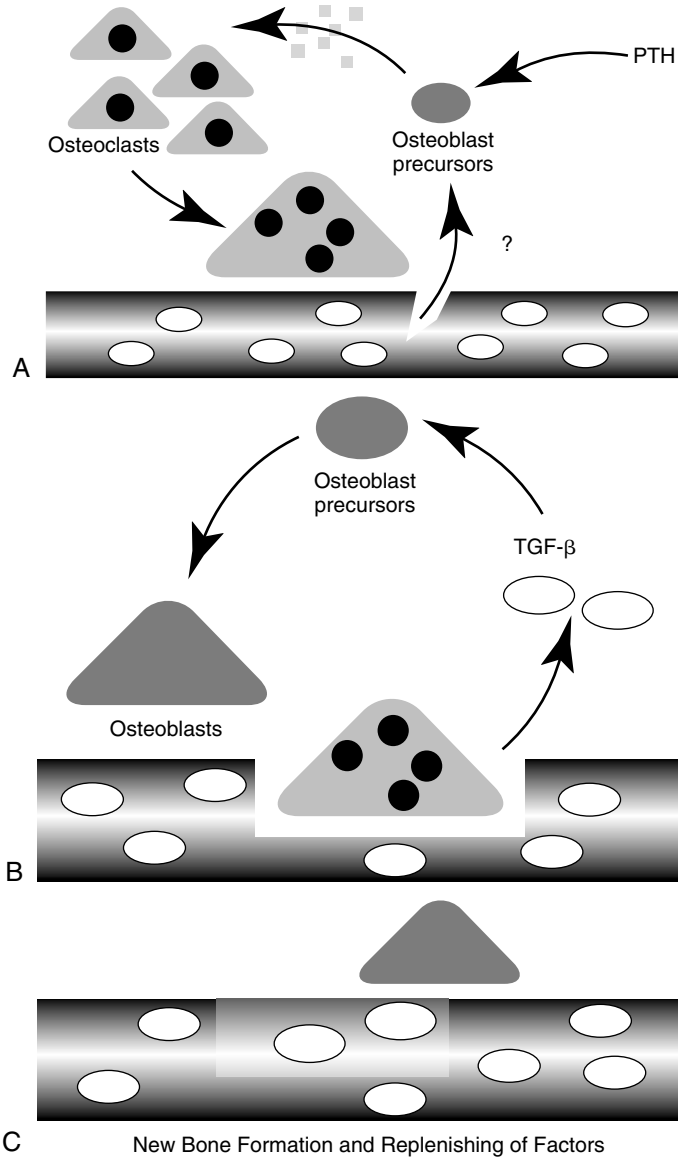

FIGURE **34-5** Normal physiologic bone processes. **A,** Microfractures that occur in bone release chemical mediators (as yet still unknown) that stimulate osteoblastic precursors to release cytokines (RANK ligand is among them). Parathyroid hormone *(PTH)* provides a similar stimulus. The cytokines trigger osteoclasts to coalesce into activated multinucleated cells. **B,** Activated osteoclasts break down the bone surrounding the microfracture. In so doing, they liberate transforming growth factor-β *(TGF-β)* and other cytokine factors housed in the structural bony matrix. TGF-β stimulates the osteoblast precursors to differentiate terminally into mature osteoblasts. **C,** Mature osteoblasts set down new bone matrix and replenish the intramatrix supply of growth factors. (Adapted from Green JR: Bisphosphonates: preclinical review, *Oncologist* 9[Suppl 4]:3-13, 2004.)

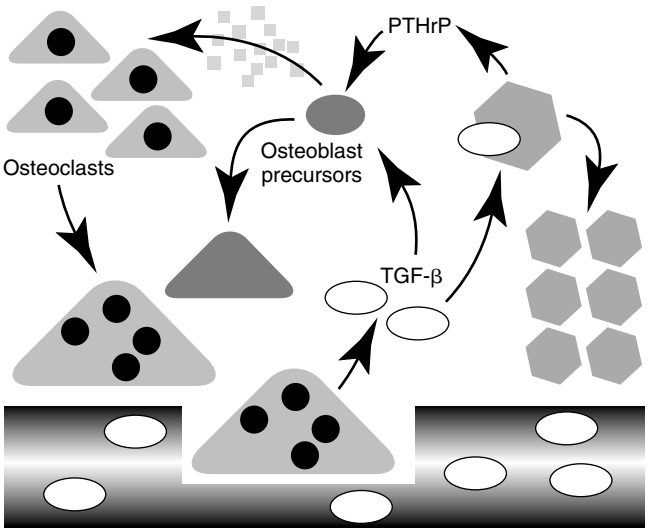

FIGURE **34-6** Cancer disruption theory. Metastatic cancer cells (illustrated as *hexagons*) are believed to disrupt the normal physiologic process in several ways. First, they "rob" the system of transforming growth factor-β *(TGF-β)* and use this growth factor to stimulate their own proliferation, giving rise to additional cancer cells. Second, they release parathyroid hormone–related peptide *(PTHrP)*, a similar peptide that can stimulate the osteoblastic precursors to release additional cytokines capable of activating the osteoclasts. Conceptually, with less TGF-β available to differentiate the osteoblasts and more cytokines available to activate the osteoclasts, the osteoclast numbers outweigh the osteoblasts, causing lytic lesions to occur in the bone. This process, coupled with the additional cancer cells, gives rise to metastatic lesions in bone and a state of hypercalcemia. (Adapted from Green JR: Bisphosphonates: preclinical review, *Oncologist* 9[Suppl 4]:3-13, 2004.)

phonates are poorly absorbed after administration, with only about 2% of the drug taken into the bloodstream. Food significantly decreases absorption. These drugs should be taken only with water, after an overnight fast, and 2 hours before breakfast. Bioavailability is reduced if coffee or orange juice is taken concurrently with these drugs. The lack of a sizable absorption profile is considered to be one of the major reasons why the risk of osteonecrosis of the jaw is very low with orally administered drugs, even if they are from the higher potency classes (e.g., alendronate and risedronate). The intravenously administered drugs, pamidronate and zoledronic acid, are estimated to have about 40% of their dose available to the bone after liver conjugation and renal elimination. The risk for osteonecrosis becomes much higher with the intravenous forms of these drugs, and in particular with zoledronic acid because of its particularly high potency. Orally administered drugs include alendronate, etidronate, ibandronate, risedronate, and tiludronate.

Bisphosphonates, in contrast to pyrophosphate, are not metabolized and are excreted unchanged in the urine. Plasma levels decrease by more than 95% within 6 hours, but the terminal half-life may exceed 10 years because they are slowly released from the skeleton, to which they bind.

Therapeutic uses

Bisphosphonates are used to treat diseases in which there is rapid bone turnover or excessive osteolytic activity.[19] They are used to treat osteoporosis, Paget's disease, and malignant bone disease. In the treatment of osteoporosis, alendronate and risedronate have been shown to decrease the incidence of fractures significantly and improve bone mineral density.[9,21] These two drugs do not have the effect of decreasing bone formation that is seen with etidronate.

In cancer, particularly breast cancer, inhibition of osteolysis has proved to be effective therapy for decreasing metastases to the jaws and malignancy-associated hypercalcemia and for adjunctive therapy in delaying or preventing cancer-related skeletal pain. Therapy reduces the incidence of fractures and

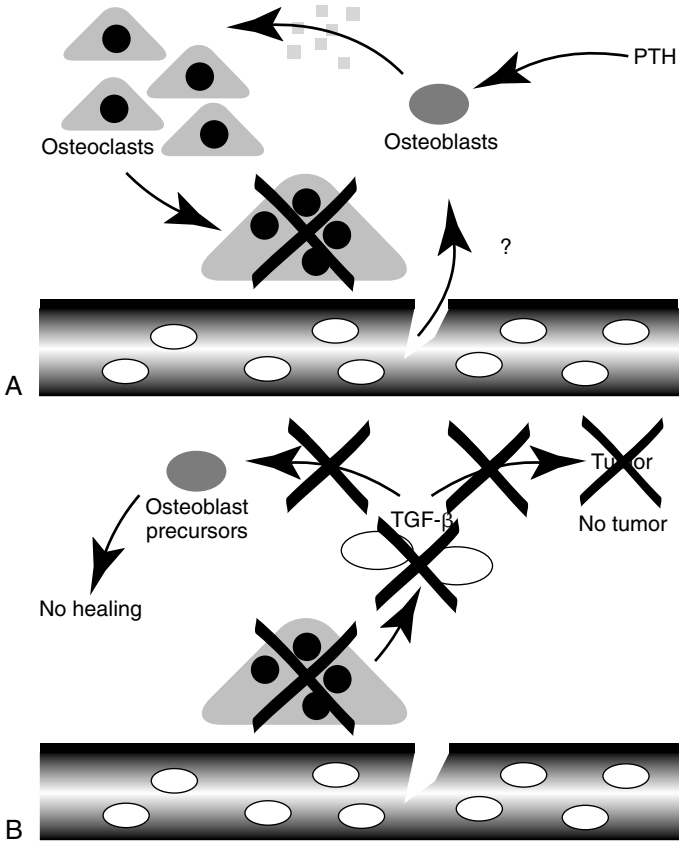

FIGURE **34-7** Effects of bisphosphonate drugs. Bisphosphonates are incorporated into the bony matrix by resembling pyrophosphate. Some bisphosphonates can stay bound and active for months to years. **A,** Bisphosphonates, through at least two different methods, act to disrupt the function of or induce apoptosis in osteoclasts (or both), rendering them partially or completely unable to break down the bone. *PTH*, parathyroid hormone. **B,** Without bony breakdown, transforming growth factor-β *(TGF-β)* is not released from the matrix, which not only limits tumor formation and hypercalcemia, but also reduces the ability of the bone to heal. This effect is presumed to be incomplete because not all osteoclasts are impeded. There is also an unanswered question of why this process seems to occur in the mandible to a greater degree than other bones of the body. (Adapted from Green JR: Bisphosphonates: preclinical review, *Oncologist* 9[Suppl 4]:3-13, 2004.)

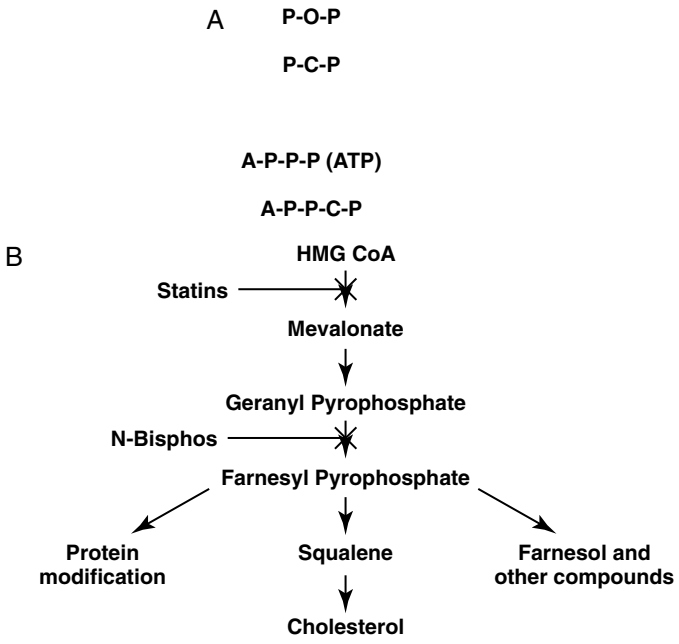

FIGURE **34-8** Pathways by which bisphosphonates seem to function. **A,** Bisphosphonates have a phosphate-carbon-phosphate structure that mimics the phosphate-oxygen-phosphate structure of pyrophosphate. In the non-nitrogen class of bisphosphonates (e.g., etidronate, clodronate, tiludronate), the osteoclastic inhibitory effect seems to result from integrating the bisphosphonate into adenosine 5′-triphosphate *(ATP)*, yielding a derivative *(A-P-P-C-P)* incapable of intracellular energy transfer by disrupting mitochondrial ATP/adenosine 5′-diphosphate translocase. **B,** In the nitrogen-containing bisphosphonates *(N-Bisphos)* (e.g., alendronate, pamidronate, risedronate, zoledronic acid), the mechanism seems to be interruption of a crucial rate-limiting step in the formation of farnesyl. Ras protein requires farnesylation to be activated. Without Ras activation, cytochrome *c* is released from the mitochondria, which causes caspase-3 activation, an apoptotic signaler. Statin drugs also interrupt this pathway but not as effectively because of their limited systemic uptake. The caspase-mediated apoptotic effect seems to be stronger than the ATP analogue effect provided by the non-nitrogen class of bisphosphonates. (Adapted from Green JR: Bisphosphonates: preclinical review, *Oncologist* 9[Suppl 4]:3-13, 2004.)

may reduce the need for radiation therapy. In Paget's disease, bisphosphonates reduce the rapid bone turnover rate and slow disease progression.[11]

Adverse effects

The most common adverse effects of bisphosphonates are gastrointestinal tract disturbances. Esophagitis can occur with oral preparations. To prevent esophagitis, oral preparations are given with liberal amounts of water and with the patient in an upright position. Proton pump inhibitors (see Chapter 33) can also be used. The use of an intravenous form of bisphosphonate such as zoledronic acid is another alternative. Bisphosphonates may cause musculoskeletal pain. Bisphosphonates have been shown to cause osteonecrosis, especially in the mandible and, to a much lesser extent, the maxilla. There is little evidence that these agents cause significant lesions elsewhere in the body. Although osteonecrosis occurs infrequently, it is most common in patients receiving intravenous bisphosphonate therapy. The risk of developing osteonecrosis in patients taking oral bisphosphonates is estimated to be about 1 per 100,000 person-years' exposure. For patients who are receiving intravenous bisphosphonate therapy for malignant neoplasms, it is recommended that the dentist avoid extractions unless critically necessary.

HYPOTHALAMIC, PITUITARY, THYROID, AND PARATHYROID DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Hypothalamic and pituitary drugs*	
Conivaptan	Vaprisol

CHAPTER 35

Adrenal Corticosteroids

CLARENCE L. TRUMMEL

The adrenal gland is the source of a diverse group of hormones essential to metabolic control, regulation of water and electrolyte balance, and modulation of the body's response to stress. The medullary portion of the gland secretes epinephrine and norepinephrine on sympathetic stimulation. These hormones and their physiologic effects and pharmacologic actions have been previously discussed (see Chapters 5 and 6). The adrenal cortex produces numerous substances derived from cholesterol and collectively known as *corticosteroids*. Certain corticosteroids and their synthetic analogues are used in medicine for replacement in adrenal insufficiency. They are used even more widely for an array of nonadrenal diseases, primarily for their notable ability to suppress the acute or chronic inflammation that accompanies injury and many diseases. When corticosteroids are administered in hyperphysiologic doses over long periods, as they often are in chronic inflammatory disorders, severe and even lethal toxicity can result. To understand the therapeutic applications and limitations of this group of drugs properly, the physiologic role of corticosteroids must be reviewed.

GENERAL PHYSIOLOGIC AND PHARMACOLOGIC ACTIONS

Using cholesterol as a substrate, the adrenal cortex synthesizes and secretes two types of steroid hormones—the 19-carbon androgens and the 21-carbon corticosteroids (Figure 35-1). The latter group can be considered derivatives of pregnane (Figure 35-2). The corticosteroids can be classified further on the basis of their major actions. Some of these compounds, such as hydrocortisone (the nonproprietary name for the natural hormone cortisol), have greater effects on carbohydrate metabolism, as measured by liver glycogen deposition, and are termed *glucocorticoids*. They also possess potent anti-inflammatory actions and are used therapeutically for this purpose. Other compounds, represented by aldosterone, are most active in enhancing Na^+ retention and are referred to as *mineralocorticoids*. These corticosteroids do not have anti-inflammatory effects (Table 35-1). The structures of hydrocortisone and aldosterone are shown in Figure 35-2.

Production of corticosteroids and androgen is highly compartmentalized in the adrenal cortex (Figure 35-3). The mineralocorticoid aldosterone is produced by the outer layer cells (*zona glomerulosa*), cortisol and other glucocorticoids are produced by the middle layer (*zona fasciculata*), and the androgens are produced by the inner layer (*zona reticularis*) adjacent to the medulla. The corticosteroids are not stored to any extent in the adrenal gland but are continuously synthesized and secreted. The total daily production of the major glucocorticoid, cortisol, is normally 20 to 25 mg. There is a strong diurnal variation in this process; plasma concentrations of cortisol are severalfold higher at 8 A.M. than at 4 P.M.

Production of all corticosteroids except aldosterone is directly regulated by the blood concentration of adrenocorticotropic hormone (ACTH) secreted by the anterior pituitary (adenohypophysis). Circulating corticosteroids act on the hypothalamus and adenohypophysis to suppress the release of ACTH, completing the control loop linking the pituitary and the adrenal cortex (Figure 35-4). By this negative feedback mechanism, the administration of large doses of corticosteroids can prevent the tropic influence of ACTH on the adrenal cortex, completely suppressing the adrenal production of corticosteroids. Aldosterone secretion is controlled primarily by a direct effect of angiotensin II on the adrenal cortex. Hyponatremia and hyperkalemia also favor the release of aldosterone. ACTH has only a minor stimulatory effect on the release of aldosterone.

Corticosteroids play diverse and complex roles in the body economy of mammalian organisms. They are involved in carbohydrate, protein, lipid, and purine metabolism; electrolyte and water balance; the functions of the cardiovascular, nervous, and immune-inflammatory systems; and the functions of the kidneys, skeletal muscle, bone, and most other organs and tissues. The hormones of the adrenal cortex play a major role in the ability of animals to withstand stressful events. Without the adrenal cortex, life is possible only when food and large amounts of salt and water are regularly ingested, a constant ambient temperature prevails, and infection and other perturbing events are absent.

Most of the diverse actions of corticosteroids seem to be achieved by regulating gene expression. As described in Chapter 32, glucocorticoids enter target cells and bind to cytosolic receptors. These receptors exist in a complex with several proteins, including heat shock protein and an immunophilin. Binding by the hormone or a synthetic analogue alters the conformation of the receptor, freeing it from the associated proteins. The hormone-receptor complex migrates to the nucleus and binds to the glucocorticoid-responsive elements on DNA of affected genes. The DNA-binding domain on the receptor is distinct from the drug-binding domain. Gene expression is regulated either negatively or positively to render the characteristic and complex glucocorticoid signature for modification of protein synthesis.[14] The mechanism of action of mineralocorticoids has been less well studied, but it seems to be similarly based on regulation of transcription in renal and other target cells.

Consistent with the mechanism described, the major effects of corticosteroids are not manifested for several hours. Other, less apparent effects are more immediate, however.

FIGURE **35-1** Major steps in the synthesis of adrenocortical steroid hormones. All three groups have cholesterol as a common precursor. Cholesterol is derived from several sources, including circulating cholesterol and cholesteryl esters, endogenous stores of cholesteryl esters, and de novo synthesis by the gland. Some of the intermediate steps are not shown. (For a detailed review of corticosteroid synthesis, see Schimmer BP, Parker, KL: Adrenocorticotropic hormone; adrenocortical steroids and their synthetic analogs; inhibitors of the synthesis and actions of adrenocortical hormones. In Brunton LL, Lazo JS, Parker KL, editors: *Goodman & Gilman's the pharmacological basis of therapeutics*, ed 11, New York, 2006, McGraw-Hill.)

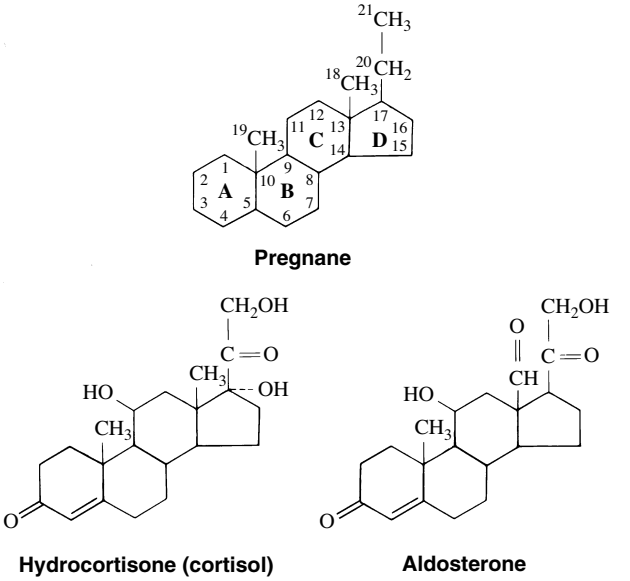

FIGURE **35-2** Structural formulas of pregnane, the basic corticosteroid nucleus, and hydrocortisone (cortisol) and aldosterone, the prototypic glucocorticoid (hydrocortisone) and mineralocorticoid (aldosterone).

These likely occur through other receptor mechanisms involving the plasma membrane of target cells.[7]

The pharmacologic effects of glucocorticoids are largely exaggerations of the physiologic functions of the endogenous corticosteroids. These effects simulate the pathologic features of Cushing's syndrome, a metabolic disorder resulting from an excess of corticosteroids, primarily cortisol. A review of these features and their pathophysiologic basis is helpful in understanding the pharmacologic and toxic actions of glucocorticoids.[15]

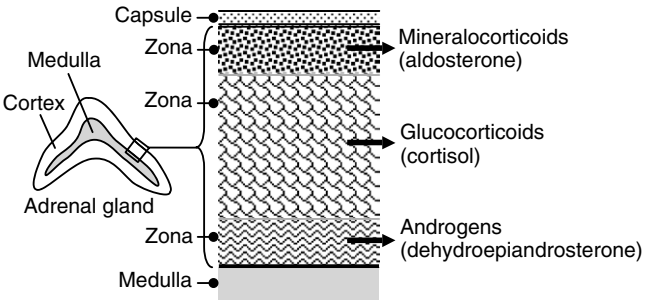

FIGURE **35-3** Schematic representation of the adrenal cortex and its major hormones. The cortex consists of three histologically and functionally distinct cellular compartments: *zona glomerulosa*, *zona fasciculata*, and *zona reticularis*. Biosynthesis of the mineralocorticoids (primarily aldosterone), glucocorticoids (primarily cortisol), and androgens occurs in these compartments.

TABLE **35-1**

Potencies of Commonly Used Corticosteroids (Relative to Hydrocortisone)

	LIVER GLYCOGEN DEPOSITION*	Na^+ RETENTION
11-Desoxycorticosterone	0	100
Aldosterone	0.1	3000
Cortisone	0.8	0.8
Hydrocortisone	1	1
Prednisolone	4	0.8
Triamcinolone	5	0
Fludrocortisone	10	3000
Dexamethasone	25	0
Betamethasone	25	0

*Generally paralleled by anti-inflammatory activity.

Carbohydrate and Protein Metabolism

Through several actions, glucocorticoids exert prominent anti-insulin effects. Glucocorticoids decrease the peripheral use of glucose by decreasing the cellular uptake of glucose. In the liver, glucocorticoids specifically stimulate glucose synthesis from amino acids (gluconeogenesis)[8]; concurrently, they mobilize amino acids by inhibiting protein synthesis in muscle, connective tissues, and skin (antianabolic effect). These actions are reflected in the parallel increases in blood glucose, liver glycogen, and urinary nitrogen excretion seen after the administration of glucocorticoids. As a consequence of these actions, prolonged high titers of glucocorticoids cause clinical manifestations of protein wasting: retardation of linear growth in children, wasting of the skin and increased capillary fragility resulting in ecchymoses, loss of muscle tissue leading to weakness (which may be extreme), and osteoporosis associated with enhanced bone resorption.

Lipid Metabolism

The effects of glucocorticoids on lipid metabolism antagonize the actions of insulin further. Glucocorticoids inhibit fatty acid synthesis and exert a permissive action on fatty acid mobilization from adipose tissue by lipolytic hormones. Long-term administration of large doses of glucocorticoids causes redistribution of fat from peripheral stores to more central locations on the back, shoulders, abdomen, and face; the result is termed *centripetal obesity*. Cutaneous striae form on

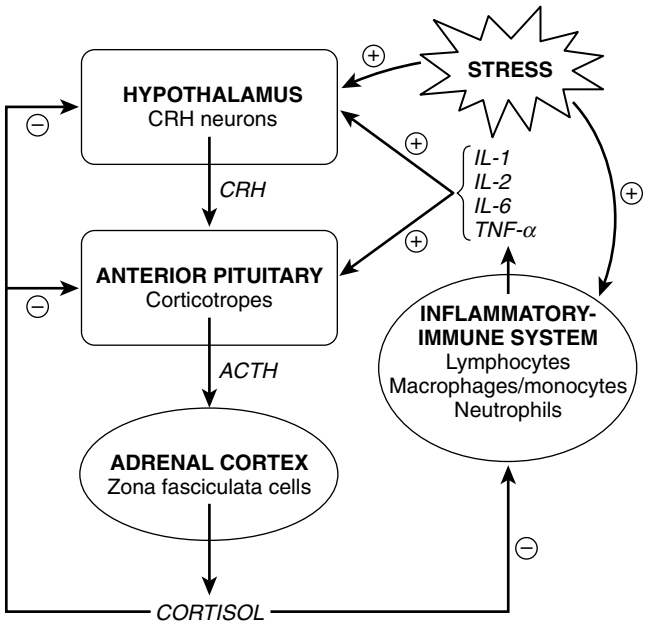

FIGURE **35-4** Hypothalamic-pituitary-adrenal axis and its relationship to stress and the inflammatory-immune system. Cortisol exerts a negative feedback control on the secretion of corticotropin-releasing hormone *(CRH)* and adrenocorticotropic hormone *(ACTH)*. Physiologic or psychological stress increases cortisol secretion directly through neural mechanisms or by activation of the inflammatory-immune system and production of cytokines, including interleukin-1 *(IL-1)*, interleukin-2 *(IL-2)*, interleukin-6 *(IL-6)*, and tumor necrosis factor-α *(TNF-α)*.

areas of the trunk where the skin is stretched by the accumulation of fat.

Electrolyte and Water Balance

Excesses or deficiencies of corticosteroid hormones are associated with severe disturbances in electrolyte and fluid balance. These disturbances result from the following actions of corticosteroids on the kidney: stimulation of reabsorption of Na^+ from the tubular fluid and increased urinary excretion of K^+ and H^+ ions. Excessive concentrations of corticosteroids lead to Na^+ retention, hypokalemia, alkalosis, and expanded extracellular fluid volume. These changes are manifested clinically by edema and hypertension; they may lead to left ventricular hypertrophy and predispose the patient to congestive heart failure and stroke. In corticosteroid deficiency (Addison's disease), essentially the opposite occurs (loss of Na^+, hyperkalemia, reduced extracellular fluid volume, and generalized cellular hydration) and, if severe, may lead quickly to death.

Anti-inflammatory Properties

Glucocorticoids are potent inhibitors of the inflammatory response. This anti-inflammatory activity is independent of the initiating stimulus and occurs at multiple points throughout the process (see Figure 35-4). The actions of glucocorticoids are due to many effects resulting from glucocorticoids binding to glucocorticoid receptors. The activated receptors bind to glucocorticoid response elements in the DNA, resulting in gene expression. In addition, activated glucocorticoid receptors can bind directly to transcription factors resulting in inhibition of inflammatory gene expression. Several resulting actions are especially prominent.

Glucocorticoids, by their action on gene expression, induce the production of numerous proteins with anti-inflammatory action, including annexin-1 (formerly lipocortin-1). Annexin-1 is a multifunctional protein that inhibits phospholipase A_2 as one of its actions. The resulting decrease in the production of arachidonic acid leads to a reduction in the synthesis of prostaglandins and leukotrienes, important mediators of inflammation. (See Chapter 21 on nonsteroidal anti-inflammatory drugs [NSAIDs].) This effect is particularly important in macrophages, monocytes, endothelial cells, and fibroblasts. Glucocorticoids also suppress the synthesis of cyclooxygenase. The net result of these two actions is an inhibition of neutrophil, eosinophil, and monocyte chemotaxis (from inhibition of leukotriene B_4 synthesis), inhibition of capillary permeability and bronchoconstriction (from decreased leukotrienes C_4 and D_4 and the prostaglandin $PGF_{2\alpha}$), and inhibition of the vascular and inflammatory responses to the prostaglandins PGI_2 and PGE_2.

In addition, glucocorticoids inhibit the production of eosinophils, basophils, monocytes, and lymphocytes; the synthesis of various cytokines (interleukins and tumor necrosis factor-α) in macrophages, lymphocytes, monocytes, and endothelial cells; and the release of histamine. Glucocorticoids inhibit the synthesis of adhesion molecules in endothelial cells; this impairs the attachment of inflammatory cells and hinders their recruitment to sites of inflammation.

Immune Responses

Glucocorticoids are widely used to suppress undesirable immune reactions such as graft rejection. The mechanism for this effect is complex but involves glucocorticoid inhibition of T-lymphocyte activation and proliferation. Production of plasma cells is also inhibited. These effects on T and B lymphocytes seem to be largely caused by the reduced production of cytokines, as described previously. Glucocorticoids impair the ability of inflammatory cells to migrate into sites of immunologic or inflammatory reactions. Phagocytosis and subsequent digestion (processing) of antigen by macrophages, events necessary for the development of some immune responses, are inhibited. Finally, glucocorticoids suppress antibody production.

ABSORPTION, FATE, AND EXCRETION

All the natural and synthetic corticosteroids except desoxycorticosterone are well absorbed from the gastrointestinal tract. Significant amounts of these drugs may also be absorbed from sites of local application, such as the skin, mucous membranes, and eye. In normal circumstances, more than 90% of circulating corticosteroids are bound to plasma proteins, principally an α-globulin (corticosteroid-binding globulin, also known as *transcortin*), which has a high affinity but low capacity for these compounds, and albumin, which has the opposite characteristics.

Hydrocortisone is rapidly degraded in the liver by reduction, conjugated with glucuronic acid, and excreted in the urine. Most other corticosteroids are similarly metabolized, although at different rates. The plasma half-life of hydrocortisone is approximately 1.5 hours. Synthetic analogues of hydrocortisone generally have longer half-lives; the potent long-acting compound dexamethasone has a plasma half-life of approximately 4 hours and a tissue half-life of approximately 2 days. Because the corticosteroids act by modifying gene expression, the time course of effect bears little correspondence to the plasma concentration.

The major metabolic products of corticosteroid metabolism found in the urine, 17-hydroxycorticosteroids and 17-ketosteroids, were formerly measured by clinical laboratories to assess adrenal-pituitary function. This method has been

largely supplanted by direct measurement of plasma cortisol concentrations by radioimmunoassay.

GENERAL THERAPEUTIC USES

Glucocorticoids are used clinically in two ways. The first and most intuitive is replacement therapy. Insufficient production of corticosteroids can result from a defect in the adrenal cortex, anterior pituitary, or hypothalamus; these defects may be congenital or acquired. Depending on the degree of insufficiency, the outcome may be either acute or chronic. Acute adrenal insufficiency (adrenal crisis) is a life-threatening emergency characterized by extreme weakness, gastrointestinal symptoms, dehydration, and hypotension. It frequently follows abrupt cessation of long-term high-dose therapy with glucocorticoids and stems from a drug-induced suppression of adrenal-pituitary function (which may require 2 years for full recovery). The features of chronic adrenal insufficiency (Addison's disease) are similar to, but milder than, features of acute adrenal insufficiency. Treatment of adrenal insufficiency, regardless of the cause, requires replacement with appropriate corticosteroids.

In addition to replacement therapy, glucocorticoids are used on a purely empiric basis in many conditions (Box 35-1). These conditions, although varied, are generally characterized by chronic inflammatory and immune phenomena and are associated with tissue destruction and functional impairment. For this reason it is widely assumed that the salutary effects of glucocorticoid therapy in these diseases are related to suppression of inflammation and immune reactions. In none of these conditions do the corticosteroids have specific actions on the basic disease process, despite their ability in some cases to produce dramatic improvement and remission of signs and symptoms. The destructive aspects of the primary disease may continue unchecked; in rheumatoid arthritis, glucocorticoids can effectively relieve the distressing inflammation and pain, but deterioration of affected joints progresses.[10] The use of corticosteroids in other than replacement therapy must be considered palliative.

Because of their lack of specificity and their considerable potential for causing harm, the long-term use of corticosteroids to treat inflammatory disorders should be viewed with caution. Before corticosteroids are considered, less toxic agents and nonpharmaceutical measures should be used to the maximum extent possible. This approach is well illustrated in rheumatoid arthritis. Systemic corticosteroids should seldom be necessary in this disease and should not be used as the initial agent. Most patients improve considerably with NSAID therapy in large, regular doses combined with application of heat and appropriate physical therapy. This program may be supplemented by other drugs, such as methotrexate. Patients in whom these drugs are ineffective or intolerable are candidates for corticosteroid therapy, but corticosteroids should be used in the smallest possible dosage for the shortest time as adjuncts to other measures.

The use of glucocorticoids in the treatment of asthma involves several strategies to minimize systemic toxicity. Depending on the severity of an acute asthmatic attack, intravenous or oral administration can be used, with doses tapering off as the condition subsides.[4] Inhaled steroids are preferred for long-term therapy because they minimize systemic uptake.[2]

When corticosteroids are used on a long-term basis, they are often administered on alternate days to minimize suppression of the pituitary-adrenal axis. Giving a glucocorticoid every other day between 6 and 9 A.M. mimics the normal diurnal pattern of corticosteroid secretion. Such a regimen seems to lessen suppression of the adrenal cortex and permits increased endogenous corticosteroid production in response to stress. Alternate-day therapy may not adequately control symptoms in some cases, especially in patients with rheumatoid arthritis and ulcerative colitis. Glucocorticoid therapy for 1 week usually does not cause significant suppression of pituitary or adrenal function.

BOX 35-1

Conditions Treated with Corticosteroids

- Adrenal insufficiency (acute or chronic, primary or caused by anterior pituitary insufficiency)
- Cerebral edema and increased intracranial pressure (brain tumors, meningitis, trauma, cerebrovascular accidents)
- Collagen vascular diseases
  - Lupus erythematosus
  - Polymyositis
  - Polyarteritis nodosa
  - Chronic granulomatous disorders (sarcoidosis and others)
  - Temporal (giant cell) arteritis
  - Mixed connective tissue disease syndrome*
- Dermatologic conditions
  - Psoriasis
  - Dermatitis (atopic, allergic, irritant)
  - Pemphigus
  - Lichen planus
- Gastrointestinal diseases
  - Ulcerative colitis
  - Crohn's disease
  - Celiac disease
- Hematologic diseases
  - Malignancies (acute and chronic lymphocytic leukemia, lymphoma, multiple myeloma)
  - Hemolytic anemia (autoimmune or drug-induced)
  - Idiopathic thrombocytopenic purpura
- Hepatic diseases
  - Chronic active hepatitis
  - Alcoholic hepatitis (severe forms with hepatic encephalopathy)
  - Hypercalcemia (sarcoid, malignancies, vitamin D intoxication)
- Multiple sclerosis (acute episodes)
- Nephrotic syndrome
- Ocular diseases with inflammatory or allergic components
- Pulmonary disorders
  - Asthma
  - Chronic bronchitis (acute episodes)
  - Aspiration pneumonia
- Rheumatic diseases and joint ailments
  - Rheumatic arthritis
  - Rheumatic carditis
  - Osteoarthritis (intra-articular administration)
  - Bursitis (intracapsular administration)
- Shock
- Solid tumors (breast)
- Tissue grafts and organ transplants

*Must be differentiated from scleroderma, which is usually not altered by corticosteroids.

THERAPEUTIC USES IN DENTISTRY

Glucocorticoids have limited applications in dentistry. As in medicine, they are used largely to reduce the signs and symptoms of unwanted inflammatory reactions. These potential uses fall into the following general categories: oral

ulcerations, pulpal hypersensitivity, temporomandibular joint pain, postoperative sequelae, and anaphylaxis and other allergic reactions.

Oral Ulcerations

A wide variety ulcerative lesions of the oral mucosa are frequently treated by the topical application of glucocorticoids. Relief of symptoms and abbreviation of the clinical course are usually obtained, regardless of the cause of the ulceration. Applicable conditions are denture-induced and other traumatic ulcers, recurrent ulcerative (aphthous) stomatitis, erosive lichen planus, erythema multiforme, pemphigus, desquamative gingivitis and stomatitis, geographic tongue, and angular stomatitis (cheilitis).[12,13] Despite their usual salutory effects on signs and symptoms, glucocorticoids do not alter the underlying pathogenesis of chronic ulcerative lesions of the oral mucosa. Although severe disorders with dermatologic and mucosal manifestations, such as pemphigus, are usually treated with systemic glucocorticoids, further improvement of associated oral ulceration may be obtained by topical application of glucocorticoids. Despite the fact that herpetic ulcers may respond favorably, the use of glucocorticoids to treat this condition is contraindicated because suppression of the host response may allow dissemination of the herpesvirus. It is important for the clinician to make a careful diagnosis of oral ulcers before instituting glucocorticoid therapy.

The benefit of glucocorticoids applied topically is greatest when the period of contact with the tissue is maximal. Retention at the site of application is difficult in the oral cavity. A partial solution is to apply the drug in a paste that adheres to the mucosa and resists dissolution and displacement. One such vehicle is carboxymethylcellulose in a base of polyethylene resin and mineral oil (Orabase); it is available with or without a glucocorticoid. Symptomatic relief of many oral ulcers, particularly ulcers likely to be limited in duration, may be obtained with the adhesive paste alone.

Pulpal Hypersensitivity

Hypersensitivity of the dental pulp can result from various conditions that induce an inflammatory response in the pulp, including operative trauma, invasion of the pulp by bacteria or their products, and exposure of dentin to the oral environment. Glucocorticoids have been variously applied directly or indirectly to the pulp to reduce pain. Although success has been claimed, the value of this therapy in the management of pulpal inflammation has not been established, and it cannot be recommended.

Temporomandibular Joint Disorders

Pain originating in the temporomandibular joint may have many possible causes, including trauma, bruxism, anatomic anomalies, rheumatoid arthritis, and psychophysiologic disorders. Treatment of such conditions should be conservative and based on careful diagnosis. NSAIDs, antianxiety muscle relaxant drugs, carbamazepine, and tricyclic antidepressants have proved useful for short-term pharmacotherapy. Nondrug approaches include rest, heat, gentle stretching, bite-plane appliances, and occlusal adjustments. In refractory cases of temporomandibular joint pain or when acute pain is initially so severe that it precludes a course of conservative therapy, intra-articular injection of a glucocorticoid such as prednisolone or dexamethasone may be beneficial. Relief of symptoms may be full or partial, permanent or temporary (especially if the underlying cause of the disorder is not corrected). Although deterioration of the articular surfaces of the joint has been claimed to result from intra-articular injection of corticosteroid, the weight of available evidence does not support such an association. Nevertheless, the best responses to intra-articular injection seem to occur in patients free of radiographic changes in the joint.

Postoperative Sequelae

Glucocorticoids are often used to lessen postoperative complications, mainly reduction of edema and trismus, after dental surgical procedures.[5] Although the risk of adverse effects from a short, intensive perioperative course of glucocorticoids is slight, it is uncertain whether the modest benefits typically obtained justify such "prophylactic" use. What is certain, however, is that careful surgical technique is of primary importance in the reduction of uncomfortable postoperative sequelae.

Anaphylaxis and Other Allergic Reactions

The immunosuppressant and anti-inflammatory effects of glucocorticoids may be used to treat the manifestations of various allergic reactions, such as urticaria, contact dermatitis, angioneurotic edema, allergic rhinitis and conjunctivitis, insect bites, drug reactions, and serum sickness. Because histamine is an important mediator in most of these conditions, H_1 antihistamines are major drugs in the treatment of milder reactions involving histamine release (e.g., urticaria). Systemic glucocorticoids are useful in more severe responses. In anaphylaxis, although epinephrine is the drug of choice, large doses of glucocorticoids may be beneficial in reducing bronchospasm and laryngeal edema. In this situation, glucocorticoids also act to increase the cardiac and vascular effects of catecholamines. In addition, because the maximal effects of glucocorticoids are delayed for several hours after administration, the prolonged duration of action of glucocorticoids can afford added benefit. The glucocorticoids are not the primary drugs in treating the life-threatening cardiovascular failure of anaphylaxis; they add a supplemental benefit after the administration of epinephrine.

ADVERSE EFFECTS

Although glucocorticoids are valuable agents in some situations, they have considerable potential to cause greater harm than good. Actualization of this potential depends on, among other factors, the intensity and duration of therapy. A single large dose or a short course of moderate doses of hydrocortisone causes few adverse effects. If more than 20 to 30 mg of hydrocortisone (or its equivalent) is given daily for more than a week, however, some manifestations of glucocorticoid toxicity are likely to appear. In general, these manifestations are predictable from a knowledge of the pathologic features of endogenous Cushing's disease.

Major adverse effects of glucocorticoid therapy are listed in Box 35-2 and are summarized in the following paragraphs. The frequency and severity of adverse effects correlate with the dose and duration of therapy, the age and condition of the patient, and the disease being treated.

Hyperglycemia and Glycosuria

A diabetic-like state stems from the anti-insulin action of glucocorticoids. It is usually mild and controllable with diet, insulin, or both. In diabetics, the requirement for insulin or oral hypoglycemic agents is increased.

Myopathy

Large doses of glucocorticoids, especially the more potent fluorinated synthetic compounds, cause muscle wasting, manifested chiefly as weakness of the musculature of the limbs. Significant reduction of muscle mass in the extremities can occur. Recovery may be incomplete after cessation of therapy.

BOX **35-2**

Major Adverse Effects of Glucocorticoid Therapy

Neurologic	Insomnia, agitation, mania, withdrawal syndrome
Infectious	Increased infections, opportunistic infections
Vascular	Hypertension, increased atherosclerotic disease risk
Skin and mucosa	Atrophy
Skeletal	Reduced Ca^{++} absorption, osteoporosis, avascular osteonecrosis, impaired growth
Muscular	Myopathy, wasting
Metabolic	Glucose intolerance, obesity, hyperlipidemia
Reproductive	Hypogonadism
Gastrointestinal	Peptic ulcer
Ocular	Cataracts

Osteoporosis and Osteonecrosis

Osteoporosis is a common sequela of long-term glucocorticoid therapy and can lead to compression fractures of the vertebrae and to an increased susceptibility to traumatic fractures.[1] In postmenopausal women and other individuals prone to develop osteoporosis, this complication may be especially serious. Several mechanisms are responsible. Glucocorticoids reduce Ca^{++} absorption from the intestine and increase renal excretion of Ca^{++}. Resorption of bone occurs through an increase in parathyroid hormone release and a direct inhibitory effect of glucocorticoids on osteoblasts. Aseptic osteonecrosis may involve the large joints, especially the head of the femur. The condition is often progressive, necessitating joint replacement. Studies indicate that concurrent treatment with bisphosphonates such as alendronate can reduce bone wasting in patients on long-term glucocorticoid therapy.[11]

Suppression of Growth

In children and adolescents, glucocorticoids can inhibit skeletal growth and maturation.

Negative Nitrogen Balance

A net nitrogen loss results from the imbalance between protein synthesis and degradation. It reflects the antianabolic effects of glucocorticoids in cutaneous and musculoskeletal tissues.

Peptic Ulcer

There is an increased incidence of gastric ulcers in patients treated with glucocorticoids, especially patients with rheumatoid arthritis. Because such patients are often concurrently taking aspirin or other NSAIDs, it is difficult to implicate glucocorticoids only in the pathogenesis of these ulcers.[9] Nonetheless, when they occur, ulcers associated with glucocorticoid therapy have a high incidence of complications, such as hemorrhage and perforation. The mechanism is likely related to the decreased synthesis of PGI_2 and PGE_2, which provide protection for the gastric mucosa.

Ocular Effects

Increased intraocular pressure, which may produce irreversible damage, and posterior subcapsular cataracts can result from either topical or systemic administration of glucocorticoids. Children and patients with diabetes are particularly susceptible to untoward ocular effects.

Central Nervous System Effects

Psychological disturbances can occur during glucocorticoid therapy. These reactions are reversible and range in severity from mild (euphoria, insomnia, or nervousness) to pronounced (manic-depressive or schizophrenic psychosis).

Edema and Hypokalemia

Although water retention with hypokalemia is a potentially serious complication of glucocorticoid therapy, the incidence and severity can be greatly minimized by dietary Na^+ restriction and by the use of a synthetic glucocorticoid essentially devoid of mineralocorticoid activity.

Altered Distribution of Body Fat

Long-term treatment with glucocorticoids often causes changes in the distribution of body fat deposits, leading to the classic cushingoid appearance. The most characteristic of these changes are a round ("moon") face, accumulation of fat in the back of the neck ("buffalo hump") and supraclavicular region, and increased abdominal fat. The obese trunk may markedly contrast with the thin, wasted extremities. The enhanced lipolysis seen with glucocorticoids leads to these changes; however, the reason for the redistribution is unknown.

Increased Susceptibility to Infection

Because of the effect on inflammation and the immune system, the body's reaction to infectious agents is depressed by glucocorticoids. Fungal, bacterial, and viral pathogens that would otherwise cause localized or no infection may become widely disseminated with serious or fatal consequences. Latent tuberculosis may be reactivated after the initiation of glucocorticoid therapy.

Suppression of Pituitary-Adrenal Function

Prolonged administration of glucocorticoids (greater than physiologic amounts for >1 week) results in suppression of ACTH and, consequently, suppression of adrenal corticosteroid production; the degree of suppression is dose-related. Abrupt withdrawal or significant reduction of glucocorticoid dosage can precipitate acute adrenal insufficiency. Acute exacerbation of the disease being treated may occur during withdrawal. Cessation or reduction of glucocorticoid therapy must be done slowly and with great caution to permit the recovery of normal pituitary and adrenal function.

Various physiologic stressors, such as acute illness, trauma, pain, anxiety, infection, blood loss, surgery, and general anesthesia, elicit a rapid increase in circulating concentrations of hydrocortisone and other glucocorticoids. This increase is crucial to the success of the body's response to these stresses. In subjects with adrenal suppression resulting from disease or induced by long-term glucocorticoid therapy, any needed surge of glucocorticoid output is impaired. This impairment can quickly lead to a condition known as *acute adrenal insufficiency*, or *adrenal crisis*. The risk of this condition is a function of the degree of adrenal suppression and the demand for increased glucocorticoid production. The onset of adrenal crisis is often signaled by any or all of the following: severe nausea, vomiting, and diarrhea, leading to dehydration; chills and fever; sudden penetrating pain in the lower back, abdomen, and legs; profound muscle weakness; extreme lethargy; hypoglycemia; hypotension and tachycardia; and tachypnea. These symptoms may be followed by confusion, psychotic manifestations, loss of consciousness, convulsions, cardiovascular and respiratory collapse, and death. Adrenal crisis is a medical emergency, and appropriate and timely intervention is essential. Treatment consists of intravenous glucocorticoids; correction of fluid, electrolyte, and glucose deficits; and vasopressors and other supportive measures as needed.

Miscellaneous Effects

Acne, thinning of the skin and mucosa, hirsutism, weight gain, intestinal perforation, pancreatitis, hyperlipidemia, hypertension, hepatomegaly, and poor wound healing may occur during long-term glucocorticoid therapy.

IMPLICATIONS FOR DENTISTRY

Patients treated with large doses of glucocorticoids for long periods present special problems in dentistry. As noted previously, such patients are likely to have a decreased resistance to infection and a poor wound healing response. Actual or potential sources of infection in the oral cavity, such as carious teeth and inflamed tissues, should be promptly treated. If surgical procedures are necessary, they should be as conservative, atraumatic, and aseptic as possible. Preoperative antimicrobial prophylaxis may be indicated in some cases.

A second consideration in patients treated with glucocorticoids is suppression of pituitary-adrenal function. The degree of adrenal suppression depends on the length of treatment, the frequency and manner of administration, and the glucocorticoid preparation used (glucocorticoid potency of individual agents may vary >25-fold; see Table 35-1). As described earlier, an individual with intact adrenal function responds to a stressful situation, such as anxiety, an acute infection, or a surgical procedure, with an increased release of ACTH and production of cortisol. Patients with suppressed adrenal function are unable to increase cortisol production. In assessing the degree of suppression, a good guideline is to assume that any patient who has received 30 mg of hydrocortisone or its equivalent for 4 or more weeks or 80 mg of hydrocortisone for more than 2 weeks has some degree of adrenal suppression. It is a time-honored but unproven notion that these patients may develop signs and symptoms of adrenal insufficiency during stressful dental situations (surgery or acute infection). It is often suggested that the dose of glucocorticoids be increased during and immediately after treatment in such patients to compensate for the lack of endogenous hormone production. The recommended dose is typically at least double or triple the patient's maintenance dose, depending on the degree of suppression of adrenal function and the severity of the stressful event. When the period of stress is over, the dose is gradually reduced over several days to the maintenance level.

A careful review of the literature suggests that patients with glucocorticoid-induced adrenal suppression are at little risk of acute adrenal insufficiency as a result of routine dental treatment, including simple extractions and minor periodontal or endodontic surgery.[6] Given this, it is likely quite safe for such patients to forego perioperative glucocorticoid supplementation ("steroid cover"). Patients should be scheduled for an appointment in the morning when circulating cortisol concentrations are the highest and instructed to take their usual dose of corticosteroid within 2 hours of the procedure. Measures to reduce anxiety are also appropriate.

More invasive surgical procedures, such as removal of impacted teeth, bone resection, or quadrant periodontal surgery; lengthy procedures (>1 hour); procedures that may cause considerable blood loss; and any procedure done under general anesthesia constitute more stressful episodes, and may require essentially complete corticosteroid replacement in a patient with adrenal suppression. One commonly accepted approach is to give 100 mg of cortisone acetate intramuscularly approximately 8 hours before the procedure. Sufficient hydrocortisone or its equivalent is given intravenously during the procedure so that the total dose on the day of the operation is 300 mg of hydrocortisone or its equivalent. If the postoperative course is uneventful, corticosteroid dosage is tapered over a 2- to 3-day period (e.g., 300 mg of hydrocortisone on the day of the procedure, 150 mg the following day, 75 mg on the next day, and the usual maintenance dose on the third postoperative day).[3] A low-dose alternative is to infuse 25 mg of hydrocortisone during the induction of anesthesia, followed by a continuous infusion of 100 mg during the next 24 hours.

Because recovery of glucocorticoid-induced adrenal suppression may be slow, dental patients formerly treated for prolonged periods with glucocorticoids and assumed to have adrenal suppression by the above-mentioned criteria may need to receive glucocorticoids during stressful situations for 1 year after cessation of glucocorticoid therapy. Consultation with the patient's physician is essential for the optimal management of a patient who is receiving or has received long-term glucocorticoid therapy.

PREPARATIONS

Numerous glucocorticoids are available in various forms for local, oral, and parenteral administration. These include the natural hormone hydrocortisone and synthetic compounds prepared by modifying the chemical structures of hydrocortisone and other natural hormones; three of these are shown in Figure 35-5. Relative to hydrocortisone, the synthetic compounds are, in varying degrees, longer acting and more potent. These differences are the basis for classifying glucocorticoids as short-acting (<12 hours), intermediate-acting (12 to 36 hours), and long-acting (>36 hours) (Box 35-3). Representatives of these three categories are hydrocortisone, prednisolone, and dexamethasone. Intermediate-acting and long-acting compounds also have a greater ratio of glucocorticoid to mineralocorticoid activity. Consequently, these agents are preferred for long-term use in the treatment of chronic inflammatory disorders because they cause less disturbance of electrolyte and fluid balance than hydrocortisone.

In the clinical management of inflammatory or allergic disorders, the dosage of glucocorticoids varies widely accord-

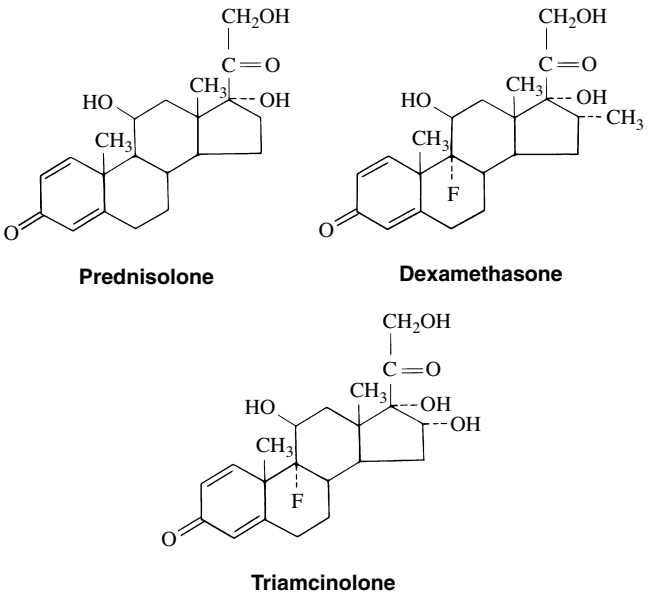

FIGURE **35-5** Structural formulas of three synthetic glucocorticoids.

TABLE **35-2**

Commonly Used Corticosteroid Preparations

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	RELATIVE POTENCY	USUAL ADULT DOSE	ROUTE OF ADMINISTRATION	PREPARATIONS
Hydrocortisone	Hydrocortone	1	20-240 mg/day	Oral	Tablets: 5, 10, and 20 mg
Hydrocortisone acetate	Orabase HCA	1	2-3 times daily	Topical	Paste: 0.5%, containing gelatin, pectin, and sodium carboxymethylcellulose in a polyethylene and mineral oil base
	Hydrocortone acetate	1	5-50 mg	Intra-articular	Suspension: 25 and 50 mg/mL
Hydrocortisone sodium succinate	Solu-Cortef	1	100-500 mg/day	Intravenous or intramuscular	Powder: 100, 250, 500, and 1000 mg
Prednisone	Deltasone, Orasone	4	5-60 mg/day	Oral	Tablets: 1, 2.5, 5, 10, 20, 25, and 50 mg
Prednisolone	Delta-Cortef	4	5-60 mg/day	Oral	Tablets: 5 mg
Prednisolone acetate	Econopred	4	1-2 drops	Ophthalmic	Suspension: 0.12% and 1%
Triamcinolone acetonide	Kenalog in Orabase	5	2-3 times daily	Topical	Paste: 0.1%, with gelatin, pectin, and sodium carboxymethylcellulose in a polyethylene and mineral oil base
Triamcinolone diacetate	Aristocort	5	5-40 mg every 1-8 wk	Intra-articular	Suspension: 25 and 40 mg/mL
Dexamethasone	Decadron	25	0.75-9 mg/day	Oral	Tablets: 0.25, 0.5, 0.75, 1, 1.5, 2, 4, and 6 mg
Dexamethasone acetate	Decadron-LA	25	1-5 mg*	Intra-articular	Suspension: 8 and 16 mg/mL
Betamethasone	Celestone	25	0.6-7.2 mg/day	Oral	Tablets: 0.6 mg

*Dose recommended for the temporomandibular joint.

BOX **35-3**

Biologic Half-Lives* of Commonly Used Corticosteroids

8-12 hr (short-acting)	Cortisone
	Hydrocortisone
18-36 hr (intermediate-acting)	Methylprednisolone
	Prednisolone
	Prednisone
	Triamcinolone
36-72 hr (long-acting)	Betamethasone
	Dexamethasone
	Paramethasone

*Biologic half-life of corticosteroid is defined as the period of suppression of the hypothalamus-pituitary-adrenal axis.

GLUCOCORTICOIDS

Nonproprietary (generic) name	*Proprietary (trade) name*
Beclomethasone	Beclovent, Vanceril
Betamethasone	Celestone
Cortisone	Cortone
Dexamethasone	Decadron, Dexone, Hexadrol
Fludrocortisone	Florinef
Flunisolide	AeroBid
Hydrocortisone (cortisol)	Cortef, Hydrocortone, Solu-Cortef
Methylprednisolone	Depo-Medrol, Medrol, Solu-Medrol
Prednisolone	Delta-Cortef, Predalone, Pediapred
Prednisone	Deltasone, Orasone
Triamcinolone	Aristocort, Kenacort, Kenalog

ing to such factors as the nature, severity, and probable duration of the condition being treated and the patient's response. In acute or life-threatening situations, a glucocorticoid should be given in sufficient doses to control the disorder quickly; treatment should be discontinued as soon as possible. In the long-term management of chronic diseases such as rheumatoid arthritis, alternate-day therapy with the minimum dosage that achieves an acceptable reduction of symptoms is the regimen of choice. Table 35-2 lists some of the many different preparations currently available, some of the dosage forms, and a range of doses for a given route of administration.

CHAPTER 36

Insulin, Oral Hypoglycemics, and Glucagon

GAIL T. GALASKO

INSULIN AND THE ENDOCRINE PANCREAS

The pancreas has exocrine and endocrine functions. The exocrine system comprises the acinar cells, which secrete digestive enzymes. The islets of Langerhans, which make up the endocrine system, contain four types of cells, each of which synthesizes and secretes different polypeptide hormones (Table 36-1). Insulin is produced by the β cells, which constitute most (60% to 80%) of the islet and form its central core. The β cell is the primary glucose sensor for the islet.

Insulin is a polypeptide containing 51 amino acids. It has a molecular weight of approximately 5800 Da. It is composed of two chains (called the *A and B chains*) that are joined by two disulfide bridges. Insulin is formed by proteolysis of a large, single-chain precursor, proinsulin. In proinsulin, shown in Figure 36-1, the A and B chains are joined by a connecting (C) peptide. Proinsulin is converted to insulin when the C peptide is removed; this occurs within the secretory granules of the pancreatic β cell. Approximately equimolar amounts of insulin and C peptide are stored in the granules and released by exocytosis when the β cell is stimulated. C peptide has no known biologic function, but it can serve as an index of insulin secretion. Units of insulin, originally defined by activity, are now defined on the basis of weight. There are approximately 28 U/mg of insulin.

Insulin is a member of a family of related peptides known as *insulin-like growth factors (IGFs)*. IGF-I and IGF-II have molecular weights of approximately 7500 Da and structures that are homologous to proinsulin. The receptors for insulin and IGF-I are closely related. Insulin can bind to the receptor for IGF-I with low affinity and vice versa. The growth-promoting actions of insulin seem to be mediated, at least in part, through the IGF-I receptor. In contrast to insulin, IGFs are produced in many tissues, where they are more important in regulating growth than in regulating metabolism. IGFs mediate the anabolic and growth-promoting effects of growth hormone. IGF-I and IGF-II were originally known as *nonsuppressible insulin-like activity (NSILA)* because of their ability to produce insulin-like effects in bioassays that were not suppressed by the addition of excess anti-insulin antibodies.

Regulation of Insulin Secretion

The pancreas secretes insulin into the portal vein. Insulin secretion is a tightly regulated process designed to provide stable concentrations of glucose in the blood during fasting and feeding. Regulation of plasma glucose is achieved by the coordinated interplay of various nutrients, gastrointestinal hormones, pancreatic hormones, and autonomic neurotransmitters. A basal secretion of insulin is present during fasting periods.[15] There is a subsequent rapid increase in insulin secretion after ingestion of a meal. Glucose is the principal stimulus to insulin secretion in humans. It is more effective in provoking insulin secretion when taken orally than when administered intravenously.[5]

Actions of Insulin

The classic action of insulin is to decrease the blood glucose concentration. Insulin does this by affecting glucose use and glucose production. Liver, muscle, and fat are the important target tissues for regulation of glucose homeostasis by insulin, but insulin exerts potent regulatory effects on other cell types as well. Insulin stimulates glucose transport into muscle and fat by promoting translocation of the intracellular transporter, glucose transporter 4 (Glut 4), to the cell surface (Figure 36-2).[14] Insulin does not stimulate glucose uptake into the liver, but it inhibits hepatic glucose production. Insulin inhibits catabolic processes, such as breakdown of glycogen, fat, and protein. Glycogenolysis and gluconeogenesis are inhibited. Insulin receptors are found on virtually all cells. Activation of the insulin receptor leads to a cascade of phosphorylation or dephosphorylation reactions, or both. As a result, insulin affects the activities of various enzymes involved in intracellular use and storage of glucose, amino acids, and fatty acids. Glycolysis (use) and glycogen synthesis (storage) are promoted. The effects of insulin are summarized in Table 36-2.

In addition to the short-term metabolic effects, insulin has other, longer term actions. It affects synthesis of key enzymes and is believed to have important growth-regulating effects in vivo. Insulin regulates gene transcription,[13] affecting protein synthesis; increases cell proliferation and differentiation; and decreases apoptosis.

Pharmacokinetics

Insulin is biotransformed in various tissues, including the liver, kidney, and skeletal muscle. Almost half of the insulin secreted by the pancreas is destroyed by the liver before it reaches the general circulation. Metabolism of insulin results in the production of inactive peptides. The half-life of exogenous insulin in plasma is approximately 8 minutes in nondiabetic subjects and diabetic subjects with no complications.

Insulin Receptor Interactions

The insulin receptor in mammalian cells is a large transmembrane glycoprotein. It is composed of two α subunits and two β subunits linked by disulfide bonds to form a β-α-α-β heterotetramer. Binding of hormone to the α subunits of

the insulin receptor leads to the rapid intramolecular autophosphorylation of tyrosine residues in the β subunits. A series of events is initiated that culminates in a cascade of phosphorylation or dephosphorylation reactions. This activity is shown schematically in Figure 36-2.

Insulin Signaling

There is evidence that insulin acts by synthesis of second messengers that enter the cell to mediate some of the hormone's actions on intracellular enzymes (e.g., phosphorylation, dephosphorylation). These mediators are of the inositolphosphoglycan (IPG) class.[8] IPGs represent a family of second messengers or mediators that are increasingly being implicated as having an important role in signal transduction, not only for insulin, but also for other hormones and growth factors. They are discussed later in this chapter.

TABLE **36-1**

Pancreatic Islet Secretions

CELL TYPE	HORMONE SECRETED
α (A) cell	Glucagon
β (B) cell	Insulin, amylin (islet amyloid polypeptide)
δ (D) cell	Somatostatin
F (PP) cell	Pancreatic polypeptide
G cell	Gastrin

DIABETES MELLITUS

Diabetes mellitus is a group of syndromes characterized by hyperglycemia. Virtually all forms of diabetes mellitus are due to either a decrease in the circulating concentration of insulin (insulin deficiency) or a decrease in the response of peripheral

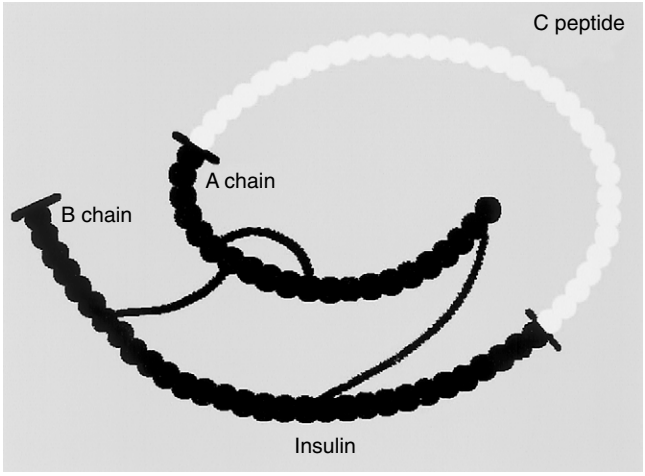

FIGURE **36-1** Structure of proinsulin. When the connecting *(C)* peptide is removed, insulin is formed. The A and B chains of insulin are shown in black; C peptide is white.

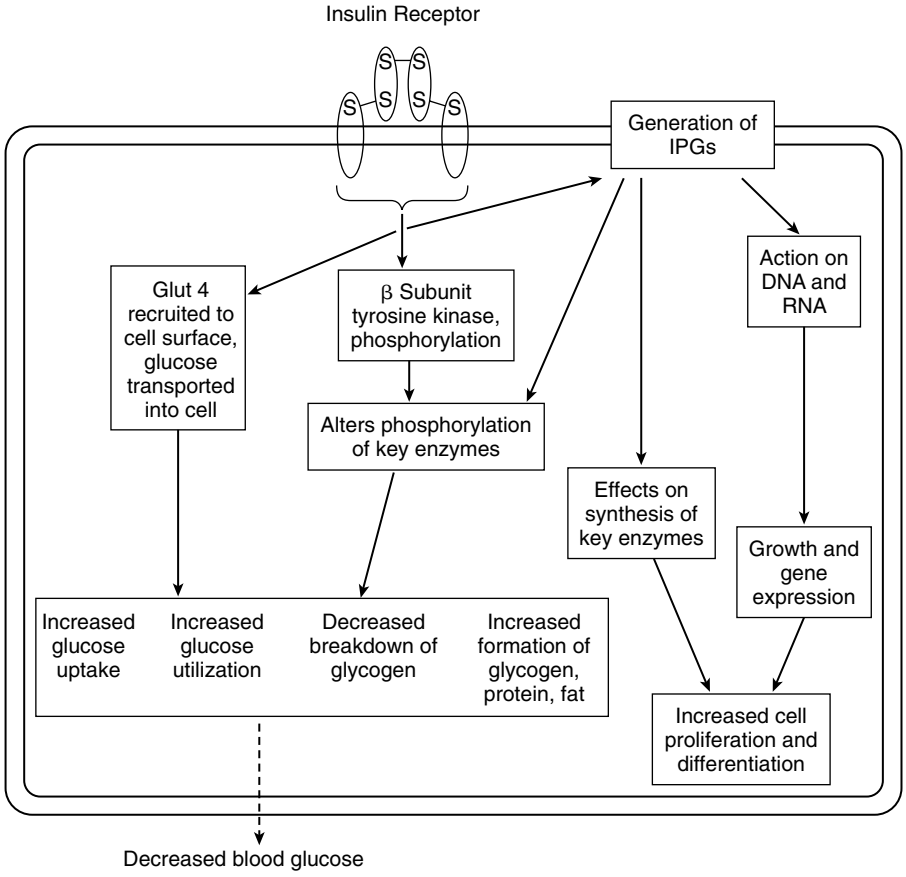

*Inositolphosphoglycans (*IPGs*) are released on the outside of the cell and then transported back into the cell.

Metabolic Actions of Insulin

TYPE OF METABOLISM	ACTION OF INSULIN	MAJOR TARGET TISSUE*
Carbohydrate	Increases glucose transport	Muscle, fat
	Increases glycogen synthesis	Liver, muscle
	Decreases gluconeogenesis	Liver
	Increases glycolysis	Liver, muscle
	Increases glucose oxidation	Fat
Fat	Increases lipogenesis	Liver, fat
	Decreases lipolysis	Liver, fat
	Increases synthesis of triglycerides	Fat
Protein	Decreases protein breakdown	Liver
	Increases protein synthesis	Muscle, various
	Increases amino acid uptake	Muscle, various

*Insulin exerts potent regulatory effects on other cell types in addition to liver, muscle, and fat, the classically important target tissues for glucose regulation.

tissues to insulin (insulin resistance). The disease has two major forms. Currently, the preferred nomenclature is *type 1* and *type 2 diabetes mellitus*. Older names include *juvenile-onset* or *insulin-dependent diabetes mellitus* for type 1 and *maturity-onset* or *non–insulin-dependent diabetes mellitus* for type 2.

Evidence indicates that the incidence of type 1 and type 2 diabetes mellitus is increasing worldwide. In 1999, the prevalence was predicted to double by 2010.[7] Type 2 diabetes is becoming increasingly common and is an emerging problem in children and adolescents, particularly minorities.[3] In the United States, the annual number of newly diagnosed diabetes cases tripled during 1980-2005. Major risk factors for type 2 diabetes are obesity and physical inactivity. The incidence of type 1 diabetes is reported to be increasing by approximately 3% per year.[16]

Type 1 Diabetes Mellitus

There is considerable evidence that type 1 diabetes is an autoimmune disease of the pancreatic β cell, resulting in degeneration. In type 1 diabetes, there is an absolute lack of insulin. Genetic predisposition and environmental components are involved, with the incidence in homozygous twins being approximately 50%.[17] Approximately 5% to 10% of diabetics have type 1 diabetes.

Type 2 Diabetes Mellitus

Approximately 90% to 95% of diabetics have type 2 diabetes mellitus. In type 2 diabetes, target cells are relatively insensitive to insulin.[6] This is known as *peripheral resistance to insulin*. Impaired glucose metabolism in muscle and liver are key features of type 2 diabetes. Genetic predisposition is important in type 2 diabetes; there is greater than 95% concordance in identical twins.[17] In addition, most type 2 diabetics are obese. Type 2 diabetics have impaired glucose taste detection,[11] which may reflect a generalized defect in glucose sensitivity, including the glucose-sensing pancreatic β cells.

Glycosylation of Hemoglobin

Nonenzymatic glycosylation of proteins can occur as a result of elevated blood glucose concentrations. Hemoglobin is glycosylated on its amino terminal valine residue to form the glycosyl valine adduct, termed *hemoglobin A_{1c} (HbA_{1c})*. Because the half-life of HbA_{1c} is the same as that of red blood cells, the concentration of HbA_{1c} in the circulation can be used to assess the severity of the glycemic state over an extended period (4 to 12 weeks) before sampling.

Insulin Therapy

Insulin is the mainstay for treatment of virtually all type 1 and many type 2 diabetic patients. When necessary, insulin may be administered intravenously or intramuscularly. Long-term treatment generally relies on subcutaneous injection of the hormone, however.

Subcutaneous administration of insulin differs from physiologic secretion of insulin in two major ways. First, the kinetics of absorption are relatively slow and do not mimic the normal rapid increase and decrease of insulin secretion in response to ingestion of nutrients. Second, the injected insulin diffuses into the peripheral circulation instead of being released into the portal circulation. Any preferential effect of secreted insulin on hepatic metabolic processes is lost.

Insulin preparations

Insulin occurs in the pancreas complexed with zinc and is extracted in the form of zinc insulin, which is not water-soluble at neutral pH. This form can be converted to the Na^+ salt, which is water-soluble at neutral pH. Available preparations include human insulins and insulin analogues. Human insulins, so called because they have the same structure as normal human insulin, are made by genetic engineering (recombinant DNA). In ultrashort-acting insulin analogues (insulin aspart, glulisine, and lispro), amino acids are substituted, or reversed. Long-acting insulin analogues (insulin detemir and glargine) have groups added. Insulin analogues have been developed to alter the kinetics.

Insulin preparations are classified according to their duration of action into rapid-acting (ultrashort-acting and short-acting), intermediate-acting, and long-acting preparations. Insulin products available in the United States are listed in Table 36-3.

Rapid-acting (ultrashort-acting and short-acting) insulin preparations. Ultrashort-acting insulin preparations—insulin aspart (NovoLog), insulin glulisine (Apidra), and insulin lispro (Humalog)—all are insulin analogues. They may be used with a pump.* Regular insulins (Humulin R and Novolin R) are short-acting preparations. They are soluble, have a rapid onset, and are dispensed as clear solutions at neutral pH.

Intermediate-acting and long-acting insulin preparations. Insulin analogues—insulin glargine (Lantus) and insulin detemir (Levemir)—are soluble, long-acting insulin preparations. Their duration of action is longer and their time-action profile is flatter (peakless) than NPH (neutral protamine Hagedorn) insulin preparations. They causes less hypoglycemia at night.

Other intermediate-acting and long-acting insulin preparations contain particles and are cloudy suspensions at neutral pH. The larger the particles, the more slowly they dissolve, and the longer the duration of action of the preparation. NPH insulin is a protamine zinc suspension of insulin, at neutral pH, developed in Hagedorn's laboratory. Isophane insulin is NPH insulin in which there is no excess of either protamine or insulin. For therapeutic purposes, dosages and concentrations of insulin are expressed in units. Most commercial preparations of insulin are supplied in solution at a concentration of 100 U/mL (approximately 3.7 mg/mL).

*Insulin lispro, more than the others, may precipitate in pump infusion systems, resulting in unexplained hyperglycemia in patients on continuous subcutaneous insulin infusion therapy.

TABLE **36-3**

Insulin Preparations

PREPARATION	ONSET	PEAK	DURATION
Rapid—Ultrashort-Acting			
Insulin aspart (NovoLog)	5-15 min	1-2.5 hr	≤5 hr
Insulin glulisine (Apidra)	5-15 min	0.5-1.5 hr	2-5 hr
Insulin lispro (Humalog)	5-15 min	0.5-1.5 hr	2-5 hr
Rapid—Short-Acting			
Humulin R	30-60 min	2-4 hr	≤16 hr
Novolin R	30 min	2.5-5 hr	8 hr
Intermediate-Acting			
Humulin N	1-2 hr	4-12 hr	≤24 hr
Novolin N	1-2 hr	4-12 hr	24 hr
Premixed (% NPH/% Regular)			
Humulin 70/30	30-60 min	2-4 hr	≤24 hr
Humulin 50/50	30-60 min	2-4 hr	≤24 hr
Novolin 70/30	30 min	2.5-5 hr	24 hr
Premixed			
Humalog Mix (75% insulin lispro protamine/25% insulin lispro)	10-30 min	1-6 hr	≤24 hr
NovoLog Mix 70/30 (70% insulin aspart protamine/30% insulin aspart)	10-20 min	1-4 hr	15-18 hr
Long-Acting			
Insulin detemir (Levemir)	50-120 min	No peak	≤24 hr
Insulin glargine (Lantus)	1-2 hr	No peak	24 hr

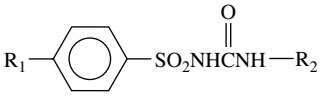
Kinetics of insulin preparations vary with site of injection.
N, NPH; *R*, regular.

Pharmacokinetics

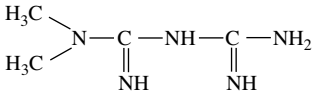
Insulin is given by injection, usually subcutaneously. Absorption of insulin after subcutaneous administration is affected by the site of injection, the subcutaneous blood flow, the volume and concentration of the injected insulin, and the presence of circulating insulin antibodies. Insulin absorption is usually most rapid from the abdominal wall, followed by the arm, buttock, and thigh. Increased subcutaneous blood flow (brought about by massage, hot baths, and exercise) increases the rate of absorption. Soluble insulins may also be given intravenously. The onset of action of insulin after intravenous injection is very fast, but the duration of action is short.

Adverse effects

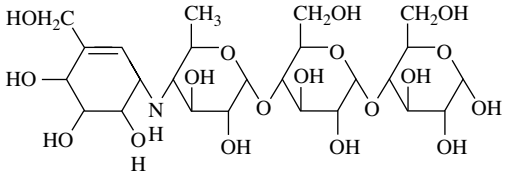
Hypoglycemia is the most common adverse reaction to insulin. Hypoglycemia may result from an inappropriately large dose, a mismatch between the time of peak delivery of insulin and food intake, increased sensitivity to insulin (e.g., adrenal insufficiency), or increased insulin-independent glucose uptake (exercise). The more vigorous the attempt to achieve euglycemia, the more frequent the episodes of hypoglycemia. The most frequent symptoms of hypoglycemia include sweating, tachycardia, tremor, blurred vision, weakness, hunger, confusion, and altered behavior. Loss of consciousness may follow. Hypoglycemia may be confused with inebriation by onlookers.



General structure of sulfonylureas



Metformin



Acarbose

FIGURE **36-3** Chemical structures of the sulfonylureas, metformin and acarbose.

With long-standing type 1 diabetes, the mechanisms for counteracting hypoglycemia may be blunted or absent in many patients, putting them at higher risk of developing hypoglycemia. Mild-moderate hypoglycemia may be treated by ingestion of sugar or honey. When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of glucagon.

ORAL ANTIHYPERGLYCEMIC AGENTS

Sulfonylureas

Sulfonylureas are sulfonamide derivatives (Figure 36-3). They are traditionally divided into two groups or generations of agents. Second-generation sulfonylureas are considerably more potent than the earlier drugs. Table 36-4 lists sulfonylureas available in the United States.

Mechanism of action

Sulfonylureas are effective only in patients with functioning pancreatic β cells. These drugs stimulate release of insulin by blocking adenosine 5′-triphosphate (ATP)–dependent K^+ current in pancreatic β cells. The effects of sulfonylureas are initiated by their binding to and blocking an ATP-sensitive K^+ channel. Glimepiride has been shown to have an additional effect: it increases the sensitivity of peripheral tissues to insulin.[9] This may be true for the other sulfonylureas (especially second-generation drugs) as well.[2] The predominant effect is on insulin secretion.

Pharmacokinetics

Sulfonylureas are well absorbed after oral administration. Glipizide absorption is delayed by food. All sulfonylureas are highly bound to plasma protein (90% to 99%). Plasma protein binding is least for chlorpropamide and greatest for glyburide. Sulfonylureas are metabolized in the liver and excreted in the urine.

The half-life and extent of metabolism vary considerably among first-generation sulfonylureas. Metabolism of chlorpropamide is incomplete, and approximately 20% of the drug is excreted unchanged, which can be a problem for patients with impaired renal function.

TABLE **36-4**

Sulfonylureas Available in the United States

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	ONSET (hr)	SERUM HALF-LIFE (hr)	DURATION OF ACTION (hr)
First-Generation				
Acetohexamide	Dymelor	1	6-8	12-24
Chlorpropamide	Diabinese	1	36	24-60
Tolazamide	Tolinase	4-6	7	12-24
Tolbutamide	Orinase	1	4.5-6.5	6-12
Second-Generation				
Glimepiride	Amaryl	2-3	9	10-24
Glipizide (glydiazinamide)	Glucotrol, Glucotrol XL	1-3	2-4	10-24
Glyburide (glibenclamide)	Diaβeta, Micronase, Glynase PresTabs	1-4*	4-10	10-24

*Micronized forms have a faster onset of action.

Therapeutic uses
Sulfonylureas are used to control hyperglycemia in type 2 diabetics who cannot achieve appropriate control with changes in diet and exercise alone.

Adverse effects
Adverse effects are infrequent, occurring in approximately 4% of patients taking first-generation drugs and perhaps slightly less often in patients receiving second-generation agents. The most important adverse effect is hypoglycemia, which, if severe, can lead to coma. Hypoglycemia is a particular problem in elderly patients with impaired hepatic or renal function who are taking longer acting sulfonylureas.

Sulfonylureas have a sulfonamide structure, which is the basis for cross-sensitivity with antibacterial sulfonamide drugs. Hypersensitivity reactions occur with some regularity. Other adverse effects of sulfonylureas include nausea and vomiting, occasional hematologic reactions (especially leukopenia and thrombocytopenia, and hemolytic anemia in susceptible patients), cholestatic jaundice, and dermatologic effects. Sulfonylureas are teratogenic in animals (large doses). Patients taking sulfonylureas tend to gain weight, which is a problem in type 2 diabetics, who tend to be obese.

Sulfonylureas have a disulfiram-like effect. In patients who take alcohol concurrently, sulfonylureas may decrease aldehyde dehydrogenase, causing acetaldehyde accumulation (see Chapter 43). As a result, the patient may have flushing, headache, nausea, vomiting, sweating, and hypotension shortly after alcohol ingestion. This reaction is not as likely to occur with a single occasional drink.

BOX **36-1**

Sulfonylurea Drug Interactions

Drugs That Increase the Effect of Sulfonylureas
Antihistamines (H_2 antagonists)
Azole antifungals
Clofibrate
Mg^{++} salts
Methyldopa
Monoamine oxidase inhibitors
Oral anticoagulants
Salicylates
Sulfonamides
Tricyclic antidepressants
β-Adrenergic receptor blockers

Drugs That Decrease the Effect of Sulfonylureas
Ca^{++} salts
Corticosteroids
Diazoxide
Estrogens
Phenothiazines
Sympathomimetics
Thiazide diuretics
Thyroid hormones

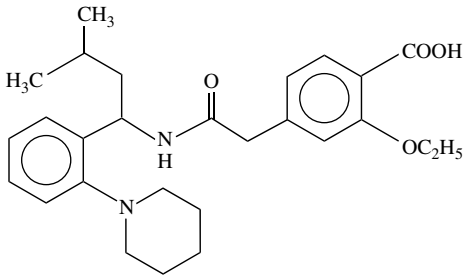
Drug interactions
As shown in Box 36-1, numerous drugs interact with sulfonylureas by enhancing or decreasing their effect on blood glucose concentration.

Contraindications
Contraindications to the use of sulfonylureas include hypersensitivity to sulfonylureas and drugs that have similar structures (see earlier) and pregnancy. Caution should be exercised in cases of reduced renal or hepatic function. Patients with ketoacidosis should receive insulin, not an oral antihyperglycemic agent.

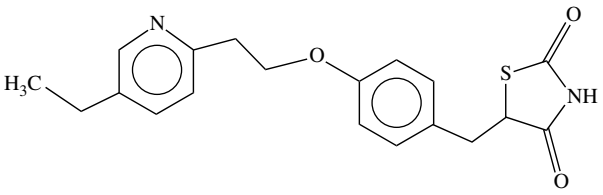
Meglitinides

Meglitinides that are approved for use in the United States are repaglinide and nateglinide. The structure of repaglinide is shown in Figure 36-4. These drugs are effective only in patients with functioning pancreatic β cells. Similar to sulfonylureas, they stimulate release of insulin by blocking ATP-dependent K^+ channels in pancreatic β cells. They may be used alone or in combination with metformin (see later) and may be given to patients who are allergic to sulfonamides.

Pharmacokinetics
Repaglinide and nateglinide are rapidly absorbed after oral administration. They are metabolized primarily by the liver. Repaglinide peak plasma levels occur within 1 hour, and the plasma half-life is 1 hour. It is recommended that this drug be taken just before each meal. Nateglinide is most effective if taken 1 to 10 minutes before a meal. These drugs offer the advantage of rapid and short-term control over blood glucose.



Repaglinide



Pioglitazone

FIGURE **36-4** Chemical structure of repaglinide and pioglitazone.

Adverse effects
Hypoglycemia is the major adverse effect of repaglinide and is most likely to occur if a meal is delayed or skipped or in patients with hepatic insufficiency.

Drug interactions
Ketoconazole, miconazole, and erythromycin decrease biotransformation and potentiate the effect of repaglinide. Nonsteroidal anti-inflammatory drugs, salicylates, sulfonamides, and other highly protein-bound drugs may potentiate the hypoglycemic effects of repaglinide.

Biguanides

Metformin is currently the only biguanide approved for use in the United States (see Figure 36-3). Phenformin and buformin, two other biguanides, are widely used in Europe and elsewhere.[4] Phenformin was withdrawn from the United States in 1977 because of its ability to cause lactic acidosis.

Mechanism of action
The mechanism of action of biguanides differs from that of sulfonylureas or meglitinides. Biguanides decrease blood glucose concentrations by several different actions. They decrease hepatic gluconeogenesis, improve tissue sensitivity to insulin, increase peripheral glucose uptake and use, and decrease intestinal absorption of glucose. Biguanides do not cause hypoglycemia. In addition, patients do not gain weight, in contrast to patients taking sulfonylureas. The action of biguanides does not depend on functioning pancreatic β cells, and they are often used in combination with sulfonylureas and other hypoglycemic agents such as thiazolidinediones.

Pharmacokinetics
Approximately 50% to 60% of an oral dose of metformin is absorbed after oral administration. Food decreases the extent of absorption and delays it slightly. Protein binding is minimal, and metformin is excreted unchanged in the urine by tubular secretion. Approximately 90% is excreted within 24 hours. It has a plasma half-life of approximately 6 hours.

Adverse effects
Gastrointestinal tract symptoms, such as nausea, anorexia, vomiting, diarrhea, flatulence, and cramps, are common adverse effects of metformin (biguanides). These effects are dose-dependent and may be transient. In some patients they are severe enough to make the drug intolerable. Metformin may cause a decrease in vitamin B_{12} levels, possibly by decreasing absorption from the vitamin B_{12} intrinsic factor complex. Lactic acidosis is a rare but serious complication of biguanides. When it occurs, it is fatal in roughly 50% of patients.

Contraindications
Biguanides are contraindicated in patients with renal disease, hepatic disease, or conditions predisposing to tissue anoxia (including cardiopulmonary dysfunction) because of concern regarding lactic acidosis.

Thiazolidinediones

Thiazolidinediones currently available are pioglitazone and rosiglitazone. The structure of pioglitazone is shown in Figure 36-4.

Mechanism of action
Thiazolidinediones act by increasing insulin sensitivity in tissues. They are agonists at the nuclear peroxisome proliferatoractivated receptor-γ (PPARγ). They depend on the presence of insulin for their activity. Thiazolidinediones decrease hepatic gluconeogenesis and increase insulin-dependent glucose uptake in muscle and fat.[10] They act synergistically with sulfonylureas and metformin.

Pharmacokinetics
Thiazolidinediones are taken orally, once a day, with or without food. The maximal effect is not seen for 6 to 12 weeks. They are metabolized by the cytochrome P450 oxidative enzyme system.

Adverse effects
Thiazolidinediones now carry a "black box" warning of congestive heart failure and myocardial ischemia. There is also weight gain and a risk of edema, osteoporosis, and fractures.[18] Hepatotoxicity is also a possible adverse effect.

Drug interactions
Concurrent administration of pioglitazone with oral contraceptives containing ethinyl estradiol and norethindrone results in decreased plasma concentrations of the contraceptive and can result in loss of contraceptive effect. Ketoconazole has been shown to inhibit pioglitazone metabolism in vitro.

Incretin-Related Drugs

Incretin-related drugs include exenatide and sitagliptin. Vildagliptin is in clinical trials. Although exenitide is not given orally, these drugs are generally classified with oral antihyperglycemic agents.

It has long been known that oral glucose produces greater release of insulin than intravenous glucose. Two hormones, secreted from the gastrointestinal tract, have been shown to stimulate insulin secretion. They are known as *incretins*. The two compounds are glucagon-like peptide 1 (GLP-1), and glucose-dependent insulinotropic polypeptide (GIP). Their secretion is increased by food and elevated glucose levels. GLP-1 has been shown to augment glucose-dependent insulin secretion. It also reduces glucagon secretion, slows gastric emptying, and decreases appetite. GLP-1 is rapidly inactivated by dipeptidyl peptidase 4 (DPP-4). Exenatide is an agonist at GLP-1 receptors, but it is resistant to DPP-4. It is given by injection twice daily. There are reports of rare cases of hemorrhagic or necrotizing pancreatitis with exenatide.

Sitagliptin inhibits GPP-4, decreasing the biotransformation of GLP-1. It is given orally.

Analogue of Amylin

Pramlintide is an analogue of amylin that is approved in the United States. Amylin is a peptide containing 37 amino acids. It is produced by pancreatic β cells and cosecreted with insulin. Amylin has a role in the maintenance of glucose homeostasis. It decreases glucagon secretion, slows gastric emptying by a vagally mediated mechanism, and decreases appetite centrally. Pramlintide is an analogue of amylin and has an action similar to amylin. It is used in patients who are being treated with insulin (type 1 and type 2 diabetics). It is given by injection at mealtimes.

MISCELLANEOUS DRUGS USED IN THE TREATMENT OF DIABETIC PATIENTS

α-Glucosidase Inhibitors

Acarbose and miglitol are α-glucosidase inhibitors approved for use in the United States. The structure of acarbose is shown in Figure 36-3. α-glucosidases facilitate digestion of complex starches, oligosaccharides, and disaccharides into monosaccharides, allowing them to be absorbed from the small intestine. α-glucosidase inhibitors are competitive, reversible inhibitors of intestinal α-glucosidases. Acarbose also inhibits α-amylase. α-glucosidase inhibitors delay absorption of most carbohydrates. This delayed absorption limits the postprandial increase in glucose. They do not directly affect insulin secretion.

Pharmacokinetics

α-Glucosidase inhibitors are taken at the beginning of meals. Absorption of acarbose is poor. It is metabolized in the gastrointestinal tract, principally by intestinal bacteria. Miglitol is absorbed after oral administration.

Adverse effects

Adverse effects include flatulence, diarrhea, and abdominal pain from the presence of undigested carbohydrates in the lower gastrointestinal tract. These effects tend to decrease with continued use. When given alone, α-glucosidase inhibitors do not cause hypoglycemia. Hypoglycemia may occur, however, with concurrent sulfonylurea therapy. Hypoglycemia should be treated with glucose, not sucrose, because breakdown of sucrose may be inhibited. Miglitol has minor lactase inhibitory activity, but should not induce lactose intolerance.

Drug interactions

Miglitol decreases plasma concentrations of several drugs, including glyburide and metformin.

Contraindications

Contraindications to α-glucosidase inhibitors include hypersensitivity to these agents, inflammatory bowel disease, and intestinal obstruction.

Inositolphosphoglycans

Evidence suggests that interaction of insulin with its receptor leads to the release of low-molecular-weight IPGs, which enter the cell and act as mediators of insulin action. IPG mediators have been shown to reproduce various short-term effects of insulin (see Figure 36-2). Two families of IPG insulin mediators have been isolated. Myoinositol is a major component of one; chiroinositol is a major component of the other. Studies have shown the presence of hypochiroinositoluria in type 2 diabetics. In addition, there is decreased chiroinositol content and decreased chiroinositol mediator activity in type 2 diabetics.[1] There is evidence that chiroinositol decreases elevated blood glucose concentrations in diabetic monkeys and rats. Studies have also shown that pinitol, which is 3-O-methyl chiroinositol, decreases hyperglycemia in a diabetic murine model and in humans with diabetes.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers have been shown to delay the onset and reduce significantly the progression of diabetic nephropathy. They are given to diabetics to decrease the incidence of these complications of the disease.[12]

GLUCAGON

Glucagon is synthesized in the α cells of the pancreatic islets. It is a 29-amino acid peptide with a molecular weight of approximately 3500 Da. Similar to insulin, it is formed from a larger precursor molecule by proteolytic cleavage. Glucagon binds to specific G_s protein–linked receptors in the liver, causing an increase in adenylyl cyclase activity and production of cyclic adenosine 3′,5′-monophosphate. This ultimately results in an increase in glycogen phosphorylase activity and a decrease in glycogen synthase. Glucagon increases blood glucose concentration by decreasing glycogen synthesis, stimulating breakdown of stored glycogen, and increasing gluconeogenesis in the liver. It does not affect skeletal muscle glycogen, presumably because of a lack of receptors in skeletal muscle. Glucagon has potent inotropic and chronotropic effects on the heart. These are similar to effects resulting from β-adrenergic receptor stimulation.

Pharmacokinetics

Glucagon is rapidly degraded in the plasma, liver, and kidney. Its half-life is 3 to 6 minutes.

Therapeutic Uses

Glucagon may be used in the emergency treatment of severe hypoglycemic reactions (sufficient to cause unconsciousness). It is given parenterally. Glucagon is also used to reverse the cardiac effects of toxic amounts of β-adrenergic receptor blockers.

Adverse Effects

Adverse effects include nausea (usually transient) and vomiting. Glucagon may cause transient tachycardia and hypertension.

IMPLICATIONS FOR DENTISTRY

There are approximately 23.6 million diabetics (approximately 7.8% of the population) in the United States. About a quarter of diabetics are unaware that they have the disease. In the United States, the annual number of newly diagnosed diabetes cases tripled during 1980-2005.

Type 2 diabetes is becoming increasingly common and is an emerging problem in children and adolescents, particularly minorities. Major risk factors for type 2 diabetes are obesity and physical inactivity. Dentists can expect to have an increasing number of diabetic patients, many of whom are unaware of their condition.

Diabetes mellitus is a complex, chronic disease that is characterized by hyperglycemia. It is an incurable disease, and the need for lifelong compliance is a problem for many patients. Complications of the disease include neuropathy, microangiopathy, and macrovascular disease. Diabetic neu-

ropathy may cause numbness, tingling, or a deep burning pain. Neuropathy may manifest as oral paresthesias and burning mouth. Diabetics are more susceptible to infection and have an impaired ability to deal with infection. They also have delayed wound healing. In addition, infection, stress (emotional or physical), and surgical procedures commonly disturb the control of diabetes.

Numerous oral complications may occur in diabetes, including xerostomia; infection; poor healing of wounds or lesions; and an increased incidence and severity of caries, candidiasis, gingivitis, periodontal disease, and periapical abscesses. Diabetics often have progressive periodontal disease and may have multiple periodontal abscesses. Diabetics may have burning mouth syndrome or loss of sensation. Type 2 diabetics have impaired sweet taste detection (glucose and sucrose).

Because of the antihyperglycemic drugs or irregular eating habits or both, patients may become hypoglycemic. Signs and symptoms of mild hypoglycemia include hunger, weakness, tachycardia, pallor, and sweating. Tachycardia may be masked by β-adrenergic receptor blockers. β Blockers, especially nonselective ones, also tend to worsen hypoglycemia. Signs of moderate hypoglycemia include incoherence, uncooperativeness, belligerence, lack of judgment, and poor orientation. If hypoglycemia is severe, the patient may become unconscious.

Diabetics are more susceptible to infection and may need antimicrobial therapy more often. Morning appointments are usually best for diabetic patients because that minimizes the chance of stress-induced hypoglycemia. A source of sugar should be readily available. Patients taking α-glucosidase inhibitors need glucose, not sucrose, because breakdown of sucrose may be inhibited by these drugs.

ANTIHYPERGLYCEMIC AND HYPERGLYCEMIC AGENTS

Nonproprietary (generic) name	*Proprietary (trade) name*
Antihyperglycemic agents	
Acarbose	Precose
Acetohexamide	Dymelor
Chlorpropamide	Diabinese
Exenatide	Byetta
Glimepiride	Amaryl
Glipizide	Glucotrol, Glucotrol XL
Glyburide	Micronase, Diaβeta, Glynase PresTabs
Insulin	See Table 36-3
Metformin	Glucophage, Riomet
Miglitol	Glyset
Nateglinide	Starlix
Pioglitazone	Actos
Pramlintide	Symlin
Repaglinide	Prandin
Rosiglitazone	Avandia
Sitagliptin	Januvia
Tolazamide	Tolinase
Tolbutamide	Orinase
Combined preparations	
Glipizide + metformin	Metaglip
Glyburide + metformin	Glucovance
Pioglitazone + glimepiride	Duetact
Rosiglitazone + glimepiride	Avandaryl
Rosiglitazone + metformin	Avandamet
Sitagliptin + metformin	Janumet
Hyperglycemic agents	
Glucagon	—
Glucose	Insta-Glucose

CHAPTER 37

*Steroid Hormones of Reproduction and Sexual Development**

ANGELO J. MARIOTTI

The central focus of endocrinology is on specific regulatory molecules (i.e., hormones) that govern reproduction; growth and development; maintenance of the internal environment; and energy production, usage, and storage. As a result of these global demands within the organism, the actions of hormones are complex and diverse in nature. A single hormone may elicit a different outcome in various tissues, or a variety of hormones may be required to produce a single, particular effect in a group of tissues. Estrogens can function independently to stimulate growth of the breast (promotion of fat accumulation, connective tissue development, and ductal growth) yet must work in concert with other hormones (prolactin, progesterone, placental lactogen, glucocorticoids, thyroxine, and oxytocin) to regulate lactation. Despite the complex and diverse nature of hormones, it is possible to categorize these compounds into two classes depending on their chemical structure: the peptide/amino acid derivative hormones and the steroid hormones.

Steroid hormones are derivatives of cholesterol and consist of a combination of three rings of six carbon atoms each (phenanthrene) and one ring of five carbon atoms (cyclopentane) to form a complex hydrogenated cyclopentanoperhydrophenanthrene ring system (Figure 37-1). Steroid hormones can be divided further into three principal sets: corticosteroid hormones (glucocorticoids and mineralocorticoids), Ca^{++}-regulating steroid hormones (vitamin D and its metabolites), and gonadal or sex steroid hormones (estrogens, androgens, and progestins).

The past 50 years have dramatically improved our perceptions concerning the actions of sex steroid hormones in health and disease. Although there is no doubt of the importance of sex steroid hormones in reproductive endocrinology, evidence has accrued that gonadal hormones have a much broader role in human tissues. Androgens, estrogens, and progestins are now believed to be directly or indirectly involved in the regulation of various diverse tissues, such as the brain, heart, kidney, skin, liver, and tissues of the oral cavity. Reports of the effects of sex steroid hormones in the periodontium, a unique structure composed of two fibrous (gingiva and periodontal ligament) and two mineralized (cementum and alveolar bone) tissues, have been noted for more than a century. The effect of sex steroid hormones on each periodontal tissue has heightened interest in defining the specific relationships among androgens, estrogens, and progestins and their role in normal function and disease in the periodontium.

Since the identification of gonadal hormones in the early twentieth century, the use of these agents has exploded. Today, steroidal and nonsteroidal compounds with properties of sex steroid hormones are extensively used in the prophylaxis or treatment of disease and for birth control. Although dentists do not typically prescribe these agents, their ubiquitous presence in the population requires a careful understanding of the actions and interactions of sex steroids with other pharmacologic agents and how they affect structures in the oral cavity.

STRUCTURE AND FUNCTION

Androgens

Androgens (Figure 37-2) are derived from a 19-carbon tetracyclic hydrocarbon nucleus known as *androstane*. One of the most potent androgenic hormones, testosterone, is synthesized by the Leydig cells of the testes, the thecal cells of the ovary, and the adrenal cortex. In men, testosterone is the principal plasma androgen and is reduced to dihydrotestosterone, the mediator of most actions of the hormone.[32] The irreversible metabolic conversion of testosterone to dihydrotestosterone occurs only in tissues that contain the enzyme 5α-reductase.[51] Testosterone (but not dihydrotestosterone) can also be aromatized to estradiol by numerous extragonadal tissues (primarily adipose tissue and skeletal muscle), a common route of estrogen production in men. In women, the major plasma androgen is androstenedione (androst-4-ene-3,17-dione), which can be secreted into the bloodstream or converted into either testosterone or estradiol by the ovary.

When secreted into the bloodstream, most androgens are transported to their sites of action by a liver-secreted carrier protein termed *sex hormone–binding globulin* (44% bound) and serum albumins and other proteins (54% bound).[7] Secreted plasma androgens are also metabolized to physiologically weak or inactive molecules consisting of either 17-ketosteroids or polar compounds (diols, triols, and conjugates) for excretion by the kidney or liver.[20]

Androgens may be administered orally, topically, or through intramuscular injections (Table 37-1). Testosterone is generally not administered enterally because extensive first-pass hepatic metabolism rapidly reduces plasma concentrations. The bioavailability of androgens is increased by intramuscular injections in an oil vehicle, by transdermal application, or by alkylation at C17, which significantly decreases hepatic metabolism and makes oral administration therapeutically possible.

The biologic activities of androgens are manifested in virtually every tissue of the body. Important functions of andro-

*The author recognizes Dr. William Warner for his past contributions to this chapter.

gens include (1) male sexual differentiation of wolffian ducts, external genitalia, and brain in utero; (2) development of adult male phenotype, including growth and maintenance of male sex accessory organs and anabolic actions on skeletal muscle, bone, and hair; (3) facilitation of human sexual behavior; and (4) regulation of specific metabolic processes in the liver, kidney, and salivary glands.[32]

Estrogens

Estrogens (Figure 37-3)—estrone, estradiol, and estriol—are characterized by an aromatic A ring, a hydroxyl group at C3, and either hydroxyl groups (C16 and C17) or a ketone group (C17) on the D ring. Estradiol is the most potent estrogen

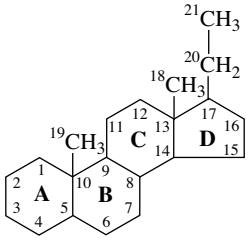

FIGURE **37-1** Ring structure for pregnane and numbering system for steroids. Progesterone contains 21 carbons. Androgens, estrogens, and some progestins lack carbons 20 and 21. Estradiol and synthetic estrogenic steroids have an aromatic ring A and lack carbon 19.

FIGURE **37-2** Structural formulas of testosterone and other androgens.

TABLE **37-1**

Anabolic-Androgenic Drugs

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	INDICATIONS	DOSE	MISCELLANEOUS
Danazol	Danocrine	Endometriosis, fibrocystic breast disease, hereditary angioedema	Oral, 800 mg/day	Suppresses pituitary-ovarian axis; weak androgen
Fluoxymesterone	Halotestin	Delayed puberty in boys, hypogonadism, breast cancer	Oral, 10-40 mg/day depending on indication	Methylated androgens are more likely to cause jaundice
Methyltestosterone	Android, Testred, Virilon	Delayed puberty in boys, hypogonadism, breast cancer	Oral, 5-200 mg/day depending on indication	Methylated androgens are more likely to cause jaundice
Oxandrolone	Oxandrin	Catabolic or tissue-depleting processes	Oral, 2.5-20 mg/day depending on indication	Methylated androgens are more likely to cause jaundice
Testosterone propionate	Testex	Lichen sclerosus, microphallus	Injected or topical (ointment)	Ester forms of testosterone increase its duration of action

TABLE **37-2**

Estrogenic Drugs

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	INDICATIONS	DOSE	MISCELLANEOUS
Diethylstilbestrol	Stilphostrol	Prostatic carcinoma	Oral, 1 mg/day	Not available in U.S., available in Canada
Ethinyl estradiol	Estinyl	Prostatic carcinoma; menopausal vasomotor symptoms; estrogen deficiency from surgery, ovarian failure, or hypogonadism; contraception	Oral, 0.02-0.15 mg/day depending on indication	Used in combination with progestins in oral contraceptives
Conjugated estrogens	Premarin	Menopausal symptoms, prevention of postmenopausal bone loss, atrophic vaginitis, hypoestrogenism	Oral, 0.3-1.25 mg/day (more in certain circumstances); intravenous or intramuscular (for hormone imbalance), up to 50 mg/day; vaginal cream, 0.5-2 g/day	

and is secreted by the ovary, testes, placenta, and peripheral tissues. Estrone is also secreted by the ovary; however, the principal source in women and men is through extragonadal conversion of androstenedione in peripheral tissues.[43] In premenopausal women, the most abundant physiologic estrogen is estradiol; in men and postmenopausal women, the most abundant estrogen in the plasma is estrone.[54] Similar to other lipid-soluble hormones, estrogens are transported in the blood principally bound to carrier proteins; estradiol in the plasma is bound by either albumin (60%) or sex hormone–binding globulin (38%), leaving only 2% of the hormone free.[53] Estradiol and estrone are metabolized principally to estriol, which is the major estrogen detected in the urine.

Estrogens may be administered orally, topically, or through intramuscular injections (Table 37-2). Although estradiol is available for enteral administration, it is generally not used in this manner because concentrations in the bloodstream remain low because of extensive hepatic metabolism.[10] The half-life of estrogenic compounds can be increased by synthetic substitutions on the C or D ring (see Figure 37-3). The half-life of estradiol is a few minutes, whereas the half-life of ethinyl estradiol (ethinyl substitution at the C17 position) may be more than 13 hours. Nonsteroidal compounds may also have estrogenic activity; examples of such compounds include diethylstilbestrol, flavones, isoflavones, and certain pesticides (e.g., p,p′-DDT) and plasticizers (e.g., bisphenol A).

The biologic activities of estrogens in women include (1) development, growth, and maintenance of secondary sex characteristics; (2) uterine growth; (3) pulsatile release of luteinizing hormone from the pituitary; (4) thickening of the vaginal mucosa; and (5) ductal development in the breast. In men, the physiologic significance of estrogens is largely unknown, but may be involved in the regulation of plasma androgen and estrogen levels and sexual behavior.

Progestins

Progestins (Figure 37-4), or steroids that have progestational activity, are derived from a 21-carbon saturated steroid hydrocarbon known as *pregnane*. The principal progestational hormone secreted into the bloodstream is progesterone, which is synthesized and secreted by the corpus luteum, placenta, and adrenal cortex. As with androgens, most progesterone is

TABLE **37-3**

Progestins

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	INDICATIONS	DOSE	MISCELLANEOUS
Medroxyprogesterone acetate	Provera, Depo-Provera	Dysfunctional uterine bleeding, endometrial carcinoma, contraception	Oral and injectable (IM), 5-20 mg/day orally or 150 mg IM for 3 mo to 400 mg IM per month depending on indication	
Norethindrone	Aygestin, Micronor, Nor-QD	Dysfunctional uterine bleeding, endometriosis, contraception	Oral, variable depending on indication	For contraception, 0.35 mg/day
Norgestrel	Ovrette	Contraception	Oral, 0.075 mg/day	

IM, Intramuscular.

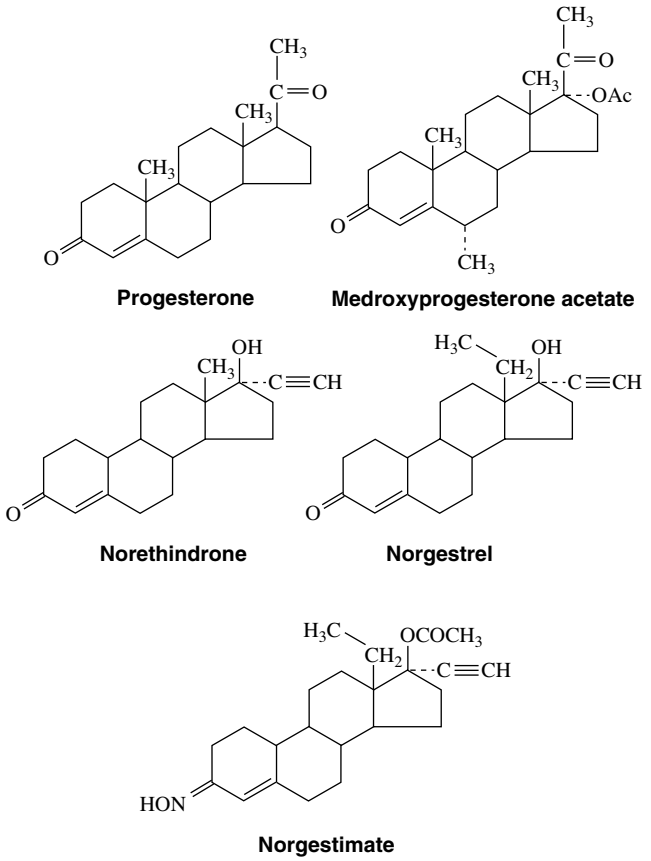

FIGURE **37-4** Structural formulas of progesterone and progestins.

transported in the bloodstream by plasma proteins; however, progesterone in humans is primarily nonspecifically bound to globulin and albumin proteins. The fate of plasma progesterone depends on hepatic, extrahepatic, and extra-adrenal metabolism. 5-α-Dihydroprogesterone and deoxycorticosterone are the most probable active progesterone metabolites. Metabolic inactivation of progesterone to pregnanediol is accomplished by the liver.

Progestins may be administered orally, topically, or through intramuscular injections (Table 37-3). Progesterone is available for enteral administration; however, it is generally not administered in this manner because concentrations in the bloodstream remain low because of extensive first-pass hepatic metabolism. The bioavailability of progestins can be increased by intramuscular injections in oil, by vaginal suppositories, or by ethinyl or other substitution at C17, which significantly decreases hepatic metabolism.

The biologic activities of progestins are principally observed during the luteal phase of the menstrual cycle and pregnancy. Progesterone is necessary for glandular endometrial development before nidation, the development of mammary lobules and alveoli, and the maintenance of pregnancy (i.e., endometrial gland function, decreased excitability of myometrium, and possible effects on the immune system to decrease rejection of the developing fetus). Progesterone also decreases hepatic secretion of very-low-density lipoprotein and high-density lipoprotein, diminishes insulin action, stimulates the hypothalamic respiratory center, elevates basal core body temperature at ovulation, and enhances sodium excretion by the kidneys.

MECHANISM OF ACTION

In the bloodstream, sex steroid hormones exist in extremely low concentrations (in the femtomolar to nanomolar range), yet are capable of regulating differentiation and growth in selected tissues distant from the site of secretion. The actions of sex steroid hormones become even more intriguing when one considers that the distinct biologic effects of these hormones depend on nominal differences between relatively small (molecular weight approximately 300 Da) molecules. Testosterone, which is capable of powerful virilizing effects, differs from estradiol by only one carbon atom and four hydrogen atoms. (Estradiol is aromatic, as are the other estrogens.) These differences in molecular structure of steroid hormones change biologic activity. Specificity of hormone response also depends on the presence of intracellular proteins or receptors, which specifically recognize and selectively bind the hormone and act in concert with the hormone ligand to regulate gene expression.

The current hypothesis of sex steroid hormone action[2] begins with the absorption of the hormones into the bloodstream, where they circulate, principally bound (approximately 98%) to plasma proteins. In the circulation, the unbound or free hormone can enter the cell by diffusion and bind to receptors. These large intracellular protein receptors are located in the nucleus of the cell. When the steroid hormone is bound to the receptor, it transforms the receptor to an active configuration, and the activated receptor-steroid hormone complex binds with high affinity to specific nuclear sites (e.g., discrete DNA sequences, nuclear matrix, nonhistone proteins, nuclear membrane). When the receptor-hormone complex is bound to nuclear regulatory elements, a coactivator is usually recruited to the promoter region

to allow gene activation and transcription of messenger RNA. After the nuclear interaction, the receptor-hormone complex dissociates, leaving an unoccupied receptor and the steroid hormone. The dissociated receptor is thought to be in an inactive configuration that requires conversion to a form that can bind the steroid again, and the steroid hormone is metabolized and eliminated from the cell.

Although the regulation of gene transcription by hormone-receptor complexes in the nucleus seems to be the major biologic action of sex steroid hormones, these molecules also have other behaviors that are distinct from actions at nuclear receptors. Androgens, estrogens, and progestins have membrane effects and can influence the production of second messenger systems, which can affect neural transmission, the transport of Ca^{++} ions into cells, and the intracellular concentration of polyamines.[28]

Steroid Hormone Receptor Structure

The receptors for steroid hormones are able to initiate a wide assortment of responses yet are very similar to one another, not only in their mechanism of action, but also in their structure.[9,22] In general, steroid hormone receptors consist of asymmetric protein subunits with long (10:10 1) axial ratios. These subunits, which form either dimers or tetramers at low ionic strengths, range in weight from 80 to 100 kDa. As a class of regulatory proteins, the different steroid hormone receptors have a high degree of homology. Each protein can be divided into six sections, designated as regions *A* through *F*.[32]

The A/B regions located at the N-terminal are exceedingly variable in size (50 to >500 amino acids) and have negligible amino acid similarities between different receptors. The C region, located between the N-terminus and C-terminus, is a remarkably conserved area that contains the DNA-binding domain. The hydrophilic D region is not conserved in length or sequence but may serve as a hinge between the hormone-binding and DNA-binding domains. The E/F regions located at the C-terminal are similar in size (250 to 300 amino acids), have moderate amino acid homology among the different steroid receptor proteins, and contain the hormone-binding domain. Areas in the N-terminal and the C-terminal are responsible for the transcriptional activation of the DNA.[13,23]

From these six regions, two important binding domains are present for sex steroid hormone receptors. In one binding domain, the functional activation of the receptor depends on a distinct, high-affinity binding site for a specific hormone. This steroid hormone-binding domain is a large hydrophobic region located near the C-terminal. The other receptor-binding domain recognizes specific sites on DNA. This DNA-binding domain of the steroid receptor is a highly conserved area that contains a tetrahedral arrangement of four cysteine residues around a zinc ion to form a zinc finger-like structure.[30] On activation of the receptor, the receptor-steroid complex binds to a specific site on the DNA that is referred to as a *steroid responsive element*. Steroid responsive elements are unique for each receptor but have common nucleotide characteristics.

THERAPEUTIC USES

Androgens

The least controversial and principal indication for androgen therapy is for the treatment of testosterone deficiency in adolescent boys and men. Transdermal testosterone preparations have been used to mimic normal serum levels for testosterone-deficient boys to develop normal genitalia and secondary sex characteristics and for the normal virilization of hypogonadal men. Other, less common and more controversial applications for androgens include uses for male senescence, female hypogonadism, enhancement of athletic performance, male contraception, catabolic and wasting states, angioneurotic edema, and blood dyscrasias.

Estrogens

The two principal reasons for the prescription of estrogens are for the prevention of conception and to reduce the sequelae associated with declining hormone levels after menopause. Oral contraceptives are among the most widely used medications in the world and most often are a combination of estrogens and progestins (Table 37-4). Combination oral contraceptives principally affect conception by suppressing the surge of luteinizing hormone, which consequently prevents ovulation (Figure 37-5).[24] The estrogen component of combination oral contraceptives usually contains either ethinyl estradiol or mestranol. In these preparations, the estrogen content ranges from 20 to 50 μg; pills containing less than 35 μg are usually considered low-dose contraceptives.

Examples of Contraceptive Agents

PROPRIETARY (TRADE) NAME	ESTROGEN	PROGESTIN
Ovcon-35 (monophasic), Ortho-Novum 10/11 (biphasic), Necon 7/7/7 (triphasic), Loestrin 24 Fe* (monophasic)	Ethinyl estradiol	Norethindrone
Norinyl 1/50 (monophasic), Ortho-Novum 1/50 (monophasic)	Mestranol	Norethindrone
Ortho-Cyclen (monophasic), Ortho Tri-Cyclen (triphasic)	Ethinyl estradiol	Norgestimate
Lo/Ovral (monophasic), Cryselle (monophasic)	Ethinyl estradiol	Norgestrel
Yaz* (monophasic), Yasmin (monophasic)	Ethinyl estradiol	Drospirenone
Seasonale (84-day therapy, extended cycle), Seasonique (84-day therapy, extended cycle)	Ethinyl estradiol	Levonorgestrel
Lybrel†	Ethinyl estradiol	Levonorgestrel
Micronor†	—	Norethindrone
Depo-Provera	—	Medroxyprogesterone acetate
Implanon (implant)	—	Etonogestrel
Ortho Evra (transdermal)	Ethinyl estradiol	Norelgestromin
NuvaRing (transvaginal)	Ethinyl estradiol	Etonogestrel
Plan B (emergency)‡	—	Levonorgestrel
Preven (emergency)‡	Ethinyl estradiol	Levonorgestrel

*24-day formulation followed by 4 days of inert tablets.
†Continuous therapy, without a placebo or pill-free period.
‡Emergency, postcoital preparation.

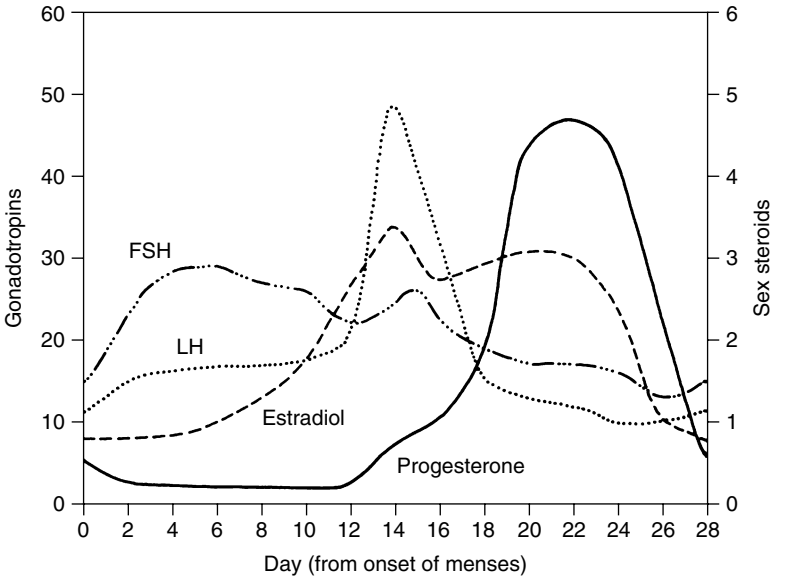

FIGURE **37-5** Hormonal changes during the normal menstrual cycle. The gonadotropins follicle-stimulating hormone *(FSH)*, and luteinizing hormone *(LH)* are measured in mU/mL; the sex steroids estradiol and progesterone are plotted in units (1 unit = 100 pg/mL of estradiol and 2 ng/mL of progesterone). Combination oral contraceptives prevent ovulation by inhibiting LH (and FSH) secretion, resulting in no LH peak at mid-cycle.

Combination oral contraceptives include monophasic, biphasic, or triphasic preparations. Monophasic preparations maintain a fixed dose of estrogen and progesterone over a 21-day period; biphasic contraceptives maintain a fixed dose of estrogen but increase the progestin dose over a 21-day period; and triphasic preparations may have varying amounts of estrogen and progestin for 21 days. In each case the 21-day treatment regimen is followed by 7 days of placebo or no drug. Biphasic and triphasic oral contraceptives were designed to approximate more closely the ratios of estrogen and progesterone during the menstrual cycle. The progestin in the oral contraceptive also protects the endometrium of the uterus against the proliferative action of the estrogen. The inclusion of a progestin reduces the risk of endometrial cancer. A modification of these regimens is 24 days of drug treatment (monophasic) followed by 4 days of placebo.

More recently, extended-cycle and continuous contraceptive dosing were introduced. A combination of ethinyl estradiol and a progestin, usually levonorgestrel, is administered. Extended-cycle preparations (Seasonale and Seasonique) involve 84 days of drug treatment followed by placebo for 7 days or 7 pill-free days (see Table 37-4). An advantage with extended-cycle preparations is that menses occurs only four times a year in most cases. Continuous dosing involves no drug-free period; in this case, one adverse effect that has been reported is breakthrough bleeding. Contraceptives may also be administered transdermally or vaginally (see Table 37-4). An advantage to these routes of administration is the ability to reduce liver exposure to the hormones. Estrogens, by their effects on the liver, increase certain blood clotting factors and renin substrate, which increases the risk for thromboembolism and hypertension.

Another major use of estrogen has been in postmenopausal women for the prevention of osteoporosis-related fractures to vertebral or long bones. Osteoporosis is characterized by reduced bone mass and microarchitectural deterioration of cortical and trabecular bone and is a major public health problem among elderly women. In the United States, one in three postmenopausal women is affected by osteoporosis; by age 90 years, one in two women and one in six men are likely to sustain an osteoporosis-related fracture. Of affected elderly individuals, 12% to 20% die of fracture-related complications, making osteoporosis the twelfth leading cause of death in the United States.[34] It has been estimated that more than $19 billion was required to treat the 2 million Americans who had an osteoporosis-related fracture and its sequelae. It is estimated that the costs of managing osteoporosis will increase to approximately $25.3 billion by 2025.[33] As the elderly population continues to increase, so will the incidence of osteoporosis and its complications.[14,17,34]

To reduce the incidence of osteoporosis, and if estrogen receptor agonists are indicated, treatment with a traditional estrogen or raloxifene (see later) in combination with exercise and an appropriate diet should begin before there is significant bone loss (Table 37-5). Estrogens can prevent further bone loss but cannot restore lost bone; the benefits of estrogen replacement therapy require continuous use of the drug. Estrogen replacement therapy has also been shown to be effective in the treatment of vasomotor symptoms associated with menopause (e.g., hot flashes, paresthesia, hyperhidrosis) and postmenopausal urogenital atrophy. Orally or locally administered estrogens can prevent the symptoms (e.g., pruritus vulvae, urinary incontinence, dysuria, dyspareunia) associated with a thinning epithelial lining of the vagina or bladder. As in oral contraceptives, the addition of a progestin in postmenopausal therapy protects against endometrial cancer.

In addition to the use of estrogens for postmenopausal women, estrogen treatment has been successful in adolescents when ovaries do not develop and puberty is absent.[1] Treatment with estrogen can promote normal growth of genital structures and breasts and assist in bone growth.

Progestins

Similar to estrogens, progestins can be used alone or in combination with estrogen for contraception and are used in combination for hormone replacement in postmenopausal women (see Table 37-5). The dose of the progestin component for combination oral contraceptives has greater variability because of differences in the potency of the progestin used. In most preparations, the progestin content ranges from 0.1 to 1 mg. Progestins commonly used in oral contraceptives include norethindrone and levonorgestrel. A unique progestin, drospirenone, is presently used in two oral contraceptive preparations (see Table 37-5). Drospirenone is also an antiandrogen and an antimineralocorticoid drug. Drospirenone has been shown to reduce blood pressure, hirsutism, acne, and premenstrual tension, which makes oral contraceptives with this progestin advantageous to many patients. It should not be used with

TABLE **37-5**

Comparison of Drugs Used to Treat Postmenopausal Osteoporosis

PREPARATIONS AND COMPONENTS	PROPRIETARY NAME(S)	COMMENTS
Oral Combinations		Traditional estrogens protect bone and reduce hot flashes, but increase the risk of thromboembolism and breast cancer. The progestin component protects against endometrial cancer
Estradiol/norgestimate	Prefest	
Estradiol/norethindrone	Femhrt, Activella	
Conjugated equine estrogens/ medroxyprogesterone	Prempro, Premphase	
Estradiol/drospirenone	Angeliq	Drospirenone reduces blood pressure but increases the risk of hyperkalemia in patients with renal insufficiency or patients taking other drugs that can increase plasma K^+
SERM		
Raloxifene	Evista	Protects bone, reduces risk of breast cancer, very little effect on the uterus, but increases the risk of thromboembolism and does not prevent hot flashes
Transdermal		Transdermal administration reduces liver effects of estradiol
Estradiol	Alora, Climara, Divigel, Elistrin, Estraderm, Evamist (spray), Menostar, Vivelle	
Estradiol/norethindrone	Combi-Patch	
Estradiol/levonorgestrel	Climara Pro	

SERM, Selective estrogen receptor modulator.

other drugs that tend to increase plasma potassium concentrations or in patients with renal insufficiency because hyperkalemia may result.

Progestin-only contraceptives are also available and can be administered daily by oral administration. Long-acting (3 months to 3 years) preparations of progestin-only contraceptives are also available as subdermal implants (etonorgestrel) or through intramuscular injection (medroxyprogesterone acetate). Progestins can also be used for uterine bleeding disorders, infertility (luteal-phase support), and premature labor and as a diagnostic test for estrogen secretion and endometrial responsiveness.

ADVERSE EFFECTS

Androgens

In men, major untoward effects of pharmacologic doses of androgens include bladder irritation, breast soreness, gynecomastia, and priapism. In women, amenorrhea or oligomenorrhea and virilism (e.g., acne, decreased breast size, hirsutism, enlarged genitalia, male-pattern baldness, hoarseness, deepening of voice) can occur. For prepubertal children, virilism is a common untoward reaction of androgens, and stunting of linear growth is possible because of the premature closure of the epiphyses by androgens. Rarely in men and women, hepatic necrosis and hepatocellular tumors may develop in individuals who use 17α-alkylated androgens for a long duration or at high doses.[5]

Estrogens and Progestins

Major concerns about untoward effects associated with estrogens have involved thromboembolic disorders, neoplasms, and hypertension. The use of estrogen-only preparations can significantly increase endometrial cancer[42] in postmenopausal women, but the risk declines if low doses of estrogen are combined with a progestin.[38] The association between estrogens, progestins, and breast cancer is more controversial. Analysis of epidemiologic studies has suggested that breast cancer increases by approximately 25% in women who use combination oral contraceptives.[18] In older premenopausal women, the risk for breast cancer with oral contraceptive use increases probably as a result of other increasing health hazards.[18] The incidence of breast cancer 10 years after discontinuation of oral contraceptives is not different from the incidence in women who have never used these agents.[18]

Other untoward consequences associated with estrogen therapy include an increased risk of thromboembolic disorders[15] and stroke. Finally, estrogen therapy has also been implicated in increasing rates of gallbladder disease, nausea, vomiting, breast tenderness, edema, migraine, and endometriosis. More recent evidence indicates a small but significant cardiovascular risk with at least one type of postmenopausal hormone replacement therapy, and this has led to more restricted recommendations regarding such therapy.[52] Despite the benefits of hormone replacement therapy, the risks of such therapy may outweigh the benefits.[52] Risks include cardiovascular disease, breast cancer, and dementia, which for many women outweigh the reduction in bone loss and relief of postmenopausal symptoms. These findings are likely to change treatment strategies in many postmenopausal women. Options include other drugs to reduce osteoporosis and a reduction in the dose of sex hormones used in this age group.

Oral Contraceptives and the Periodontium

Numerous clinical studies from the late 1960s through the early 1980s have recorded gingival changes that develop as a result of the use of oral contraceptive agents. Several case

reports described gingival enlargement induced by oral contraceptives in otherwise healthy women with no history of gingival hyperplasia.[16,26] In all cases, the gingival enlargement was reversed when oral contraceptive use was discontinued or the dosage was reduced. Other clinical studies have shown that oral contraceptives have the ability to induce gingival diseases[8,35] that could ultimately lead to periodontal attachment loss.[19] Since the 1970s it has become evident that many of the side effects elicited by oral contraceptives are dose-dependent. This realization led to the development of current, low-dose oral contraceptive formulations. In a prospective, longitudinal, clinical study, women using low-dose oral contraceptives were found to be at no greater risk of gingival disease than women who were not using these drugs.[39] Data from a cross-sectional study of the National Health and Nutrition Examination Survey (NHANES) I and NHANES III have not shown an association between current low-dose oral contraceptives and increased levels of gingival disease.[47] These studies support the premise that current low-dose oral contraceptives have little or no effect on the gingival inflammatory status of women using these drugs.

DRUG INTERACTIONS

Androgens

The effects of anticoagulants, antidiabetic drugs, insulin, and cyclosporine all are increased with androgens. Hepatotoxic medications pose a greater risk with androgenic agents. The dentist should use caution when prescribing corticosteroids because concomitant use of androgens and corticosteroids can increase edema and exacerbate existing cardiac or hepatic disease.

Estrogens

Estrogens may increase the effect of corticosteroids. Rifampin, barbiturates, carbamazepine, phenytoin, and topiramate all tend to decrease the effects of estrogens because the former drugs induce liver metabolism of estrogens. The administration of corticosteroids may need to be adjusted in patients taking estrogens because estrogen can increase the therapeutic and toxic effects of corticosteroids.

Progestins

Hepatic enzyme–inducing medications (see earlier) decrease the effect of progestins.

Oral Contraceptives and Antibiotics

Numerous anecdotal observations have suggested that antibiotics, such as rifampin, penicillins, tetracyclines, and metronidazole, may reduce oral contraceptive efficacy. The mechanism for this change is clear for rifampin, which induces enzymes in the liver that metabolize steroids. For the other antibiotics, it has been suggested that antibiotics may increase urinary and fecal excretion of oral contraceptives, decrease enterohepatic circulation or intestinal absorption of oral contraceptives, or antagonize either estrogen or progesterone receptors.[40] Changes in intestinal flora leading to enhanced fecal excretion have been proposed as mechanisms. A reduction in bacteria that elaborate β-glucuronidase could result in a reduced regeneration of metabolized estrogens in the gut.

Currently, there is no large, prospective clinical trial to determine whether a significant interaction between antibiotics (except rifampin) and oral contraceptives exists. The American Medical Association Council on Scientific Affairs has reviewed the available literature and suggested that women face a significant risk of oral contraceptive failure when concomitantly using rifampin; other antibiotics pose a small risk for reducing the efficacy of oral contraceptives.[6] In all cases, the administration of antibiotics to patients using oral contraceptives should involve discussion of the possible interaction between the drugs, counsel about nonhormonal methods of controlling pregnancy, and the design of treatment regimens that are medically appropriate yet take into consideration personal concerns.

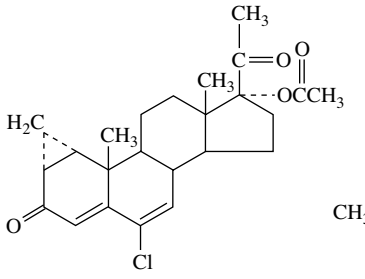
HORMONE ANTAGONISTS AND PARTIAL AGONISTS

Androgens

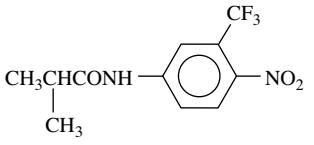
Agents that block the effect of androgens (Figure 37-6) can be categorized into three principal groups: inhibitors of testosterone synthesis, androgen receptor antagonists, and 5α-reductase inhibitors (Table 37-6). In addition, analogues of gonadotropin-releasing hormone are used occasionally to treat breast and prostate cancer and are usually given with an inhibitor of estrogen or androgen synthesis. Ketoconazole, an antifungal drug, has been shown to block testosterone synthesis, but because of its inhibition of cortisol and its hepatotoxicity, the intentional use of this drug to inhibit androgen synthesis is not indicated. Spironolactone and cyproterone acetate are weak androgen receptor antagonists that can be used to treat hirsutism. Flutamide, bicalutamide, and nilutamide are androgen receptor blockers and are used to treat prostate cancer. Finasteride is an inhibitor of the type 2 isozyme of 5α-reductase. Dutasteride in an inhibitor of type 1 and type 2 isozymes of 5α-reductase. 5α-Reductase inhibitors have been developed for the treatment of benign prostatic hypertrophy. In addition, finasteride is used to treat androgenetic alopecia.

Estrogens

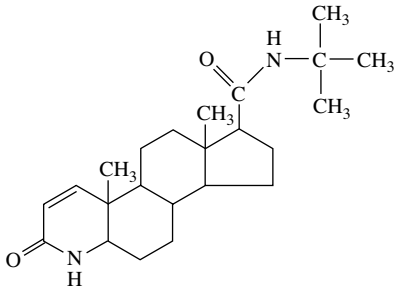
Agents that modulate estrogen activity (Figure 37-7) can be categorized into three principal groups: selective estrogen receptor modulators (SERMs), pure estrogen receptor antagonists, and estrogen synthesis inhibitors (see Table 37-6). SERMs are also referred to as *partial estrogen receptor agonists*.



Cyproterone acetate



Flutamide



Finasteride

FIGURE **37-6** Structural formulas of two antiandrogens and finasteride.

TABLE **37-6**

Examples of Hormone Antagonists

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	CLASSIFICATION	INDICATION
Anastrozole	Arimidex	Aromatase inhibitor	Early and advanced breast carcinoma
Clomiphene	Clomid, Serophene	SERM	Induction of ovulation
Exemestane	Aromasin	Aromatase inhibitor	Early and advanced breast carcinoma
Flutamide	Eulexin	Androgen receptor antagonist	Prostatic carcinoma
Finasteride	Propecia, Proscar	Type II 5α-reductase inhibitor	Benign prostatic hypertrophy, androgenetic alopecia
Mifepristone	Mifeprex	Progesterone receptor antagonist	Early pregnancy termination
Tamoxifen	Nolvadex	SERM	Adjunctive and preventive treatment of breast cancer
Toremifene	Fareston	SERM	Adjunctive treatment of breast cancer
Raloxifene	Evista	SERM	Postmenopausal osteoporosis prevention

SERM, Selective estrogen receptor modulator (also referred to as *partial estrogen receptor agonist*).

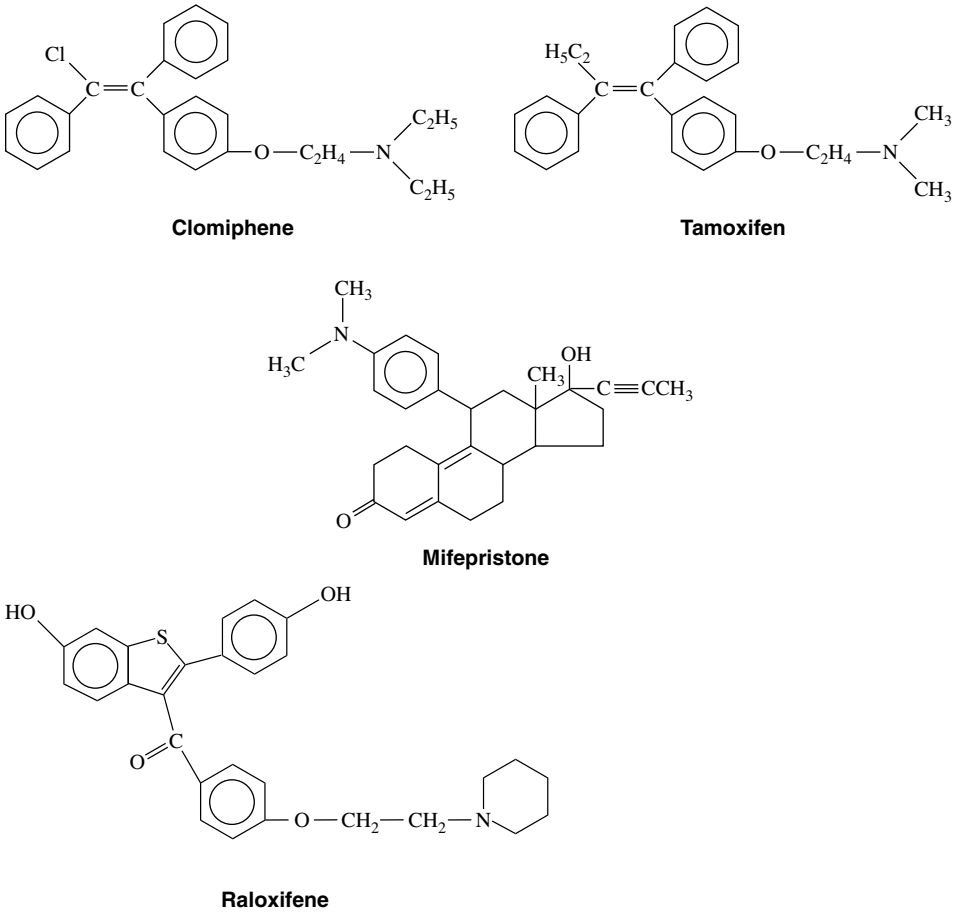


FIGURE **37-7** Chemical structures of partial estrogen receptor agonists and the antiprogestin mifepristone.

The pharmacologic goal of SERMs is to provide agonist activity in tissues where estrogen action is desired and antagonist or no activity in tissues where estrogen activity may be harmful. The selective modulation of estrogenic activity in tissues is possible because of the location of two distinct estrogen receptors (α and β forms) with variable tissue distribution and variable drug affinity to these estrogen receptor forms.[37] The partial agonistic activity of these drugs accounts for some degree of selectivity.

Raloxifene has been approved for the prevention and treatment of osteoporosis. The drug is a partial agonist at estrogen receptors and in effect stimulates estrogen receptors in bone, but inhibits estrogen receptors in the breast and many other tissues. Tamoxifen and toremifene are examples of drugs that are often referred to as *antiestrogens* even though they are partial agonists. They also display tissue selectivity, as does raloxifene (Table 37-7). Tamoxifen has been approved for the adjunctive treatment of breast neoplasms and as a prophylactic agent for women who are at high risk for breast cancer. Toremifene is used for the treatment of metastatic, estrogen receptor–positive breast cancer in postmenopausal women. In contrast to raloxifene, tamoxifen, and toremifene, clomiphene shows little, if any, tissue selectivity. It has been shown to act as an estrogen antagonist (actually a partial agonist) in all tissues studied. Clomiphene has been approved to promote ovulation in women.

The term *SERM* is usually applied to raloxifene, whereas SERM is less often applied to tamoxifen, toremifene, and

TABLE **37-7**

Comparison of Representative Selective Estrogen Receptor Modulators (SERMs)

ESTROGEN RECEPTOR SITE	SERM		
	RALOXIFENE	TAMOXIFEN	TOREMIFENE
Breast	–	–	–
Uterus	0, –	+	+
Bone	+	–, +*	0
Hypothalamus	–	–	–

*Tamoxifen may increase or decrease bone density depending on clinical conditions.
–, Inhibits estrogen receptors; +, stimulates estrogen receptors.

especially clomiphene because these three drugs are used for their ability to block estrogen receptors. Fulvestrant is a pure estrogen receptor antagonist. It is used to treat breast cancer. Therapeutic estrogen synthesis inhibitors involve blocking the activity of aromatase, the enzyme responsible for the conversion of testosterone to estradiol. Aromatase inhibitors (e.g., exemestane, anastrozole) have been used for the adjunctive treatment of breast cancer patients who have been unresponsive to tamoxifen.

Progestins

Agents that block the effect of progesterone (see Figure 37-7) are primarily potent, competitive antagonists of the progesterone receptor (see Table 37-6). Progesterone receptor antagonists, such as mifepristone, can be used as contraceptives and abortifacients and for treatment of endometriosis, leiomyomas, breast cancer, and meningiomas.[4] In the United States, mifepristone is primarily used for the termination of early pregnancy (defined as ≤49 days).

IMPLICATIONS FOR DENTISTRY

The homeostasis of the periodontium is a complex, multifactorial relationship that involves, at least in part, the endocrine system. The assertion that hormone-sensitive periodontal tissues exist relies on several salient observations, including the retention and metabolic conversion of sex steroid hormones in the periodontium and the presence of steroid hormone receptors in periodontal tissues.[28] These biologic findings correlated with clinical observations confirm an increased prevalence of gingival diseases with fluctuating sex steroid hormone levels, even when oral hygiene remained unchanged. The dramatic increase in steroid hormone levels during puberty has been accompanied by an increase in gingival inflammation in circumpubertal individuals of both sexes. During pregnancy, the prevalence and severity of gingival disease have been reported to be elevated until parturition, which is further evidence of the relationship between sex steroid hormones and the periodontium.[3,25] A cross-sectional study examined 121 pregnant and 61 postpartum women for changes in gingival inflammation and found the prevalence and severity of the gingival inflammation were significantly higher in the pregnant versus the postpartum patients, even though plaque scores remained the same between the two groups.[44] Gingival probing depths are larger,[25,31] bleeding on probing or toothbrushing is increased,[3,31] and gingival crevicular fluid is elevated in pregnant women. Finally, women who are pregnant also exhibit a significant prevalence (0.5% to 0.8%) of localized gingival enlargements.[25,31] These pregnancy-induced gingival overgrowths are reversed after parturition.

In contrast to pregnancy, when hormone levels are significantly elevated, during menopause ovarian function is declining, and there is a reduction in the production and secretion of sex steroid hormones. During this period, the question has arisen whether osteoporosis can affect the periodontal attachment apparatus. Although theories for the pathogenesis of osteoporosis are diverse, it is known that estrogen deficiency is an important factor in bone loss.[46] In addition, positive correlations between estrogens and bone density have been shown.[46] Considering these findings, it is not surprising that bone mass from edentulous mandibles has been shown to differ by age and sex. Several cross-sectional studies have shown decreased bone mass and density[21] and reduced bone mineral content[49] in edentulous mandibles of postmenopausal women. Various studies have attempted to provide insight into the relationship of osteoporosis to periodontitis, but the results of these studies have been equivocal.*

In addition to the intentional prescription of estrogens, new compounds that have estrogenic activity are being released into the environment. Many environmental estrogens do not bind tightly to estrogen receptors and are poorly absorbed from the gastrointestinal tract, yet the constant exposure, bioaccumulation in adipose tissue, and persistence in the environment have heightened consideration of these chemicals as possible toxic agents in humans. Currently, the prescribed use of Bis-GMA–based resins for restoration of the dentition has increased the concern of dentists about the safety of what were previously considered inert materials.[45] On the basis of existing research, certain impurities may be present in some Bis-GMA–based resins, and release of impurities from such restorations is potentially estrogenic.[45] Under extreme conditions, these impurities are capable of inducing weak estrogenic effects on target tissues. The amounts of bisphenol A that may be present as an impurity or produced as a degradation product from dental restorations, including sealants, are quite small and far below the doses needed to affect the reproductive tract.[29]

The specific relationship of sex steroid hormones to periodontal endocrinopathies remains an enigma; however, the most reasonable explanations of hormone action in the periodontium have focused on hormone effects on microbial organisms, the vasculature, the immune system, and specific cells in the periodontium.[28] When one considers the primary functions of sex steroid hormones, the periodontium would seem to be an odd target; however, given the influence of sex steroid hormones on periodontium, the health and lifestyles of women may be significantly affected.

PEPTIDE HORMONES

Human menopausal gonadotropins (menotropins) that contain follicle-stimulating hormone and luteinizing hormone, urofollitropin, and chorionic gonadotropin are used as fertility drugs in women and in men with hypogonadism and cryptorchidism. These drugs, derived from the urine of postmenopausal (menotropins, urofollitropin) and pregnant (chorionic gonadotropin) women, are injected intramuscularly. Short-acting gonadotropin-releasing hormone analogues such as gonadorelin, given in a pulsatile manner, are used to increase fertility in women and to treat cryptorchidism in men. Long-acting gonadotropin-releasing hormone analogues such as leuprolide are used to treat precocious puberty, prostate cancer, endometriosis, and estrogen-dependent tumors in women. (The long-acting nonpulsatile administration of the drugs inhibits release of the gonadotropins.) The gonadotropin-releasing hormone analogues are given intravenously, subcutaneously, and by nasal spray.

CHAPTER 38

*Principles of Antibiotic Therapy**

THOMAS J. PALLASCH

INFECTIOUS DISEASE PAST AND PRESENT

In 1967 the U.S. Surgeon General declared, "The time has come to close the book on infectious diseases." In 1993, 17 million people died of infectious diseases throughout the world, with 11.4 million deaths (mostly of children) caused by bacterial diarrhea and pneumonia. In the same year, 15.6 million died of cardiovascular disease and cancer combined.[69] The four primary disease killers caused by infection are the same as in 1900: diarrhea, pneumonia, tuberculosis, and malaria.[19] One third of the world population has tuberculosis, and Africa accounts for 90% of the 300 to 500 million new cases of malaria annually, with 1.5 to 2.7 million deaths per year. In World War II, 55 million people were killed; by 2010, 65 million will have died of acquired immunodeficiency syndrome (AIDS).

The Surgeon General was echoing the prevailing wisdom of the 1960s era of optimism regarding antibiotics. In the late 1950s the medical community became alarmed at the extent and rapidity of *Staphylococcus aureus* resistance to the penicillins, erythromycin, and tetracyclines and the discovery that bacteria could transfer the genes for antibiotic resistance among themselves. In the early 1960s, a plethora of new antibiotics became available: cephalosporins, β-lactamase–resistant penicillins, lincosamides, and new aminoglycosides. The belief that humankind would always stay several steps ahead of the microbes because they could not possibly match human intelligence was widely accepted. Assumptions are the genesis of most disasters, and, as one of "Murphy's laws" states, "Optimism indicates that the situation is not clearly understood."

The U.S. Centers for Disease Control and Prevention estimates that 65,000 to 90,000 deaths annually in U.S. hospitals result from nosocomial (hospital-acquired) infections. This figure may be a significant underestimate and the number may be closer to 200,000 to 300,000 because infectious disease deaths may be misclassified as cardiac arrest or respiratory or renal failure instead of their underlying microbial causes. In 1977, 100,000 gram-negative nosocomial bacteremic deaths were estimated annually in the United States[57]; bloodstream infections (septicemia and bacteremia) alone, among all nosocomial infections, may now be the eighth leading cause of death in the United States.[114,115]

Hospitals are currently plagued by vancomycin-resistant enterococci, vancomycin-resistant or glycopeptide-intermediate–resistant *S. aureus,* coagulase-negative staphylococci (CoNS), and other microorganisms resistant to multiple antibiotics, particularly *Streptococcus pneumoniae* and extended β-lactamase–producing enteric bacilli. The community is now beset by methicillin-resistant *S. aureus* (MRSA), which was previously thought to be a problem only in hospitals; penicillin-resistant and macrolide-resistant *S. pneumoniae* and viridans group streptococci (VGS); β-lactamase–producing *Haemophilus influenzae* and *Moraxella catarrhalis*; and widespread fluoroquinolone resistance. The oral cavity is home to β-lactam–resistant VGS and β-lactamase–producing *Prevotella* and *Porphyromonas*.

Mechanisms for resistance to antibiotics have likely always existed in some form to allow microbes to ensure their survival against competing microorganisms and find a niche in their environment to survive and thrive. Our current problems are of human origin, however—we disturbed the delicate microbial ecology for our own benefit, never realizing how formidable microbial retaliation would be. We are approaching the loss of one of our greatest gifts.

The importance of two medical discoveries that have essentially doubled the human life span in first-world countries since the 1850s—anesthesia and the control of infectious diseases—cannot be overestimated. Without the ability to operate internally within the human body free of excruciating pain, the gains of medical and dental surgery would be void. In the United States in 1776, the average life span was less than 40 years of age. In England in 1853, infectious disease was responsible for 37% of all deaths. At the beginning of the twentieth century in the United States, the infant mortality rate was 100 per 1000; now it is less that 10 per 1000.[69] A child in 1900 had a 10% chance of death between ages 1 and 4 years from pneumonia or diarrhea.[69] Many adults, infants, and children died of typhus, typhoid, diphtheria, whooping cough, yellow fever, malaria, influenza, measles, smallpox, and streptococcal and staphylococcal infections.

Even before the advent of the modern germ theory of disease in the 1870s, many individuals surmised that filth had a substantial bearing on disease. The "sanitary movement" began in Great Britain in the 1850s and the United States in the 1870s with improvement in wages, housing, education, and personal hygiene. Civil engineers cleaned the streets, water, and air, and cities removed refuse and their attendant rodent vectors of disease. Waste disposal, clean water, and hand hygiene by public health engineering have reduced the transmission of 35 to 40 infectious diseases.[31]

The modern era of infectious disease began with the first visualization of microbes by Anton van Leeuwenhoek in 1683, the "animicules" of dental plaque scraped from his upper gingiva and killed with salt (the first periodontal chemotherapy).[47] In 1776, Edward Jenner administered the first

*The author recognizes Dr. Edward Montgomery for his past contributions to this chapter.

smallpox vaccination. In 1848, Ignaz Semmelweiss introduced clean surgical operating technique ("gentlemen, wash your hands"). In 1854, John Snow showed the link between cholera and drinking water.[47]

In the 1860s, Louis Pasteur first used the word *germ* for living entities that produced disease, and Joseph Lister used carbolic acid to disinfect wounds. In the 1870s, Robert Koch proved the bacterial causation of anthrax and tuberculosis, and in the 1880s, Pasteur developed anthrax and rabies vaccines. In 1891, Paul Ehrlich showed that antibodies were responsible for immunity. In 1897, Ivanowski and Beiternick discovered viruses. The mosquito vector for yellow fever was shown in 1900, *Treponema pallidum* was found to be the cause of syphilis in 1905, human immunodeficiency virus (HIV) was identified in 1983, *Helicobacter pylori* was discovered as a cause of peptic ulcer in 1984, and the West Nile virus was identified in 1999.[47]

In the early 1900s, Paul Ehrlich used the term *magic bullet* for his predicted chemical that would affect only microbial cells and have no effect on mammalian cells. He later used fuchsin and mercury (Salvarsan) to treat syphilis. In 1928, Alexander Fleming serendipitously discovered that a mold, *Penicillium chrysogenum*, lysed staphylococci; this was later developed to its full potential by the isolation of penicillin from *Penicillium notatum* by Florey and colleagues at Oxford in the late 1930s and early 1940s. The first use of penicillin was in 1941 on an English police constable with streptococcal and staphylococcal skin abscesses. In the United States, penicillin was first used in 1942 on Anne Miller, who had streptococcal toxemia of pregnancy. All of these firsts have possibly overshadowed arguably the greatest of all medical advances: the demonstration in 1935 by Gerhard Domagk that sulfanilamide could be safely used systemically to treat infectious disease. The "dreaded disease of summer" (poliomyelitis) declined from 57,879 cases in the United States in 1953 to 72 cases in 1965 with the advent of the polio vaccine.[71] By 1977, smallpox was eradicated from the world as a contagious disease. During 1900-1997, the American life span increased by 60% to a median age of 76.[19]

In the developing world, a different story has unfolded. In 1998, the World Health Organization determined that infectious disease caused 25% (13 million) of the 54 million deaths in the world that year, with pneumonia (3.5 million), AIDS (2.3 million), diarrhea (2.2 million), tuberculosis (1.5 million), malaria (1.1 million), and measles (1 million) the top killers.[19] The incidence of emerging infections (defined by the Institute of Medicine as new, re-emerging, or drug-resistant infections whose incidence has increased in the last 2 decades or whose incidence threatens to increase) has increased.[19] Now included in this category are legionnaires disease, toxic shock syndrome, respiratory syncytial virus, Lyme disease, Nipah virus, *Hantavirus*, hemorrhagic viral diseases (dengue, Ebola, Marburg), *Escherichia coli* O157:H7, malaria, yellow fever, cholera, and multidrug-resistant tuberculosis. All of these infections and more are potentially transmitted by 500,000 world refugees and 1.6 billion annual airline passengers, 500 million of which cross borders each year.[69]

All of the media attention to these potential pathogens has led to a second "germ panic" with the revival of the focal infection theory of disease,[73] which alleges that many or most current diseases are caused by various microbes, including cardiovascular disease; various forms of emotional disorders such as obsessive-compulsive disorder, Tourette's syndrome, autism, and schizophrenia; preterm births; chronic fatigue syndrome; and multiple sclerosis. The first germ panic of 1900-1940 was fostered by the focal infection theory as espoused by Hunter and colleagues, in which a localized infection in one area of the body could move and occur elsewhere in the body and cause various pathologic conditions, such as arthritis, neuritis, myalgia, osteomyelitis, endocarditis, brain abscess, skin abscess, pneumonia, anemia, indigestion, gastritis, pancreatitis, colitis, diabetes, emphysema, goiter, thyroiditis, Hodgkin's disease, "obscure fever," nervous diseases, headache, mental apathy, and mental incompetence.[73] All of these were disorders for which medicine at the time (and many currently) had no explanations and no answers.

These foci of infection were conveniently located in areas of the body readily accessible to surgery (particularly in the wealthy): teeth, tonsils, and the facial sinuses, leading to an excessive number of dental extractions, tonsillectomies, and other surgeries in the first half of the twentieth century.[42,73,117,118] The resurrection of the foci of infection concept today is based on limited scientific evidence and questionable studies that lack attention to sound epidemiologic methods.

Very rarely, microbes leave the oral cavity and metastasize to other areas of the body to initiate a nonspecific inflammatory infectious process manifested as liver, splenic, or brain abscesses or bacterial endocarditis. These microorganisms are almost always VGS and almost never pathogens associated with periodontal disease. That these metastatic infections are so rare is truly remarkable and speaks well for our immune defense mechanisms, particularly in the oral cavity and blood, and the reticence of microorganisms to leave their ecologic niches for foreign environments. Currently, little evidence suggests that the oral cavity is the source of significant systemic disease.[72,73]

PATTERNS OF ANTIBIOTIC USE AND MISUSE

Antibiotics are the most widely abused prescribed drugs on the basis of inappropriate indications, dosages, and duration of use. Approximately half of all antibiotics used in hospitals are given to patients without signs or symptoms of infection, in many cases to "prevent" infections and to ensure that "everything was done" to avoid later criticism. Antibiotics are often used as "drugs of fear"[45] to cover for potential errors of omission or commission and prevent a claim of negligence. The abuse of negligence (tort) law has been a major contributing factor to the massive overuse of antibiotics and the attendant mortality rate associated with highly antibiotic-resistant microorganisms.

In hospitals, one third of antibiotics are used empirically, one third for prophylaxis, and one third with appropriate culture and sensitivity tests.[69] Because hospitals save money by not using culture and sensitivity tests, the demand has been for broader spectrum antibiotics, which has created a vicious cycle by disturbing the hospital microbial ecology further and fostering even greater microbial resistance.[98]

Outpatient antibiotic use is characterized by the "80:80 rule": 80% of all antibiotics are used in the community, and 80% are used for respiratory infections—most of which are viral in cause and not amenable to antibiotic therapy.[69] Of the 50% of people with acute respiratory illness who seek medical treatment, 50% to 80% may receive an antibiotic, but pneumonia (the only respiratory tract disorder requiring an antibiotic) may account for only 2% of these cases.

The prescribing of antibiotics can vary 15-fold among physicians. Physicians who tend to prescribe many drugs also prescribe many antibiotics. Antibiotic prescriptions are a quick way to end an office visit and reduce return visits.[90]

Dentists prescribe 7% to 11% of all common antibiotics (β-lactams, macrolides, tetracycline, metronidazole, clindamycin), and abuse of such antibiotics can be substantial.[18] In England, 33% to 87% of various antibiotics were judged to be inappropriately prescribed by dentists according to the Dental Practitioners Formulary.[74] Experts in England are in agreement that antibiotics are used too long for the

management of orofacial infections and that shorter durations are more appropriate and reduce the selection of drug-resistant microbes.[56]

In a survey of 505 Canadian dentists, the average length of antibiotic therapy was 6.92 days (range 1 to 21 days), and 17.5% did not use the 1997 American Heart Association (AHA) guidelines for endocarditis prophylaxis.[27] Two thirds of the dentists used antibiotic prophylaxis for patients with rheumatic fever without rheumatic heart disease; 25%, for patients with HIV/AIDS; 70%, for prosthetic joints; and two thirds, for restorative dentistry not associated with significant bleeding even though not advocated by the AHA.

AHA prophylaxis for patients with cardiac valve prostheses was not used by 20% of dental specialists. The study concluded that antibiotics are underused for symptomatic infections, overused for surgical prophylaxis, and commonly used at suboptimal dosing with prolonged dosing schedules and often not according to antibiotic prophylaxis guidelines.[27]

In a survey of antibiotic use by 1606 members of the American Association of Endodontists, 12.5% used antibiotics as an analgesic for post-treatment pain; 37.3%, as antibiotic prophylaxis after surgery; 44.8%, after incision and drainage without systemic involvement or patient immunosuppression; and 12% to 54%, for situations in which they are not effective, such as the following: (1) irreversible pulpitis with moderate-severe symptoms with or without apical periodontitis; (2) asymptomatic necrotic pulps with chronic apical periodontitis but no swelling; (3) necrotic pulps with acute apical periodontitis, no swelling, and moderate-severe symptoms; and (4) asymptomatic necrotic pulps with chronic periapical periodontitis with or without a sinus tract.[119] The authors concluded that not much had changed in the past 25 years.

Inappropriate antibiotic use in dentistry includes the following situations: (1) antibiotic therapy initiated after surgery to prevent an infection unlikely to occur and not documented effective for this purpose by clinical trials; (2) failure to use prophylactic antibiotics according to the principles established for such use; (3) use of antibiotics as analgesics in endodontics; (4) overuse in situations in which patients are not at risk for metastatic infections; (5) treatment of chronic periodontitis almost totally amenable to mechanical therapy; (6) administration of antibiotics instead of mechanical therapy for periodontitis; (7) long-term administration in the management of periodontal diseases; (8) antibiotic therapy instead of incision and drainage; (9) administration of antibiotics to avoid claims of negligence; and (10) administration in improper situations, dosage, and duration of therapy.[69]

ANTIBIOTIC MECHANISMS OF ACTION

To appreciate how microbes defend themselves against chemicals in their environment, one must first determine how antimicrobial agents kill microbes or prevent their replication. Antibiotics are chemicals most often, but not always, derived from microorganisms (commonly yeasts and fungi) that are intended in nature to perform as part of the system that maintains the ecologic balance in the microbial world. This system is composed of various entities, including bacteriophages (bacterial viruses); cationic peptides; antibiotics; and the quorum-sensing system that conveys chemical messages to microbes regarding metabolic activities, surface adhesion, colony formation, virulence, and the presence of chemicals intended to do harm. Virtually all clinically useful antibiotics are derived from naturally occurring entities, with only three synthetically produced: sulfonamides, fluoroquinolones, and oxazolidinones.

Antimicrobials affect the viability of microorganisms by five known processes: (1) inhibition of cell wall synthesis, (2) alteration of cell membrane integrity, (3) inhibition of ribosomal protein synthesis, (4) suppression of deoxyribonucleic acid (DNA) synthesis, and (5) inhibition of folic acid synthesis (Table 38-1, Figure 38-1). Microbial cell wall synthesis inhibition and membrane effects are extracytoplasmic, and inhibition of nucleic acid, protein, and folic acid synthesis is intracytoplasmic. Drugs that affect bacterial cell wall or membrane integrity and DNA synthesis are usually, but not always, bactericidal (inducing cell death), and protein and folic acid synthesis inhibitors are usually bacteriostatic (preventing cell growth or replication).

Whether an antimicrobial agent is bactericidal (cidal) or bacteriostatic (static) can also depend on its concentration at the infected site and the particular offending organism because some static drugs become cidal at high concentrations. The previous preference for cidal drugs over static antibiotics (cidal drugs allegedly do not rely on host defenses) has become less distinct because of the appreciation of the long post-antibiotic effects (continued antibiotic activity when the drug blood levels have declined) of bacteriostatic drugs.

Cell Wall Synthesis Inhibitors

The principal cell wall inhibitors are β-lactam antibiotics and glycopeptides. Bacterial cell walls are rigid and composed of alternating peptidoglycan (murein) units of N-acetyl-D-glucosamine and N-acetylmuramic acid (NAM). These are cross-linked via short peptides by amide linkages to a D-alanyl group on NAM. Various bacterial enzymes (transglycosylases, transpeptidases, carboxypeptidases, endopeptidases), termed *penicillin-sensitive enzymes* or *penicillin-binding proteins (PBPs)*, catalyze the formation of the rigid cell wall by incorporating new peptidoglycan into existing peptidoglycan by attaching a free amino group on the NAM-pentapeptide to a terminus opened by displacement of D-alanine. β-Lactam antibiotics competitively inhibit this final transpeptidation reaction to prevent three-dimensional rigid cell wall formation. The internal osmotic pressure of the bacterium causes lysis of the bacterial cell because the wall is no longer an effective barrier.

In addition, in some organisms, the β-lactams inhibit the inhibitor (derepression) of an endogenous bacterial autolysin (N-acetyl-muramyl-L-alanine amidase), which, when activated, causes the lysis of the bacterial cell wall, initiating bacterial suicide. Microbes that lose this autolysin system can become tolerant to antibiotics, with the antibiotic becoming bacteriostatic instead of bactericidal. Glycopeptides inhibit gram-positive bacterial cell wall synthesis by complexing with the D-alanyl-D-alanine portion of the muramyl peptide precursors to inhibit the action of transglycosylase and transpeptidase at a stage just before that of the β-lactams.

Alteration in Cell Membrane Integrity

Polymyxin B disrupts the integrity of the cell membrane by displacing Ca^{++} and Mg^{++} from membrane lipid phosphate groups. Cationic antimicrobial peptides are part of humans' natural skin and mucosal defense system and act by disrupting cell wall or membrane integrity by an effect on the gram-negative lipopolysaccharide component that literally puts holes in the wall or membrane.

Inhibition of Ribosomal Protein Synthesis

The macrolides bind to the P site of the 50S ribosomal subunit to inhibit RNA-dependent protein synthesis by inhibiting peptidyl transferase or by increasing the dissociation of peptidyl tRNA from the ribosome. Clindamycin similarly attaches to the same 50S subunit and can compete with the macrolides for this site. Cross-resistance between these two disparate antibiotics is common. Tetracyclines attach to the 30S

TABLE **38-1**

Mechanisms of Action of Common Antibiotics

FIGURE **38-1** Site and mechanism of action of antimicrobial agents. *PGP,* Peptidoglycan; *TA,* teichoic acid.

ribosomal subunit to block ribosomal protein synthesis by inhibiting the binding of tRNA to mRNA on the ribosome. Aminoglycosides attach to the 30S subunit to inhibit ribosomal protein synthesis, but may also induce the formation of abnormal bactericidal proteins. Streptogramins (quinupristin-dalfopristin) bind to two different sites on the 50S subunit of the 70S ribosome to prevent newly synthesized peptide chains from extruding from the ribosome. The oxazolidinone, linezolid, attaches to the 50S ribosome near the interface with the 30S subunit to prevent the initiation complex required for bacterial translation.

Inhibition of Nucleic Acid Synthesis

The 5′ nitro group of metronidazole is reduced in sensitive obligate anaerobes by nitro reductase to cell toxic nitro, nitroso, and hydroxylamine compounds that damage DNA or inhibit its synthesis. Fluoroquinolones inhibit topoisomerase IV and DNA gyrase that control the supercoiling of DNA and DNA replication, recombination, and repair. Fluoroquinolones may also induce the SOS response, which constitutes a repair system of DNA (the bacterial response to DNA damage) that normally functions to inhibit cell division to prevent the replication of damaged DNA. When the SOS repair system is affected by fluoroquinolones, unbalanced growth, vacuoles, filamentation, and cell lysis occur.

Inhibition of Folic Acid Synthesis

Sulfonamides and trimethoprim are antimetabolites that inhibit sequential steps in the bacterial synthesis of folic acid essential for one-carbon transfers in nucleic acid synthesis. Mammalian cells do not synthesize folic acid but acquire it from the environment. Sulfonamides are structural analogues of *p*-aminobenzoic acid (PABA) and block the conversion of PABA to dihydrofolic acid by inhibiting tetrahydropteroic acid synthetase, which has greater affinity for sulfonamides than PABA. Trimethoprim blocks the next step in folic acid synthesis by inhibiting dihydrofolate reductase, which catalyzes the conversion of dihydrofolic acid to tetrahydrofolic acid.

MICROBIAL RESISTANCE TO ANTIBIOTICS

Microbial resistance to antibiotics has become a major factor in determining when and which antibiotic is used and dosages and length of administration. It also has spurred renewed interest in antibiotic pharmacokinetics and pharmacodynamics.

Procedures designed to reduce antibiotic-resistant pathogenic microorganisms have been developed, including education of health care providers and the general public, improved handwashing techniques, better hospital infection control, isolation of patients with highly resistant bacteria, control of antibiotic use in hospitals through formularies and pharmacist oversight, and the removal of antibiotics for growth promotion in agricultural animals. Many of these programs have had little effect to date.

All microbial resistance is local; the patterns and extent of this resistance are determined by the use of antibiotics in a particular community. What is true in Florida may not be true in Los Angeles or in Paris, London, Rome, or New Delhi. If tetracyclines are used widely in the community for acne or Lyme disease, a high resistance level to the drug is likely to be present in that locale. If not, the microbial resistance level is likely to be low. If an antibiotic or its analogue has been used widely in agriculture, this may strongly influence resistance patterns—to the point of rendering a new antibiotic far less useful. In Taiwan, virginiamycin (a streptogramin) has been used for more than 2 decades as a growth promoter in food animals. When quinupristin-dalfopristin, a new streptogramin, was tested on human bacterial isolates before its clinical introduction, more than 50% of some pathogens were already resistant to the drug. Antibiotics are truly societal drugs that cumulatively affect the individual receiving the drug and many others as well.[50]

Microorganisms have developed seven known mechanisms to evade the bactericidal or bacteriostatic actions of antimicrobials, as follows: (1) enzymatic inactivation, (2) modification/protection of the target site, (3) limited access of antibiotic (altered cell membrane permeability), (4) active drug efflux, (5) failure to activate the antibiotic, (6) use of alternative growth requirements, and (7) overproduction of target sites (Table 38-2).[69,88]

Enzymatic inactivation is one of the more common methods and is typified by β-lactamase hydrolysis of penicillins and cephalosporins and acetyltransferases that inactivate

TABLE 38-2

Antibiotic Resistance Mechanisms

chloramphenicol, aminoglycosides, and tetracyclines. Altered target sites include ribosomal point mutations for tetracyclines, macrolides, and clindamycin; altered DNA gyrase and topoisomerase for fluoroquinolones; and modified PBPs for VGS and pneumococci. Most microorganisms have developed ways to alter their cell wall or membrane permeability to limit access of the antibiotic to its receptor by deleting outer membrane proteins or closing membrane pore channels. Altering antibiotic access to the cell interior usually does not confer a high level of resistance on the organism and must be combined with another mechanism for significant resistance potential. Several hundred efflux proteins are available that extrude waste products from the microbial cell but that now have been adapted over time to eliminate antibiotics specifically from the cell interior virtually as fast as they can enter. Enterococci can evade destruction by developing alternative metabolic growth requirements (auxotrophs). Sulfonamide resistance may occur from the overproduction of PABA, and some enteric organisms evade β-lactam antibiotics by overproducing β-lactamase (hyper–β-lactamase producers).

Antibiotic tolerance occurs when the antibiotic no longer kills the microorganism, but merely inhibits its growth or multiplication. Tolerant microorganisms start to grow after the antibiotic is removed, whereas resistant microorganisms multiply in the presence of the antibiotic. Tolerance is usually caused by the loss of autolysin activity through a failure to create or mobilize the autolytic enzymes. Vancomycin tolerance in *S. pneumoniae* is unique; a mutation in the sensor-response system controls the bactericidal autolysin activity.

Most experts agree that the major factor in the development and maintenance of antibiotic resistance in microbes is their ability to eliminate sensitive microorganisms and allow resistant ones to multiply and dominate. Although this selection process is crucial, other factors also contribute. Lengthy antibiotic regimens are commonly advocated to kill all the resistant strains or prevent stepped resistance (the development of resistance by a sequence of mutations occurring over several generations of microbial multiplication). Theoretically, if the antibiotic is given long enough, all these mutants are exposed to the antibiotic and killed at cell division. This is the rationale for taking the entire prescribed antibiotic rather than stopping the antibiotic when the patient is well. This concept is false for three reasons: (1) microbial mutations rarely occur during antibiotic treatment; (2) stepped resistance occurs even with prolonged antibiotic use[4]; and (3) most antibiotic resistance is gained by the transfer of genetic material between microbes, which is greatly enhanced by low-dose, prolonged antibiotic therapy.[50] Combination antibiotic therapy against the stepped resistance seen with *Mycobacterium tuberculosis* is unique for this organism, but should not be extrapolated to all microbes. Also, a directive to "take all the antibiotic" assumes that the prescriber knows the exact duration of the infection, which is impossible.

Microbial resistance is most likely to occur when subtherapeutic antibiotic doses are used—doses that do not kill or inhibit the microorganism, but rather allow it to perceive the chemical as a threat to its survival and to react by mutation to resistance, acquisition, or transfer of resistance genes/virulence factors or induction (expression) of latent resistance genes.[32,50] The gastrointestinal tract is a massive reservoir for resistance genes readily transferred within and between enteric microbial species,[93] a process greatly enhanced by antibiotics that readily induce the expression or transfer of resistance genes, such as tetracyclines, imipenem, cefoxitin, and clavulanic acid.[82]

Bacteria-carrying resistance genes may have a reduction in "fitness" (a biologic cost) that results in slower growth rates, loss of virulence, and an increased biologic burden (synthesis of nucleic acids). Studies indicate, however, that many bacteria can adapt to this new genetic burden or even require resistance genes for survival. If this situation becomes common, removal of the antibiotic from the environment would have little effect on reducing resistance in the hospital or community, a point that may already have been reached with some microbes.

SPECIFIC RESISTANCE MECHANISMS

β-Lactamases

The most important acquired mechanism for β-lactam resistance, particularly in gram-negative microorganisms, is the production of various β-lactamases that hydrolyze the β-lactam ring to form a linear metabolite incapable of binding to PBPs. In 1984, 19 plasmid-mediated β-lactamases were known; the number now has increased to more than 340 chromosomally and plasmid-mediated β-lactamases—70 of the TEM-1 and TEM-2 and 20 of the SHV-1 types alone.[11]

β-Lactamases have been variously classified by Richmond-Sykes (I to V), Ambler (A to D), and Bush (1 to 4).[11] β-Lactamase enzymes can be chromosomally mediated or easily transferred by transposable elements. Many are of the TEM type (from a patient named Temoniera in Greece, in whom a β-lactamase was isolated in the early 1960s) or the SHV type (sulfhydryl variable).[11] The most pressing difficulties with β-lactamases are their widespread dissemination throughout the microbial environment, ability to move between widely disparate organisms, tendency to inhibit new antibiotic agents rapidly, and increasing resistance to β-lactamase inhibitors (clavulanic acid, sulbactam, and tazobactam). β-Lactamases have been observed in numerous gram-positive and gram-negative pathogens. The cohabitation of staphylococci and enterococci on human skin in hospitals has likely led to the incorporation of β-lactamase genes into enterococci after the latter organisms had successfully avoided this transfer for billions of years.

Point mutations have appeared more recently in TEM and SHV β-lactamases, resulting in extended-spectrum β-lactamases in *Klebsiella pneumoniae* that hydrolyze the latest cephalosporins (cefotaxime, ceftazidime, cefepime) and aztreonam. Certain enteric microorganisms (*Escherichia coli*, *Citrobacter freundii*, *K. pneumoniae*, *Proteus mirabilis*) can produce massive amounts of TEM-1 β-lactamase (hyper–β-lactamase producers) that can overwhelm β-lactamase inhibitors. Metallo-β-lactamases possess the broadest spectrum of inhibitory activity and hydrolyze all β-lactam antibiotics except monobactams (aztreonam) and are not inhibited by any of the β-lactamase inhibitors currently available.

The first plasmid encoded β-lactamases with the ability to hydrolyze cephalosporins were termed the *extended-spectrum β-lactamases (ESBLs)*.[13] These ESBLs microbes were also resistant to aminoglycosides, tetracyclines, and trimethoprim/sulfonamides.[13] ESBLs cause resistance to third-generation cephalosporins (cefotaxime, ceftriaxone, ceftazidime) and monobactams (aztreonam) but are sensitive to cefamycins (cefoxitin, cefotetan) and carbapenems (imipenem, meropenem, ertapenem). These ESBLs are horizontally transmitted by mobile genetic elements from food, animals, or family members and induce greater mortality than enteric bacilli without these ESBLs.[77]

Multidrug Antibiotic Efflux Pumps

A mechanism by which bacteria move an antibiotic out of the cell as soon as it enters was first detected in *E. coli* by Levy in 1978; the first gene (*qac*A) encoding a multidrug efflux protein was subsequently detected in an isolate of *S. aureus*.[69]

Currently, more than 50 such systems have been described, and these cytoplasmic membrane transport proteins (multidrug efflux pumps) have likely evolved to protect the cell from foreign chemical invasion and allow its secretion of cell metabolic products.[110] Efflux pumps operate in *E. coli*, *Pseudomonas aeruginosa*, staphylococci, *Streptococcus pyogenes* and *S. pneumoniae, Bacillus subtilis, Pasteurella multocida, Neisseria gonorrhoeae,* mycobacteria, and enterococci.[110] For tetracyclines, these efflux pumps are the major mechanism for resistance and are becoming increasingly so for the fluoroquinolones.[110] Efflux pumps are classified into five main groups: (1) the major facilitator family; (2) the small/staphylococcal multidrug resistance family; (3) the resistance, nodulation, and cell division family; (4) the adenosine 5′-triphosphate binding cassette superfamily; and (5) the multidrug and toxic compound extrusion family.[110]

These chromosomal and plasmid-mediated efflux transporter proteins may be quite specific for antibiotics and metabolic product substrates and are regulated by numerous genes and gene products. Repressors are also present and are highly regulated to prevent the accidental overproduction of efflux pumps. Tetracyclines derepress this system, leading to an overproduction of efflux proteins and increasing resistance to themselves and any other antibiotics carried by these proteins.[81]

Transposable Elements

Microorganisms possess three mechanisms for genetic variation: (1) local nucleotide changes in the genome, (2) rearrangement of genomic sequences, and (3) horizontal acquisition of DNA from other microorganisms. Such genetic alterations have allowed for their evolution and survival for 3.5 billion years. The rearrangement of genes and particularly the acquisition of new genetic information are commonplace and are now the major mechanism controlling microbial resistance to antibiotics.

In the 1950s, McClintock described genetic controlling elements that did not follow the Mendelian Laws of Genetics and acquired an independent existence (selfish genes, jumping genes). In the early 1970s, Hedges and Jacob first used the term *transposon* for a mobile genetic element conveying resistance to ampicillin. Microbes acquire new genetic information by three mechanisms—transformation, transduction, and conjugation—and use numerous transposable elements, such as bacteriophages, transposons, integrons, and plasmids.

During transformation, bacteria acquire "naked" DNA from their environment to incorporate into their genome. Such genetic transformations are uncommon and require unique circumstances involving genes, binding, uptake, and integration. At least 50 bacteria are sufficiently competent to acquire environmental genes from their fellow microbes, plants, yeasts, and animals. VGS and *S. pneumoniae* have the DNA recognition sites and a quorum-sensing peptide (competence-stimulating peptide) that allows for the acquisition of each other's genes when released into the environment on their death. Because they coinhabit the oropharynx, and penicillin resistance occurs in a stepwise manner with gradual amino acid mutations in at least four PBPs for high penicillin resistance, this resistance likely evolved over many years and indicates that transformation is a slow but ultimately efficient mechanism for genetic change.

Transduction is the movement of DNA from one bacterium to another by a bacteriophage (bacterial virus) intermediary. Conjugation is the self-transfer of genetic information by plasmids or transposons to other microorganisms, generally by physical contact with a sex pilus in gram-negative organisms and stimulated by various pheromones (small peptides). Mobile elements commonly require site-specific combination sites but not DNA segment identity, allowing for broad DNA movement. Mobile elements of various types include bacteriophages, transposons, plasmids, integrons, and shufflons.

Transposons are DNA segments that cannot self-replicate, but can self-transfer between plasmids, bacteriophages, and chromosomes. Transposons can recruit as many genes as required for their purpose, and the mechanisms that control this process are essentially unknown. That we know so little about a system with so much potential for genetic change is worrisome. Between 30% and 40% of the human genome is composed of transposable element sequences or gene sequences directly derived from them.[23]

Plasmids may be conjugative (self-transmissible) or nonconjugative (unable to effect their own transfer) and may be narrow range (replication in only one or a few hosts) or broad range (replication in many hosts). Too great a concentration of plasmids in one microorganism is usually intolerable because of the high energy costs to maintain it; plasmids have an autoregulatory system (iterons) that allows them to determine their own rate of replication.

Plasmids may also be constitutive (ongoing formation) or inductive (formed only when stimulated or induced by a foreign chemical). Plasmids carry resistance genes and virulence genes or pathogenicity islands that carry all the components necessary to damage the host directly or initiate host responses, such as inflammation, that harm the host. Plasmids are common in oral and gastrointestinal *Bacteroides, Porphyromonas,* and *Prevotella* isolates.

Researchers previously hoped that resistance genes and their transporters would pose such a fitness problem for bacteria (requiring so much energy) that bacteria no longer exposed to the antibiotic would lose their resistance genes. Such genes may become so important for bacterial functions, however, that they become permanent. The tetracycline efflux pumps can become necessary for bacterial survival by functioning in Na^+-K^+ exchange across the bacterial membrane.[6] The problem is compounded when the resistance gene for a particular antibiotic becomes part of an integron-containing multiple antibiotic resistance gene array. Eliminating the one antibiotic does nothing; all the antibiotics must be eliminated from the environment for the integron to be lost.

Integrons

Antibiotic resistance has been enhanced further by the discovery of the integron, a genetic element that captures and disseminates genes by site-specific integration of DNA (gene cassettes) that can mediate resistance, virulence, and biochemical functions.[79] Integrons have three distinct genes encoding for an integrase enzyme, a recombination site, and a promoter element.[79] Integrons resemble bundled products with a computer operating system; they package resistance determinants to allow for widespread gene dissemination.

Each gene is a cassette, and five genes may commonly be present in one integron.[79] Superintegrons have been isolated in *Vibrio cholerae* that contain hundreds of gene cassettes that encode many bacterial functions beyond those of resistance and virulence. Gene cassettes have been identified for all antibiotics except fluoroquinolones, and they exist for quaternary ammonium compounds. Integrons cannot promote self-transfer because they lack transporter genes, but they are commonly associated with transposons and conjugative plasmids.

Horizontal Gene Transfer

Horizontal gene transfer (HGT), also known as *lateral gene transfer,* has been a major impetus for the exceptional diversity and survival of the microbial world. Ancient integrons, bacteriophages, plasmids, transposons, and now insertion sequence common regions have changed the otherwise clonal mode of prokaryotic life[95] and allowed for gene capture and

dissemination from the global gene pool.[8] These mobile bacterial elements move from one bacterial cell to another via transduction and conjugation as circular, usually double-stranded DNA and often via a sex pilus as an extension from the donor to the recipient cell. Technically, a third form of DNA transfer is via transformation whereby "naked" DNA from disrupted cells is taken up from the extracellular fluid by certain "competent" cells.

These mobile genetic elements include plasmids, transopsons, bacteriophages, integrons, and insertion sequence common regions that move from bacterial cell to bacterial cell or, when translocated, from various DNA sites within the bacterial cell.[8] These DNA elements carry genes for antibiotic resistance, heavy metal toxins, and virulence determinants and can induce or repair DNA damage.[8]

HGT encompasses two processes that move genetic material from one bacterium to another to enable unique phenotypic characteristics or to translocate genes from one location (plasmids) to another (chromosomes).[59] The combination of integrons, transposons, and insertion elements results in antimicrobial resistance islands.[59] Insertion sequences are mobile genetic elements that promote and translocate genes and are inserted into transposons to mobilize DNA resistance genes for β-lactamase of the CTX-M type.[59]

HGT facilitates genome rearrangement, deletions, and insertions to allow adaptation to changing environments and is induced by antimicrobials, metals, and organic contaminants (environmental stress).[7] This facilitation of gene transfer occurs in four steps: (1) packaging of nucleic acids for transfer via excision and circularization of the transposons, (2) transfer of the DNA via contact with the recipient cell (conjugation), (3) entrance into the cell and integration with host chromosomal DNA, and (4) transfer of chromosomal DNA or the replicating elements into the daughter cells and subsequent generations.[7]

RESISTANCE IN MAJOR MICROBIAL PATHOGENS

Streptococcus pneumoniae

Microbial resistance to antibiotics in *S. pneumoniae* is most serious because the organism is responsible for 3000 cases of meningitis, 50,000 cases of bacteremia, 500,000 cases of pneumonia, and 2 million cases of otitis media in the United States annually and 3 to 5 million deaths annually worldwide.[69] Resistance to sulfonamides was first detected in 1943 and to penicillin in the late 1960s in Australia and New Guinea. The mechanism of penicillin resistance is a single point mutation in PBP2x or PBP2b, with an altered PBP2a requiring mutation also in pBP2x (the organism has six PBPs).

High penicillin resistance (usually a plasma concentration of ≥2 μg/mL) is seen in 14% of U.S., 6.8% of Canadian, 10.4% of European, and 17.8% of Asian-Pacific isolates.[38] Resistance of the pneumococcus to penicillin can vary significantly with geographic area: 38.8% in Tennessee, 15.3% in Maryland, 65.3% in Japan, 60.8% in Vietnam, 15.6% to 48.2% in Latin America, and 79.7% in Korea.[69]

Tolerance to vancomycin has been detected in an isolate responsible for meningitis and high-level resistance to quinupristin-dalfopristin and cefotaxime. Tetracycline resistance in *S. pneumoniae* is currently low but is increasing, which may pose a significant problem because doxycycline has become an important drug for community and nosocomial-acquired pneumonia caused by *S. pneumoniae, Mycoplasma pneumoniae, Legionella pneumophila,* and *Chlamydia pneumoniae*.

Methicillin-Resistant Staphylococci

In a 1999 review of more than 10,000 bloodstream infections at 49 U.S. hospitals, *S. aureus* accounted for 16% and CoNS for 32% of all isolates, with most of the CoNS being methicillin-resistant.[69] Some isolates are susceptible only to vancomycin; others are susceptible to linezolid and quinupristin-dalfopristin; and still others are susceptible to older agents such as macrolides, tetracyclines, aminoglycosides, rifampin, clindamycin, sulfonamides, and fluoroquinolones. The mechanism of methicillin resistance is an altered PBP2 (PBP2a or PBP2′) conferred through a *mec*A gene that results in a much lower binding affinity of methicillin for PBP2a. This mode of resistance requires the cooperation of PBP2 and PBP2a sites and two enzymes, one natural and one environmentally acquired.

The first MRSA isolate was detected in the United Kingdom in 1961, and MRSA remained rare in the United States until 1976. MRSA spread throughout the hospital by nasal secretions, hands, clothing, bedding, air currents, fomites, and skin boils (furuncles). The anterior nares is the prime carrier site of *S. aureus* in humans, with 80% of people either persistent or intermittent carriers and possibly 25% of healthy individuals colonized with CoNS. High concentrations of staphylococci are also found in the throat, axilla, and perineum (groin and upper thighs).

Enterococci

Of the 17 species of enterococci found in the human oral cavity and gastrointestinal and genitourinary tracts, *Enterococcus faecalis* accounts for 90% of human infections, and *E. faecium* accounts for approximately 10%.[69] Enterococcal infections are classic examples of a relatively harmless commensal organism becoming a serious pathogen by the acquisition of multiple resistance genes.

Enterococci are intrinsically resistant to cephalosporins and have varying degrees of resistance to aminoglycosides, macrolides, tetracyclines, and clindamycin. Vancomycin resistance, particularly in *E. faecium*, has been of major concern since the late 1980s. Enterococci cause 800,000 nosocomial infections annually in the United States, with more than 50% caused by vancomycin-resistant *E. faecium*; resistance is more than 90% in *E. faecium* bacteremias. Currently, 17% of enterococcal strains in the United States are resistant to vancomycin.[52]

Vancomycin-resistant enterococcus (VRE) infections, particularly of the bloodstream type, are becoming extremely difficult to treat. Doxycycline has been enlisted more recently in the treatment of VRE.[52] Enterococcal resistance is complicated further by the observations that (1) streptococci, staphylococci, and enterococci often share the same resistance genes; (2) β-lactamase in enterococci is identical to that in staphylococci, indicating sharing of genetic information; (3) enterococci can transfer resistance genes, particularly for vancomycin to staphylococci and other organisms, in vitro and in animal models; (4) staphylococci and enterococci coinhabit the skin; and (5) the possibility exists that vancomycin resistance may one day appear in many VGS.[69]

Helicobacter pylori

Chronic gastritis, peptic ulcer, and gastric cancer have been linked to *H. pylori*. Depending on the geographic area and the prevalence of antibiotic use, alarming reports have appeared of resistance to all antibiotic agents used in its management, including metronidazole, clarithromycin, tetracycline, and amoxicillin. Resistance to metronidazole acquired by a decreased ability to reduce its nitro group ranges from 10% to 50% in developed countries and up to 100% in developing countries, where it is widely used to treat parasitic diseases. Resistance to amoxicillin ranges from 0% in The Netherlands to 18% in Mexico to 72% in Shanghai, China. Resistance to clarithromycin ranges from 1.7% in The Netherlands to 10% to 12% in the United States to 24% in Mexico.

Tetracycline has been added more recently to antibiotic regimens, and resistance rates are 0% in The Netherlands, 5.3% in Korea, and 58.8% in Shanghai, China, with the disturbing possibility that tetracycline-resistant *H. pylori* may exhibit cross-resistance with metronidazole. Metronidazole resistance in *H. pylori* may decrease the effectiveness of therapy by 37.7%, and clarithromycin resistance may decrease the effectiveness of therapy by 55%.[25] The widespread use of systemic metronidazole and tetracycline is difficult to justify in the management of a relatively trivial, mechanically responsive disease such as periodontitis when such a practice may promote resistance in a microbial pathogen responsible for very serious diseases such as peptic ulcer and gastric cancer.

Human Immunodeficiency Virus

The current therapy for HIV infection entails highly active antiretroviral therapy (HAART) (see Chapter 40) with a combination of drugs that interfere with several steps in viral replication, including reverse transcriptase inhibitors, protease inhibitors, and the new integrase inhibitors that prevent HIV from integrating into the genome of the host cell. Difficulties have arisen with this therapeutic approach because the virus provides for reservoirs of replication-competent HIV in resting CD4 T lymphocytes throughout many years of intensive HAART. It is estimated that more than 60 years of HAART may be necessary to eradicate the virus from these reservoirs.[69] More than 50% of HIV-infected individuals in the United States receiving HAART are resistant to one or more of the drugs, and 78% of individuals with measurable viral loads are resistant to at least one drug, encompassing about 100,000 people in the United States.[99] From 1994-2000, 14% of new HIV cases had one or more HIV mutations associated with antiretroviral drug resistance; in 2000, it was 27%. Approximately 25% of newly infected, therapy-naïve individuals carry at least one key HIV drug-resistant mutant.[78]

SPECIFIC ANTIMICROBIAL AGENT RESISTANCE

Vancomycin

The long-feared arrival of vancomycin resistance in MRSA was realized in El Salvador, Japan, France, and the United States during 1996-1999.[69] Because the glycopeptides (vancomycin, teicoplanin) are the only consistently effective agents against MRSA, the appearance of such resistance has the potential for microbiologic disaster, as 50% of nosocomial *S. aureus* and 80% of CoNS are methicillin resistant. Some of these strains are at least for now susceptible to streptogramins, tetracyclines, sulfamethoxazole/trimethoprim, chloramphenicol, and fluoroquinolones. More recently, streptogramin resistance has been reported in glycopeptide-intermediate *S. aureus*. Vancomycin tolerance is now found in *S. pneumoniae,* group G streptococci, *Streptococcus bovis, Streptococcus mitis, Staphylococcus epidermidis,* and *Staphylococcus haemolyticus*. Possibly 2% to 3% of all *S. pneumoniae* strains are tolerant to vancomycin.[65] In 1994, 61% of all surveyed hospitals reported VRE compared with 23% in 1992.[69] The mortality rate for bloodstream infections with VRE is 36% versus 16% for vancomycin-sensitive enterococci. Five genes (*van*A, *van*B, *van*C, *van*D, *van*E) modulate vancomycin resistance with spread by all transposable elements.

One mechanism of vancomycin resistance is caused by an altered peptidoglycan terminus of D-ala-D-lac rather than the usual D-ala-D-ala, which results in reduced vancomycin binding and failure to prevent rigid cell wall synthesis.[14] Resistance in vancomycin-intermediate *S. aureus* may be caused by the production of abnormal mucopeptides (false binding sites) in the cell wall that bind vancomycin and prevent its access to the peptidoglycan receptor or increase peptidoglycan within the cell wall to produce thickened cell walls.[15] The mechanism for vancomycin tolerance in *S. pneumoniae* is unique in that a mutation in the sensor-response system controlling autolysin activity is necessary to kill bacteria.[69] This sensor system is also required for the bactericidal activity of β-lactams, fluoroquinolones, and aminoglycosides.

Macrolides

Within 1 year of its introduction in 1952, erythromycin resistance was detected in the United States, Japan, and Europe; after 6 months of use at Boston City Hospital, virtually all staphylococci were resistant to the drug. The current global resistance rate for erythromycin is approaching epidemic proportions. In the United States, resistance in *S. pneumoniae* and *S. pyogenes* has reached 40% to 60% in some areas. In Taiwan, where the macrolides are over-the-counter drugs, resistance rates are among the highest in the world: 80% for MRSA, 30% for methicillin-sensitive *S. aureus,* 58% for *S. pneumoniae,* and 42% for *S. pyogenes*. In a 1995-1999 Centers for Disease Control and Prevention study of 15,481 invasive isolates of *S. pneumoniae,* macrolide use increased 13% in adults and 320% in children younger than 5 years, and macrolide resistance increased from 10.6% of isolates in 1995 to 20.4% in 1999.[69]

In 66 VGS isolates from the blood of neutropenic cancer patients, 68.8% of the isolates highly resistant to penicillin were also resistant to erythromycin, as were 43.6% of the *S. mitis* isolates.[69] Of much concern is the ability of VGS to confer the *mef*A resistance gene (M phenotype) to *S. pneumoniae* and *S. pyogenes* because 50% to 60% of the VGS in the pharynx possess the M phenotype. VGS may provide a reservoir for erythromycin resistance genes available for transfer to various other streptococci.

The principal mechanism for resistance to the macrolides is by an *erm* (*e*rythromycin-*r*esistant *m*ethylase) gene encoding an enzyme that catalyzes the demethylation of the 2058 residue of bacterial 23S ribosomal RNA, resulting in decreased macrolide binding to its ribosomal receptor site (a ribosomal protection mechanism).[69] The *erm* genes are constitutive and inducible with induction on exposure to the 14-membered and 15-membered, but not the 16-membered macrolides. Approximately 21 *erm* genes have been identified.[84] The *erm* genes are often associated with other antibiotic resistance genes, particularly genes for tetracycline (*tet*Q, *tet*M), making it possible to select for resistance to both drugs while using only one.

Macrolide resistance genes are also commonly combined with resistance genes for lincosamides (clindamycin) and streptogramins (quinupristin-dalfopristin) in the MLS_B aggregate. Because resistance has now been detected in new ketolide analogues of macrolides, a new designation has arisen of MLKS resistance (*m*acrolide, *l*incosamide, *k*etolide, *s*treptogramin). Other macrolide resistance mechanisms include active efflux encoded by *mef*A and *mef*E genes for 14-membered and 15-membered macrolides and esterification by phosphorylation or glycosylation to inactivate the macrolides.[84]

Fluoroquinolones

Resistance to fluoroquinolones was detected early after their introduction and was easily predictable because it required only a single point mutation, and its precursor, nalidixic acid, showed rapid development of resistance. Little attention was paid to this potential for serious difficulties with this group of antibiotics. One of the major factors in the epidemic increase in potentially fatal *Clostridium difficile*–associated diarrhea (CDAD) was the massive overuse of fluoroquinolone antibiotics in hospitals resulting in a mutation in the regulating protein in C. *difficile* that controls the production of toxins A and B.

Resistance to fluoroquinolones is chromosomally mediated by three mechanisms: (1) target alteration by point mutations for DNA gyrase (serine 83 and aspartate 87 of *gyr*A) and topoisomerase IV (serine 79 and aspartate 83 of *par*C), (2) active efflux pumps, and (3) reduction in permeability from loss of outer membrane protein F (OmpF). No bacterial enzyme capable of metabolizing fluoroquinolones has yet been detected, and the significance of a transferable resistance plasmid in *K. pneumoniae* is unknown. Microorganisms displaying efflux mechanisms include VGS, staphylococci, enterococci, *S. pneumoniae,* Enterobacteriaceae, *P. aeruginosa*, *Campylobacter jejunum*, *Bacteroides fragilis,* and *N. gonorrhoeae*.

Clinical microbial resistance to fluoroquinolones has become widespread, necessitating the development of newer agents that are only marginally better than the older agents and still susceptible to the same resistance mechanisms. Resistance in *N. gonorrhoeae* increased in Japan from 6.6% in 1993-1994 to 24.4% in 1997-1998.[69] A single 500-mg antibiotic prophylaxis dose of ciprofloxacin increased the percentage of resistant *E. coli* in the colon from 3% to 12%.[112]

Tetracyclines

Microbial resistance to tetracyclines is widespread, inducible, transposable, and sometimes permanent because the genes for tetracycline resistance are commonly associated with other antibiotic resistance genes on transposons, bacteriophages, and plasmids. None of these resistance genes may be lost until all antibiotics whose resistance genes are carried on the transposable element are eliminated from the environment, or, conversely, tetracycline may select for all antibiotic resistance genes carried on the element. Because tetracyclines have been rediscovered as effective therapy for nosocomial VRE and MRSA and community-acquired *S. pneumoniae* and *H. pylori*, the unwarranted use of tetracycline poses potentially serious clinical difficulties.

Three mechanisms exist for tetracycline resistance: drug efflux pumps, ribosomal protection, and enzymatic inactivation.[17] At least 29 different tetracycline resistance genes (*tet*) have been characterized, with at least 19 for specific and nonspecific efflux pumps, 8 for ribosomal protection, and the *tet*X gene for enzymatic activation.[17] Resistance determinants encoding at least one of these mechanisms are likely in most genera of bacteria.

The major mechanism for tetracycline resistance is drug efflux and *tet* efflux genes, which encode at least 300 different active efflux proteins[17] and in gram-negative bacteria are widely distributed and associated with large conjugative plasmids that carry resistance genes for other antibiotics, heavy metals, bacterial toxins, and virulence factors. Any chemical that selects for one of these genes can select for them all. Nine genes encode for cytoplasmic ribosomal proteins that bind to the ribosome to alter its configuration and prevent tetracycline from attaching to its receptor.[17] Enzymatic inactivation is encoded by a *tet*X gene currently present only in *Bacteroides*. Mutation in the *tet*A and *tet*B genes promotes efflux resistance in the new glycylcyclines.

Since the 1970s, resistance to tetracyclines has become common in Enterobacteriaceae, staphylococci, streptococci, *Bacteroides, H. influenzae,* and *P. aeruginosa*, ranging from 25% to 97% of all isolates.[17] Considering the close association of tetracycline resistance genes with transposable elements, this is not surprising. Thirty-nine genera of gram-negative bacteria and 23 genera of gram-positive organisms have acquired tetracycline resistance with an ongoing process of new gene discovery. Oral VGS have acquired *tet*M, *tet*O, *tet*L, and *tet*K genes, as have *S. pneumoniae* and *S. pyogenes*.

Not only is tetracycline almost exclusively associated with multiple drug resistance, it may also induce bacterial expression of resistance genes. The drug also downregulates a repressor gene that controls efflux mechanisms. Only nanomolar amounts of tetracycline are necessary to derepress this efflux control system. After that, regardless of the concentration, tetracycline can stimulate its own microbial cell efflux and that of other intracellular chemicals.

Subinhibitory levels of tetracycline that are allegedly insufficient to prevent microbial growth or stimulate resistance as used in agriculture and some therapeutic regimens increase antibiotic resistance in streptococci and staphylcococci.[69] Tetracycline promotes gene transfer by stimulating the frequency of bacterial conjugation, and colonic *E. coli* may express tetracycline and other resistance genes only when the drug is present.[64] Resistance gene (*tet*Q) transfer in the colon is widespread and occurs readily by conjugative transfer with more than 95% of DNA sequence homology with *erm*F and *erm*G genes for erythromycin.[93]

With standard tetracycline doses, within 24 hours, more than 95% of coliform bacteria in the gastrointestinal tract show resistance to tetracycline that lasts as long as the drug is present and for at least 4 to 6 months or longer in some cases after tetracycline is discontinued.[76] Family members of individuals taking tetracyclines for acne may have a 1000 times greater chance of multidrug-resistant bacteria than those whose members do not take tetracycline.[58]

It was long assumed that the massive resistance to tetracyclines observed from the 1960s to the 1980s would always remain and that the drugs were essentially useless against most major pathogens, particularly nosocomial pathogens. To the contrary, more recent clinical studies document a very low level of tetracycline resistance (1.3% in some studies) in common outpatient pathogens: *S. pneumoniae, H. influenzae, C. pneumoniae, Chlamydia trachomatis, M. pneumoniae, Mycoplasma hominis,* and *Ureaplasma urealyticum*. Tetracyclines have now become accepted, if not primary, antibiotics against community-acquired *S. pneumoniae,* and many are lifesaving against VRE and MRSA.[69]

The advocates of long-term low doses of doxycycline for periodontitis maintain that such doses produce a maximum blood level of 0.79 ± 0.285 μg/mL and that such blood/tissue levels do not adversely affect oral bacteria or increase levels of resistance.[106] Limited data are presented regarding resistance in other body areas (colon, skin). Ample evidence suggests that such blood levels of tetracyclines, particularly doxycycline, are therapeutic and even lifesaving at 0.06 to 0.25 μg/mL or less, many times below the 0.79 ± 0.285 μg/mL or less seen with a dosage of 20 mg twice/day.[69] A choice must be made between long-term therapy with tetracycline for whatever benefit, if any, it may have in periodontitis and the possibility of losing these drugs again by resistance development for serious and sometimes life-threatening diseases.

Heavy Metal Resistance

Microbial resistance to the heavy metals (e.g., silver, mercury, lead) is widespread in nature among various microorganisms. The most widely studied has been mercury resistance systemically and in the oral cavity. Not only do microorganisms develop genetic resistance mechanisms to the toxic effects of heavy metals (mercury damages thiol-containing enzymes), but these genes are also associated with antibiotic-resistance genes (penicillin, aminoglycosides, tetracyclines, chloramphenicol) in transposable elements and induce the transfer of resistance genes among microorganisms.[117]

Controversy has arisen regarding the potential effect of dental amalgam mercury on the resistance patterns of oral and fecal bacteria (silver has not been studied). Monkeys given 12 to 16 occlusal amalgams at one time showed that shortly after placement, mercury-resistant bacteria increased in the oral cavity and feces and were associated with resistance to several

antibiotics (ampicillin, tetracycline, aminoglycosides).[117] Clinical studies in three separate populations (subjects in whom all amalgams had been removed, subjects never having had an amalgam, and subjects with a varying number of amalgams) showed no differences in the minimal inhibitory concentrations (MICs) of oral and fecal microorganisms in their resistance patterns to tetracycline, chlorhexidine, cefuroxime, penicillin, and mercury chloride.[48,66]

The animal studies placed a large number of amalgams at one time with no data on their mercury content or the occlusal volume of the restoration and studied the resistance patterns for a maximum of 12 weeks, at which time the fecal mercury level had decreased so as not to present any selective advantage to resistance.[103] If the mercury resistance genes are transient and are later lost, the effect of mercury on the oral and fecal bacteria would likely be insignificant. Conversely, if the metal resistance genes become permanent residents of the oral or fecal flora, associate as part of a multidrug-resistant transposable element, or significantly induce resistance gene transfer among bacteria, a significant problem could exist. At least one study documents such gene transfer[117]; further study is warranted. Currently, no compelling evidence indicates that dental amalgam possesses any significant long-term adverse effect on microbial resistance patterns in the oral or fecal flora.

New vaccines are on the horizon against staphylococci, enterococci, and VGS. New antibiotics will be developed, but progress in developing new classes of drugs is limited. Meanwhile, the public, agribusiness, and health practitioners must use antimicrobial agents with much wisdom and circumspection. In the words of Norman Simmons: "We screwed up, and we ought to say so and apologize. Doctors were handed the wonderful gift of antibiotics but are destroying them through indiscriminate use. We know what to do, we should use them less."[97]

FACTORS INFLUENCING ANTIMICROBIAL THERAPY

The goal of microbial culture and sensitivity testing is to predict the outcome of treatment for an infection managed with an antibiotic agent. Identification of the microorganism allows for the ideal choice of antimicrobial agent. Empiric antibiotic therapy remains satisfactory for infections in which the microbial cause is likely to be routinely predictable or unlikely to be associated with drug-resistant strains, but empiric therapy may not be satisfactory for nonpredictable infections.[41]

The mere recovery of an organism from an infection does not indicate that it is involved in disease causation.[63] Orofacial infections are characterized by a rapid onset, prompt resolution with the elimination of the source, and a multiplicity of potential pathogens. Orofacial infections differ substantially from infections elsewhere in the body, where the onset is typically slow with protracted resolution and commonly monomicrobial in causation with rarely an opportunity to perform incision and drainage. Orofacial infections, if treated properly and caused by antibiotic-sensitive organisms, are commonly in remission before the culture tests are available. Because of their polymicrobial cause, determining the etiologic pathogens is difficult to impossible.

The issue of whether microbial culture and sensitivity tests are required or even desirable for the management of orofacial infections has been debated.[33,113] Because of the clinical features of orofacial infections (rapid onset and resolution, polymicrobial nature, well-established pathogens), routine culture and sensitivity tests are unlikely to be necessary, much less useful, unless the infection is very serious or fails to respond to diligent intervention. Polymicrobial infections defy the detection of the precise offending pathogens.

The breakpoints for minimal inhibitory concentrations (MIC) determinations are established in the United States by the National Committee for Clinical Laboratory Standards (NCCLS) but can vary widely throughout the United States and the rest of the world. One locale may use 0.1 μg/mL for penicillin resistance, whereas another may use 1 μg/mL. These breakpoints should reflect the reasonable blood level of the antibiotic that can be achieved by conventional and practical doses. Sometimes breakpoints are used that, although approved by the NCCLS, cannot be attained in the body except by unusual dosing. The use of such breakpoints can imply lack of resistance when for all clinical purposes the organism is resistant. The NCCLS recommendations are currently under criticism for just such difficulties. As stated by Jacobs and colleagues[39]: "Many of the NCCLS breakpoints are actually higher than the peak concentrations of the agent in serum and tissue, so that clinically achievable concentrations can never reach, let alone exceed, the concentrations needed to inhibit organisms for which the MICs are at or close to the susceptibility breakpoint value."

ANTIBIOTIC PHARMACOKINETICS AND PHARMACODYNAMICS

Despite being used clinically for more than 60 years, antibiotic unit doses, dosing intervals, and duration of therapy are not generally established for most infections.[44,80] Because antibiotics produced such remarkable cures not previously encountered and were essentially nontoxic drugs, clinicians would often forgo clinical trials and merely administer the drug until the patient got well or died. Very few clinical studies were ever performed on dosage, with one of the only being the 10-day therapy for the treatment of streptococcal sore throat, which was then extrapolated to most infections—10 days for all infections regardless of cause and locale. This was another case of an assumption determining therapy without any scientific basis.

Many dosing guidelines are empiric and should not be relied on blindly[5,108]; substantial resistance is encountered to changing package insert dosages even in the light of new data and understanding of antibiotic pharmacokinetics and pharmacodynamics.[35] The formula approach does not take into account mechanisms of action or postantibiotic effects, host-microbe interactions, or whether the antibiotic effect is concentration-dependent or time-dependent. It does not incorporate clinical data on microorganism virulence, anatomic location of the infection, whether incision and drainage can be established, microbial resistance, the physical signs and symptoms of the patient, and the status of the host defense mechanisms.

Formulas are a poor way to treat multifactorial infections unique to each patient because antibiotic therapy is not an exact science. Suspicion lingers that because of the common practice of inadequate antibiotic dosing, many patients get well by themselves with the antibiotic contributing little to their recovery. A clear understanding of current concepts of antibiotic pharmacokinetics (dose, absorption, distribution, metabolism, excretion) and pharmacodynamics (serum concentrations, dosing, host-microbe interaction, postantibiotic effects) is essential to achieving optimal efficacy and reducing microbial resistance.

PRINCIPLES OF ANTIBIOTIC DOSING

The goal of antibiotic therapy is to aid the body's defenses to clear the tissues of the microbial pathogens by achieving antibiotic levels in the infected area equal to or greater than the

MIC.[49] To accomplish this, the organism must be susceptible, and the drug concentration must be sufficient at the infected site until the next dose. Local factors that interfere with antibiotic activity must be minimized, with all efforts being made to eliminate the organism physically (incision and drainage). Host defenses need to be adequate to eradicate the pathogen and associated metabolic products (toxins) eventually.[49]

Minimal Inhibitory Concentration

The MIC is the lowest antibiotic concentration that prevents growth of microorganisms after an 18- to 24-hour incubation period with a standard organism inoculation of 10^4 to 10^5 cfu/mL. The minimal bactericidal concentration, which is rarely used as a clinical measure, is the lowest concentration of the antibiotic that causes the complete destruction of the organism or permits survival of less than 0.1% of the inoculum. Because the concentration of the antibiotic cannot be measured at the site of the infection, the serum antibiotic concentration and the MIC serve as surrogate markers attempting to quantify antibiotic activity.[10]

Although useful, the MIC has certain inherent difficulties. The MIC is a point in time only and tells nothing about the true antibiotic activity at the locus of the infection (antibiotic pharmacodynamics). The concentration of organisms (inoculum size) at the site of the infection is commonly 10^8 to 10^{10} cfu/mL, many times greater than that used to determine the MIC in the laboratory. The growth of microorganisms in vitro is exponential, whereas growth in vivo can be very slow to none.[49] The laboratory MIC determination is also subject to considerable variables, including temperature, inoculum size, pH, and growth medium, which may substantially differ from those occurring in the patient.

The MIC can be useful, however, in determining certain guides to antibiotic dosing: (1) the ratio of the peak drug concentration in the serum to the MIC (peak/MIC ratio), (2) the duration of time the serum drug concentration exceeds the MIC (time above the MIC), and (3) the ratio of the 24-hour area under the curve (AUC) to the MIC (AUC_{24}/MIC ratio).[49] The AUC is the measure of the drug exposure to the bacteria over time. The time above the MIC is very important in the efficacy of time-dependent β-lactam antibiotics, linezolid, and, to some extent, macrolides and clindamycin. The ratio of the 24-hour AUC to the MIC is important for concentration-dependent aminoglycosides and fluoroquinolones. A general rule of thumb is that the concentration of the antibiotic in the blood should exceed the MIC by a factor of two to eight times to offset the tissue barriers that restrict access to the infected site.[63] Substantial differences exist in interpretation of MICs when used to direct clinical antibiotic choices and dosing, particularly in the interpretation of antibiotic resistance studies. The clinically useful breakpoint (i.e., the threshold above which the bacterium is unlikely to respond to the specified MIC of the antimicrobial agent) depends on the amount of antibiotic that can readily be achieved in the blood of the patient.[40]

All of these guidelines apply only if the offending microorganism can be cultured and the MICs can be determined. Such determinations are not commonly performed in outpatient medicine, are not performed as often as they should in hospitals, and are virtually never performed in dentistry. These principles are useful, however, and have led to the concepts of concentration-dependent versus time-dependent antibiotics.

Concentration-Dependent Versus Time-Dependent Antibiotics

Depending on their mechanism of action, some antibiotics are much more effective if very high blood (and presumably tissue) concentrations are reached periodically (peak and trough effects, concentration-dependent), and others are more effective if the blood levels are maintained above the MIC for as long a time as possible (time-dependent). The antibacterial activity of aminoglycosides, metronidazole, and fluoroquinolones depends on high drug concentrations at the infected site because the killing rate is proportional to the drug concentration.[49] Conversely, some antibiotics, such as β-lactams and vancomycin, are less dependent for their activity on tissue concentrations and are much more effective with a long time of exposure of the microorganism to the antibiotic (time-dependent killing).

Because these agents require organisms in the process of cell division for their activity, antibiotics with slow time-dependent killing should ideally be continually present in the infected area because bacteria divide at different times and at different rates. Bacterial cell walls can be inhibited only while being formed; hence, β-lactams have no effect on cells with fully formed cell walls. The goal of dosing with cell wall inhibitors is to maximize the time of exposure to active drug levels and maintain the blood and tissue concentrations above the organism's MIC for as long as possible.[49] For pragmatic purposes, the blood/tissue concentrations of β-lactams should exceed the organism MIC for at least 60% to 70% of the dosing interval for pathogens with a short or no postantibiotic effect and 40% to 50% of the dosing interval for pathogens with long postantibiotic effects.[20]

Increasing the dosage of β-lactams to gain tissue concentrations more than four to five times the MIC does not result in increased killing and may end in a paradoxic or "Eagle" effect, in which very high β-lactam concentrations produce reduced rates of microbial killing.[67,70] It may be theoretically possible to have too high a dose of an antibiotic, but little or no evidence suggests that this paradoxic effect contributes to antibiotic failures.

Time-dependent killing with current package insert dose regimens is easy to achieve with β-lactams with long half-lives, such as amoxicillin, but difficult with penicillin V, cephalexin, or cephradine, which have short half-lives of about 45 minutes or less. If the peak blood level of these agents is achieved 1 hour after oral administration, and the standard formulas for half-lives and blood levels are at work (50% of the drug left at one half-life, 25% at two half-lives, 12.5% at three half-lives), at 4 hours from the original dosing, less than 12.5% of the peak blood level of the short half-life β-lactam remains. Unless the organism is very sensitive to the β-lactam (something that is unknown without culture and sensitivity tests), this concentration is unlikely to be above the MIC, leading to at least a 2-hour time period below the MIC because the package insert dosing interval for these agents is typically 6 hours. This considerable time period below the MIC allows for more rapid regrowth of the organism and increased risk of the emergence of resistant strains, both of which are associated with therapeutic failure. These dosing intervals merit serious reassessment.

Postantibiotic Effects

The concepts of time-dependent or concentration-dependent killing primarily involve bactericidal antibiotics that inhibit either nucleic acid or cell wall synthesis. For bacteriostatic antibiotics (macrolides, clindamycin, tetracyclines) that act by ribosomal protein synthesis inhibition and possess long postantibiotic effects (PAEs), such critical blood and tissue concentrations are considerably less imperative. A PAE is the persistent suppression of microbial growth after short-term exposure to an antimicrobial agent.

The concept of the PAE is gaining increasing interest as an important corollary to concentration-dependent versus time-dependent dosing. The antibiotic concentration may be well below the MIC, or the drug may even no longer be

present, yet suppression of bacterial replication persists, and the organism may be more susceptible to phagocytosis and the postantibiotic leukocyte effect (greater susceptibility of microorganisms to white blood cells after exposure to antibiotics). Humoral and cellular immune processes undergo altered morphologic characteristics and lose their adhesive properties, which may be important in the antibiotic prevention of bacterial endocarditis. The PAE may also render bacteria less susceptible to cell wall inhibitors, but allow for longer dosing intervals for bacteriostatic agents.

Virtually all antibiotics have demonstrable PAEs, but the duration is most significant with intracellular bacteriostatic agents and least with β-lactams. Various factors influence the PAE, including the particular organism, inoculum size, growth medium, organism growth phase, antibiotic mechanism of action, antibiotic concentration, and exposure time to the antibiotic. β-Lactams have a short PAE (1 to 3 hours) in gram-positive organisms and no PAE in gram-negative organisms. Under ideal circumstances, antibiotics that suppress ribosomal protein synthesis may have 5- to 10-hour PAEs, whereas fluoroquinolones and aminoglycosides possess intermediate PAEs of 2 to 4 hours.[29]

The exact mechanism for PAEs is unknown but is related to the time necessary to recover from sublethal structural and metabolic alterations that prevent resumption of bacterial regrowth (replication).[29] The precise clinical benefits of PAEs are difficult to determine but likely allow for less concern about rigid dosing intervals for bacteriostatic agents and undermine the old clinical adage that bactericidal antibiotics are always superior to bacteriostatic agents.

Microbial Persistence and Regrowth

The next antibiotic dose must be given before significant microbial regrowth can recur.[49] Microbial regrowth is not related to resistance but rather to the subpopulation of organisms that is not inhibited or killed during a given dosing interval (the residual bacteria at the end of each dosing cycle), which can re-establish themselves and continue growth. The size of the residual population is related to the initial population size (inoculum size), bactericidal activity, organism MIC, postantibiotic effects, antibiotic pharmacokinetics, and the doubling time of the organism.[49] The doubling time of VGS in bacterial endocarditis and *S. pneumoniae* in pneumonia can be every 20 minutes, whereas the doubling time for *Treponema pallidum* in syphilis may be 36 hours. Any rapidly expanding or spreading infection implies a very rapid microbial doubling time and a necessity to reduce the residual population available for regrowth to as low a number as possible.

Dosing and Resistance

The antibiotic concentration in the tissues should ideally exceed the MIC by a factor of 8 to 10 times to reduce or prevent the emergence of a resistant subpopulation.[49] The likelihood for the emergence of resistant strains during antibiotic therapy increases with greater spontaneous mutations, reduced host ability to eliminate the mutants, and, most important, the concentration of the antibiotic at the site of infection (the greater the concentration, the less likely the emergence of resistance; the lower the concentration, the greater the risk of resistance emergence).[49]

The less time the pathogen is exposed to sub-MIC doses, the less the chance of resistance mutations.[89] The ability of the resistant subpopulation to develop and overgrow decreases exponentially with greater antibiotic concentrations.[107]

Antibiotic Loading Doses

Because most acute orofacial infections begin and peak rapidly, high antibiotic blood levels must be achieved quickly; this is best and often only achieved with oral loading doses (two to four times the maintenance dose).[67,70,116] An antibiotic loading dose should be used whenever the half-life of the antibiotic is longer than 3 hours or a delay of 12 hours or longer to achieve therapeutic blood levels is unacceptable. If an antibiotic loading dose is not used, approximately four maintenance doses spaced at the recommended intervals are required to achieve a steady-state blood level of the antibiotic. Most antibiotics useful in orofacial infections have half-lives of less than 3 hours, but the acute nature of orofacial infections necessitates therapeutic blood levels earlier than 12 hours. With antibiotics with exceptional bioavailability, such as amoxicillin, a loading dose is not as crucial as with penicillin V or cephalexin, which are not as rapidly or as well absorbed.

Duration of Antibiotic Dosing

There is a natural but irrational tendency to treat infections for longer than necessary when shorter durations would be just as effective and decrease the overall selection pressure or microbial resistance.[22,56] Determining the optimal duration of antibiotic treatment is usually difficult because bacterial kinetics and effects of drugs are not precisely known. Although some bacteria may occasionally mutate to resistance in a stepwise fashion, and the presence of the antibiotic and high or prolonged doses might stop these mutants from attaining complete resistance, the reality of today is that virtually all resistance occurs by transposable element gene transfer promoted by the use of antibiotics, particularly at low doses and for long durations.[50,69]

Antibiotics should be used aggressively and for as short a time as is compatible with patient remission of disease.[67,70] With infectious diseases that do not rebound (return at cessation of the antibiotic), the proper duration of the antibiotic is determined by the time required for the patient's host defenses to gain control of the infection. The ideal antibiotic duration is the shortest time that prevents clinical and microbiologic relapse. The only practical guide to effectiveness of antibiotic therapy and the duration of therapy is clinical improvement of the patient as judged by remission of the infection. Antibiotic success is best determined by clinical improvement.

The following four misconceptions are the major reasons for the unnecessary prolonged use of antibiotics: (1) prolonged antibiotic therapy destroys resistant bacteria, (2) prolonged antibiotic therapy is necessary to prevent oral rebound infections, (3) antibiotic dosages and duration of therapy can be extrapolated from one infection to another, and (4) the antibiotic prescriber knows how long the infection will last.

Certain infections (fungal, urinary tract, respiratory) tend to recur when the antibiotic is terminated because the organisms may not be eliminated but only suppressed. Orofacial infections rarely, if ever, rebound, particularly if the source of the infection is eradicated. Often in medicine the temptation has been to extrapolate from one infection to another regarding dosage and duration of therapy. Many regimens have been based on the 10-day therapy against group A β-hemolytic streptococcal sore throat with little thought that such therapy might not apply to infections in the rest of the body.

Even experts get caught up in the adage to finish the course of the antibiotic and "make sure you take it all." In many cases, this advice is based on a fallacious assumption—that the prescriber knows beforehand just how long the particular infection will last. This foreknowledge is unlikely considering the number of variables involved in any given infectious process. The dentist should prescribe a reasonable amount of antibiotic (commonly for 3 to 5 days) with an initial loading dose (probably unnecessary with amoxicillin) and then re-evaluate the patient shortly into the infection (in 1 or 2 days) and monitor the patient's progress until he or she

is well. Prescription refills are designed for additional antibiotic administration if necessary. The antibiotic is terminated when, in the dentist's best clinical judgment, the patient's host defenses have gained control of the infection, and it is well on its way to or at termination.

Incision and Drainage

The reduction in the inoculum size of the infecting organism is paramount in the management of infections. As stated by Cunha and Ortega,[21] "Most patients who develop abscesses and are being treated with antibiotics cannot hope to be cured by antibiotics alone. . . . Surgical drainage remains the cornerstone of the therapeutic approach in the patient with abscesses."

With some clinical infections (pericoronitis, indurated cellulitis), the infection is too diffuse or has no nidus that would respond to incision and drainage. With most orofacial infections, incision and drainage is imperative because (1) antibiotics do not diffuse well into infected areas; (2) some antibiotics are inactive at abscesses because of acidic pH and other reasons; (3) abscess microorganisms may not be dividing or may be at a very low metabolic state, negating the effects of antibiotics, particularly β-lactam cell wall inhibitors; and (4) high levels of antibiotic inhibitors (β-lactamases or other enzymes) may be present to inactivate the antibiotic.[67,70]

Antibiotic Dosing Variables

Additional pharmacokinetic factors determining antibiotic efficacy include diffusion to the site of the infection, lipid solubility, plasma protein binding, inoculum effect, surface area/volume ratio, pregnancy, age, and renal and hepatic function. The ease with which antibiotics penetrate to the site of infection follows the same path as other drugs and is guided by the pK_a, tissue pH, and lipid and water solubility. Lipophilic antibiotics, such as tetracyclines, macrolides, and fluoroquinolones, pass through tissue barriers better than hydrophilic β-lactams. Tetracyclines and macrolides are highly concentrated within cells, making them effective against intracellular pathogens and providing for a drug depot within macrophages. β-Lactams, vancomycin, and aminoglycosides are principally confined to the extracellular fluid. Diffusion through the capillary endothelium is easy for rifampin, metronidazole, and chloramphenicol; difficult for β-lactams and aminoglycosides; and intermediate for tetracyclines, fluoroquinolones, and trimethoprim.

Only an antibiotic not bound to plasma protein is free to diffuse through capillary walls and other barriers to its site of action. The degree of plasma protein binding can vary from 80% to 96% for oral anti-staphylococcal penicillins, clindamycin, and doxycycline; 50% to 80% for penicillin V, penicillin G, erythromycin, and tetracycline; and less than 25% for amoxicillin, ciprofloxacin, cephalexin, metronidazole, and aminoglycosides. Protein binding may increase with infection, inflammation, malignancy, and diabetes and decrease with cirrhosis, burns, and malnutrition. The clinical significance of antibiotic protein binding is currently debated, but, all things being equal, drugs with lower protein binding may be preferable.

The inoculum effect (loss of antibiotic efficacy against dense microbial populations) may significantly affect antibiotic activity and the ability of the drug to penetrate to the core of the infection. A large mass of bacteria results in a decreased growth rate, less phagocytic activity, increased β-lactamase activity, more glycocalyx production, and reduced pH. The deleterious effect of inoculum size can be eliminated by early and vigorous antibiotic therapy combined with mechanical removal of the microorganisms (incision and drainage, scaling, and root planing). Antibiotics penetrate poorly into dense biomasses.

The antibiotic concentration at the site of the infection also depends on the ratio of the surface area of the vascular bed to the volume of the tissue compartment to be supplied.[85] With a high vascular bed/volume ratio (high vascularity and low infection volume), as is found in areas of inflammation and minimal purulence, the antibiotic concentration (except for β-lactams) may be similar to that of blood; in areas of low vascular bed/volume ratio (low vascularity and high infection volume), the antibiotic concentration may be much lower than serum. Incision and drainage can create a high vascularity, low infection volume situation that promotes better antibiotic penetration.

In pregnancy, all tetracyclines are contraindicated because of their tooth-staining effects and hepatotoxicity. The estolate form of erythromycin is contraindicated because it has a greater tendency to induce cholestatic hepatitis, including during pregnancy. Metronidazole and fluoroquinolones affect DNA synthesis and have been studied for any teratogenic, mutagenic, or carcinogenic effects. None seem to exist, but metronidazole carries a warning that its use should be avoided if possible in the first trimester of pregnancy. Similar caution should be exercised for fluoroquinolones.

Few data exist on the effect of hepatic disease on antibiotic pharmacokinetics, but impaired renal function or renal failure can have significant effects on antibiotic blood levels. As a rule in renal dysfunction, the dosage interval is increased for concentration-dependent antibiotics, and the dose is decreased for time-dependent antibiotics.[28,35] In renal dysfunction, dosage modification is required for many antibiotics. Clindamycin, dicloxacillin, azithromycin, and doxycycline do not require dosage adjustment in renal dysfunction.[35,51] The central nervous system effects of fluoroquinolones, the toxic effects of aminoglycosides, the platelet aggregation resulting from some penicillins, and the deafness associated with macrolides may be seriously increased with renal insufficiency.[51]

The following modifications should be used for antibiotics used in dentistry in patients with renal failure: amoxicillin, increase dose interval to 8 to 12 hours with moderate failure and to 24 hours with severe failure; ciprofloxacin, reduce dosage by 25% to 50%; cephalexin, increase dose interval to 8 to 12 hours; cefaclor, decrease dosage by 50%; cephradine, decrease dosage by 50% with moderate failure and 75% with severe failure; metronidazole, decrease dosage by 25% with severe failure; clarithromycin, decrease dosage by 25% to 50%; and erythromycin, decrease dosage by 25% to 50%.[51]

Drug pharmacokinetics in neonates (first month of life) and infants (1 month to 2 years) may differ substantially from children (2 to 13 years) and adults.[67,70] Infants and neonates have a significantly greater percentage of body weight compared with body water, leading to a greater volume of distribution and increased serum half-lives. Other factors in neonates and infants versus children and adults are reduced gastric emptying and acidity, plasma protein binding, and reduced glomerular filtration rate. Renal function may be assumed to be totally functional by age 1 year.[12]

Elderly patients must also be considered substantially different from younger adults because of normal aging processes, underlying illness, and reduced host defenses predisposing to more serious infections[67,70] and altered pharmacokinetics. Altered pharmacokinetics in the elderly include reduced total body water and lean body mass (more body fat) and reduced cardiac output, gastric acid, gastric emptying time, and renal function. Age may have little effect on most antibiotic pharmacokinetics, but renal insufficiency must always be a concern. Elderly patients also tend to be noncompliant about taking medication because of impaired memory, hearing, and vision; fear of drug interactions; perceived ineffectiveness of antibiotics; or the desire to save the medication for "the next time" because of the high cost of drugs.

COMBINATION ANTIBIOTIC THERAPY

Some established but limited situations may require combining antibiotics. The use of more than one antibiotic agent to treat an infection is often controversial because the efficacy of such therapy is likely to be microorganism-specific and may promote the emergence of resistant organisms, as many antibiotic resistance genes are now carried on multiple gene transposable elements. A common empiric reason for combined antibiotic therapy is to broaden the antibacterial spectrum when confronted with a probable polymicrobial infection of unknown origin.[9] Other proposed benefits include a reduction of dose for each agent (rarely done clinically), antibiotic synergism, and a decrease in adverse drug reactions. In most cases, unless documented by certain laboratory tests (fractional inhibitory concentration, checkerboard or time-killing curve methods) or proven empiric data, the disadvantages of combination antibiotic therapy commonly outweigh the advantages; the more drugs are present, the greater the likelihood of adverse reactions, antibiotic antagonism, increased financial costs, greater microbial resistance, greater environmental spread of resistance genes, and increased risk of superinfections (appearance of a new infection when treating a primary one).[67,70]

Antibiotic synergism is the combined effect of two or more antibiotics that is greater than the effectiveness of the antibiotics individually. Antibiotic combinations that have been documented to be synergistic are (1) cell wall inhibitors and aminoglycosides, (2) β-lactams with β-lactamase inhibitors, (3) β-lactams that act on different PBPs, (4) streptogramin combinations, and (5) sulfonamides and trimethoprim.[4,67,70] Other combinations that may be synergistic include doxycycline and aminoglycosides for brucellosis; amoxicillin, tetracycline, macrolides, and metronidazole for *H. pylori*; vancomycin, rifampin, and aminoglycosides for MRSA; penicillin and clindamycin for group A streptococci; and fluoroquinolones and macrolides for *L. pneumophila*. A special case exists in the treatment of active tuberculosis, in which the use of combination antibiotic therapy is required, not because of a synergistic effect of antibiotics, but because of the necessity of reducing the growth of strains of *M. tuberculosis* resistant to a single or multiple drugs.

Antibiotic antagonism (a decrease in the efficacy of two or more antibiotic agents in combination) is not well documented clinically. Some examples of antagonism include penicillin and macrolides in the treatment of *S. pneumoniae*, β-lactam induction of β-lactamase production in enteric bacilli, and macrolide and lincosamide combination against *S. aureus* leading to induction of MLS_b resistance.[3]

ANTIBIOTIC FAILURES

The inability of antibiotic therapy to control and eliminate an infection can be the result of many factors (Box 38-1), which primarily involve microbial resistance, poor antibiotic pharmacokinetics, faulty dosing, and inadequate host response to the infection.[67,70] Antibiotic failures are marked by persistent fever, lack of clinical improvement, and clinical deterioration of the patient.[21]

A common factor in antibiotic failures is patient noncompliance with the prescribed antibiotic regimen. The most common reason for antibiotic failure in orofacial infections is a lack of or inadequate incision and drainage. A typical initial reaction to an apparent antibiotic failure is to add an additional antibiotic in the assumption that the current antibiotic has an inadequate spectrum of activity against the pathogen, when the most likely reason is poor antibiotic penetration to the infected site.[21] The specter of increased microbial resistance in the oral cavity is expected to play a greater role in antibiotic failures with an anticipated increased spread of oral infections to the orbit and submandibular regions.

BOX 38-1

Common Reasons* for Antibiotic Failure

HOST-MICROBE-ANTIBIOTIC INTERACTIONS

Host Defenses

Except in immunocompromised patients, antibiotics do not cure patients; patients cure patients. The innate immune system of humans provides a wide variety of defense mechanisms to recognize the microbial pathogen, activate effector mechanisms to isolate and destroy the invader, and eliminate its waste products eventually. Antibiotics gain time for this system, initially overwhelmed by the invasion and rapid multiplication of the organism, to re-establish its control of defense against microbial pathogens.

Microorganisms attempting to gain access to the interior of their host first encounter the physical barriers of the skin and mucosa along with skin-associated lymphoid tissue, dendritic (antigen-processing) cells, defensins, cathelicidins and associated cationic antimicrobial peptides, and secreted IgA that increases mucosal stickiness.[88] If these barriers are breached, specific and nonspecific defenses assert their protective effects.

Antibiotics and Immune Function

The assumption that antibiotics act synergistically with the immune system against microbial pathogens seems reasonable, but this is not always the case. Antibiotics may assist by PAE and postantibiotic leukocyte effect activities and by altering microbial adherence and virulence. Conversely, antibiotics, most notably tetracyclines, may reduce macrophage and polymorphonuclear cell chemotaxis, decrease phagocytic activity, and reduce the oxidative burst. Some antimicrobials may reduce inflammation (macrolides), whereas most are capable of releasing microbial toxins (endotoxins) on microbial cell death. In general, most cell wall inhibitors have no effect on the immune system, whereas fluoroquinolones, imipenem, and some cephalosporins may enhance the immune response.[46] The data on macrolides are presently equivocal, and tetracyclines, rifampin, sulfamethoxazole/trimethoprim,

aminoglycosides, and chloramphenicol may impair immune function. The clinical significance of these interactions is currently unknown, but does imply that host-microbe-antibiotic interactions are complex.

Microbial Virulence

The virulence (pathogenicity) of a microorganism depends on the following necessary traits: the ability to colonize, penetrate, grow, inhibit, or avoid host defenses and induce host damage.[96] Microbial virulence is highly regulated by population density, growth phases, osmolality, pH, iron/ion concentrations, temperature, adhesin expression,[24] and "quorum sensing"—the ability of microbes to convey the information for all these factors to each other to maintain optimal existence and occasionally attack their hosts.

The genes for virulence are contained in pathogenicity "islands" that are distinct genetic elements encoding virulence factors for pathogenic bacteria acquired by horizontal gene transfer and fully capable of enclosure in integrons for transfer to other bacteria. These pathogenicity islands contain the genes for adherence factors (adhesins, fimbriae), toxins (hemolysins, enterotoxins), iron uptake systems, apoptosis, and mobile elements (transposons, integrons, insertion sequence elements).[36]

ANTIBIOTIC ADVERSE REACTIONS

This section discusses adverse drug reactions, some of which are unique to antibiotics; others are not exclusive to antimicrobials, but are clinically more significant than the common adverse reactions seen with most drugs.

Antibiotic Teratology

Few studies have been published regarding the ability of antibiotics to cause birth defects. Most antibiotics are in the U.S. Food and Drug Administration (FDA) class B or C categories (see Table 3-7), indicating little, if any, risk. Several studies have followed the long-term use of metronidazole and found its use in pregnancy does not seem to be associated with any increased rate of birth defects, preterm delivery, or low birth weight. Studies on aminoglycosides, cephalosporins, and oxacillin have likewise shown no teratogenic effects.

Antibiotic-Induced Mania

Acute mania has been described in association with clinical antibiotic therapy. Worldwide, 103 cases have been reported, making such reactions rare but disconcerting. The prime causative agents are clarithromycin followed by the fluoroquinolones and isoniazid.[2] Other antibiotics less commonly implicated are metronidazole, erythromycin, sulfamethoxazole/trimethoprim, and amoxicillin.[2] All but two of these reactions were reversible with antibiotic discontinuance and are likely to be due to the antibiotic, although some occurred in patients taking other medications that could cause mania. The mechanism may be related to altered γ-aminobutyric acid (GABA) activity in the brain because fluoroquinolones and isoniazid are GABA antagonists.[2]

Long QT Interval Syndrome

Long QT interval syndrome is a cardiac disorder caused by ion channel abnormalities that prolong the time interval between the beginning of the QRS complex and the end of the T wave on the electrocardiogram (see Chapter 24). Long QT interval syndrome may be either congenital or acquired, with the congenital mutations in the genes controlling the cardiac K^+ channels. The acquired form is caused by metabolic disorders or certain drugs. Metabolic disorders include reduced blood K^+, Ca^{++}, and Mg^{++}, and diseases include heart failure, myocardial ischemia, mitral valve prolapse, and liver and renal disorders. Antibiotics that have been implicated in the cause of torsades de pointes include fluoroquinolones (gatifloxacin, levofloxacin, moxifloxacin, sparfloxacin), macrolides (erythromycin, clarithromycin), and clindamycin.[105]

The FDA Adverse Event Reporting System has analyzed 202 cases of macrolide-induced or fluoroquinolone-induced torsades de pointes and found that 77% were caused by macrolides and 23% by fluoroquinolones; 89% to 95% were in older patients; 9% to 13% were fatal; the mean time to the adverse event was 4 to 5 days; and 42% to 62% had cardiac disease, 7% to 11% had renal disease, and 17% had low blood K^+ or Mg^{++} levels.[92] The risk rate has been estimated to be 1 per 1 million exposures to ciprofloxacin, 3 per 1 million exposures to clarithromycin, and 14.5 per 1 million exposures to sparfloxacin.

Antibiotics and Oral Contraceptives

In response to a few case reports, in the 1980s the FDA issued a warning that antibiotics may interfere with the action of oral contraceptives, potentially resulting in unwanted pregnancies. The proposed mechanisms of reduced contraceptive blood concentrations leading to decreased efficacy include (1) increased urinary/fecal excretion from antibiotic-induced diarrhea, (2) increased microsomal liver metabolism, (3) receptor displacement, (4) reduced gastrointestinal absorption, and (5) reduced enterohepatic circulation. The antibiotic rifampin stimulates the liver metabolism of the oral contraceptives, reducing blood levels. No other experimental data or controlled clinical studies have documented the interference of any other antibiotics with the activity of oral contraceptives.

The most likely theoretic mechanisms are the gastrointestinal reduction in free estrogen or a reduction in enterohepatic circulation. Several studies document no effect of antibiotics on the blood levels of ethinyl estradiol, norethindrone, and progesterone in patients taking doxycycline (100 mg/day for 7 days),[62] tetracycline (500 mg every 6 hours for 10 days),[61] and ciprofloxacin (500 mg three times per day for 7 days).[54] No effort has been made to determine whether the failure rate of oral contraceptives in women taking antibiotics is greater than the normal failure rate of oral contraceptives in women not taking antibiotics. No official authoritative body has ever examined this alleged drug interaction to investigate the evidence and make a recommendation. The initial FDA response has never been updated.

From a purely scientific point of view, no reason exists to believe that any antibiotics except rifampin interfere with the action of oral contraceptives. From a medicolegal point of view, the dentist may wish to advise a patient taking oral contraceptives and receiving antibiotics to use an additional contraceptive method or practice abstinence during the time the antibiotic is present and for several days after its termination to allow for complete antibiotic excretion (usually five times the half-life of the drug). The oral contraceptive should never be stopped during antibiotic therapy because it is the most effective means of contraception with the exception of abstinence.

Antibiotic-Induced Agranulocytosis

Various antibiotics have been implicated as rare causative agents in reduced blood neutrophil counts with accompanying signs and symptoms of fever and septicemia or septic shock. The median onset of agranulocytosis is 12 to 14 days after beginning antibiotic therapy. The mortality rate in the literature from all drug-induced agranulocytosis is 6% to 20%, with antibiotics possibly causing 20% of the cases. The most commonly involved antibiotics are sulfonamides and β-lactams, followed by aminoglycosides and macrolides.

Antibiotic-Induced Photosensitivity, Photoallergy, and Phototoxicity

Antibiotics (along with phenothiazine antipsychotics) are among the most common drugs inducing skin reactions on exposure to sunlight. Photosensitivity may occur in one of two forms: (1) phototoxicity, in which chemicals (drugs) are deposited in the skin, absorb ultraviolet light, and transfer the energy to local tissue, resulting in inflammatory responses, or (2) photoallergy, in which sunlight causes a hapten to become a complete antigen in the skin, eliciting an immediate or a delayed allergic reaction. The signs and symptoms (erythema, urticaria, eczema, lichenoid dermatitis, bullous lesions) may be the same, but the mechanisms are different (photoallergy may need a sensitizing dose unless the drug is continually taken for ≥5 to 10 days). The most common antibiotics that induce photosensitivity are sulfonamides, tetracyclines, and fluoroquinolones. Photosensitivity is managed by discontinuing the drug, avoiding sunlight, and wearing protective clothing.

Antibiotic Effects on Body Flora and Superinfection

The question of whether human exposure to antibiotic doses at the low concentrations seen in agriculture and aquaculture, as therapy for inflammatory or other diseases, or in the food and water supply alters body flora or promotes emergence of resistant microbes or the transfer of resistance genes is of crucial importance to public health. Some data from veterinary studies indicate that daily doses of tetracycline at 15 mg per 60 kg/day of animal body weight or 2 mg/day of oxytetracycline may have no effect on gastrointestinal carbohydrate or fat metabolism and do not cause any increase in antibiotic-resistant enteric bacilli; however, 20 mg of oxytetracycline twice a day can promote such resistance.[104] Several studies have been unable to document the transfer of resistance genes from animals to farmers or shared resistance plasmids between farm animals and farmers. At times when resistance is not detected, the chosen breakpoint for such a determination was extremely high (e.g., 32 μg/mL for vancomycin), which is not comparable to concentrations achieved with human doses.

On balance, the evidence is substantial that antimicrobial agents at any dose or concentration for virtually any length of time do select for resistance and promote the acquisition and transfer of drug-resistant genes.[69] Many of these species exhibit extraordinary resistance patterns: 50% to 100% of *Salmonella*, staphylococci, and enteric bacilli are resistant to tetracycline, and 32% to 47% are resistant to β-lactams, with 49.7% exhibiting polyantibiotic resistance; 30% of *S. aureus* is resistant to ciprofloxacin and 47% to tetracycline; 72% of *Campylobacter* in humans and 99% in chickens and pigs are resistant to ciprofloxacin; and *E. coli* exhibits 70% to 94% resistance to amoxicillin, and 62% to 98% resistance to tetracycline.[1,30,55,86,111] If the very low (nanogram/nanomolar) concentrations of antibiotics found in the food chain and used in nature to control bacterial ecologic niches induce such resistance patterns, the assumption (until proven otherwise) must be that subtherapeutic dosages in humans would do the same. Subtherapeutic is not synonymous with biologically or pharmacologically inactive. If microbes employ nanogram amounts of antibiotics to control their own microbial ecology (kill fellow microorganisms, promote resistance gene expression and transfer), it is difficult to believe that micrograms would not do the same in humans.

Of possibly greater importance is the ability of antibiotics to induce microbial resistance or promote the transfer of resistance genes from one species to another. The mere presence of a β-lactam antibiotic produces a 100-fold to 1000-fold increase in induction of β-lactamase in microorganisms producing extended-spectrum β-lactamases.[53] *E. coli* carries resistance genes that are not expressed until tetracycline is present.[69] Concentrations of tetracyclines at 0.1 to 1 μg/mL per gram in meat cause the dissemination of resistance genes in the human gastrointestinal tract,[34] and 1 μg/mL of tetracycline in drinking water results in a 10-fold increase in the transfer of conjugative plasmids from *E. faecalis* to *Listeria monocytogenes*.[26]

In oral plaque biofilm, tetracycline resistance genes can be transferred from *B. subtilis* to streptococci, illustrating that nonoral bacteria have the potential to transfer genes to opportunistic oral microorganisms.[83] The presence of tetracycline increases the conjugative transfer of Tn916 by a factor of 19 to 119 times in matings between *B. subtilis* and *Bacillus thuringiensis* and 15 times between *E. faecalis* and *B. thuringiensis*[94] and *B. subtilis*.[109] The self-transfer of *Bacteroides* conjugative transposons can be increased 100-fold to 1000-fold by the presence of low levels of tetracycline (1 μg/mL)[101,102] because of the transcription of a three-gene operon near the middle of a transfer element.[87]

Oral streptococci can harbor tetracycline resistance genes in dental plaque and disseminate such genes by mobile elements to other microflora: *E. faecalis*, *Veillonella*, and other streptococci.[83] Salyers and colleagues[87] stated that "the fact that tetracycline acts as an inducer of transfer gene expression illustrates how the use of an antibiotic could accelerate the spread of antibiotic resistance genes not only by selecting for their acquisition but also by stimulating their transfer."

A significant and unappreciated adverse effect of antibiotics is the potential to decrease colonization resistance of indigenous anaerobic flora in the digestive tract and other anatomic areas (skin, oral mucosa). The role of colonization resistance is to limit the concentration of potentially pathogenic flora of either an exogenous or endogenous nature in a given body part. Removal of indigenous flora by antibiotics can promote growth of microorganisms not sensitive to the drug (superinfection). Many superinfections result from a reduction in the endogenous microorganisms important for colonization resistance, with the most notable example being antibiotic-induced diarrhea and colitis.

Antibiotic-Induced Diarrhea and Pseudomembranous Colitis

Adverse colonic effects of antibiotics range from simple diarrhea (antibiotic-associated diarrhea) to mucosal inflammatory diarrhea/colitis (antibiotic-associated colitis), with or without associated *C. difficile* (*C. difficile*–associated colitis [CDAC]), to potentially fatal pseudomembranous colitis (PMC). Of the 25 million people affected by serious diarrhea annually in the United States, approximately 10% of these cases are the result of antibiotics, particularly broad-spectrum agents.[68] Most of these cases of antibiotic-associated diarrhea are not clinically significant and respond to drug discontinuance and rehydration if necessary.

Nevertheless, a significant portion of cases are a manifestation of "benign" colitis or the far more menacing PMC caused by toxins from *C. difficile*. Approximately 3 million cases of CDAD or CDAC may occur annually in the United States, primarily in hospitalized patients.[68] The outpatient toll of CDAD or CDAC is approximately 20,000 cases per year, with a range of 7.7 to 20 cases per 100,000 patient-years worldwide.

PMC was first described in 1893 as "diphtheric colitis" and before the introduction of antibiotics was ascribed to staphylococci, heavy metal intoxication, sepsis, surgical shock, and uremia. Antibiotic-associated PMC was described in the 1950s with the advent of penicillins, tetracyclines, and chloramphenicol. In 1977, the association of PMC with a toxin from *C. difficile* was discovered, and the relationship between the organism and antibiotic-associated diarrhea and PMC was established in 1978.[68]

Virtually all cases of CDAD, CDAC, and PMC are associated with antibiotics, with 92% of patients exposed to the antibiotic within 2 weeks of onset of the diarrhea and 100% within 8 weeks, of which 87% were nosocomially acquired.[68] Any antibiotic is capable of inducing diarrhea, colitis, or PMC but the most common agent involved is amoxicillin, followed by third-generation cephalosporins and clindamycin. When the colonic flora are disturbed by antibiotics or disease, the colonization resistance of the gastrointestinal tract is reduced by the suppression of natural antagonists of C. *difficile* such as *Bacteroides, Lactobacillus,* pseudomonads, staphylococci, streptococci, peptostreptococci, enterococci, and *E. coli*. It is no accident that these antibiotics are involved because their antibacterial spectrum includes these microbial antagonists of C. *difficile*. Antibiotic-associated colitis and CDAC are classic superinfections.

C. *difficile* is a spore-forming, gram-positive obligate anaerobic bacillus commonly acquired by cross-infection by oral ingestion and widely found in rivers, seas, lakes, swimming pool water, soil, domestic animals, and raw vegetables. C. *difficile* is cultured in 19% of patients with antibiotic-associated diarrhea without colitis, 60% of patients with antibiotic-associated colitis without PMC, and 95% with PMC.[68]

CDAC is caused by cytotoxins (A and B) that gain access to the intestinal mucosa to alter Rho proteins (guanosine 5′-triphosphate–binding proteins) to disrupt the F-actin structures and cause cell rounding and eventual intestinal cell death.[68] The initial diarrhea may appear 1 to 10 days or 6 to 10 weeks after initiating the antibiotic therapy. The incubation period after exposure to or acquisition of C. *difficile* may be less than 1 week, with a median time of diarrhea onset of 2 days.

As the disease progresses, the signs and symptoms include fever; diarrhea with abdominal tenderness; profuse green, watery, foul-smelling, bloody diarrhea with abdominal distention; and fecal and blood leukocytosis. The onset of PMC is heralded by high fever; marked abdominal tenderness; dehydration; and the initiation of 2 to 20 mm in diameter, raised, adherent yellow plaques interspersed between relatively normal colonic mucosa. From patchy epithelial necrosis, these plaques may proceed to ulcerations overlaid by a pseudomembrane consisting of fibrin, mucus, leukocytes, and cellular debris. In fulminant colitis, the colonic muscle tone may be lost, resulting in toxic colonic dilation (toxic megacolon), paralytic ileus, or colonic perforation with peritonitis. CDAD is diagnosed by the presence of diarrhea and one of the following: (1) a pseudomembrane on colonoscopy, (2) positive cytotoxin stool assay for toxin B, (3) a stool assay for toxins A and B, or (4) a positive stool culture for C. *difficile*.[68]

In 15% to 25% of CDAD cases the diarrhea resolves with antibiotic discontinuance only. The antibiotic of choice for unresolved CDAC or PMC is metronidazole (250 mg orally four times per day or 500 mg three times per day) for 10 days.[68] Vancomycin (125 mg orally four times per day for 10 days) is now reserved only for cases that do not respond to metronidazole or in severely ill patients because of concerns about selection of vancomycin-resistant organisms in the hospital. Other therapies that have been attempted are bacitracin; fusidic acid; teicoplanin; vancomycin plus rifampin; vancomycin in tapering doses; and the re-establishment of the colonic flora with the probiotics lactobacilli, nonenterotoxigenic C. *difficile,* and *Saccharomyces boulardii*.

Resolution of CDAD occurs in an average of 2 to 4 days with metronidazole and 2.6 to 4.2 days with vancomycin.[68] The hospital stay for patients acquiring antibiotic-associated diarrhea may be extended to 18 to 21 days. Studies on the mortality rates associated with nosocomial CDAD are virtually nonexistent, but several have reported a 3% to 17% death rate. The mortality rate associated with community-acquired CDAC or PMC is very low.[37,100]

The range for relapse and recurrence rates of CDAD is 4.8% to 66%, with an average of 20% seeming reasonable.[68] Relapse may be caused by the incomplete eradication of C. *difficile* and recurrence or the acquisition of a new organism. Most individuals with recurrence or relapse respond to the same initial metronidazole or vancomycin regimen, but refractory CDAD can occasionally become persistent and elude long-term cure for years. Risk factors for recurrence include acquisition during the spring, female sex, diarrhea that resolves but then recurs within 2 weeks after the antibiotic treatment is terminated, and, most important, receiving antibiotics again within 2 months of the initial recurrent CDAD.

The fear of inducing a potentially fatal case of PMC has led to a reluctance to use clindamycin because early and faulty preliminary data reported a 10% association of PMC with the drug.[68] More recent data indicate that incidence of antibiotic-associated diarrhea and CDAC associated with clindamycin in community use of the drug is very low. The overall risk rate for community-acquired C. *difficile*–associated PMC from retrospective data may be 1 per 10,000 antibiotic prescriptions, and the risk of hospitalization may be 0.5 to 1 per 100,000 patient-years.[37] In a study of 376,590 antibiotic prescriptions given to more than 280,000 patients over a 4-year period, four cases of acute antibiotic-associated colitis were detected.[100] The incidence rate was calculated to be 1.6 per 100,000 persons exposed to ampicillin, 2.9 per 100,000 persons exposed to dicloxacillin, and 2.6 per 100,000 persons exposed to tetracycline with no antibiotic-associated diarrhea seen in the 1509 patients receiving oral or topical clindamycin.

In another retrospective study, 51 cases of CDAD were detected in 662,500 person-years (7.7 per 100,000 person-years).[37] All patients recovered, and only six were hospitalized. The overall risk rate for community-acquired CDAD in this study was less than 1 per 10,000 antibiotic prescriptions, and the risk of hospitalization was 0.5 to 1 per 100,000 patient-years.[37] The risk for hospitalization from community-acquired, antibiotic-induced diarrhea or colitis seems to be very low.[37,100]

On the basis of the preceding epidemiologic data, it seems that the fears of significant PMC associated with the outpatient use of clindamycin are unfounded. Statistically, PMC is more likely to occur with amoxicillin than clindamycin. Clinicians should refrain from unnecessary antibiotic therapy in patients within the first 2 months after the elimination of CDAD. Any elective dental procedure requiring antibiotic treatment or prophylaxis would best be postponed for this 2-month period. If antibiotic therapy is required, the use of antibiotics far less commonly associated with CDAD (penicillin V, macrolides) is appropriate.

NEW ANTIMICROBIAL APPROACHES

Since 1998, only linezolid and daptomycin have been introduced with novel new antibiotic mechanisms of action, and only caspofungin and voriconazole have been presented as new antifungal agents.[60] Pharmaceutical companies see new antibiotic development as problematic for economic, regulatory, and scientific reasons.[60] As a result, 10 of the 15 largest drug companies have reduced or eliminated antibiotic research since 1999.[43] The costs of development may be prohibitive for venture capital companies because the time from drug discovery to marketing can be 14 years.[43,75]

The scientific difficulty with developing new antibiotics is that all the easy targets in bacteria have already been

discovered with possibly only a few remaining. From 1996-2004, greater than 125 antibacterial screens for 60 different antibiotic targets by 34 different companies have yielded no credible antibiotic candidates.[75] The current pattern of formulating "new" antibiotics that are merely derivatives of existing antibiotics will not solve the problems of microbial resistance. Entirely new approaches to unique mechanisms of antibiotic action attacking heretofore unknown microbial metabolic processes require a much better basic understanding of microbial life and considerable risk-taking on the part of the pharmaceutical industry.

Some of the following approaches currently under study include (1) inhibiting species-specific enzymes; (2) using bacteriophages; (3) using natural cationic peptide antibiotics; (4) inhibiting glycosyltransferases that control bacterial membrane lipopolysaccharide synthesis; (5) using antisense RNA inhibitors; (6) sequestering the iron necessary for microbial survival; (7) sequencing the bacterial genome to identify unique antibiotic targets; (8) improving the immune system's ability to recognize and destroy microbial pathogens; (9) developing highly specific narrow-spectrum antibiotics to target specific microbes identified by real-time polymerase chain reaction; (10) developing chemicals that inhibit microbial surface adhesion; and (11) interfering with microbial quorum sensing so that bacteria misread signals for virulence, adherence, and growth.

Peptide antibiotics and cationic antimicrobial peptides are natural antibiotics that function as a component of all immune systems of living species. Some 500 cationic antimicrobial peptides have been isolated, with some living species possessing 30 or more entities. Nonribosomally synthesized peptides include gramicidins, polymyxins, bacitracins, and glycopeptides; ribosomally synthesized peptides include defensins, cathelicidins, cecropins, and magainins.

Peptide antibiotics function to kill all invading microorganisms (bacteria, viruses, parasites, fungi), elicit the inflammatory response and IgG production, recruit neutrophils and T cells, increase phagocytosis and chemotaxis, and participate in apoptosis.[91] Cationic antimicrobial peptides are located in epithelial cells, neutrophils, and macrophages and on the epithelial surfaces of the skin, mucosa (including the oral cavity), lungs, kidneys, and gastrointestinal tract. Cationic antimicrobial peptides may act on the microbial membrane to disrupt its permeability.

The use of cationic antimicrobial peptides as antibiotic agents is hampered by their destruction in gastric acid; however, they may function as topical agents because they seem to be essentially nontoxic and nonallergenic. Cationic antimicrobial peptides have been used experimentally in the management of oral mucositis and to sterilize catheter sites.

An intriguing approach to the control of pathogenic bacteria is the possibility of interfering with their ability to communicate with each other. Quorum sensing is the process by which microbes exchange signaling chemicals (autoinducers) that allow the bacterial population to coordinate gene expression for virulence, symbiosis, conjugation, sporulation, mobility, apoptosis, antibiotic production, and biofilm development.[16] Quorum sensing is related to the size of the colony, where a single autoinducer from a single microbe is incapable of inducing change, but when the colony reaches a critical density (quorum), a threshold of autoinduction is reached, and gene expression begins.

The autoinducers can be specific to each bacterial species and usually consist of acetylated homoserine lactones in gram-negative and oligopeptides in gram-positive bacteria. A boron-containing sensor, AI-Z, has been identified as a possible universal signal for interspecies communication.[16] Quorum sensing may explain how microorganisms can build geometrically perfect colonies without ever seeing them. Interference with these signals for virulence or adhesiveness may prove to be of significant benefit to humans.

Some of these new approaches pose difficulties. Bacteriophages are bacterial viruses that are specific for a single bacterium and require precise identification of the pathogen to be effective. Cationic peptides are a vital part of our natural defense to microbial pathogens and have protected us for millions of years, but are unstable in the gastrointestinal tract and may be effective only topically. If resistance were to occur to these peptides when used as therapeutic agents, a "Satan bug" might be created that is unaffected by our most basic defense mechanism.[10] Just such resistance has been detected in *Porphyromonas gingivalis*, which secretes a peptide that destroys cationic peptides.[120] Widespread resistance of this type would be catastrophic. Soil microorganisms serve as potential reservoirs for new antibiotic agents, but to date only 1% have been identified, and these organisms seem to be very difficult to grow in the laboratory.

CHAPTER 39

*Antibacterial and Antibiotic Drugs**

THOMAS J. PALLASCH

OROFACIAL INFECTIONS

Infectious diseases are commonly and mistakenly managed as if they all were essentially the same, when the opposite is true because few diseases are associated with more variables than infectious diseases. Each infectious disease process is uniquely dependent on its anatomic location, etiologic microorganism and virulence patterns, accessibility to surgical drainage, signs and symptoms, and, most important, the host response to the process. Pneumonia differs from otitis media, which differs from urinary tract infection, which differs from infective endocarditis.

Orofacial infections are unique and do not mimic infections in other anatomic locations. They can be chronic (e.g., periodontitis), chronic-subacute with acute exacerbations (e.g., pericoronitis, periodontal abscesses), or intensely acute (e.g., necrotizing ulcerative gingivitis, periapical abscesses, or cellulitis with or without extension into the orbital or submandibular spaces). Acute orofacial infections commonly arise rapidly and may spread easily into fascial planes because of their streptococcal component; they are often rapidly terminated by incision and drainage along with antibiotic therapy if appropriate and necessary. The accessibility of orofacial infections to mechanical incision and drainage procedures is often not shared by other bodily infections except infections of surgical sites and prosthetic devices.

As with other infectious diseases, various orofacial infections share a commonality among their etiologic microbial pathogens. Otitis media and sinusitis are almost always associated with *Streptococcus pneumoniae, Moraxella catarrhalis,* or *Haemophilus influenzae,* whereas orofacial infections commonly are associated with viridans group streptococci (VGS), *Prevotella*, *Porphyromonas, Fusobacterium*, *Peptostreptococcus, Eubacterium*, *Veillonella*, and *Actinomyces*. Otitis media or sinusitis is usually associated with only one of its three pathogens, whereas orofacial infections are polymicrobial in nature with two to eight or more microbial species involved. This situation makes determining the precise etiologic microbe virtually impossible—if only one is the cause. In orofacial infections, it is essentially impossible to determine which are the principal pathogens and which are only commensals.

Many infections are monomicrobial in etiology and are caused by microorganisms that, by their nature, are primary pathogens capable of producing disease in the absence of other factors. Orofacial pathogens are rarely, if ever, primary pathogens, but rather are usually opportunists that cause disease when local or systemic variables change—such as trauma, necrosis, tissue oxidation, microbial acquisition of virulence or resistance genes, loss of microbial antagonists from antibiotic therapy, and, probably most often, a reduction or loss of host immune defense mechanisms. A thorough knowledge of the commonalities and vagaries of oral microbial pathogens is as important as the effective use of antibiotic agents in the successful management of orofacial infections.

Oral Microbial Pathogens and Associated Oral Infections

Acute orofacial infections

Table 39-1 presents quantifiable data from 12 clinical studies from 1976-1996 on the microbiology of acute orofacial infections. The average number of isolates per case was 3.6, with a maximum of 12. The data in Table 39-1 indicate that acute orofacial infections are polymicrobial, dominated by anaerobes, and often contaminated by various microorganisms, particularly from the pharynx, sinuses, and gastrointestinal tract.

Substantial commonality exists in the microbial cause of acute orofacial cellulitis, pulpal infections, periodontal abscesses, periimplantitis, pericoronitis, acute necrotizing gingivitis, osteomyelitis, and their serious extensions (e.g., Ludwig's angina, mediastinal infections). These entities differ primarily in quantitative rather than qualitative microbiologic characteristics. Rapidly spreading infections often have a VGS component because streptococci possess various "spreading factors" (e.g., hyaluronidase, streptokinase, streptodornase) that promote rapid movement by fascial planes. Staphylococci rarely move except in blood, whereas gram-negative oral anaerobes may move in tissue but rarely in blood to cause metastatic infections elsewhere; streptococci move easily in blood and tissue.

Metastatic infections from *Porphyromonas gingivalis*, *Prevotella intermedia*, and *Prevotella nigrescens* and other anaerobic periodontal pathogens apparently are very rare,[68,83] whereas respiratory tract infections may commonly precede pericoronitis. Staphylococci isolated from facial cellulitis are most likely contaminants because these organisms are not a normal component of the subgingival flora residing primarily on oral mucosal surfaces. They can be a major factor in the cause of oral mucositis. Anterior nares carriage of *Staphylococcus aureus* occurs permanently in 20% and intermittently in 60% of the population.[53] Subgingival staphylococci may appear because of selection by local or systemic antibiotic therapy.[23] Retropharyngeal abscesses seem to have the same microbial cause as facial cellulitis.

*The author recognizes Dr. Edward Montgomery for his past contributions to this chapter.

TABLE **39-1**

Microorganisms Associated with Acute Orofacial Abscesses Based on 2339 Isolates in 12 Studies from 1976-1996

MICROORGANISM	NO. OF ISOLATES	PERCENT OF TOTAL
Aerobes/Facultative		
VGS	470	20.1
Staphylococcus aureus/ Staphylococcus epidermidis	136	5.8
β-Hemolytic streptococci	68	2.9
TOTAL	674	28.8
Anaerobes		
*Prevotella/ Porphyromonas**	641	27.4
Peptostreptococcus	388	16.6
Fusobacterium	181	7.7
Eubacterium	87	3.7
Veillonella	58	2.5
Actinomyces	47	2
TOTAL	1402	9.8

Each of the following species is less than 1% of total but together constitute 11.3% of all isolates: *Acinetobacter; Aggregatibacter actinomycetemcomitans; Arachnia; Citrobacter; Corynebacterium; Eikenella corrodens; Clostridium; Enterobacter; Escherichia coli;* group A, B, C, D, and G streptococci; *Haemophilus influenzae; Klebsiella pneumoniae; Lactobacillus; Neisseria; Propionibacterium acnes; Serratia;* and spirochetes (most likely contaminants).
*Most studies list as *Bacteroides*.
VGS, Viridans group streptococci.

Pulpal and periapical pathogens

It may be artificial to separate acute orofacial infections from the microbiologic features of pulpal and periapical lesions because acute facial cellulitis is most often a sequela to dentition-derived infections. Yet this separation is often made in the literature, and at times it is difficult to determine precisely what type of infection is being studied, making a review of both of these entities necessary.

Numerous studies have attempted to determine the significance and quantity of microbial pathogens responsible for pulpal and periapical infections. Some studies maintain that certain microorganisms work synergistically to initiate orofacial infections, whereas others have concluded that each pulpal infection has its own distinct flora. More recent studies have isolated a high prevalence of black-pigmented anaerobes (e.g., *P. nigrescens, P. intermedia, P. gingivalis,* and *Porphyromonas endodontalis*); however, this may reflect better anaerobic isolation technique, rather than a shift in pathogenic flora. The percent of obligate anaerobes isolated varies with the particular study from 21% to 80%, possibly reflecting the skill in taking the culture. These infections are polymicrobial, with the number of species isolated varying from 1 to 33, with 5 to 7 species commonly reported as an average. Achieving a general consensus of the major pathogenic microorganisms responsible for pulpal/periapical infections is hampered by methodologic difficulties, including small sample sizes, lack of randomization or use of consecutive case series, varying expertise in culturing, presence or absence of dental caries or periodontal disease, and bacterial contamination of cultures. The major exception is VGS, which is prominent in periodontal health and acute orofacial infections.

Commonly isolated microorganisms associated with pulpal/periapical lesions seem to be VGS, other streptococci (β-hemolytic, β-hemolytic, group D), *Fusobacterium*, *Peptostreptococcus micros, Lactobacilli, Actinomyces, Porphyromonas, Prevotella, Veillonella, Eubacterium,* and *Bacteroides forsythus*. Other microorganisms found less commonly or rarely include *Propionibacterium acnes, Candida albicans, Enterococcus,* staphylococci, *Pseudomonas aeruginosa, Enterobacter aerogenes, Serratia marcescens, Eikenella corrodens, S. pneumoniae, Corynebacterium, Capnocytophaga, Selenomonas,* and *Wolinella* (Box 39-1). A significant portion of these may be contaminants.

Periodontal abscesses

An acute periodontal abscess is characterized as a lesion of periodontal breakdown located within the gingival wall of the periodontal pocket and manifested as a localized accumulation of purulence.[40] An acute periodontal abscess may result from an exacerbation of local periodontitis pathology, after periodontal debridement procedures, or from the lodgment of a foreign object in the periodontal pocket (e.g., popcorn husks, dental floss, calculus).[40] The microbial cause of a periodontal abscess is similar to that of adult periodontitis, and the flora is commonly indistinguishable from the microflora of the subgingival plaque in adult periodontitis.[40] The predominant microflora are *P. gingivalis* (55% to 100% of isolates), *P. intermedia* (25% to 100% of isolates), *Fusobacterium nucleatum* (44% to 65% of isolates), *Aggregatibacter actinomycetemcomitans* (25% of isolates), *Campylobacter rectum* (80% of isolates), *Prevotella melaninogenicus* (22% of isolates), and *Treponema denticola* (71% of isolates)[40]; other organisms include *P. micros* and *B. forsythus*.[40] It has been estimated that 74% may be anaerobes and 67% may be gram-negative rods, with streptococci significant only at the base of the abscess.[73]

The principal and sometimes only therapy of periodontal abscess is incision and drainage through the external tissue and compression of the soft tissue wall.[40] Curettage or root planing is not usually required unless a reasonable chance exists to eliminate the periodontal pocket.[40] The abscess tends to become fistulous readily and rarely results in metastasis or acute orofacial cellulitis, possibly because VGS have been replaced by periodontal pathogens that do not spread by fascial planes as do streptococci. On fistulization, the lesion is self-limiting, as opposed to dentoalveolar abscesses of pulpal origin, which may readily end in cellulitis.

Periodontal abscess often can be treated simply with incision and drainage without antibiotics because it is rarely associated with fever, malaise, lymphadenopathy, and other signs of systemic involvement; periodontal abscess may necessitate

antibiotic therapy only if the signs and symptoms of systemic involvement or cellulitis are present, or incision and drainage cannot be performed.[40,60,80] This is in contrast to antibiotic therapy of pulpal/periapical infection, which should be more aggressive because there is a much greater tendency to spread into the fascial planes. If antibiotic therapy of a periodontal abscess is indicated, the situation is classic for short-term, high-dose therapy, as opposed to commonly longer therapy for dentoalveolar abscess.[60,81] Periodontal pathogens rarely, if ever, metastasize to the heart or other organs and tissues.[82,83]

Acute necrotizing ulcerative gingivitis

The microbiology of acute necrotizing ulcerative gingivitis (trench mouth, Vincent's infection) is characterized primarily by *Treponema*, *Fusobacterium*, *Selenomonas,* and *P. intermedia* and secondarily by *Veillonella*, *Neisseria*, *Capnocytophaga*, *E. corrodens, Bacteroides, Actinomyces,* and gram-positive cocci.[65]

Pericoronitis

The microbial flora of pericoronitis are a complex mixture of organisms resembling that of periodontitis and gingivitis,[58] often with a high concentration of VGS. Common microorganisms found in 40% or more of samples include *Stomatococcus, Rothia dentocariosa, Actinomyces naeslundii, Actinomyces israelii, Prevotella, Neisseria, Haemophilus, P. micros, Capnocytophaga, Corynebacterium, Bifidobacteria*, and treponemes.[58] Other, less common isolates include coagulase-negative staphylococci (CoNS), lactobacilli, *Veillonella*, *Fusobacterium*, and *Porphyromonas*.[58]

Periimplantitis

The microbial causes of chronic periodontitis, refractory periodontitis, and periimplantitis (an inflammatory process of the tissues surrounding an osseointegrated implant resulting in loss of supporting bone) are remarkably similar, differing primarily in the quantitative and not qualitative isolation of the predominant species: *B. forsythus, F. nucleatum, P. gingivalis, P. intermedia, P. nigrescens,* C. *rectum,* and treponemes (spirochetes).[62] Healthy dentulous or implant periodontium usually exhibits fewer of the above-mentioned organisms and is dominated by VGS, *Actinomyces, Veillonella, E. corrodens,* and *Capnocytophaga*.[57]

Periimplantitis results from a shift in periodontal flora with facultative anaerobic streptococci (VGS) and nonmotile rods replaced by gram-negative anaerobic bacilli and spirochetes, similar to what occurs in periodontitis.[57,62] The issue of whether implant success is compromised in patients with periodontitis (treated or untreated) is controversial, but it seems reasonable to postulate that the gingival sulcus in patients with periodontitis is a reservoir for periodontal microbial pathogens.[84] Host resistance and factors that reduce immunity (stress) are as likely a complicating factor in periimplantitis as they are in aggressive periodontitis.

Osteomyelitis

Osteomyelitis is an infectious inflammatory process resulting in bone destruction. There are several clinical descriptions of osteomyelitis as follows: (1) secondary to a contiguous infection, (2) secondary to vascular deficiency and diabetic foot infection, (3) in association with an infected prosthesis (e.g., dental implant, prosthetic joint), (4) hematogenous, (5) chronic, and (6) acute.[21,59] Osteomyelitis, resulting from local spread from a contiguous contaminated or infectious source, commonly follows trauma, bone surgery, or joint replacement. Approximately 15% of diabetics develop foot pathology requiring amputation with contributing factors of bone and soft tissue ischemia and peripheral motor, sensory, and autonomic neuropathy. The amount of osteomyelitis associated with various bone implants is increasing; this includes dental implants.[21,59] Spread of bacteria to bone via the hematogenous route is particularly common in prepubertal children and immunocompromised elderly patients. Chronic osteomyelitis is a long-standing infection of months to years in duration characterized by persistent microorganism, low-grade inflammation, sequestrum formation, and fistulous tracts. Acute osteomyelitis evolves over a few days or weeks.

The treatment of osteomyelitis usually involves antibiotic therapy and surgery. Because of the multiplicity of etiologic organisms, it seems imperative to get a culture and sensitivity test as soon as possible to initiate the most appropriate antibiotic therapy.[45] The disease may have a polymicrobial etiology with an average of 3.9 microbes per culture. The microbial cause of oral osteomyelitis varies to some extent with the anatomic site. The most common microorganisms in orofacial osteomyelitis include streptococci, lactobacilli, *Eubacterium*, *Klebsiella pneumoniae, S. aureus, Acinetobacter baumanii*, and *P. aeruginosa*.[21]

Deep neck space infections

Deep neck space infections arise most commonly from upper airway infections (47.5% to 53.2%) and odontogenic infections (28.8% to 30.5%).[10,46] The spaces involved include the sublingual, submylohyoid (submental, submandibular), lateral pharyngeal (parapharyngeal, peripharyngeal, pterygopharyngeal, retropharyngeal), and masseter spaces (masseter, pterygotemporal, parotid, peritonsillar).[87] These infections include Lemierre's syndrome (suppurative thrombophlebitis of the internal jugular vein from septic emboli) and Ludwig's angina. Deep neck infections seem to be more common in patients with diabetes mellitus[47] and patients with low socioeconomic status and with poor oral hygiene.[3]

The microbiology of deep neck space infections is primarily that of commensal microorganisms that for some reason travel quickly through the fascial planes, which likely have acquired virulence genes they do not normally possess. These organisms include VGS, *S. aureus, Peptostreptococcus, K. pneumoniae,* and oral anaerobes (*Porphyromonas, Prevotella*, and *Fusobacterium* species).[9]

There are no data to support pretreatment or postsurgical antibiotic prophylaxis to prevent deep neck space infections (see Chapter 49). For unknown reasons, these normally commensal and harmless bacteria become very aggressive and spread rapidly to the submandibular regions. These infections are often polymicrobial, making antibiotic treatment alone very difficult, and most must be treated by incision and drainage.

Ludwig's angina

As first described by Ludwig in 1836, Ludwig's angina is characterized by a massive bilateral edema of the mouth floor with pathognomonic elevation of the tongue against the palate and posterior pharyngeal wall along with glottic edema, resulting in potentially life-threatening airway obstruction—hence the vernacular terms *morbus strangulatoris, angina maligne,* and *garotillo* ("hangman's noose"). Ludwig's angina involves the connective tissues, fascia, and muscle and spreads by fascial planes through the submandibular, sublingual, and submental spaces and potentially on to the pharynx, retropharyngeal region, and mediastinum.[77] Approximately 70% to 80% of cases are of odontogenic origin, with 99% exhibiting bilateral swelling in the neck; 95%, an elevated tongue; 89%, fever; and 51%, trismus.[77] In 71 patients in whom cultures were obtained, 35% of species were VGS, 28% were "other" streptococci, 14% were staphylococci, and 27% were *Porphyromonas* and *Prevotella* and other anaerobes, with a few isolates of *P. aeruginosa, K. pneumoniae, H. influenzae, S. pneumoniae,* and *Escherichia coli*.[70] The heavy preponderance of streptococci emphasizes the ability of these organisms to move through tissue rapidly.

Mediastinal infections

Rarely, oral microorganisms may traverse anatomic pathways to locate in the mediastinum. The microbial flora is typically diverse, with the single predominant organisms being VGS, followed by *Porphyromonas, Prevotella, Fusobacterium*, and staphylococci. Rare isolates included *E. coli, P. aeruginosa, Clostridium perfringens, Enterobacter, Enterococcus, H. influenzae, K. pneumoniae,* and *Proteus vulgaris*.

Necrotizing fasciitis

Necrotizing fasciitis is a rare but often fatal infection involving the superficial fascial layers of the neck, extremities, abdomen, and perineum.[36] It was first described by Hippocrates and has also been known as *streptococcal, hospital,* or *galloping gangrene*. Most recently, the lay press has labeled it the "flesh-eating disease." The term *necrotizing fasciitis* was first employed in 1952.[36]

The most common cause of head and neck necrotizing fasciitis is dental infection (odontogenic origin) with 9% of all cases located in the head and neck region.[38] In a review of 125 literature cases, it was found that (1) the male/female ratio was 3:1; (2) the origin of the infection was 66 in the mandible, 11 in the maxilla, and 48 nondelineated; (3) periapical infection was the most common cause; and (4) 70 of 125 patients had systemic complications (e.g., alcoholism, hypertension, liver cirrhosis, acquired immunodeficiency syndrome [AIDS], intravenous drug abuse, and renal insufficiency). Despite aggressive therapy, the mortality rate was 19.2%.[103] In other scenarios, death may occur within hours, and the mortality rate may be 50%.

Cervicofacial actinomycosis

The most common organisms causing actinomycosis are *A. israelii, A. naeslundii, Actinomyces odontolyticus,* and *Actinomyces viscosus*. Cervicofacial actinomycosis commonly appears in one of two distinct patterns: (1) a chronic, slowly progressive mass evolving into multiple abscesses and fistulas or (2) an acute fluctuant suppurative pyogenic mass. Involved sites in the head and neck include the tongue, larynx, hypopharynx, mandible, cheek, scalp, paranasal sinuses, palate, and parotid gland. The characteristic sulfur granule is a small colony of intertwined actinomycoses filaments grossly resembling a granule of sulfur. It is likely also to be associated with *A. actinomycetemcomitans, E. corrodens, Fusobacterium* species, *S. aureus,* streptococci, and enterococci. *Actinomyces* species are usually susceptible to penicillin G or penicillin V and may require surgical removal.

Microbial Resistance in Orofacial Pathogens

The data on the antibiotic sensitivity of orofacial pathogens are very limited, vary with the community's exposure to antibiotics, and depend crucially on what mean minimal inhibitory concentration (MIC) is selected as the "breakpoint" for resistance (the higher the chosen MIC, the lower the number of organisms labeled "resistant"). The breakpoint is the MIC at which microbes are said to be resistant if they are not killed or inhibited in growth.

Although data on microbial resistance patterns in orofacial pathogens are limited, the data are adequate to determine that difficulties exist. Until more recently, it was, and may still be, the impression in dentistry that the oral cavity somehow has remained relatively unscathed by the antibiotic resistance epidemic that has plagued other human microbial ecologic systems. It is now apparent that no such immunity exists and that oral pathogenic microbes may exhibit substantial antibiotic resistance that can compromise treatment.

In the 1950s and 1960s it was apparent that oral streptococci and *S. pneumoniae* (pneumococcus) coinhabit the oropharynx (but not the oral cavity) and had the potential for gene transfer between species. Later it became apparent that VGS and pneumococci possessed identical β-lactam resistance mechanisms: an altered penicillin binding protein-2b that greatly decreased the affinity of penicillin for its receptor. The genes for this resistance spread from oral streptococci to oropharyngeal *S. pneumoniae* with devastating effects on the management of one of the world's worst microbial killers.

In the 1970s, viridans and anaerobic streptococci were universally sensitive to the β-lactams, with 90% to 99% also sensitive to erythromycin and clindamycin. In 1983, a high rate of penicillin resistance in VGS was detected in South Africa in the oral flora of children with a similar high penicillin resistance in pneumococci.[35] Currently, β-lactamase enzymes are common in oral microorganisms, and VGS (*Streptococcus*

milleri, *Streptococcus mutans*, *Streptococcus salivarius*, *Streptococcus sanguis*, *Streptococcus mitis* groups) with altered penicillin binding proteins (PBPs) are increasingly resistant to β-lactams and macrolides.

In children treated for otitis media and exposed to repeated antibiotics who had samples taken of their supragingival plaque, 60% of *S. sanguis* isolates were resistant to at least one antibiotic; 26%, to at least two antibiotics; 32%, to amoxicillin; 24%, to penicillin V; and 20%, to amoxicillin and penicillin V.[31] In 139 cultures of VGS isolated from mixed orofacial infections, 23% were resistant to penicillin G; 45%, to erythromycin; 46%, to clindamycin; and 44%, to levofloxacin; 100% were sensitive to minocycline.[55] Reports of 23% to 81% resistance rates of VGS to ampicillin and amoxicillin in hospitalized patients and patients in the community are common, depending on the breakpoint chosen for resistance.

In a cohort of Japanese children at high risk for bacterial endocarditis, 31.7% of VGS exhibited resistance at MICs of 4 to 16 μg/mL.[74] Children treated with long-term penicillin for the prevention of rheumatic fever were found to have resistance rates of 78% to 81%. The problem is compounded further because many oral streptococci are resistant to multiple antibiotics with reduced sensitivities to cephalosporins, macrolides, and clindamycin,[55] as shown by a Taiwan study reporting a 20% to 50% resistance rate to clindamycin and 30% to 70% resistance to tetracycline in penicillin-resistant *Streptococcus oralis*.[99]

In the United States, 40% to 50% of sampled VGS are resistant at MICs greater than or equal to 0.25 μg/mL,[49] whereas in a study of 43 U.S. medical centers from 1993-1994, 352 VGS blood cultures exhibited a resistance rate of 13.4% at MICs greater than or equal to 4 μg/mL (high resistance) and 42.9% at MICs of 0.25 to 2 μg/mL (intermediate resistance).[28] Intermediate resistance commonly escalates to high resistance over time.

Of considerable concern is the high β-lactam resistance rate in VGS in patients with neutropenia associated with hematologic malignancies and patients at risk for infective endocarditis. Approximately 18% to 21% of bacteremias experienced by immunocompromised patients may be caused by VGS, particularly *S. mitis* with a 3.2% to 40% resistance rate to penicillin G and cephradine,[86] with some at MICs of 0.25 to 4 μg/mL for penicillin and 2 to 32 μg/mL for cephradine.

Approximately 25 studies have detected β-lactamase production in *Prevotella* and *Porphyromonas* species associated with periodontitis or acute orofacial infections. The prevalence of β-lactamase in these clinical isolates ranges from 11% to 100% depending on study year and type of organisms, but most studies document a 30% to 50% median/mean prevalence of β-lactamase in pigmented and nonpigmented gram-negative anaerobes in the oral cavity. Commonly, these organisms presently remain susceptible to β-lactam/β-lactamase inhibitor combinations, metronidazole, and azithromycin.

β-Lactamase production is also present in oral *Veillonella*, *Fusobacterium*, *Capnocytophaga*, *P. aeruginosa*, and *B. forsythus*. Lengthy or repeated antibiotic exposure increases the presence of β-lactamase in oral *Prevotella*, *Porphyromonas*, and *Fusobacterium*.[41,76] Resistance genes may be shared between family members.[54]

Resistance to fluoroquinolones in VGS is increasing, and the resistance factors can be transferred between VGS, *Streptococcus constellatus*, and *S. pneumoniae*, providing for efflux mechanisms or point mutations in topoisomerase IV or DNA gyrase. Methicillin-resistant *S. aureus* (MRSA) may be present in the oral cavity of children for 5 or more years.[97]

In a study of gingival crevicular fluid microorganisms found in periodontitis patients and their sensitivities to seven antibiotics at two different time periods (1980-1985 and 1991-1995), the resistance rates increased by 172% to tetracycline, 193% to doxycycline, 133% to penicillin G, 238% to amoxicillin, 116% to erythromycin, and 108% to clindamycin.[107] VGS showed variable sensitivities: 85% to 100% to penicillin G, 75% to 100% to amoxicillin, 46% to 100% to clindamycin, and 34% to 74% to tetracyclines.

Veillonella species were 83% to 100% sensitive to tetracyclines, 89% sensitive to penicillin G, 67% sensitive to amoxicillin, 86% sensitive to erythromycin, and 94% sensitive to clindamycin. *P. micros* was 67% to 82% susceptible to tetracycline and amoxicillin, 82% susceptible to erythromycin, 95% susceptible to penicillin G, and 91% susceptible to clindamycin. The breakpoint MICs used for resistance determination in this study were high in some cases: 4 μg/mL for various tetracyclines and 2 μg/mL for penicillins, erythromycin, and clindamycin. Many studies use lower breakpoints, which would likely have shown an even higher percentage of resistance strains.

The resistance patterns for orofacial pathogens depends on many variables, including frequency and duration of exposure to antibiotics from health care providers and the environment, age, family member exposure to antimicrobials, patterns of antibiotic use in geographic locales, and the particular MICs chosen as breakpoints for resistance. Breakpoints that are too high underestimate levels of microbial resistance, and breakpoints that are too low overestimate it. The proper breakpoint is the MIC commonly attained in humans by reasonable doses.

The oral cavity is as much a part of the microbial world of antibiotic resistance as any other portion of the body and is subject to the same forces that ensure microbial survival elsewhere. The more we look for microbial resistance in the oral environment, the more we are likely to find. It is probable that antibiotic failures in the management of orofacial infections will continue to increase, resulting in more severe orofacial infections and a greater dependence on vigorous incision and drainage and sophisticated antibiotic therapy, unless wise and judicious use of antimicrobials becomes the universal rule.

ANTIBACTERIAL ANTIMICROBIAL DRUGS

Antibacterial drugs are primarily classified according to their chemical class and mechanism of action.[5] They also can be distinguished based on spectrum and adverse effects. In addition to these aspects of antimicrobial drugs, the therapeutic uses, including dental applications, of each class of drugs are discussed.

β-Lactam Antibiotics

Penicillin has been said to have "brought more curative power to a barefoot, itinerant care provider in the deepest reaches of Africa than the collective powers of all the physicians in New York City."[69] Yet with the seemingly infinite ability of humans to push a system until it breaks, we now have a multiplicity of microorganisms that were initially exquisitely sensitive to the antimicrobial effects of penicillins but that are now highly resistant to their killing power. β-Lactam antibiotics remain the most widely used antibiotics in the world, however, because of their broad spectrum of activity and relative lack of toxicity despite a relatively high incidence of allergy.

β-Lactams are composed of five different groups of antibiotics, with the β-lactam nucleus as the common feature: penicillins, cephalosporins, carbapenems, monobactams, and carbacephems. Penicillins and cephalosporins are the most important with carbapenems (imipenem, meropenem, ertapenem), monobactams (aztreonam), and carbacephems (lor-

acarbef) reserved for serious infections such as nosocomial (hospital-acquired) infections. β-Lactams as a group have the widest spectrum of antimicrobial activity, but range from an extremely narrow spectrum (e.g., β-lactamase–resistant penicillins) to a very wide spectrum (e.g., imipenem and some cephalosporins).

Penicillins

Penicillin is a generic term for a group of antibiotics that share the β-lactam ring nucleus, similar adverse drug reactions, and similar mechanism of action, but differ in their antibacterial spectrum, pharmacokinetics, and resistance to β-lactamase enzymes.

Chemistry and classification. Penicillin is a cyclic dipeptide consisting of two amino acids (D-valine, L-lysine), a particular molecular configuration unknown in higher life forms (Figure 39-1). The synthesis in 1958 of the basic structure of penicillins (6-aminopenicillanic acid) allowed for its manipulation by the addition of various side chains to the β-lactam and thiazolidine rings. Different salts (Na^+, K^+, procaine, benzathine) were also created for pharmacokinetic purposes. On the basis of these modifications, penicillins can be divided into four groups: penicillin G and its congeners, β-lactamase–resistant (stable) penicillins, extended-spectrum penicillins, and extended-spectrum penicillins with β-lactamase inhibitors (Table 39-2).

Acid-stable penicillins are resistant to breakdown in stomach acid, indicating their usefulness as oral drugs. Penicillin V, amoxicillin, and cloxacillin are examples. Other examples of orally useful drugs are listed in Table 39-2. Penicillinase-resistant penicillins are resistant to some β-lactamases.

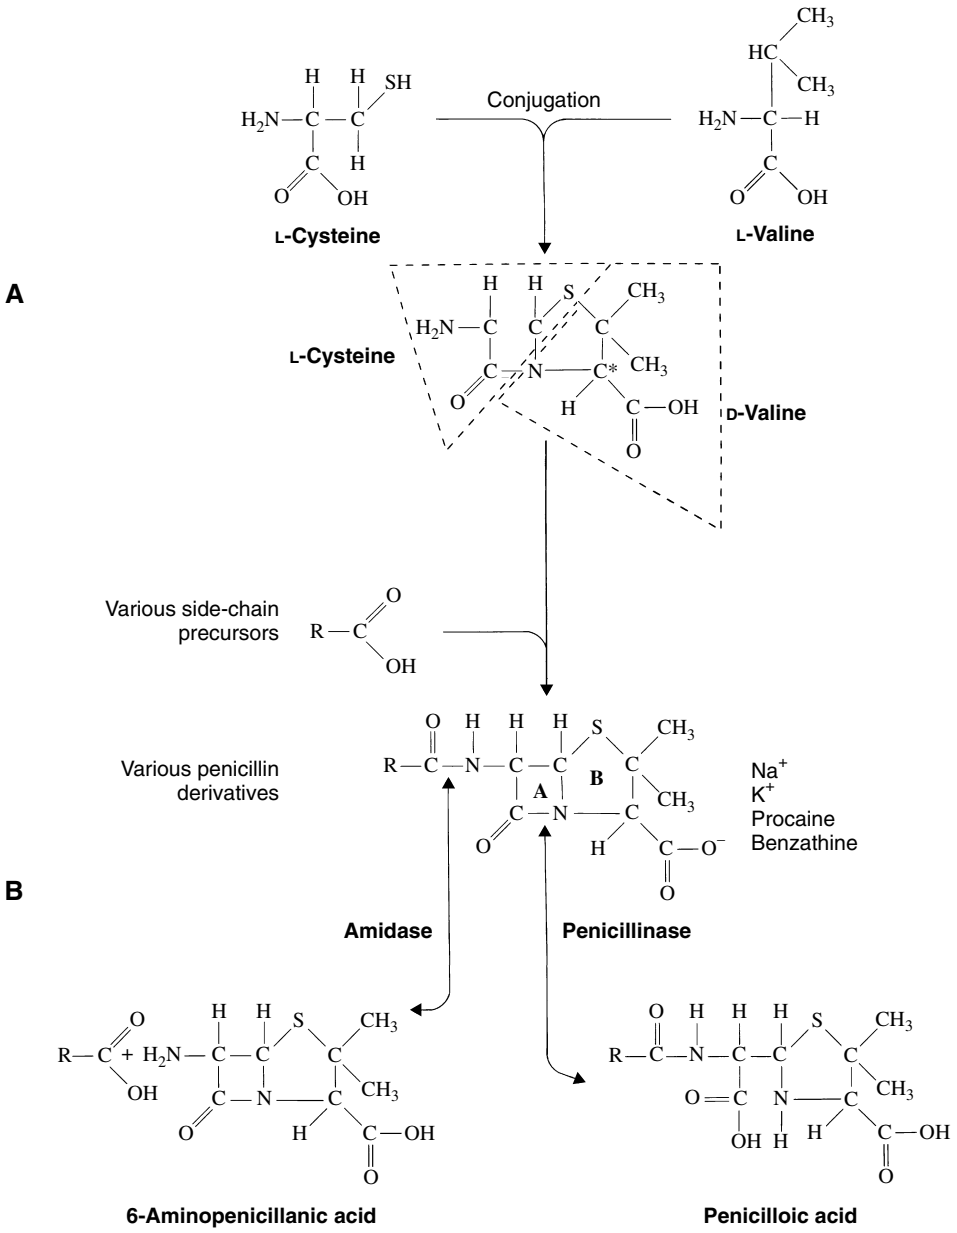

FIGURE **39-1** Biosynthesis and hydrolysis of penicillins (isomeric conversion of L-valine and D-valine during conjugation). **A,** β-Lactam ring. **B,** Thiazolidine ring.

Bacteria, particularly staphylococci, develop resistance to penicillins chiefly through the elaboration of β-lactamase enzymes (penicillinases) that inactivate the penicillins by cleavage of the 6-aminopenicillanic acid nucleus to yield penicilloic acid derivatives. The production of staphylococcal penicillinase is encoded in a plasmid and may be transferred to other bacteria. Methicillin was the first semisynthetic derivative to be introduced that was stable in the presence of β-lactamase. Subsequently, nafcillin and three isoxazolyl derivatives (oxacillin, cloxacillin, and dicloxacillin) were marketed. The structural formulas for these semisynthetic derivatives are shown in Table 39-2.

Extended-spectrum penicillins are represented by two groups of penicillin derivatives. One group includes ampicillin, the first extended-spectrum penicillin to be introduced; amoxicillin, a close congener of ampicillin; and bacampicillin, a drug that is rapidly hydrolyzed in vivo to yield ampicillin (which accounts for its pharmacologic and toxicologic effects). The second group contains carbenicillin, the first penicillin to exhibit activity against *Pseudomonas* and indole-positive *Proteus* species, and ticarcillin, mezlocillin, and piperacillin, drugs with improved activity against *P. aeruginosa*.[75] The molecular structures of these agents are depicted in Table 39-2. Carbenicillin for injection is no longer available in the United States, but carbenicillin indanyl, the oral form, is still used.

Mechanism of action and antibacterial spectrum. Early in the discovery of penicillin, it was noted that the drug acted only on rapidly dividing organisms, and it was later determined that bacterial cell wall precursors (the Park nucleotides) accumulated in sensitive bacteria exposed to the penicillins. Penicillin was determined to be a structural analogue of D-alanine; the final step in the formation of the bacterial rigid cell wall was a transpeptidation reaction involving the enzymatic removal of a terminal D-alanine to allow for the formation of the completed peptidoglycan cell wall. β-Lactams are competitive inhibitors of various enzymes (transpeptidases, carboxypeptidases), collectively termed *penicillin-sensitive enzymes*, or more commonly PBPs. β-Lactams promote the formation of cell wall–deficient microorganisms of different shapes (oval, oblong, spherical) depending on the particular PBP affected, which cannot maintain their internal osmotic pressure and eventually burst. The mechanism of action of β-lactams is a

Disease Entities for Which Penicillin G, Penicillin V, and Amoxicillin Are of Major Use

Abscesses, including orodental
Bacteremia (gram-positive)
Endocarditis
Gas gangrene
Mastoiditis
Meningitis
Orodental infections
Osteomyelitis
Pericarditis
Periodontal infections
Pharyngitis
Pneumonia
Rat-bite fever
Scarlet fever
Suppurative arthritis
Syphilis
Vincent's stomatitis
Weil's disease
Wound infections

These diseases are caused by various gram-positive cocci and bacilli and some gram-negative organisms, spirochetes, and anaerobic microorganisms. Susceptibility testing may be essential for some to determine therapeutic mean inhibitory concentrations.

classic example of Ehrlich's goal of the "magic bullet," or more specifically a chemical that inhibits a cellular activity present only in bacteria (a rigid cell wall) and not found in mammalian cells.

In some bacterial species, β-lactams have an additional mechanism of action as they activate an enzyme, muramyl synthetase, responsible for the separation of daughter cells after cell division. Activation of this enzyme in the absence of cell division produces lysis of the cell wall (autolysis) and literally bacterial suicide.

Considering these mechanisms, it is apparent why consistently high blood levels of β-lactams are required for optimal success (not all bacteria divide at the same time) and why penicillins do not kill rapidly (it takes time for enzyme inhibition and eventual microorganism rupture). This realization that β-lactams kill slowly has raised questions about the mechanism of action in endocarditis prophylaxis: whether they act only (or at all) by microbial killing or rather by cell wall alteration to retard attachment of the bacteria to damaged cardiac valves.

Penicillin G and penicillin V are narrow-spectrum antibiotics, showing activity against mostly gram-positive cocci and gram-positive bacilli and gram-negative cocci. Other penicillins have an extended spectrum and greater activity against some gram-negative bacilli.

Penicillins as agents of choice in treating specific organisms are listed in Box 39-2 (primarily according to the *Medical Letter of Drugs and Therapeutics*).[18,33,110] Amoxicillin and penicillin V are drugs of choice against VGS, *Peptostreptococcus, E. corrodens, F. nucleatum, A. israelii, Clostridium tetani, C. perfringens, Leptotrichia buccalis, Neisseria*, and non–β-lactamase–producing *Prevotella* and *Porphyromonas*.[18,33,110] Amoxicillin plus clavulanate is additionally effective against *K. pneumoniae, Enterobacter, M. catarrhalis, Bacteroides fragilis,* non–methicillin-resistant and β-lactamase–producing staphylococci, and β-lactamase–producing *Prevotella* and *Porphyromonas*.[33]

Amoxicillin and penicillin V are the initial drugs of choice in orofacial infections in nonallergic patients but are ineffective against streptococci (VGS) with altered PBPs. The clinical impact of antibiotic failures against these resistant streptococci and gram-negative β-lactamase–producing oral anaerobes is likely to be significant but has yet to be determined by clinical studies. On the basis of the antimicrobial spectrum of penicillin G and V and other clinical characteristics, the drugs are useful in the treatment of numerous diseases (Box 39-3).

Bacterial resistance. Bacteria evade the killing effects of β-lactams by three mechanisms: reduced drug binding to PBPs (altered target sites), hydrolysis by β-lactamase enzymes (enzymatic inactivation), or development of tolerance by the loss of the autolysis mechanism (penicillin becomes bacteriostatic instead of bactericidal). In most species, the principal mechanism is β-lactamase production.

Absorption, fate, and excretion. Table 39-3 lists important pharmacokinetic properties of oral penicillins.[13,72] Penicillin G (benzylpenicillin) is rarely used orally because of its poor gastric absorption rate. If it is prescribed orally, it should be given at doses four to five times greater than drugs used parenterally. Penicillin V and amoxicillin are well absorbed orally, with amoxicillin considerably superior in its half-life and peak serum concentrations. Better oral absorption argues for the use of amoxicillin over penicillin V, but both drugs are effective in microorganism-sensitive orofacial infections and are equally inactive against VGS with altered PBPs.

Procaine penicillin G and benzathine penicillin G are repository forms prepared for intramuscular injection with

TABLE **39-3**

Pharmacokinetics of Various Oral Penicillins

PENICILLIN	ORAL ABSORPTION (%)	HALF-LIFE (hr)	PEAK SERUM LEVELS (μg/mL)	PROTEIN BINDING	FOOD AFFECTS ABSORPTION (ACID LABILE)
Penicillin G	20	0.5	2	45-68	Yes
Penicillin V	60-73	0.5	4	75-89	No
Amoxicillin	75-90	0.7-1.4	7.5	17-20	No
Dicloxacillin	35-76	0.3-0.9	15	95-97	Yes
Amoxicillin-clavulanate	75-90	0.7-1.4	7.5	17-20	No

From Cars O: Efficacy of beta-lactam antibiotics: integration of pharmacokinetics and pharmacodynamics, *Diag Microbiol Infect Dis* 27:29-33, 1997; Neu HC: Penicillins. In Mandell GL, Douglas RG Jr, Bennett JE, editors: *Principles and practice of infectious diseases,* ed 5, New York, 1990, Churchill Livingstone.

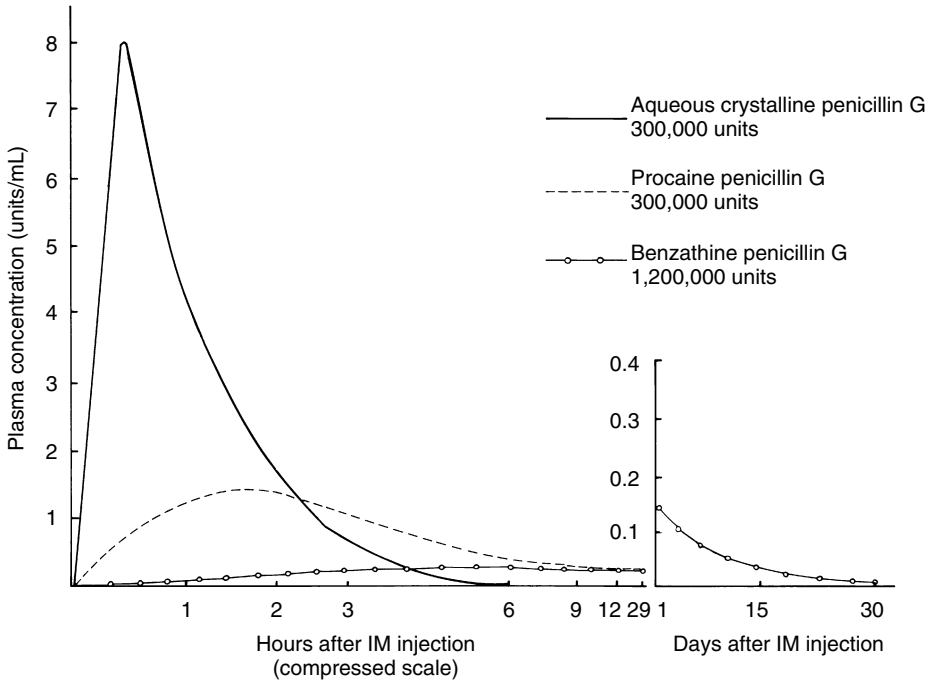

FIGURE **39-2** Comparative plasma concentrations of penicillin G obtained from soluble versus repository intramuscular *(IM)* dosage forms.

slow release from the injection site (Figure 39-2). The free non–protein-bound serum concentrations of penicillins are 0.9 μg/mL for penicillin G, 0.8 μg/mL for penicillin V, 0.45 μg/mL for dicloxacillin, and 6.2 μg/mL for amoxicillin.[13] The route of excretion is primarily by the kidneys, with limited liver metabolism.[13]

β-Lactam antibiotics produce time-dependent killing of bacteria, and frequent dosing is required to maintain relatively constant blood levels with as little fluctuation as possible.[101] The killing power of β-lactams is maximum at three to four times the MIC of susceptible microorganisms.[101] The prime determinant of the efficacy of β-lactams is the length of time the concentration of the drug in the infected area is greater than the MIC of the infecting organism.[101]

To be maximally effective, the serum and tissue concentrations of β-lactams should be greater than the MIC for 50% to 70% of the dosing interval.[22] The current package insert recommends dosing intervals of 6 hours for penicillin V and first-generation oral cephalosporins. Some drugs have very short half-lives (30 to 45 minutes),[33] and consequently 6-hour dosing intervals may result in very low serum levels in the last 2 or 3 hours. Continuous intravenous penicillin is receiving greater attention as a way to circumvent this problem.

β-Lactamase inhibitors. Currently, three agents are available to bind irreversibly to the catalytic site of susceptible β-lactamases to prevent hydrolysis of β-lactam antibiotics: clavulanic acid, sulbactam, and tazobactam. Clavulanic acid is derived from *Streptomyces clavligerus,* sulbactam is a semisynthetic penicilloic acid sulfone, and tazobactam is chemically related to sulbactam.[11] All β-lactamase inhibitors have the same mechanism of action, which is to bind to the active site of β-lactamases, where they are converted to an inactive product by β-lactamase ("suicide inhibition").[11] Only clavulanic acid is orally absorbed. Clavulanic acid is combined with amoxicillin, sulbactam with ampicillin, and tazobactam with piperacillin.

β-Lactamase inhibitors are generally effective against plasmid-mediated β-lactamases found in methicillin-sensitive *S. aureus* (MSSA), *H. influenzae, Haemophilus ducreyi, E. coli, K. pneumoniae, Proteus mirabilis, Listeria, Neisseria gonor-*

rhoeae, all anaerobes, and some Enterobacteriaceae. They are generally ineffective against chromosomally mediated β-lactamases found in *Enterobacter, P. aeruginosa*, *Morganella morganii*, *S. marcescens*, and organisms producing inducible extended-spectrum β-lactamases.

The sole therapeutic use of β-lactamase inhibitors is to prevent the hydrolysis of penicillins in the management of β-lactamase–producing microorganisms responsible for otitis media and sinusitis (*S. pneumoniae, H. influenzae, M. catarrhalis*), nosocomial pneumonia (MSSA or *K. pneumoniae*), intra-abdominal abscesses from β-lactamase–producing anaerobes and other microorganisms, and some upper respiratory tract infections. β-lactam/β-lactamase inhibitor combinations offer no advantage against non–β-lactamase–producing microorganisms and are ineffective against MRSA; many CoNS and enterococci; and the inducible β-lactamases produced by *P. aeruginosa*, *S. marcescens, Enterobacter cloacae, Citrobacter freundii*, and *M. morganii*.[11] These β-lactam/β-lactamase inhibitor combinations can often be useful as alternative antibiotics against *Bacteroides, M. catarrhalis, E. coli*, *K. pneumoniae,* indole-positive *Proteus, Providencia rettgeri*, *Providencia stuartii*, *E. corrodens, Pasteurella multocida*, and *Pseudomonas pseudomallei* (see Box 39-2).[18]

Therapeutic uses in dentistry. Because the oral route is the safest, most convenient, and least expensive mode of drug administration, it is favored in the treatment of dental patients. Currently, penicillin V is the most frequently prescribed antibiotic for chemotherapy of infections of dental origin, but amoxicillin has significantly superior pharmacokinetics. Parenteral penicillin G is largely reserved for severe infections in patients or situations in which the oral route is compromised (as in malabsorption syndrome and vomiting).

In some instances, penicillins G and V and amoxicillin are unsuitable for treating oral infections. Some dental infections are caused by β-lactamase (penicillinase)–producing organisms, and in such cases the appropriate antibiotic is a penicillinase-resistant penicillin derivative, erythromycin, or clindamycin. Patients who have been receiving extended prophylactic therapy with penicillin for the prevention of rheumatic fever generally require another antibiotic if they acquire an infection or require endocarditis prophylaxis. Certain periodontal infections are associated with gram-positive and gram-negative aerobic and anaerobic microorganisms, for which an antimicrobial agent with a more extended antibacterial spectrum, such as amoxicillin or more commonly a β-lactam/β-lactamase agent combined with metronidazole, may be the agent of choice. Table 39-4 summarizes antimicrobial therapy based on pathogens; it emphasizes the importance of penicillin V and amoxicillin.

TABLE **39-4**

Drugs Used to Treat Infections Caused by Specific Microorganisms

MICROORGANISM	DRUG OF FIRST CHOICE	ALTERNATIVE DRUGS*
Gram-Positive Cocci		
Staphylococcus species		
Methicillin-sensitive	Penicillinase-resistant penicillin (e.g., cloxacillin)	First-generation cephalosporin, vancomycin, clindamycin, imipenem, meropenem, luoroquinolone, linezolid, daptomycin
Methicillin-resistant	Vancomycin with or without gentamicin or rifampin	Quinupristin-dalfopristin, linezolid, fluoroquinolone, doxycycline, trimethoprim-sulfamethoxazole, tigecycline, daptomycin
Streptococcus pyogenes	Penicillin G or V	Cephalosporin, erythromycin, vancomycin, clindamycin, clarithromycin, azithromycin, linezolid, daptomycin
Streptococcus viridans group		
Oral infections	Penicillin G or V	Erythromycin, clindamycin, cephalosporin
Bacteremia or endocarditis	Penicillin G with or without gentamicin	Ceftriaxone, vancomycin
Streptococcus, anaerobic (*Peptostreptococcus*)	Penicillin G or V	Cephalosporin, clindamycin, vancomycin
Streptococcus pneumoniae	Penicillin G or V, amoxicillin	Cephalosporin, trimethoprim-sulfamethoxazole, erythromycin, clindamycin, clarithromycin, azithromycin, levofloxacin, gemifloxacin, moxifloxacin, meropenem, imipenem, ertapenem
Enterococcus species	Ampicillin, amoxicillin, penicillin G with gentamicin	Vancomycin with gentamicin, or linezolid, quinupristin-dalfopristin
Gram-Negative Cocci		
Neisseria gonorrhoeae	Ceftriaxone	Cefotaxime, cefixime, penicillin G
Neisseria meningitidis	Penicillin G	Cefotaxime, ceftizoxime, ceftriaxone, chloramphenicol, fluoroquinolone, sulfonamide
Moraxella (Branhamella) catarrhalis	Fluoroquinolone, cefuroxime	Trimethoprim-sulfamethoxazole, amoxicillin-clavulanate, erythromycin, clarithromycin, azithromycin, doxycycline, cefotaxime, ceftizoxime, ceftriaxone
Gram-Positive Bacilli		
Bacillus anthracis	Ciprofloxacin, tetracycline	Penicillin G, erythromycin, amoxicillin, imipenem, clindamycin, levofloxacin
Clostridium difficile	Metronidazole	Vancomycin
Clostridium perfringens	Penicillin G, clindamycin	Imipenem, meropenem, ertapenem, metronidazole, chloramphenicol
Clostridium tetani	Metronidazole	Penicillin G, doxycycline
Corynebacterium diphtheriae	Macrolide	Penicillin G

TABLE **39-4**

Drugs Used to Treat Infections Caused by Specific Microorganisms—cont'd

MICROORGANISM	DRUG OF FIRST CHOICE	ALTERNATIVE DRUGS*
Corynebacterium species (diphtheroids)	Vancomycin or penicillin G with gentamicin	Erythromycin
Gram-Negative Bacilli		
Bacteroides, oropharyngeal strains	Penicillin G	Cefotetan, cefoxitin, clindamycin, metronidazole, ampicillin-sulbactam, amoxicillin-clavulanate
Capnocytophaga canimorsus	Penicillin G or V	Cefotaxime, ceftriaxone, ceftizoxime, clindamycin, ciprofloxacin, imipenem, meropenem, vancomycin, fluoroquinolone
Eikenella corrodens	Ampicillin, amoxicillin-clavulanate	Erythromycin, ceftriaxone, doxycycline, clarithromycin, azithromycin
Escherichia coli	Cefotaxime, ceftizoxime, ceftriaxone, ceftazidime, cefepime	Ciprofloxacin, ampicillin with or without gentamicin, tobramycin or amikacin, aztreonam, extended-spectrum penicillin with penicillinase inhibitor, trimethoprim-sulfamethoxazole, imipenem, meropenem, ertapenem, fluoroquinolone, tigecycline
Fusobacterium species	Penicillin G, penicillin V, metronidazole	Clindamycin, cefoxitin, erythromycin
Haemophilus influenzae	Cefotaxime, ceftriaxone, trimethoprim-sulfamethoxazole	Ampicillin or amoxicillin with or without penicillinase inhibitor, cefaclor, cefuroxime, fluoroquinolone, clarithromycin, azithromycin
Klebsiella pneumoniae	Cefotaxime, ceftriaxone, ceftazidime, cefepime	Aminoglycoside, aztreonam, fluoroquinolone, imipenem, meropenem, ertapenem, mezlocillin, extended-spectrum penicillin with penicillinase inhibitor, piperacillin, tigecycline, trimethoprim-sulfamethoxazole
Legionella pneumophila	Azithromycin or ciprofloxacin or other fluoroquinolone with or without rifampin	Trimethoprim-sulfamethoxazole, erythromycin, doxycycline, with or without rifampin
Leptotrichia buccalis	Penicillin G, penicillin V	Clindamycin, doxycycline, erythromycin
Proteus mirabilis	Ampicillin	Aminoglycoside, cephalosporin, fluoroquinolone, ticarcillin/clavulanate, piperacillin/tazobactam, aztreonam, imipenem, meropenem, ertapenem
Pseudomonas aeruginosa	Ticarcillin/clavulanate, piperacillin/tazobactam with or without aminoglycoside, ciprofloxacin	Aztreonam, ceftazidime, cefepime or imipenem with aminoglycoside, doripenem
Salmonella typhi	Ceftriaxone, ciprofloxacin, or levofloxacin	Amoxicillin, ampicillin, trimethoprim-sulfamethoxazole, chloramphenicol
Shigella	Fluoroquinolone	Trimethoprim-sulfamethoxazole, ampicillin, azithromycin, ceftriaxone
Other Microorganisms		
Mycobacterium tuberculosis	Isoniazid with rifampin (or rifabutin or rifapentine) and pyrazinamide with or without ethambutol	Ethambutol, streptomycin, amikacin, ciprofloxacin, ofloxacin, capreomycin, kanamycin, ethionamide, aminosalicylic acid, cycloserine (in combinations)
Actinomyces israelii	Penicillin G	Doxycycline, erythromycin, clindamycin
Nocardia asteroides	Trimethoprim-sulfamethoxazole	Minocycline, sulfisoxazole, amikacin, imipenem, meropenem, ceftriaxone, linezolid, cycloserine
Treponema pallidum	Penicillin G	Ceftriaxone, doxycycline
Chlamydia psittaci	Doxycycline	Chloramphenicol
Rickettsiae	Doxycycline	Fluoroquinolone, chloramphenicol, rifampin
Candida albicans		
Oral lesions	Nystatin, clotrimazole, fluconazole	Itraconazole
Systemic infections	Fluconazole, itraconazole	Amphotericin B with or without flucytosine
Viruses†		
Herpes simplex		
Orolabial	Penciclovir	
Keratitis	Acyclovir	Trifluridine, foscarnet
Genital infection	Acyclovir	Valacyclovir, famciclovir
Encephalitis	Acyclovir	
Human immunodeficiency virus	Zidovudine with another nucleoside analogue, plus a protease inhibitor†	Zidovudine with another nucleoside analogue, plus nevirapine, with or without fusion inhibitor
Influenza A	Rimantadine	Amantadine, zanamivir, oseltamivir

*Listing does not include all alternative drugs.
†See Chapter 40.

Adverse effects. The adverse effects of penicillins are allergic and nonallergic in nature.

Penicillin Allergy. Allergic reactions to penicillins are common while allergic fatalities are far less common. Allergy to penicillins ranges from 0.7% to 8% in various studies, with a 0.7% to 4% chance of an allergic reaction (average of 2%) during any given course of penicillin therapy.[49,50] Most allergic manifestations are maculopapular or urticarial skin reactions.

Penicillin may be the most common cause of anaphylactic death in the United States, accounting for 75% of all cases and 400 to 800 annual deaths. These numbers may be low estimates, however. Penicillin-induced anaphylaxis is most common in adults 20 to 49 years old.[49,50] Estimates of severe penicillin anaphylaxis range from 0.004% to 0.015% of individuals exposed and, from the point of view of number of exposures, possibly 1 in 1200 to 1 in 2500 penicillin exposures. The fatality rate from penicillin anaphylaxis by all routes of administration may be 1 in 60,000 patient courses (16 per 1 million),[79,81] but data regarding penicillin allergy are limited.

Eventually, 1% to 10% of the general population exposed to therapeutic penicillin have an allergic reaction, with a higher positive history with increased age. Retrospective studies suggest that the incidence of allergy varies with the route of administration—oral (0.3%), intravenous (2.5%), and intramuscular (5%); the lower incidence by the oral route has been questioned because of limited data.[79,80] With higher oral doses (3.5 g of amoxicillin), the allergy rate may approach that of intramuscular penicillin, indicating that the dose and the route may be a determining factor in penicillin allergy. Fatal anaphylactic reactions after oral penicillin are well documented.[79,81]

It is probable that an acute penicillin allergic reaction is less common in children and elderly patients, but fatal reactions may be more likely in elderly patients because of their compromised cardiopulmonary function. Whether certain individuals are predisposed to penicillin allergy remains unsettled. Risk factors for penicillin allergies include multiple allergies to other drugs, particularly other antibiotics ("multiple allergy syndrome"), or atopic disease (asthma, allergic rhinitis, nasal polyps). Several studies indicate a higher rate of penicillin allergy in individuals with a history of other drug allergies, whereas other studies indicate no such increased risk.[79,81] It is possible that individuals with multiple drug allergies or atopy may have more severe penicillin allergic reactions. Allergy to the procaine component of procaine penicillin G has been detected.

In individuals with a positive history of penicillin allergy, 15% to 40% exhibit allergy on re-exposure to penicillin, and individuals with a positive history of penicillin allergy have a four to six times greater likelihood of a subsequent reaction than individuals with a negative history.[79,81] Some patients may retain penicillin-specific IgE antibodies indefinitely, whereas most lose them over time. The serum half-life of penicillin IgE antibodies ranges from 10 to more than 1000 days; the risk of recurrent penicillin allergy is higher in individuals with antibodies with long half-lives or repeated penicillin exposures. Few data are available regarding whether the 60% to 85% not exhibiting allergy on re-exposure reacquire the IgE antibodies to penicillin and then have an allergic reaction to the drug on the next (third) exposure by resensitization. In a study of patients with a positive history of penicillin allergy (25 with urticaria/angioedema, 19 with anaphylaxis, 19 with pruritic skin rash) and a negative skin test for penicillin allergy, none had an allergic reaction to three successive 10-day courses of penicillin.[91] The average length of time from the penicillin allergic reaction to rechallenge was 25 years (range 5 to 50 years), indicating that patients commonly lose their antibodies to penicillin. This study provides no information, however, on patients with a more recent history of penicillin allergy.

Because variable IgE antibody levels to penicillin are common, skin testing for penicillin allergy becomes problematic. The incidence of positive skin tests in individuals with a history of penicillin allergy ranges from 4% to 91% depending on the accuracy of the patient history, the haptens in the test solution, and the time elapsed between the allergic reaction and the skin test.[68,70] It is possible that penicillin skin tests may be reliable only for 72 hours after the test is performed.[79,81]

Penicillin skin testing can be considerably valuable in determining who might have a severe anaphylactic reaction. Approximately 95% of penicillin-allergic individuals form the penicilloyl-protein conjugate (the major antigenic determinant), and approximately 5% form the 6-aminopenicillanic acid and benzyl-penamaldic acid minor antigenic determinants (Figure 39-3).[79,81] Penicillin skin tests with the major and minor antigenic determinants eliciting a negative skin test virtually eliminate the risk for a serious IgE-mediated reaction. A positive skin reaction to the minor determinant mixture indicates a high risk for anaphylaxis.

Penicillins are primarily associated with IgE-mediated (Gell and Coombs type I) allergic reactions, but may also induce cytotoxic (type II) or immune complex (type III) reactions. Type I signs and symptoms include skin erythema, itch, angioedema, urticaria, wheezing, hypotension, and bronchospasm resulting from mast cell/basophil release of histamine along with other tissue allergic mediators. Type II reactions are caused by circulating IgM or IgG antibodies that attach to blood cells and induce blood dyscrasias, including hemolytic anemia, leukopenia, thrombocytopenia, and aplastic anemia. Type III reactions result from the deposition of soluble immune complexes on blood vessels and basement membranes resulting in serum sickness, vasculitis, and glomerulonephritis.

Allergic reactions to penicillins can also be classified according to their time of onset. Immediate IgE reactions begin within seconds to 1 hour after drug exposure and are the most life-threatening (it is an allergy truism that the more rapid the onset of the allergic reaction, the more serious the consequences). Accelerated reactions begin 1 to 72 hours after antigen exposure and usually manifest as urticaria or angioedema. Late reactions occur after 72 hours and are characterized by type II and type IV (eczema-like) Gell and Coombs reactions. Of all fatal anaphylactic reactions, 96% occur within the first 60 minutes after penicillin exposure.[79,81]

Other adverse reactions to penicillins are likely to be autoimmune in origin and have an obscure etiology, including maculopapular rashes, eosinophilia, Stevens-Johnson syndrome, and exfoliative dermatitis. A maculopapular rash is seen in 2% to 3% of patients late in penicillin therapy.

Multiple Antibiotic Allergy Syndrome. Most practitioners have encountered at least one patient with a history of allergy to multiple antibiotics (and probably other drugs as well). Whether such an antibiotic allergy syndrome exists is still undetermined, but may constitute 1% to 4% of all patients who have taken multiple antibiotics.[66] Serious adverse drug reactions such as anaphylaxis with antibiotics are rare except for the β-lactams.[88]

Some difficulties with the health history are that (1) patients may confuse any adverse drug reaction with "allergy," (2) rarely are any of these "allergies" confirmed by skin testing, and (3) often the patient's history is nebulous.[66] The management of such patients requires a detailed medical history, including (1) when during the treatment the reaction

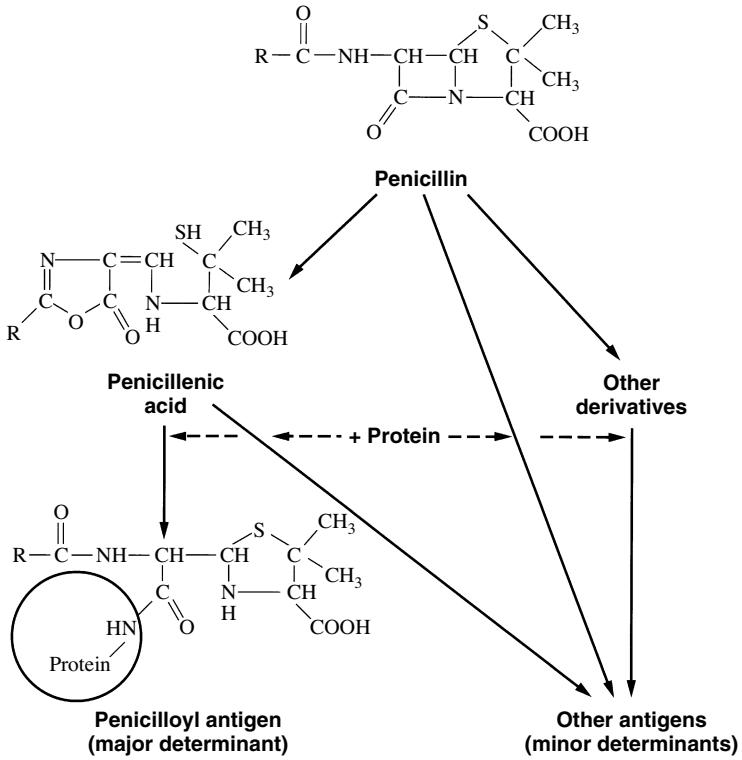

FIGURE **39-3** Antigenic determinants of penicillin allergy.

occurred, (2) what infectious disease was being treated, (3) what doses of antibiotics were taken and for how long, and, most important, (4) what were the signs and symptoms. The primary concern is to determine the signs and symptoms of an acute IgE-mediated allergic reaction—rash, angioedema, bronchospasm, and syncope—along with the time between drug ingestion or administration and onset of symptoms. If the onset of signs and symptoms occurred within 1 hour of ingestion or administration, it was likely an immediate allergic reaction. After taking a thorough history, a possible skin test (reliable only for β-lactams) is indicated and a specific management plan. Comorbid conditions that may increase the incidence of allergy in general are atopic disease (asthma, eczema), chronic urticaria, nonsteroidal anti-inflammatory drug (NSAID) intolerance, immunosuppression, human immunodeficiency virus (HIV) positivity, and a history of multiple antibiotic use.[66]

Nonallergic Adverse Effects. Ticarcillin, mezlocillin, and piperacillin may cause abnormal coagulation times; abnormal liver function tests may occur with β-lactamase–resistant penicillins, and Na^+ overload may be seen with antipseudomonal penicillins. Large intravenous doses of penicillins may induce hyperexcitability, seizures, and hallucinations. Amoxicillin is the most common cause of antibiotic-induced diarrhea/colitis because of its spectrum and widespread use. Penicillins are U.S. Food and Drug Administration (FDA) pregnancy category B drugs.

Approximately 5% to 10% of individuals receiving ampicillin or amoxicillin may have a mild pruritic rash, usually beginning on the trunk and extending to the face, extremities, and extensor portions of the knees and elbows. This nonallergic "ampicillin/amoxicillin rash" is not associated with antibody formation and is of unknown cause. It does not seem to increase the risk of true penicillin allergy. The rash may begin 24 hours to 28 days after the drug is begun and may last 90 minutes to 7 days. The incidence of ampicillin/amoxicillin rash is 95% to 100% in individuals with cytomegalovirus infection/mononucleosis and 22% in individuals given ampicillin and allopurinol.

Rare and reversible disorders reportedly associated with penicillins include acute pancreatitis, neutropenia, aseptic meningitis, hepatotoxicity, and increased prothrombin time/international normalized ratio (INR) in patients taking oral anticoagulants either through impaired platelet function or altered gastrointestinal microbial flora. Untoward bleeding may also occur in patients not taking coumarin anticoagulants and is dose-dependent, with a maximum effect 3 to 7 days after penicillin is begun, with a return to a normal bleeding time in 72 to 96 hours; this bleeding has been reported after a dental extraction.[8] The mechanism is likely due to an altered adenosine 5′-diphosphate–mediated platelet aggregation response and is seen most commonly in patients with underlying chronic illnesses associated with hypoalbuminemia and uremia.

Drug interactions. Oral penicillins (penicillin G, penicillin V, amoxicillin) may be antagonized by bacteriostatic antibiotics (tetracycline, erythromycin, clindamycin). NSAIDs and probenecid may increase the serum half-lives of penicillins by decreasing their renal excretion. Individuals taking β-adrenergic blocking drugs may have a diminished or nonexistent response to a β-adrenergic receptor agonist given for the treatment of penicillin-induced anaphylactic bronchospasm.

Contraindications. Penicillins are generally contraindicated in individuals allergic to the drugs, but it is well documented that some individuals with a previous allergic history may subsequently tolerate penicillins without allergic manifestations. The best policy is to refrain if possible from penicillin administration to anyone with a positive history. Penicillins may be contraindicated in some individuals taking coumarin

TABLE **39-5**

Recommended Doses of Some Antibiotics

ANTIBIOTIC	DOSE
β-Lactams	
Penicillin V	Adult: 250-500 mg every 6 hr; child (<12 yr old): 250-500 mg every 6 hr
Amoxicillin	Adult: 250-500 mg every 8 hr; child (<20 kg): 20-40 mg/kg in 8-hr divided doses or 6.7-13.3 mg/kg every 8 hr
Amoxicillin-clavulanate	Adult: 250-500 mg every 8 hr; child: 25-40 mg/kg/day in 8-hr divided doses or 6.6-13.3 mg/kg every 8 hr
Dicloxacillin	Adult: 125-500 mg every 6 hr; child (<20 kg): 50-100 mg/kg/day in 6-hr divided doses or 3.125-6.25 every 6 hr
Cephalexin	Adult: 125-1000 mg every 6 hr; child: 25-100 mg/kg/day in 4 divided doses
Cephradine	Adult: 250-1000 mg every 6 hr; child: 25-100 mg/kg/day in 2 or 4 divided daily doses
Cefaclor	Adult: 250-500 mg every 8 hr; child: 20-40 mg/kg/day in divided doses every 8 hr
Macrolides	
Erythromycin	Adult: 250-500 mg (stearate, base, or estolate salts) or 400 mg ethylsuccinate salt every 6 hr; child: 30-50 mg/kg per day in divided doses every 6 hr
Azithromycin	Adult: 500 mg every 12 hr; child: 5-12 mg/kg/day
Clarithromycin	Adult: 250-500 mg every 12 hr; child: 7.5 mg/kg twice daily up to 500 mg twice daily
Miscellaneous Antibiotics	
Clindamycin	Adult: 150-450 mg every 6 hr; child: 8-20 mg/kg/day in 3 or 4 equal doses
Metronidazole	Adult: 250-750 mg every 8 hr, not to exceed 4 g in 24 hr
Ciprofloxacin	Adult: 250-500 mg every 12 hr; child: 25 mg/kg/day divided every 12 hr
Doxycycline	Adult: 200 mg on day 1 (100 mg every 12 hr) then 100 mg daily; child (≥8 yr old): 4.4 mg/kg in 2 divided doses on day 1 then 2.2 mg/kg daily
Linezolid	Adult: 375-625 mg every 12 hr

From Amsden GW: Tables of antimicrobial agent pharmacology. In Mandell GL, Bennett JE, Dolin R, editors: *Mandell, Douglas and Bennett's principles and practice of infectious diseases,* Philadelphia, 2000, Churchill Livingstone; *Facts and comparisons,* St Louis, 2002, Facts and Comparisons; Neu HC: Penicillins. In Mandell GL, Douglas RG, Jr, Bennett JE, editors: *Principles and practice of infectious diseases,* ed 5, New York, 1990, Churchill Livingstone; Pallasch TJ: Antibiotics for acute orofacial infections, *J Calif Dent Assoc* 21:34-44, 1993; Wright AJ: The penicillins, *Mayo Clin Proc* 74:290-307, 1999.

anticoagulants because untoward bleeding may occur, but this seems to be highly unpredictable and rare in occurrence.

Dosage. The standard package insert doses for amoxicillin are given in Table 39-5. Amoxicillin has excellent and rapid oral absorption, yields high blood levels, and has a longer half-life than penicillin V. Based on pharmacokinetic studies, the package insert intervals of 6 hours for β-lactams with a short half-life (penicillin V, cephalexin, cephradine) seem inappropriate, and 4-hour dosing intervals would provide more constant blood and tissue levels for these time-dependent antibiotics. As with all acute infections, a loading dose of two to four times the maintenance dose is appropriate, with the possible exception of amoxicillin because of its superior pharmacokinetics.

Cephalosporins

The isolation of the fungus *Cephalosporinium acremonium* (now *Acremonium chrysogenum*) in 1948 by Brotzu from the harbor sewage of Sardinia and the subsequent isolation of the active nucleus of cephalosporin C (7-amino-cephalosporinic acid) by Florey and Abraham at Oxford University contributed in large measure to a golden age in antimicrobial chemotherapy. The massive use and misuse of cephalosporins because of their broad antibacterial spectra combined with low toxicity and allergenicity have resulted in widespread microbial resistance to these agents.

Chemistry and classification. Cephalosporins are closely related to penicillins, with a six-membered dihydrothiazine ring replacing the five-membered thiazolidine ring of penicillin (Figure 39-4). Both contain the β-lactam ring, as do the monobactams and carbapenems discussed later. Side chain modification of the 7-APA nucleus has led to differences in antibacterial spectrum, pharmacokinetics, susceptibility to various β-lactamases, affinity for different PBPs, and occasionally adverse reactions.

Cephalosporins are most commonly classified according to their "generations": first generation (introduced in the 1960s), second generation (introduced in the 1970s), third generation (introduced in the 1980s), and fourth generation (cefepime introduced in 1997) (Box 39-4).[7,33,50,67] Ceftidoren is a third-generation agent introduced in 2001. It is useful to examine cephalosporins according to their antibacterial spectrum and therapeutic uses (Table 39-6).[33]

Cephalosporins evolved from early agents primarily active against gram-positive microorganisms (first generation) to agents with a greater gram-negative spectrum (second generation) to agents with greater activity against various nosocomial pathogens, including *P. aeruginosa*, *B. fragilis*, and organisms producing extended-spectrum and ampicillin C (ampC) β-lactamases. The demand for wider spectrum cephalosporins to avoid having to isolate the organism via culture and sensitivity tests (and save money) has been a major factor in microbial resistance to these agents. Technically, second-generation agents include true cephalosporins and cephamycins (cefoxitin, cefotetan, cefmetazole), which are derived from *Streptomyces* rather than *Cephalosporinium*.

Mechanism of action and antibacterial spectrum. Cephalosporins possess a mechanism of action identical to penicillins: inhibition of bacterial cell wall peptidoglycan synthesis by inhibition of penicillin-sensitive enzymes (transpeptidases, carboxypeptidases) that are responsible for the final three-dimensional structure of the rigid bacterial cell wall. Each bacterial species may have different PBPs, and the affinity of cephalosporins for these PBPs can vary greatly.[50] Most cephalosporins bind to PBP1 and PBP3 of gram-negative organisms,[7] and depending on which PBPs are inhibited, the resulting bacterial cells may take different shapes—oval, round, or fila-

mentous.[7] The antibacterial spectrum, susceptible microorganisms, and drugs of choice or alternative indications are listed in Table 39-6.[7,18,50,67]

First-generation agents are intended for gram-positive aerobes, facultative cocci, and MSSA. Cefazolin is commonly used as single-dose antibiotic prophylaxis for clean-clean hospital surgery. Second-generation drugs have variable antistaphylococcal activity, a greater gram-negative spectrum, and some activity against anaerobes (e.g., cefotetan, cefoxitin). Third-generation agents are most active against gram-negative organisms and penicillin-resistant *S. pneumoniae,* with a subset effective against *P. aeruginosa*. Cefoperazone, ceftazidime, and cefsulodin have good antipseudomonal activity. Fourth-generation drugs have a wider antibacterial spectrum and good activity against *Pseudomonas,* penicillin-resistant *S. pneumoniae,* VGS, multidrug-resistant *S. pneumoniae* and *Entero-*

coccus, MRSA, and hyper–β-lactamase–producing organisms. Fourth-generation agents include cefilidin, cefpirone, cefclidin, cefoselis, cefpirime, and cefluprenan.[7]

Bacterial resistance. The major mechanism of resistance to cephalosporins is the microbial elaboration of various β-lactamases (cephalosporinases). First-generation agents are very sensitive to β-lactamase hydrolysis, with the second to fourth generations more resistant to β-lactamases. Moderate stability is shown by cefonicid, loracarbef, cefdinir, and cefixime; moderate-high stability, by cefoxitin, cefuroxime, ceftriaxone, cefotaxime, ceftizoxime, cefmetazole, and cefotetan;

and high stability, by cefoperazone, cefpodoxime, and ceftazidime.[7,33,50,67] The current concern is the microbial production of extended-spectrum β-lactamases derived from point mutations on TEM-1, TEM-2, and SHV-1 β-lactamases (see Chapter 38) that result in high-level resistance to ceftazidime, aztreonam (a monobactam), and third-generation cephalosporins in highly pathogenic nosocomial *E. coli*, *K. pneumoniae*, and *E. cloacae*.[50]

Absorption, fate, and excretion. Oral cephalosporins are generally well absorbed, with all except cefadroxil and cefprozil having their absorption delayed, but not reduced, by food.[33] Cephalosporins are hydrophilic and widely distributed in extracellular fluid, but do not enter the cells of the immune system (macrophages, polymorphonuclear leukocytes), as do lipophilic macrolides, tetracyclines, and lincosamides. Only cefuroxime of the first-generation and second-generation agents penetrates into the cerebrospinal fluid. Plasma protein binding ranges from 10% for ceftibuten to 80% to 90% for cefazolin, cefoxitin, and cefoperazone. Plasma protein binding is 10% for cephalexin, 25% for cefaclor, and 8% to 17% for cephradine. The serum half-lives of some oral cephalosporins are 50 to 80 minutes for cephalexin, 48 to 80 minutes for cephradine, and 35 to 54 minutes for cefaclor.[33] In patients with end-stage renal disease, these half-lives may increase to 19 to 22 hours for cephalexin, 8 to 15 hours for cephradine, and 2 to 3 hours for cefaclor.

General therapeutic uses. Cephalosporins have wide applications in the treatment of infections. Tables 39-4 and 39-6 indicate their clinical importance as antimicrobial drugs. The utility of these drugs depends on the generation. First-generation drugs are used to treat infections caused by staphylococci and streptococci. They also are useful in surgical and endocarditis prophylaxis. Some gram-negative bacilli, such as *P. mirabilis* and *K. pneumoniae*, may be sensitive. Second-generation drugs have limited use, although a subset of this group represented by cefoxitin has good activity against many gram-negative anaerobes.

Third-generation drugs have become prominent in the treatment of serious gram-negative coccal and bacillary infections. They are very useful in treating meningitis, pneumonia, gonorrhea, and sepsis from sensitive organisms. Cephalosporins are often given with aminoglycosides for gram-negative bacilli infections. There are significant individual differences between members of the third-generation drugs, and not all indications apply to each member. Fourth-generation cephalosporins are resistant to many β-lactamases and are effective in treating some gram-negative bacilli that produce β-lactamases.

Therapeutic uses in dentistry. Cephalosporins have good activity against many orofacial pathogens, but limited activity against oral anaerobes. These β-lactam antibiotics are also time-dependent agents without significant post-antibiotic effects, and the serum and tissue concentrations of cephalosporins should remain greater than the organism's MIC for at least 60% of the dosing interval to retard organism regrowth as much as possible.[22] At the current package dosing intervals of 6 hours for oral cephalosporins with a short half-life (e.g., cephalexin, cephradine, cefaclor), these serum levels are not likely to be attained. At three half-lives after ingestion (approximately 4 hours), only 12.5% of the β-lactam remains in the blood or tissue and may well be less than the organism's MIC. Brief peak blood concentrations followed by a significant period below the organism's MIC are not ideal for time-dependent antibiotics and allow for recovery of the pathogen from inhibition of β-lactam cell wall formation.[20] Shortening the dosing interval to 4 hours for these agents may resolve this pharmacokinetic difficulty.

Adverse effects. Serious adverse reactions associated with cephalosporins are rare, with the major concern being the potential for cross-allergy with penicillins. Unusual adverse reactions include transient increases in liver enzymes, nephrotoxicity, reversible neutropenia, eosinophilia and thrombocytopenia, aseptic meningitis, and disulfiram-like reactions associated with cephalosporins with the methylthiotetrazole side chain (e.g., cefotetan, cefoperazone, cefamandole). Pseudomembranous colitis is rare with first-generation and second-generation agents, but is more common with third-generation cephalosporins, possibly because of their anti-*Bacteroides* activity (*Bacteroides* and antagonistic C. *difficile* in the colon). Some cephalosporins (e.g., cefoperazone, cefotetan, cefmetazole, cefmenoxime) may induce hypoprothrombinemia by reduced synthesis of vitamin K–dependent clotting factors.

The inherent allergic potential of cephalosporins along with their cross-allergenicity with penicillins is of major concern. Cutaneous allergic reactions to cephalosporins (rash, pruritus, urticaria) are commonly reported to occur in 1% to 3% of patients. Serum sickness or a morbilliform rash may be seen in children receiving cefaclor. Stevens-Johnson syndrome and toxic dermal necrolysis have been reported.[33] In 6573 patients receiving cephalosporins,[73] 1.1% exhibited an allergic reaction.[24]

Anaphylactic reactions to cephalosporins seem to be rare, with an incidence ranging from 0.0001% to 0.1% of individuals exposed.[51] In 9388 patients without a history of penicillin allergy given cephalosporins, two anaphylactic reactions were reported (0.2%).[51] In a retrospective study of 350,000 adverse drug reactions, six fatal cases of cephalosporin-induced anaphylaxis were reported, with three of the six cases in patients with a history of penicillin allergy.[85]

The issue of cross-sensitivity between the cephalosporins and penicillins has never been satisfactorily resolved. Estimates range from 1.1% (the same as the allergy incidence to cephalosporins in the general population) to 18% in the earliest studies.[79,81] Penicillin-allergic individuals may have a fourfold greater risk of allergy to cephalosporins than individuals not allergic to penicillins; however, penicillin-allergic individuals have a three to four times greater risk of allergy to any drug. No skin test is available to detect cephalosporin allergy, and experience with desensitization is limited and not standardized.

It is generally agreed that it is reasonably safe to give cephalosporins to patients with a history of a mild skin reaction to penicillins or a positive penicilloyl-polylysine (major determinant mixture) skin test.[79,81] Cephalosporins are generally contraindicated in patients with a positive penicillin skin test to the minor determinant mixture or a history of local or systemic penicillin anaphylaxis (severe urticaria, bronchospasm, hypotension, exfoliative dermatitis), unless cephalosporins are mandated in the management of a life-threatening infection, and anaphylaxis antidotal therapy is readily available.

Drug interactions. Antacids decrease the plasma concentrations of cefaclor, cefdinir, and cefpodoxime; H_2 histamine receptor antagonists reduce the plasma concentrations of cefpodoxime and cefuroxime, and iron supplements reduce the gastric absorption of cefdinir.[33] Food decreases the oral absorption of cefuroxime and cefpodoxime. Cefmetazole, cefoperazone, and cefotetan may induce a disulfiram reaction with ethanol and hypoprothrombinemia. Nephrotoxicity may be seen with the combination of cephalosporins with aminoglycosides or loop diuretics. Cephalosporins may produce a false-positive reaction for urine glucose with Benedict's solution, and cephradine may produce a false-positive reaction for urinary proteins with tests using sulfosalicylic acid.[33]

Contraindications. Cephalosporins are contraindicated in patients allergic to these drugs and in individuals with a history of severe penicillin reactions or a positive skin test reaction to the penicillin minor determinant mixture.

Other β-lactam antibiotics

Carbapenems. Carbapenems are derivatives of thienamycin (from *Streptomyces cattleya*) and differ from penicillins by the replacement of the sulfur by a methylene group in the five-membered ring of the β-lactams (see Figure 39-4). Currently, four carbapenems are available for parenteral use in the United States: imipenem, meropenem, ertapenem, and doripenem. Imipenem is combined with cilastatin to reduce the hydrolysis of imipenem by a renal peptidase.

Carbapenems have a very wide antibacterial spectrum, have a high specificity for PBP2 of gram-positive and gram-negative microorganisms (resulting in ovoid organisms), and are not hydrolyzed by most β-lactamases.[39] Carbapenems are drugs of choice for the management of infections caused by *Campylobacter fetus, C. freundii, Enterobacter, Acinetobacter, S. marcescens,* and *Rhodococcus equi* and alternative drugs against MSSA, penicillin-resistant or non–penicillin-resistant *S. pneumoniae, Bacillus subtilis, Bacillus cereus, C. perfringens, Bacteroides, E. coli, K. pneumoniae, P. mirabilis,* indole-positive *Proteus, P. stuartii, Capnocytophaga canimorsus, H. influenzae,* and *P. aeruginosa*.[18]

Microorganisms that are generally resistant to carbapenems include *Enterococcus faecium, Pseudomonas cepacia, Stenotrophomonas maltophilia, Flavobacterium,* JK *Corynebacterium,* MRSA, and methicillin-resistant CoNS. Organisms with varying resistance include *P. aeruginosa, S. marcescens,* penicillin-resistant *S. pneumoniae, K. pneumoniae,* and vancomycin-resistant enterococci. Metallo-β-lactamases derived from *K. pneumoniae, P. cepacia,* and *S. maltophilia* readily metabolize the carbapenems and induce the production of cephalosporinases, which significantly increase microbial resistance to third-generation cephalosporins.[7] Microbial resistance to carbapenems is via the loss of an outer membrane protein retarding cell wall penetration of the drugs, altered PBPs in *E. faecium* and MRSA, and hydrolysis by metallo-β-lactamases and other β-lactamases.[39]

Carbapenems are classified as FDA pregnancy category B or C drugs, are cross-allergenic with other β-lactams, may increase the level of serum liver transaminases, may induce pseudomembranous colitis, and are associated with a 3% to 4% incidence of skin rash. Imipenem, meropenem, and ertapenem are associated with increased central nervous system (CNS) toxicity and seizures. Doripenem has a lower risk of CNS toxicity.

Monobactams. Aztreonam is a monocyclic β-lactam (monobactam) lacking the thiazolidine ring of penicillin (Figure 39-5).[7,39] It is available only parenterally. It does not bind to the PBPs of gram-positive or anaerobic microorganisms; its spectrum is limited to aerobic gram-negative species (binding to PBP3 to produce filamentous organisms), primarily Enterobacteriaceae, *K. pneumoniae, P. mirabilis, C. freundii, Yersinia enterocolitica, P. multocida, Salmonella, Shigella, Providencia, Neisseria, Haemophilus,* and *P. aeruginosa*. Aztreonam can be combined with clindamycin, metronidazole, and vancomycin and can be used with aminoglycosides (which have a similar antibacterial spectrum) in the management of infections caused by *E. coli, K. pneumoniae, P. mirabilis, P. stuartii, S. marcescens,* and *P. aeruginosa*. Aztreonam is metabolized by β-lactamases elaborated by *K. pneumoniae* and *P. aeruginosa*. Aztreonam is not the initial drug of choice for any infection.[18]

Aztreonam is an FDA pregnancy category B drug and lacks cross-allergenicity with β-lactams. Aztreonam induces β-lactamase production and may be synergistic with the renal toxicity and ototoxicity of aminoglycosides.

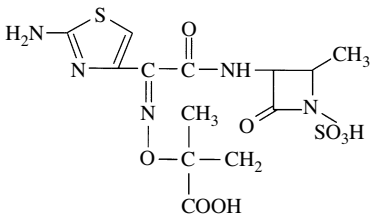

FIGURE **39-5** Structural formula of aztreonam.

Macrolide and Ketolide Antibiotics

Chemistry and classification

Macrolide antibiotics are characterized by large 14-membered, 15-membered, or 16-membered lactone rings. Box 39-5 details the macrolides available in the United States. Erythromycin, as derived from *Streptomyces erythreus,* was introduced in 1952, and azithromycin and clarithromycin were introduced in 1991 and 1992. Azithromycin is a 15-membered macrolide with an added nitrogen and N-methylation (making it technically an azalide), whereas clarithromycin is formed by the alkylation of a hydroxyl group of erythromycin (a 14-membered ring) (Figure 39-6). Troleandomycin is a synthetic derivative of oleandomycin, dirithromycin is a prodrug yielding erythromycylamine in the intestine, and telithromycin is a derivative of erythromycin A and a 14-membered macrolide with a 3-keto group substitution.[33]

Mechanism of action and antibacterial spectrum

The mechanism of action of macrolides is to bind reversibly to the P site of the 50S ribosomal subunit and inhibit RNA-dependent protein synthesis by stimulating the dissociation of peptidyl transfer RNA (tRNA) from the ribosome.[20,33] Box 39-6 lists the infections for which macrolides are drugs of choice or alternative agents.[33,89] In general, macrolides have similar activity against gram-positive aerobic/facultative staphylococci and streptococci, gram-negative anaerobes (*M. catarrhalis, Bordetella pertussis, Legionella pneumophila*), and *Mycoplasma pneumoniae,* but differing activity against other

microorganisms. *The Medical Letter*[18] lists erythromycin as a drug of choice against *Corynebacterium diphtheriae, Bartonella henselae, Bartonella quintana*; azithromycin as a drug of choice against *H. ducreyi*, *L. pneumophila*, and *Ureaplasma urealyticum*; clarithromycin as a drug of choice against *Mycobacterium fortuitum/Mycobacterium chelonae* complex; erythromycin or azithromycin as a drug of choice against *Campylobacter jejunum*; azithromycin or clarithromycin as a drug of choice against *Mycobacterium avium*; and erythromycin, azithromycin, and clarithromycin as equally effective drugs of choice against *Chlamydia pneumoniae, Chlamydia trachomatis* (depending on the disorder), *M. pneumoniae,* and *B. pertussis*.

Erythromycin is an alternative drug against *Bacillus anthracis, Corynebacterium* JK group, *Erysipelothrix rhusiopathiae, E. corrodens, H. ducreyi*, *L. buccalis, A. israelii*, and *R. equi*; azithromycin is recommended against *Shigella, B. henselae,* and *B. quintana*; clarithromycin is recommended against *Mycobacterium kansasii*, *Mycobacterium marinum*, and *Mycobacterium leprae*; clarithromycin or azithromycin is recommended against *B. pertussis* and upper respiratory infections, *U. urealyticum*, and *Borrelia burgdorferi*; and erythromycin, azithromycin, and clarithromycin are recommended as equally effective against *Streptococcus pyogenes, S. pneumoniae,* and *M. catarrhalis*.

Microorganisms generally resistant to macrolides include *H. influenzae, Peptostreptococcus, A. actinomycetemcomitans, Pasteurella*, *Fusobacterium*, *Mycobacterium tuberculosis,* MRSA, and Enterobacteriaceae. Marginally affected organisms include *Prevotella* and *Porphyromonas*.[4]

Bacterial resistance

The major mechanism for microbial resistance is demethylation of the 2058 residue of the gene coding for the 23S ribosomal RNA peptidyl transferase region, resulting in reduced macrolide binding (ribosomal protection).[20] The *erm* (*e*rythromycin-*r*esistant *m*ethylase) gene responsible for the ribosomal protection is often associated with tetracycline resistance genes and is frequently combined with the resistance genes for lincosamides (clindamycin) and streptogramins (quinupristin-dalfopristin) to form the macrolide-lincosamide-streptogramin B (MLS_B) aggregate, which confers resistance to all three antibiotic groups simultaneously. Other macrolide resistance mechanisms include active efflux genes encoding for transport efflux proteins and an esterification gene that codes for inactivation of the macrolides by phosphorylation and glycosylation.[20]

Absorption, fate, and excretion

Despite minor structural modifications, macrolides have distinct pharmacokinetic properties.[33] Erythromycin and azithromycin are available for oral and intravenous use, whereas the remaining agents are used only orally. Bioavailability ranges from 10% for dirithromycin to 40% to 50% for azithromycin, clarithromycin, and erythromycin. Food in the stomach may increase or have no effect on the absorption of azithromycin, but the remaining macrolides should be taken 1 hour before or 2 hours after a meal except for estolate and ethylsuccinate salts of erythromycin, which may be taken without regard to meals.

Erythromycin base is poorly resistant to gastric acid and is prepared with enteric coating or as various salts (stearate), esters (ethylsuccinate), or salts of esters (estolate), which protect against gastric acid degradation. Macrolides are best absorbed in the small intestine and when given orally in standard doses generally produce adequate tissue MIC concentrations of 0.5 μg/mL for azithromycin, 1 to 3 μg/mL for clarithromycin, and 0.3 to 2 μg/mL for erythromycin.[33] Erythromycin may have a variable absorption rate resulting in tissue concentrations ranging from 0.3 to 2 μg/mL. The time to maximum blood concentrations of a single dose is 2.2 hours for azithromycin, 2 to 3 hours for clarithromycin, and 1.6 hours for erythromycin. Impaired renal function may reduce the excretion of the macrolides, with the elimination half-life of erythromycin increasing from 1.6 hours to 5 to 6 hours in anuric patients. Clarithromycin and erythromycin are primarily eliminated in the urine, and azithromycin is primarily eliminated in the bile, although erythromycin may also undergo significant biliary excretion. The average serum half-lives are 68 hours for azithromycin, 3 to 7 hours for clarithromycin, and 1.6 hours for erythromycin.

A remarkable property of macrolides and highly fat-soluble tetracyclines and clindamycin is selective uptake by phagocytic cells and fibroblasts, which function as repository drug depots and as a drug delivery system to areas of inflammation and infection. These cells concentrate the macrolides

and then transport them to areas of tissue pathology where they are released for their anti-infective and anti-inflammatory properties. The tissue concentrations of azithromycin may reach 100 to 1000 times that of blood and persist long after blood levels have declined because of their significant postantibiotic effects.[63] The tissue concentration of azithromycin may exceed the microorganism's MIC for 2 to 10 days, and the elimination half-life in abscesses may be 4 days.

General therapeutic uses

Macrolides are often indicated for treating community-acquired bacterial pneumonia because of their action against numerous causative organisms. Microbial resistance is becoming increasingly common, however. They are useful against various chlamydial infections and numerous gram-positive coccal infections. They are also active against *Corynebacterium*. The 14-membered macrolides possess anti-inflammatory effects distinct from their antimicrobial actions by decreasing proinflammatory cytokine release from phagocytes, which may prove useful in management of rheumatoid arthritis, cystic fibrosis, asthma, and chronic sinusitis. General therapeutic uses are listed in Table 39-4 and Box 39-6.

Therapeutic uses in dentistry

Erythromycin has a long and successful history of use against acute orofacial infections, particularly in β-lactam–allergic patients. Its spectrum of activity is good to excellent against gram-positive aerobic/facultative cocci (streptococci, some staphylococci). Its spectrum is not generally favorable against gram-negative anaerobes associated with orofacial infections, including *Prevotella*, *Porphyromonas*, *Fusobacterium*, and *Veillonella*. Azithromycin has been observed to be effective against oral spirochetes and pigmented anaerobes.[90] In the management of acute periapical abscesses, azithromycin, 500 mg/day for 3 days, has shown comparable efficacy to amoxicillin/clavulanic acid, 625 mg three times daily for 5 to 10 days.[1] Macrolides are also useful for endocarditis prophylaxis.

Clarithromycin is most active against gram-positive anaerobes (*Actinomyces*, *Propionibacterium*, *Lactobacillus*), whereas erythromycin is more active than azithromycin for these organisms. Azithromycin has the best activity against gram-negative anaerobes (*Fusobacterium*, *Prevotella*, *Porphyromonas*, *Wolinella*, *Selenomonas*, and *A. actinomycetemcomitans*). Azithromycin may be more active against streptococci and staphylococci than erythromycin and clarithromycin and has much less propensity for drug interactions. Prolonged use of erythromycin and possibly other macrolides may lead to superinfection with gram-negative enteric bacilli.

Adverse effects

Serious toxicity with macrolides is rare but occasionally significant. The most important adverse effects include epigastric pain, ototoxicity (deafness), ventricular arrhythmias (torsades de pointes), acute pancreatitis, mania, cholestatic hepatitis, hypersensitivity syndrome, and certain drug interactions.

Cholestatic hepatitis is much more common with the estolate form of erythromycin than with other forms of erythromycin or other macrolides. This reaction can be misdiagnosed as viral hepatitis. Symptoms usually appear after approximately 10 days of erythromycin use, disappear 2 to 4 weeks after drug discontinuance with no residual effects, and readily reappear with drug readministration. This reaction is less common in children.

The most common serious adverse reaction associated with macrolides, particularly erythromycin, is potentially severe epigastric pain resulting from stimulation of the gastric smooth muscle motilin receptor.[14] Motilin is a regulatory peptide of the gastrointestinal tract that stimulates enzyme secretions by the stomach and pancreas and induces strong phasic contractions of the stomach. The most significant agonists of the motilin receptor are the 14-membered macrolides (erythromycin); azithromycin and clarithromycin are lesser stimulants.

Approximately 30 cases have been reported of macrolide-induced hearing loss, with at least 2 cases judged to be irreversible. Most seem to be associated with erythromycin doses exceeding 4 g/day or from accumulation of lesser doses in patients with impaired renal or hepatic function. In patients with renal impairment, the dose of erythromycin should be no greater than 1.5 g/day. Ototoxicity is particularly common in patients with HIV/AIDS because of the use of macrolides as prophylaxis for *M. avium* infections. All macrolides induce ototoxicity, possibly by an effect on the auditory nerve pathways, and tinnitus has been observed even with therapeutic doses of azithromycin.

Long QT syndrome is characterized by delayed ventricular repolarization that triggers ventricular tachyarrhythmias, most notably torsades de pointes, resulting in syncope, seizures, or sudden death. Long QT syndrome may be either congenital or acquired, and the list of drugs, diseases, and metabolic disorders inducing torsades de pointes is long and impressive (see Chapter 24).

At least four cases of acute pancreatitis associated with erythromycin have been reported, and several cases of mania have been associated with clarithromycin in patients with and without HIV/AIDS. Stevens-Johnson syndrome (erythema multiforme) may occur with erythromycin along with a hypersensitivity syndrome associated with azithromycin and clarithromycin consisting of fever, rash, hepatitis, interstitial nephritis, oliguria, and xerostomia. Azithromycin and erythromycin are classified as FDA pregnancy category B drugs, and clarithromycin, dirithromycin, and troleandomycin are classified as FDA pregnancy category C drugs.[33]

Drug interactions

Macrolides are associated with many drug interactions (Table 39-7).[98] Erythromycin and clarithromycin—either through their inhibition of the liver microsomal enzyme drug metabolizing system or through their effect on gastrointestinal microbial flora—increase serum levels of fluconazole, ranitidine, alfentanil, benzodiazepines, tacrolimus, theophylline, vinblastine, bromocriptine, buspirone, carbamazepine, cyclosporine, digoxin, disopyramide, ergot alkaloids, felodipine, oral anticoagulants, methylprednisolone, and omeprazole.[33] Azithromycin and dirithromycin do not affect the liver microsomes. Macrolide blood levels may be increased by fluconazole, H_2-receptor antagonists, and omeprazole and decreased by theophylline. Antacids reduce the rate, but not the total amount, of macrolide absorption, and the combination of macrolides and oral contraceptives may result in cholestasis. Bacteriostatic macrolides may interfere with the bactericidal effect of cell wall inhibitors. Concomitant administration with fluoroquinolones, pimozide, or cisapride may lead to torsades de pointes.

After only 3 days of administration, macrolides may seriously reduce cardiac glycoside metabolism in the gastrointestinal tract by *Eubacterium lentum*, resulting in digitalis toxicity because the microorganism may metabolize 30% to 40% of the drug.[100] Macrolides may potentiate the anticoagulant effect of oral anticoagulants. Concomitant use of macrolides may increase the myopathy and rhabdomyolysis seen with the "statin" anticholesterol agents.[33]

Contraindications

Macrolides are contraindicated in patients with allergy to the drugs in patients with a history of previous allergic cholestatic hepatitis. Macrolides are also contraindicated in combinations

TABLE **39-7**

Drug Interactions Associated with Macrolides

MACROLIDE	INTERACTING DRUG(S)	ADVERSE REACTION
E	Grepafloxacin, sparfloxacin	Torsades de pointes
All	Warfarin	Bleeding
All	Cyclosporines	Nephrotoxicity and neurotoxicity
All	Theophylline	Decreased macrolide blood levels, increased theophylline toxicity
All	Benzodiazepines	Increased CNS depression
C, E	Carbamazepine	Carbamazepine toxicity
C, E	Digitalis	Digitalis toxicity
E, T	Methylprednisolone	Increased steroid effects
C, E, T	Buspirone	Increased CNS depression
C, E, T	Tacrolimus	Renal toxicity

with other drugs that may induce torsades de pointes. The maximum daily dose should be 4 g in adults with normal renal function and 1.5 g per day in patients with impaired renal function.

Ketolides

Ketolides (e.g., telithromycin) are derivatives of erythromycin A specifically designed for activity against bacteria responsible for community-acquired respiratory tract infections. Telithromycin is a 14-membered macrolide with a 3-keto group substitution.[112] The oral bioavailability of telithromycin is approximately 55%, with maximum serum concentrations of 1.9 μg/mL at 1 to 3 hours. The elimination half-life is 13.4 hours; the drug has a long post-antibiotic effect and is highly concentrated in white blood cells and pulmonary tissue. It is primarily metabolized in the liver. Telithromycin inhibits bacterial protein synthesis by binding to the 50S ribosomal subunit to inhibit translation at the peptidyl transferase site. The drug also inhibits formation of the bacterial 50S and 30S ribosomal subunits.

Telithromycin is active against a wide spectrum of respiratory pathogens, including *S. pneumoniae, H. influenzae, M. catarrhalis,* C. *pneumoniae, M. pneumoniae, L. pneumophila,* group A and B streptococci (*S. pyogenes* and *Streptococcus agalactiae*), *Enterococcus, Clostridium, Neisseria, H. pylori,* MRSA, and MSSA.[112] It is also active against some anaerobes, including *Porphyromonas, Prevotella, E. corrodens,* and some *Bacteroides* species. Telithromycin may be effective against *S. pneumoniae* with *mef*E and *erm*B resistance genes and gram-positive cocci with MLS_B resistance.

Staphylococcus epidermidis is intrinsically resistant to telithromycin, and *S. pneumoniae* and *S. pyogenes* isolates have appeared in Germany, Mexico, and Canada with very high telithromycin resistance (>100 μg/mL) because of the *erm*B and L4 mutations. In Central and Eastern Europe, *S. pyogenes* presently has a 1.5% resistance rate to telithromycin and 12.3% resistance rate to erythromycin. Telithromycin may select for staphylococci and *B. fragilis* in the gastrointestinal tract.

The most frequent adverse reactions associated with telithromycin are diarrhea (12% to 20%), nausea (2% to 12%), dizziness (2% to 5%), and headache (2.5% to 5%). Telithromycin is an inhibitor of the liver microsomal enzyme cytochrome P450 system and would be expected to increase blood levels of many drugs.[112] Similar to macrolides, telithromycin may prolong the QT interval. It is classified as an FDA pregnancy category B drug.

Telithromycin has no place in the management of acute or chronic orofacial infections unless dictated by sensitivity testing. It should be reserved for highly and multiply resistant microbial pathogens, particularly of the respiratory tract.

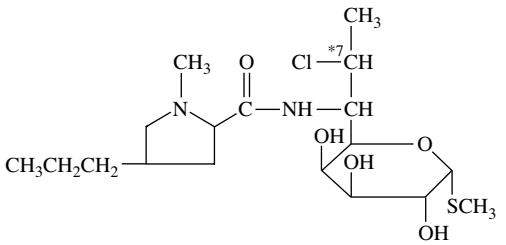

FIGURE **39-7** Structural formula of clindamycin. Substitution of the chlorine atom on the 7 carbon with a hydroxyl group yields lincomycin.

Lincosamides

Clindamycin and lincomycin are the only lincosamide antibiotics (Figure 39-7). Lincomycin was isolated from *Streptomyces lincolnensis* in 1962, and clindamycin (7-chloro-7-deoxy-lincomycin) was introduced in 1966. Clindamycin is used almost exclusively because of its greater efficacy and superior pharmacokinetics.

Mechanism of action and antibacterial spectrum

The receptor site for lincosamides is identical to that of macrolides, chloramphenicol, and streptogramins—the 23S subunit of the 50S bacterial ribosome, resulting in bacteriostatic inhibition of microbial protein synthesis. Clindamycin has significant activity against many gram-positive and gram-negative anaerobic and facultative/aerobic microorganisms, including *Bacteroides, Prevotella, Porphyromonas, Veillonella,*

Peptostreptococcus, microaerophilic streptococci, *Actinomyces*, *Eubacterium*, *Clostridium* (except C. *difficile*), and *Propionibacterium*. Gram-positive organisms generally susceptible to clindamycin include *S. pneumoniae*; VGS; *Corynebacterium*; group A, B, C, and G streptococci; and *Streptococcus bovis*, with variable susceptibility in staphylococci.[33,34] Also susceptible are *L. buccalis, B. cereus, B. subtilis, C. canimorsus,* and some β-lactamase–producing staphylococci. Microorganisms with intrinsic resistance to lincosamides include *Enterococcus,* Enterobacteriaceae, *H. influenzae, N. meningitidis, M. pneumoniae,* and most MRSA, with increasing resistance in *S. pneumoniae* and *S. pyogenes* and 12% to 20% resistance rates in *Prevotella*, *Porphyromonas*, *Fusobacterium*, and *Peptostreptococcus* in the hospital setting.

Bacterial resistance

Resistance to clindamycin occurs by three mechanisms: (1) alteration of 23S ribosomal RNA of the 50S ribosomal subunit by adenine methylation (ribosomal protection), (2) an altered single 50S ribosomal protein at the receptor site (receptor alteration), or (3) inactivation in some staphylococcal strains by a nucleotidyl transferase (drug inactivation). Adenine methylation is plasmid mediated and confers MLS_B resistance. The M phenotype macrolide resistance in *S. pneumoniae* does not confer resistance to clindamycin. If erythromycin resistance in staphylococci is inducible and not constitutive, the microorganisms are resistant only to the 14-membered and 15-membered macrolides and remain sensitive to lincosamides, streptogramins, and 16-membered macrolides. Constitutive resistance in staphylococci of the MLS_B type confers resistance to all these antibiotics simultaneously.

Absorption, fate, and excretion

Clindamycin is well absorbed orally with a 90% bioavailability not appreciably reduced by food. The time to oral peak serum levels is 45 to 60 minutes, with mean peak serum levels of 2.5 μg/mL and an elimination half-life of 2.4 to 3 hours.[33] With renal failure the elimination half-life increases to 6 hours, with a doubling of the serum level. The drug penetrates well into bone, but not cerebrospinal fluid; is metabolized primarily in the liver (>90%); and is highly concentrated in the bile, where it may alter colonic flora for 2 weeks after it is discontinued. In a manner similar to macrolides, clindamycin is concentrated preferentially in polymorphonuclear cells, alveolar macrophages, and abscess tissue.

General therapeutic uses

Clindamycin is used in the treatment of certain infections caused by susceptible strains of streptococci, staphylococci, pneumococci, or anaerobes such as *Bacteroides*. Clindamycin may be indicated in the treatment of refractory bone infections. Clindamycin is also useful in treating certain conditions involving anaerobes, such as infections of the female genital tract, pelvic infections, and abdominal penetrating wounds. It can also be used in combination for *Pneumocystis carinii* and for toxoplasmosis.

Therapeutic uses in dentistry

Although amoxicillin and penicillin V remain drugs of choice for acute orofacial infections, a resurgence in clindamycin use may be appropriate as the oral microbial resistance to β-lactams continues to increase. It is anticipated that oral microbial resistance to clindamycin will also increase proportionately along with the specter of MLS_B resistance shared with macrolides and streptogramins.

Adverse effects

Minor adverse reactions associated with clindamycin include nausea and vomiting, abdominal pain, esophagitis, glossitis, stomatitis, allergy, reversible increase in serum transaminase levels, reversible myelosuppression, metallic taste, maculopapular rash (3% to 10%), and diarrhea (2% to 20%, average of 8%).[33] High intravenous doses of clindamycin may result in a neuromuscular blockade similar to that of aminoglycosides, tetracyclines, and polymyxin B.

The major concern with clindamycin has been its purported propensity to cause antibiotic-induced diarrhea and colitis, most notably pseudomembranous colitis, based on early reports of incidences reaching 10%. It is now apparent that the association of clindamycin with these colonic disorders in outpatient use is much less than previously reported, although nonetheless real (see Chapter 38).

In a large retrospective study, the overall risk for community-acquired C. *difficile*–associated pseudomembranous colitis was determined to be 1 per 10,000 antibiotic prescriptions, with a risk rate for hospitalization of 0.5 to 1 per 100,000 patient-years.[42] In a study of 376,590 antibiotic prescriptions given to more than 280,000 patients over a 4-year period, 4 cases of acute antibiotic-induced colitis were detected.[94] The incidence rate was calculated to be 1.6 in 100,000 individuals exposed to ampicillin, 2.9 in 100,000 individuals exposed to dicloxacillin, and 2.6 in 100,000 individuals exposed to tetracycline, with no cases in patients receiving clindamycin.[94]

Although antibiotic-associated diarrhea is common in the outpatient environment and readily managed by drug discontinuance, serious antibiotic-induced colitis and potentially lethal pseudomembranous colitis seem to be rare. Such forms of colitis are more likely to occur with amoxicillin than clindamycin simply based on the much greater use of the former antibiotic, but this might change if clindamycin is used more often clinically.

Care should be taken with patients who have recently recovered from C. *difficile*–associated diarrhea or colitis for 2 months after the cessation of the disease. Any elective dental procedure requiring antibiotic therapy or prophylaxis is best postponed for this 2-month period. If antibiotic therapy is required, antibiotics far less associated with antibiotic-induced diarrhea (e.g., penicillin V, macrolides) are appropriate.

Drug interactions

Clindamycin acts synergistically with nondepolarizing (curare-like) neuromuscular blocking drugs in blocking neurotransmission at skeletal muscle. Oral absorption of clindamycin is slowed by kaolin-pectin antidiarrheal drugs.[33]

Contraindications

Clindamycin is contraindicated in patients allergic to the drug and in combination with curare-like neuromuscular blocking drugs. All antibiotics should be avoided if possible for 2 months after antibiotic-induced colitis.

Metronidazole

Metronidazole (Figure 39-8) is a synthetic nitroimidazole patterned after a naturally occurring antiparasitic substance that was isolated from a *Streptomyces* species in 1955. The drug was introduced into medicine in 1959 and was quickly found to possess strong trichomonacidal activity. Since then, metronidazole has become the drug of choice for various protozoal

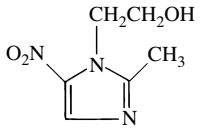

FIGURE **39-8** Structural formula of metronidazole.

infections. A chance observation that the symptoms of acute necrotizing ulcerative gingivitis were relieved in a woman receiving metronidazole for the treatment of vaginal trichomoniasis stimulated research on the drug's antibacterial effects, culminating in its approval in 1981 for the treatment of anaerobic bacterial infections. Its extensive use in treating parasitic diseases worldwide has led to significant resistance to the drug where parasites are a major problem. It was soon discovered that the drug possessed exceptional activity against obligate anaerobic and microaerophilic microorganisms, including microorganisms involved in acute orofacial infections, periodontitis, and acute necrotizing ulcerative gingivitis.

Mechanism of action and antibacterial spectrum

The antimicrobial activity of metronidazole requires entry into the cell and reduction of its nitro group to produce metabolites that damage DNA, eventually inducing cell death. Metronidazole is active only against bacteria that are obligate anaerobes. It is a concentration-dependent, rather than time-dependent antibiotic. Because metronidazole metabolites interfere with nucleic acid synthesis, concerns have been raised regarding its potential for mutagenicity, carcinogenicity, and teratogenicity.

Metronidazole penetrates all bacterial cells equally well. In sensitive anaerobes, the nitro moiety of the drug is enzymatically reduced, however, and this metabolite is the active form of the drug. Metronidazole is almost always bactericidal. The drug reacts with bacterial DNA, causing inhibition of DNA replication, fragmentation of existing DNA, and, in low doses, mutation of the bacterial genome.

Bacterial resistance

Microbial resistance to metronidazole is limited probably because of its limited clinical use except in developing countries, where it is widely used to manage parasitic diseases. A notable exception to this generalization is the high level of resistance in *H. pylori* in developed countries. Resistance to metronidazole is chromosomally mediated and plasmid-mediated by a reduction in activity or expression of several genes (*rdx*A, *nim*A, *nim*B) that control nitroreductase activity, which reduces the concentration of active metronidazole metabolites within the microbial cell.

Limited resistance is seen in *Trichomonas vaginalis, Bacteroides, Gardnerella vaginalis, C. fetus, L. buccalis,* and *Treponema pallidum*. High-level metronidazole resistance in *T. vaginalis* has been detected in 1 of 2000 to 1 of 3000 cases. During 1994-1997 in five U.S. medical centers, the sensitivity rate to metronidazole was 85% to 100% in *Prevotella*, 80.9% to 96.7% in *Peptostreptococcus,* and 93.3% to 100% in *Fusobacterium*, with a decline in sensitivity in *Fusobacterium* and *Peptostreptococcus* from 100% to 93.3% and 100% to 95%.[32] Subinhibitory concentrations of metronidazole may increase resistance rates in various periodontal pathogens, including *Fusobacterium*, *Prevotella*, *Porphyromonas,* and *Peptostreptococcus*.[56] *Bacteroides* strains resistant to metronidazole also acquire enhanced virulence properties.[27]

The most striking resistance to metronidazole has occurred in *H. pylori*, the etiologic agent in some cases of peptic ulcer and gastric cancer. The resistance rates range from 10% to 50% in developed countries and 100% in developing countries, where the drug is used for parasitic diseases. *H. pylori* resistance may significantly reduce the efficacy of other agents used along with metronidazole (e.g., omeprazole, bismuth, tetracycline, clarithromycin) and increase macrolide resistance in *H. pylori*.

Absorption, fate, and excretion

Metronidazole is almost completely absorbed from the gastrointestinal tract (oral bioavailability approaches 100%) so that serum levels are essentially the same whether the drug is administered orally or intravenously.[33] Food may delay peak serum levels of metronidazole but not the total amount absorbed. Metronidazole attains a peak blood level orally in 1 to 2 hours, has a wide volume of distribution, has excellent CNS penetration, has an elimination half-life of 8 hours, and is biotransformed into five metabolic products, all of which have antianaerobic activity. The pharmacokinetics of metronidazole are the same in pregnant and nonpregnant women, its metabolism is reduced in the presence of severe hepatic dysfunction, and its pharmacokinetics are not significantly altered with renal impairment.[33]

General therapeutic uses

The principal medical indications for metronidazole are anaerobic abdominal and CNS infections, bacterial vaginosis, protozoan and *H. pylori* infections, and the management of *C. difficile*–associated diarrhea and colitis.[18] Metronidazole is very active against obligate anaerobes (e.g., *Bacteroides, Porphyromonas, Prevotella, Fusobacterium, Peptostreptococcus, Clostridium*), many of which are associated with periodontitis, and various human parasites (e.g., *T. vaginalis, G. vaginalis, Entamoeba histolytica, Balantidium coli*). Metronidazole has variable activity against *Mycobacterium hominis, C. fetus, T. pallidum, H. pylori*, and *C. canimorsus*. *A. actinomycetemcomitans, E. corrodens, Actinomyces,* and *Propionibacterium* are commonly resistant to metronidazole. The combination of metronidazole with amoxicillin may significantly enhance its activity against *A. actinomycetemcomitans,* apparently by increasing cellular uptake of metronidazole.[105]

Three studies have used antibiotics (e.g., metronidazole, clindamycin) during pregnancy in an attempt to prevent preterm delivery in women with bacterial vaginosis, and all have been unsuccessful.[12,52,106] These results may weaken the potential association between periodontal disease and preterm birth because metronidazole is active against periodontal pathogens and pathogens associated with bacterial vaginosis.

Therapeutic uses in dentistry

Metronidazole is highly effective against gram-negative anaerobic pathogens responsible for acute orofacial infections and chronic periodontitis. Combination of metronidazole with a β-lactam antibiotic for oral infections may be indicated for serious acute orofacial infections and in the management of aggressive periodontitis.

Metronidazole is a concentration-dependent, not time-dependent, antibiotic, a fact that is not reflected in the current package insert dosing regimen for the drug. The promiscuous use of metronidazole for classic chronic periodontitis is a misuse of the drug and may contribute to the increasing resistance of metronidazole seen with parasites, *H. pylori*, and other microorganisms.

Adverse effects

Minor adverse reactions associated with metronidazole include reversible neutropenia, metallic taste, dark or red-brown urine, skin rash, urethral or vaginal burning sensation, gynecomastia, and nausea and vomiting. Rare major adverse reactions include pancreatitis; pseudomembranous colitis; peripheral neuropathy; disulfiram reaction when combined with ethanol; and CNS toxicity consisting of seizures, encephalopathy, cerebellar dysfunction, paresthesias, mental confusion, and depression. These neurologic reactions generally occur only with high prolonged cumulative doses.

Because metronidazole affects DNA synthesis, numerous studies have addressed its potential to cause birth defects. Its use in pregnancy does not seem to be associated with any congenital abnormalities, preterm delivery, or low birth weight in newborns, and the drug has an FDA pregnancy

category B classification. There also is no increase in cancer in women who take metronidazole during pregnancy, making in it very unlikely that the drug is carcinogenic.[92]

Drug interactions

Barbiturates may reduce the efficacy of metronidazole, and cimetidine may reduce its liver metabolism. The concurrent use of metronidazole and ethanol may result in acute psychosis and the disulfiram reaction (flushing, tachycardia, nausea and vomiting), although for most individuals the risk is minor.[33] Metronidazole may increase lithium blood levels, decrease the body clearance of phenytoin,[33] and significantly increase blood warfarin levels by decreasing its liver metabolism.

Tetracyclines and Glycylcyclines

Tetracyclines are a group of broad-spectrum, bacteriostatic antibiotics that have been extensively used in the treatment of numerous and varied infections. Their widespread use, and often misuse, has resulted in the appearance of many bacterial strains that are resistant to these drugs, which has curtailed their clinical usefulness. Paradoxically, the clinical use of tetracyclines has had a recent resurgence of interest with the growing realization that the drugs may be lifesaving in the treatment of serious nosocomial infections from highly and multiply antibiotic-resistant methicillin-resistant staphylococci and vancomycin-resistant enterococci. This renewed effectiveness of tetracyclines may be related to the almost complete lack of use of the drugs in hospitals for several decades, possibly leading to the loss of tetracycline resistance genes in this environment. Because of the advent of widespread resistance of *H. pylori* to metronidazole and macrolides, tetracyclines have gained importance in the treatment and prevention of peptic ulcers and gastric cancer and have emerged as a prophylactic agent in the prevention of multidrug-resistant malaria and the management of community-acquired pneumonia, particularly in penicillin-resistant and macrolide-resistant strains.

Tetracyclines comprise a group of antibiotics with a similar antibacterial spectrum but differing pharmacokinetic properties created by various chemical substitutions on the hydronaphthacene four-ringed nucleus. The first tetracycline was marketed in 1948 as chlortetracycline isolated from *Streptomyces aureofaciens*. Along with oxytetracycline, tetracycline, and demeclocycline, these four drugs constitute the first-generation tetracyclines. Second-generation agents introduced from 1965-1972 include minocycline, methacycline, and doxycycline.[19] Glycylcyclines are third-generation agents. The first microorganism clinically detected to be resistant to tetracyclines was a *Shigella dysenteriae* strain in 1953.

Chemistry

The structure of tetracycline is shown in Figure 39-9. As is implied by the name ("tetra," four; "cycline," ring), all the tetracyclines are derivatives of a four-ringed nucleus and differ structurally only with regard to the chemical moieties attached at the 2, 5, 6, and 7 positions of the nucleus. Various derivatives exhibit different pharmacologic properties, such as differences in absorption, protein binding, metabolism, excretion, and degree of activity against susceptible microorganisms.

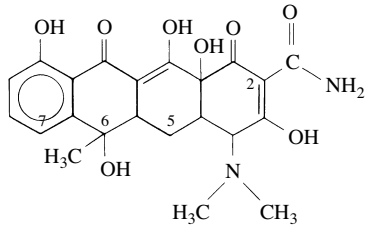

FIGURE **39-9** Structural formula of tetracycline.

Mechanism of action and antibacterial spectrum

Tetracyclines inhibit bacterial protein synthesis by preventing the association of aminoacyl-tRNA with the bacterial ribosome.[19] The drugs must transverse the gram-negative microbial outer membrane via OmpF and OmpC porin channels or through the gram-positive cell wall in its electronegative hydrophobic form and attach to a single high-affinity binding site on the ribosomal 30S subunit and protein 7 on the 16S rRNA base.[19]

Important therapeutic uses of tetracyclines are listed in Box 39-7. Tetracyclines are drugs of choice against *H. pylori*, *Chlamydia*, *Rickettsia*, *Ehrlichia*, *B. anthracis*, and *Vibrio cholerae*. The list of indications for which tetracyclines serve as alternative drugs is impressive,[18,33] including treatment of nosocomial infections from life-threatening staphylococci and enterococci, treatment of community-acquired pneumonia caused by highly antibiotic-resistant pathogens, and chemoprevention of chloroquine/mefloquine-resistant malaria.[2]

It is imperative with tetracyclines, as with all antibiotics, that a determination be made of the risk/benefit ratio associated with their use. The severity of the disease and likely response to the drugs are key considerations.

Bacterial resistance

Microbial resistance to tetracyclines is widespread, transposable, inducible, and commonly permanent because their resistance genes are almost always combined in transposable elements with the genes for resistance to other antibiotics (multidrug resistance gene cassettes). Of the three mechanisms for tetracycline resistance (drug efflux, ribosomal protection, and enzymatic inactivation), drug efflux is the most important, with at least 300 different active efflux proteins capable of extruding tetracycline from the bacterial cell.[19,93]

Tetracyclines are one of the most active chemical inducers of microbial resistance gene expression and downregulate a

†Specifically minocycline.

repressor gene that controls efflux activity for not only tetracyclines, but also possibly other antibiotics. Only nanomolar amounts of tetracycline are necessary to de-repress this system and greatly increase antibiotic efflux from bacterial cells.[19] Tetracyclines also promote the mobility of resistance determinants (transfer of resistance genes between bacteria) by stimulating the frequency of bacterial conjugation.[95] Considering these extraordinary properties of tetracyclines to induce and promote microbial resistance not only to themselves, but also other antibiotics, it would seem prudent to restrict their use to serious medical infections and restrict their use for most cases of periodontitis, where they may have limited or even undocumented value.

Absorption, fate, and excretion

Tetracyclines are adequately but variably absorbed from the gastrointestinal tract with significant differences in bioavailability, as follows: chlortetracycline, 30%; demeclocycline, tetracycline, and oxytetracycline, 60% to 80%; and minocycline or doxycycline, 95% to 100%.[33] Dairy products, Ca^{++}, Mg^{++} and aluminum compounds, and Na^{+} bicarbonate significantly impair tetracycline absorption either by chelation or by altered gastric pH.[33] Their serum protein binding ranges from 20% to 40% for oxytetracycline to 80% to 95% for doxycycline, and the percent excreted unchanged in the urine ranges from 70% for oxytetracycline to 30% to 42% for doxycycline and 12% to 16% for minocycline.[33] With renal impairment, only doxycycline and minocycline do not have increased half-lives and can be administered with reasonable safety. Other tetracyclines may accumulate in conditions of renal impairment, resulting in high blood levels and possible liver necrosis and death.

Tetracyclines are metabolized in the liver to a varying degree depending on the individual drug and are highly concentrated in the bile at levels three to five times higher than serum.[111] More recent tetracyclines are more lipid-soluble with greater tissue distribution than earlier tetracyclines. Enterohepatic circulation and incomplete absorption may lead to high drug concentrations in the feces, particularly with older agents.[33] Doxycycline may be found to some degree in the feces as an inactive form, and it is as yet unknown if this metabolic product is as capable of inducing resistance gene expression or transfer as the parent compound. The serum half-lives of the various agents are 12 to 16 hours for oxytetracycline, tetracycline, and demeclocycline; 14 to 16 hours for methacycline; 11 to 18 hours for minocycline; and 15 to 25 hours for doxycycline.[33] Peak serum concentrations of 3 to 5 μg/mL are reached in 2 hours after the usual therapeutic doses.[111] Box 39-8 lists tetracycline preparations that are available in the United States.

Minocycline hydrochloride	Minocin, Vectrin, Dynacin

General therapeutic uses

Important indications for tetracyclines are listed in Table 39-4 and Box 39-7. These lists of pathogenic microorganisms and associated diseases make it difficult to rationalize the widespread use of tetracyclines in the management of periodontitis when it is amenable to mechanical therapy. The degree of benefit of the use of tetracyclines in periodontal disease has to be weighed against the risk of developing resistant strains of microorganisms, resistance gene transfer, and induction of latent resistance genes. A careful consideration of the risk/benefit ratio is appropriate when tetracyclines are employed systemically for the management of periodontitis, particularly if the benefit is marginal at best. Acne can be a serious psychological disease in adolescents sensitive to the scorn of their peers, and long-term tetracycline use is reasonable based on risk/benefit analysis, but this does not apply to periodontitis.

Tetracyclines are major drugs in treating rickettsial diseases, *Mycoplasma*, *Chlamydia*, *H. pylori*, and *Borrelia*. (*B. burgdorferi* is the causative agent of Lyme disease.) Many other bacteria nominally within their range of activity should not be treated, at least initially, with a tetracycline because of the numerous resistant strains.

Tetracyclines have been used in the treatment of acne using oral and topical preparations. Tetracyclines are concentrated in the skin and are effective against *P. acnes* and may have an antiseborrheic action to reduce skin lipids. Because tetracyclines are deposited in bone, they can be used to measure the rate of bone growth. Other indications include plague, tularemia, cholera, brucellosis, and certain protozoal infections.

Therapeutic uses in dentistry

The use of tetracyclines in the management of acute orofacial infections is widely considered inappropriate because of their bacteriostatic activity and extensive microbial resistance, but with the advent of oral microbial pathogens increasingly resistant to β-lactams, macrolides, and clindamycin, this concept may have to be reconsidered. Systemic tetracyclines in the management of chronic periodontitis must be carefully evaluated for risk/benefit ratio considering their limited efficacy (questionable clinical efficacy and limited data on long-term efficacy), and propensity to induce microbial resistance gene expression and stimulation of drug efflux mechanisms, and common association with multiple resistance genes to other antibiotics in transposable elements. Tetracyclines are effective in the management of localized aggressive periodontitis and its associated organism, *A. actinomycetemcomitans*. Tetracyclines also seem to inhibit inflammatory matrix metalloproteinase activity. Tetracyclines may also be used subgingivally.

Adverse effects

Numerous adverse drug reactions are associated with tetracyclines. Tetracyclines may induce photosensitivity; nephrogenic diabetes insipidus (demeclocycline); blood dyscrasias; liver dysfunction (high doses and especially during pregnancy); pseudotumor cerebri and bulging fontanelles (adults and infants); *C. albicans* overgrowth; gastrointestinal difficulties (nausea, vomiting, diarrhea, pancreatitis); and various allergic manifestations, including urticaria, serum sickness, angioneurotic edema, and anaphylaxis.[33]

Minocycline in conventional doses is associated with skin, nail, and hair pigmentation and a systemic lupus erythematosus–like syndrome, mainly in adolescents taking the drug for acne. This syndrome is usually reversible but may require corticosteroid therapy; however, the absolute risk seems to be low (52.8 per 100,000 uses). Sixteen cases of autoimmune hepatitis have been described.

Minocycline is the only tetracycline that induces vestibular toxicity (ataxia, loss of balance), possibly because of its high concentration in the lipid-rich cells of the inner ear. Tetracyclines in general are one of the few groups of drugs that are toxic if ingested beyond their expiration date, inducing a Fanconi-like syndrome (azotemia, kidney damage). Tetracycline-induced acute interstitial nephritis may result in acute renal failure. Hepatotoxicity is rare except at high doses and is most likely to occur during pregnancy, leading to an absolute contraindication to the drugs in pregnancy.

The chelation properties of tetracyclines are responsible for their deposition in calcifying teeth, bone, and cartilage, and these drugs have been used as vital stains to determine bone growth. Tetracycline staining is not permanent in tissues that are remodeled (bone, cartilage), but is permanent in tissues that are not remodeled (teeth). Tetracyclines should not be used in children younger than 8 years unless other antibiotics are unlikely to be effective or are contraindicated.[33] Tetracyclines most likely to stain the dentition severely are tetracycline and demeclocycline with oxytetracycline, chlortetracycline, and doxycycline (the least likely), but the magnitude of the staining may depend more on dose and duration than the drug itself. Deposition of tetracyclines in bone and teeth eliminates their antimicrobial activity. Because of the deleterious staining effects on the teeth, tetracyclines are classified by the FDA as pregnancy category D drugs. Tetracyclines should not be used in pregnancy because of staining of teeth and potential hepatotoxicity.

Drug interactions

Tetracyclines and all other antimicrobial ribosomal protein synthesis inhibitors may reduce the efficacy of antibiotic cell wall inhibitors, which rely on cell wall division for their action. Polyvalent cations (aluminum, Ca^+, zinc, iron, magnesium, bismuth) may decrease gastric tetracycline absorption by chelation. Na^+ bicarbonate alters the gastric pH and reduces absorption of tetracyclines.

Tetracyclines may reduce insulin requirements and may alter lithium blood levels.[33] Serum blood levels of digoxin may be increased in 10% of patients, and serum levels of tetracyclines may be reduced from increased hepatic metabolism induced by barbiturates, carbamazepine, and hydantoins.[33] The addition of tetracyclines to coumarin anticoagulants (e.g., warfarin) may greatly increase the latter's effect on the INR and lead to serious bleeding episodes. The effect is partially due to the inhibitory effect of tetracyclines on the intestinal flora that produce vitamin K (see Chapter 31).

Contraindications

Tetracyclines are contraindicated in children younger than 8 years, in cases of allergy, during pregnancy, during lactation, and in individuals with sulfite sensitivity.

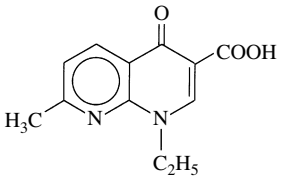
Glycylcyclines

Glycylcyclines are synthetic derivatives of minocycline that may be effective against some tetracycline-resistant bacteria and *S. pneumoniae* resistant to macrolides and penicillin where the *S. pneumoniae* possesses a lower MIC for the macrolides and penicillins than for tetracycline, minocycline, and doxycycline.[43] The resistance gene for glycylcyclines is carried on the same transposon as the resistance genes for the macrolides and tetracycline, making the use of glycylcyclines potentially limited. Tigilcycline is a glycylcycline presently undergoing clinical trials.

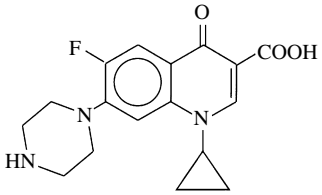
Fluoroquinolones

Fluoroquinolones were introduced in the 1980s and are C6 fluorine derivatives of nalidixic acid, which is a by-product of chloroquine (Figure 39-10). Nalidixic acid (a quinolone) was discovered in the 1960s and is still available but has the undesirable properties of CNS stimulation, rapid development of microbial resistance, poor pharmacokinetics, and chondrotoxicity (damage to cartilage). The terms *fluoroquinolone* and *quinolone* are often used interchangeably; however, this is technically incorrect because nalidixic acid, oxolinic acid, and cinoxacin are the only true quinolones (devoid of the fluorine substitution).

Fluoroquinolones and quinolones are currently classified similar to cephalosporins into first, second, third, and fourth generations depending on the time of their introduction into medicine and to a lesser extent their antibacterial spectrum (Boxes 39-9 and 39-10).[6,71,108] The first fluoroquinolone (norfloxacin) was synthesized in 1978 as a 6-fluorinated



Nalidixic acid



Ciprofloxacin

derivative of nalidixic acid with a piperazine ring at position 7. Ciprofloxacin was synthesized in 1981 and marketed in 1986. Newer fluoroquinolones have improved activity against *S. pneumoniae, S. aureus,* gram-positive cocci, anaerobes, *P. aeruginosa*, and various other organisms (see Table 39-4).[6,18,108] Potential new agents include 2-pyridones and desfluoroquinolones.

Mechanism of action and antibacterial spectrum

DNA gyrase and topoisomerases are enzymes involved in the crucial processes of DNA replication, transcription, and recombination. DNA gyrase has two subunits (A and B) regulated by two genes (*gyr*A and *gyr*B), with topoisomerase IV encoded by *par*C and *par*E genes. Both enzymes are responsible for supercoiling DNA, forming double-stranded DNA, and maintaining DNA in its physiologically stable and biologically active state. Topoisomerase IV nicks double-stranded DNA and seals the nicked DNA, whereas DNA gyrase guides the passage of the DNA through the interior of the enzyme complex. Both enzymes are responsible for supercoiling DNA, allowing for its fit into the bacterial cell. Fluoroquinolones stabilize the enzyme complex after strand breakage and before resealing, preventing DNA supercoiling.

Fluoroquinolones are broad-spectrum antibiotics that were initially greeted with great enthusiasm because they were orally effective against some of the most pathogenic nosocomial microorganisms: *S. aureus, P. aeruginosa*, and *S. pneumoniae*. As with all orally effective antibiotics, fluoroquinolones were used widely throughout the community, often in infections for which older agents were still effective. This overuse has led to widespread resistance to these agents and ultimately a race to produce new fluoroquinolones, which are only marginally better in many cases.

Fluoroquinolones are most active against aerobic bacilli and cocci, including Enterobacteriaceae, *H. influenzae, N. gonorrhoeae, Neisseria meningitidis, M. catarrhalis,* and *P. aeruginosa*. Fluoroquinolones can be classified according to their antibacterial spectrum with considerable overlap (see Box 39-10).[71] *The Medical Letter* lists fluoroquinolones as drugs of choice in the management of infections caused by penicillin-resistant *S. pneumoniae, N. gonorrhoeae, B. anthracis, Salmonella typhi*, other *Salmonella* species, *Shigella, B. henselae, L. pneumophila, P. aeruginosa* (urinary tract infection), and *R. equi* and as an alternative drug for myriad infections (Box 39-11; see Table 39-4).[18]

The in vitro MICs for sensitive microorganisms range from 0.008 to 1 μg/mL; the maximum serum concentrations range from 1.1 to 5.7 μg/mL.[33] MSSA may have MICs of 0.06 to 0.25 μg/mL, but MRSA and ciprofloxacin-resistant *S. aureus* have MICs of 1 to 4 μg/mL and 8 to 18 μg/mL for some fluoroquinolones.

The MICs for fluoroquinolones against VGS range from 0.12 to 8 μg/mL, whereas MICs for various fluoroquinolones against oral anaerobic pathogens are 0.25 to 128 μg/mL. Moxifloxacin, gatifloxacin, and trovafloxacin have the best activity against anaerobes, but the effect is highly variable depending on the species.

Bacterial resistance

Three mechanisms account for microbial resistance to fluoroquinolones: mutations in DNA gyrase and topoisomerase IV, drug efflux pumps, and reduction in microbial outer membrane permeability.[6,108] The target alterations are accom-

plished by simple point mutations in DNA gyrase (*gyr*A) and topoisomerase IV (*par*C). Significant and sometimes extensive resistance has been detected in *N. gonorrhoeae, Salmonella, Shigella, E. coli, C. jejuni*, and many gram-negative anaerobes. Microorganisms displaying efflux mechanisms include VGS, *Enterococcus, S. pneumoniae,* Enterobacteriaceae, *P. aeruginosa*, and *B. fragilis*.

Absorption, fate, and excretion

Fluoroquinolones are well absorbed orally with a 70% and 90% bioavailability for ciprofloxacin and levofloxacin.[33] Food generally delays the peak concentration of ciprofloxacin and levofloxacin, but has no effect on gatifloxacin and moxifloxacin. The percent excreted by the kidneys ranges from 27% to 73%, and protein binding ranges from 15% to 35%.[33] Fluoroquinolone half-lives vary—approximately 4 hours for ciprofloxacin and norfloxacin; 7 to 8 hours for gatifloxacin, lomefloxacin, and sparfloxacin; and 9 to 12 hours for moxifloxacin and trovafloxacin.[33] Pharmacokinetic improvements have included longer half-lives to allow for once-daily dosing and greater volumes of distribution for better tissue penetration. The post-antibiotic effects of fluoroquinolones vary from 1 to 4 hours.

General therapeutic uses

Fluoroquinolones are used to treat urinary tract infections and bacterial diarrhea (e.g., traveler's diarrhea[2]) because of their activity against many of the causative organisms (see Table 39-4). Because fluoroquinolones vary in their pharmacokinetics and in their spectra, some, but not all, fluoroquinolones are employed for upper and lower respiratory tract infections, *P. aeruginosa* infections, genital diseases caused by gonococci and *Chlamydia*, legionnaires disease, and tuberculosis.

Therapeutic uses in dentistry

Fluoroquinolones are not indicated for any acute orofacial infections unless dictated by culture and sensitivity tests. Drugs with better antimicrobial spectra are readily available. The drugs possess concentration-dependent killing not reflected in their package insert doses, and they are not predictably synergistic with β-lactams and aminoglycosides (may be additive or indifferent). Ciprofloxacin may be useful for the management of aggressive periodontitis associated with Enterobacteriaceae as dictated by culture and sensitivity tests.

Adverse effects

The major adverse effects associated with fluoroquinolones occur in the gastrointestinal tract, CNS, skin, and cartilage.[33] Less common systems involved are the cardiovascular, hepatic, and renal systems. The incidence of each adverse effect may vary among the different drugs because of chemical substitutions on the quinolone nucleus.

Gastrointestinal adverse reactions include nausea and vomiting, dyspepsia and heartburn, and abdominal pain.[33] The heavy use of fluoroquinolones has been associated with pseudomembranous colitis and diarrhea owing to overgrowth of *C. difficile*.[78] These antibiotics have become a major risk factor in this disease associated with a more virulent strain of *C. difficile*.[113] CNS effects include mild neuropathy (headache, dizziness, malaise, restlessness, bad dreams) possibly caused by central γ-aminobutyric acid inhibition or activity at the *N*-methyl-D-aspartate receptor. Dermatologic toxicity includes rash, pruritus, exfoliative dermatitis, Stevens-Johnson syndrome, and phototoxicity likely caused by dose-related ultraviolet light activation of reactive oxygen from the fluoroquinolones in the skin. Anaphylactic and anaphylactoid reactions occur at a rate of 0.46 to 1.23 per 100,000 drug exposures, with an onset of 3 to 30 minutes after drug administration.

Chondrotoxicity includes arthralgia, joint swelling, tendinitis, and tendon rupture (primarily the Achilles tendon). In a more recent study of 42 cases of tendinitis and tendon rupture, most subjects took normal doses with a median 6 days (range 1 to 510 days) until the onset of signs and symptoms (pain, edema, dysfunction, erythema, warmth), with 93% occurring within 30 days of the onset of drug intake.[104] These disorders were more likely to occur in men; patients with a median age of 68 years; and patients with concomitant corticosteroid therapy, diabetes mellitus, renal failure, other musculoskeletal disorders, or involvement in sports activity.[104] The tendinitis usually resolved with drug discontinuance. In animals given fluoroquinolones, changes have occurred in all immature joint cartilage (epiphyseal growth plate), possibly by chelation of the Mg^{++} ion.[33] These agents are not approved for children younger than 18 years except for ciprofloxacin.[104]

Other possible adverse effects include induction of a prolonged QT interval (torsades de pointes), transient increase in liver enzymes, neutropenia, serum sickness, allergic vasculitis, and renal crystalluria. Because these antibiotics affect DNA, they have been investigated as possible teratogens. At extremely high in vitro doses of 100 to 750 μg/mL for 24 hours, fluoroquinolones have induced genotoxicity in the chromosomal aberration test; however, a clinical study of 200 women exposed to ciprofloxacin and norfloxacin during gestation showed no increase in fetal malformations or musculoskeletal defects.[64]

Anecdotal reports in Europe have claimed an association between fluoroquinolones and suicidal behavior, but a study of individuals receiving the drugs for 31 to 180 days could detect no increase in suicidal behavior.[48] Two cases of possible exacerbation of myasthenia gravis have been reported.

Drug interactions

An important drug interaction with fluoroquinolones is the potential increase in CNS toxicity with the concomitant use of NSAIDs and methylxanthines.[33] The combination of sparfloxacin, gatifloxacin, and moxifloxacin with tricyclic antidepressants, erythromycin, phenothiazines, and antiarrhythmic agents (quinidine, procainamide, disopyramide) may increase the risk of torsades de pointes.[33] Fluoroquinolones may reduce the liver clearance of warfarin and procainamide and increase the toxicity of cyclosporine.[33] Cimetidine may increase fluoroquinolone blood levels, and antacids and sucralfate may reduce gastric absorption of fluoroquinolones. Fluoroquinolones may induce urine false-positive findings for opioid drugs by immunoassay techniques.

Contraindications

Ciprofloxacin should be used with caution during pregnancy and in children. For children younger than 18 years, other fluoroquinolones are contraindicated.[33] Phototoxicity may occur on skin areas exposed to sunlight, and sunscreens are not always effective.[33]

Aminoglycosides

The era of the aminoglycosides began in 1943 with the isolation of streptomycin by Waksman and the subsequent development of kanamycin (1957), gentamicin (1963), tobramycin (1968), amikacin (1972), and netilmicin (1975). Aminoglycosides are amino sugars bound by glycosidic bridges to a hexose nucleus.

Chemistry

Streptomycin is produced by *Streptomyces griseus*. Other aminoglycosides are elaborated by various species of *Streptomyces*

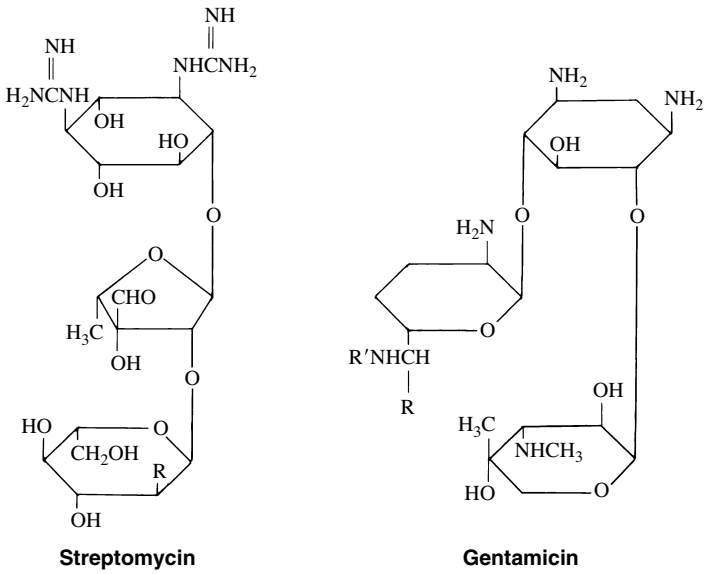

FIGURE **39-11** Structural formulas of streptomycin and gentamicin. R for streptomycin is CH_3NH. Commercial preparations of gentamicin contain three closely related gentamicins: C_1 (R = CH_3, R′ = CH_3), C_{1a} (R = H, R′ = H), and C_2 (R = CH_3, R′ = H).

and *Micromonospora* or, in the case of amikacin and netilmicin, are semisynthetic derivatives of naturally occurring aminoglycosides. As the name implies, these agents consist of a highly polar amino base attached by glycosidic linkage to one or more sugars. Streptomycin is composed of three elements: streptidine (the amino base) and the two sugar moieties streptose and N-methyl-glucosamine (Figure 39-11).

Mechanism of action and antibacterial spectrum

Aminoglycosides bind irreversibly to the 30S ribosome to interfere with the reading of the microbial genetic code and to inhibit protein synthesis. Aminoglycosides are generally bactericidal, and their efficacy in several cases can be greatly enhanced by the concomitant use of cell wall–inhibiting β-lactams and glycopeptides.

The activity of aminoglycosides is primarily directed toward gram-negative bacilli and mycobacteria. The spectrum includes Enterobacteriaceae and *P. aeruginosa*. There are some differences among aminoglycosides regarding their efficacy toward specific microorganisms: amikacin for gentamicin-resistant gram-negative bacilli, gentamicin and doxycycline for brucellosis, gentamicin and penicillins for *Campylobacter* infective endocarditis, tobramycin for *Acinetobacter* and *P. aeruginosa*, and streptomycin for tularemia and plague. Most Enterobacteriaceae remain sensitive to aminoglycosides. Significant resistance has occurred in enterococci.[29] Gentamicin is the most commonly used aminoglycoside, often acting synergistically with ampicillin, penicillin G, ceftriaxone, vancomycin, and rifampin.[29] Some original indications for aminoglycosides have been supplanted by safer extended-spectrum β-lactams and fluoroquinolones.[29]

Bacterial resistance

Three resistance mechanisms presently exist for aminoglycosides: ribosomal mutations (less affinity for the 30S ribosome), reduced intracellular transport (primarily in staphylococci and pseudomonads), and, most commonly, plasmid-mediated aminoglycoside-modifying enzymes (acetyltransferases, adenyltransferases, and phosphotransferases).

Absorption, fate, and excretion

Aminoglycosides are poorly absorbed orally and do not penetrate well into the CNS, bronchial secretions, or certain microbial cells (e.g., *Rickettsia*, *Chlamydia*) but are effective intracellularly in the treatment of tuberculosis, plague, brucellosis, and tularemia. Aminoglycosides are classic concentration-dependent antibiotics commonly administered in high parenteral doses repeated after the blood levels have decreased to a low concentration (peak and trough dosing). Single daily dosing is becoming more common, taking advantage of the long post-antibiotic effect of aminoglycosides, a reduction in cost, and lessening of renal toxicity. The normal elimination half-life of aminoglycosides is 2 to 3 hours, which can be extended to 24 to 100 hours in end-stage renal disease.[33] Aminoglycosides are excreted primarily by glomerular filtration.

General therapeutic uses

Parenteral aminoglycosides currently available include amikacin, gentamicin, kanamycin, netilmicin, streptomycin, and tobramycin. Kanamycin and neomycin are available for oral use for gastrointestinal infections. Aminoglycosides are primarily indicated for infections caused by gram-negative aerobic bacteria, including *P. aeruginosa*, *Serratia*, *Klebsiella*, *Enterobacter*, and *Proteus*. Aminoglycosides are often combined with a penicillin or cephalosporin for various infections (see Table 39-4). Their use in tuberculosis is described later.

Therapeutic uses in dentistry

Aminoglycosides have no uses in orofacial infections unless dictated by culture and sensitivity tests.

Adverse effects

The major adverse effects of aminoglycosides are renal toxicity and auditory and vestibular ototoxicity.[29] Nephrotoxicity is caused by inhibition of an intracellular lysosomal phospholipase in the renal proximal tubules, resulting in aminoglycoside accumulation and subsequent reduced glomerular filtration, reduced water and Na^+ transport, reduced mitochondrial respiration, and reduced renal protein synthesis resulting in renal necrosis.[29] The incidence of some degree of nephrotoxicity can be 10% to 20%.

A primary target for toxicity of aminoglycosides is the hair cells of the inner ear where the initial loss of the outer hair cells eventually damages the inner ear cochlear hair cells (type II).[29] Further damage may occur to the cochlear sensory epithelium and the spiral ganglion cells required for cochlear implants. Vestibular (type I) hair cell damage occurs at the apex of the macula and often earlier than the cochlear hair cell damage.[37] Initial signs and symptoms are hearing loss at the higher frequencies, which increases with dose, duration,

and noise exposure.[37] The incidence of cochlear damage may be 15%. Other adverse reactions associated with aminoglycosides include neuromuscular blockade of the curare type, rare blood dyscrasias, headache, dizziness, and urticarial and peripheral neuropathy.

Drug interactions

The nephrotoxicity of aminoglycosides is increased by vancomycin, cephalosporins, and methoxyflurane. Loop diuretics increase auditory toxicity.

Vancomycin

Vancomycin is the most important glycopeptide antibiotic, originally isolated from *Streptomyces orientalis* in Borneo in 1956 and introduced into medicine in 1958. Other glycopeptides include teicoplanin and daptomycin. Glycopeptides are seven-membered peptide chains with two sugars, vancosamine and glucose. Vancomycin is poorly absorbed from the gastrointestinal tract and causes severe pain when given intramuscularly. It is administered intravenously to treat systemic infections or orally to treat pseudomembranous colitis. Its elimination half-life is 6 hours, and it has a post-antibiotic effect of 1.5 to 3 hours.

Mechanism of action and antibacterial spectrum

Vancomycin inhibits gram-positive bacterial cell wall synthesis by complexing with the D-alanyl-D-alanine portion of the peptide precursor units to inhibit the transglycosylase reaction in peptidoglycan synthesis.[109] This inhibition is at the second stage of bacterial cell wall synthesis before the action of the penicillins at the third stage. Vancomycin may also affect cytoplasmic membrane permeability and RNA synthesis and, as with the β-lactams, requires active cell replication. Because of its large molecular size, vancomycin cannot traverse the outer cell membrane of gram-negative bacteria.

The activity of vancomycin is almost exclusively against aerobic and anaerobic gram-positive species, including staphylococci, streptococci (*S. pneumoniae*, VGS, β-hemolytic streptococci), *Corynebacterium*, *Peptostreptococcus*, *Enterococcus*, nutritionally variant streptococci (*Abiotrophia*), *Bacillus*, *Listeria*, and *Clostridium*.[109] Occasionally, *N. gonorrhoeae* is susceptible. Vancomycin is a drug of choice against MRSA, methicillin-resistant CoNS, *Corynebacterium jeikeium*, and multiple antibiotic–resistant *S. pneumoniae*. It may also be indicated for serious enterococcal infections and in patients who cannot tolerate β-lactams. *The Medical Letter* lists vancomycin as a drug of choice for MRSA, penicillin-resistant *S. pneumoniae*, MSSA, *S. epidermidis*, *B. cereus*, *B. subtilis*, *Corynebacterium* JK group, and *R. equi* and as an alternative drug for enterococcal endocarditis, VGS, group A and B streptococci, *S. bovis*, *Peptostreptococcus*, and *C. difficile*.[18]

Bacterial resistance

Vancomycin resistance is caused by an altered peptidoglycan terminus (D-ala-D-lac instead of the usual D-ala-D-ala), resulting in reduced vancomycin binding and failure to prevent cell wall synthesis.[15] Resistance in vancomycin-intermediate *S. aureus* and glycopeptide-intermediate *S. aureus* may be due to the production of abnormal peptides ("false binding sites") in the cell wall that bind vancomycin and prevent its attachment to its receptor or possibly to an increase of peptidoglycan resulting in thickened cell walls.[16] A form of resistance is seen in *S. pneumoniae* by a unique mutation in the sensor response system that controls autolysin activity necessary to kill certain bacteria.[75]

General therapeutic uses

Vancomycin is used for serious gram-positive infections caused by such organisms as methicillin-resistant staphylococci and *S. pneumoniae*. It is also useful for non–vancomycin-resistant enterococcal infections. It is effective in treating enterocolitis caused by *C. difficile*; however, metronidazole should be used for this situation if possible because of the significant risk of promoting vancomycin enterococcal resistance. Vancomycin may also be useful in treating multiple antibiotic–resistant VGS infections.

Therapeutic uses in dentistry

Glycopeptides have no uses in the management of acute or chronic orofacial infections unless dictated by laboratory culture and sensitivity tests.

Adverse effects

Major adverse drug reactions associated with vancomycin include transient or permanent ototoxicity, hypotension, reversible neutropenia, renal toxicity, skin rash, and red man (red neck) syndrome. The auditory toxicity of vancomycin is rare if the peak blood levels are maintained less than 40 to 50 μg/mL but can be exacerbated by the combination with aminoglycosides. Red man syndrome results from the direct histamine release from mast cells manifesting as pruritus; erythematous rash of the head, neck, face, and upper torso; and hypotension mimicking anaphylactic shock.[109] This glycopeptide-induced anaphylactoid reaction may occur with the first drug exposure, is tachyphylactic in nature, and can be reduced significantly by the slow infusion of vancomycin over a 1-hour period and premedication with antihistamine drugs.[109] To reduce the development of resistant bacteria, vancomycin use is contraindicated or discouraged for routine surgical prophylaxis.

Drug interactions

Vancomycin-induced nephrotoxicity or ototoxicity is increased with the concomitant use of aminoglycosides and neuromuscular blockade with curare-like agents.

Streptogramins

Quinupristin-dalfopristin, a 30/70 mixture of streptogramins A and B, is approved for intravenous use in the United States.

Mechanism of action and antibacterial spectrum

Quinupristin and dalfopristin bind sequentially to different sites of the 50S subunit of the 70S ribosome to prevent newly synthesized peptide chains from extruding from the ribosome, resulting in cell death. Quinupristin-dalfopristin is used to treat life-threatening vancomycin-resistant *E. faecium* (*Enterococcus faecalis* is resistant) and skin or skin structure infections from *S. aureus* and *S. pyogenes*. The drug is additionally approved in the United Kingdom for nosocomial pneumonia. In vitro, the drug combination is active against *E. faecium*, MRSA, MSSA, methicillin-resistant CoNS, methicillin-sensitive CoNS, penicillin-sensitive and penicillin-resistant *S. pneumoniae*, *N. meningitidis*, *M. catarrhalis*, *L. pneumophila*, *M. pneumoniae*, and *C. perfringens*. Its spectrum closely resembles that of vancomycin and linezolid.

Bacterial resistance

Microbial resistance occurs by three mechanisms: decreased ribosomal binding by methylation of an adenine residue, drug efflux, and enzymatic inactivation. This resistance belongs to the MLS_B type, potentially conferring cross-resistance to all these antibiotics. The streptogramin group also contains virginiamycin and pristinamycin, which have been used for years in some countries as animal growth promoters, resulting in microbial resistance in humans even before the drugs were clinically employed. Currently, intermediate resistance has

been detected in *S. aureus* and *E. faecium*, with vancomycin and streptogramin resistance genes detected on the same plasmid. *E. faecium* resistance may occur during drug use, and quinupristin-dalfopristin selects for superinfection with *E. faecalis*.

General therapeutic uses
Quinupristin-dalfopristin should be reserved for life-threatening and multiple antibiotic–resistant infections from *E. faecium*, staphylococci, and some streptococci encountered primarily in the hospital.

Adverse effects
Adverse effects associated with streptogramins include possible severe arthralgias and myalgias, elevation in conjugated serum bilirubin, and significant inhibition of the liver microsomal CYP3A4 drug metabolizing system.

Drug interactions
Streptogramins decrease the liver metabolism of Ca^{++} channel blockers, immunosuppressant drugs, corticosteroids, several anticancer agents, 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins), HIV protease inhibitors, quinidine, nonsedating antihistamines, sildenafil, opioids, and benzodiazepines.

Oxazolidinones
Oxazolidinones (eperezolid, linezolid) were synthesized in 1987, and linezolid was approved for use in the United States in 2000. Linezolid is the first totally synthetic new antibiotic released in approximately 40 years.

Mechanism of action and antibacterial spectrum
Linezolid has a unique mechanism of action by binding to the 50S ribosome subunit near the interface with the 30S subunit to prevent the initiation complex required for bacterial translation.[17,25,26] This unique mechanism may possibly limit cross-resistance with other antibiotics.[26] Linezolid is approved in the United States for the management of vancomycin-resistant *E. faecium*; nosocomial and community-acquired pneumonia from *S. aureus* and penicillin-sensitive *S. pneumoniae*; and complicated skin and skin structure infections from MRSA, MSSA, methicillin-resistant CoNS, *S. pyogenes*, and *S. agalactiae*.[33]

Linezolid has exhibited in vivo and in vitro bacteriostatic activity against penicillin-resistant VGS, β-hemolytic streptococci, *Bacillus, Listeria, Corynebacterium, M. catarrhalis, P. multocida, B. fragilis,* and antibiotic-resistant mycobacteria.[25] Linezolid has little useful clinical activity against Enterobacteriaceae, *Acinetobacter, P. aeruginosa*, and most gram-negative species, with some activity against mycobacteria and chlamydiae.

Bacterial resistance
Microbial resistance to linezolid has been detected in isolated cultures of vancomycin-resistant enterococci, *E. coli*, and laboratory strains of *S. aureus*. More recent reports of clinical isolates of *E. faecium* and *S. aureus* resistant to linezolid are disconcerting because the drug has been available only for a short time. The mechanism of resistance seems to be a 62,576T mutation in the gene encoding the central loop domain of 23S rRNA.[26]

Absorption, fate, and excretion
Linezolid, with a near 100% oral bioavailability, produces peak blood levels at 1 to 2 hours and can be administered parenterally as well. It has an elimination half-life of 4.4 to 5.5 hours and a post-antibiotic effect of 0.6 to 1.4 hours.[33]

General therapeutic uses
Linezolid is currently highly effective against three of the five most important nosocomial pathogens—*S. aureus, S. pneumoniae,* and *Enterococcus*—and should be reserved for highly resistant and multiple antibiotic–resistant microorganisms. The ability of *S. aureus* to mutate to resistance after only a few months of exposure to the drug is disconcerting. Linezolid has no use in orofacial infections.

Adverse effects
Approximately 2% to 3% of patients receiving linezolid experience nausea and vomiting, diarrhea, headache, tongue discoloration, taste alteration, fungal superinfections, or very rarely pseudomembranous colitis.[33] The most serious adverse reaction is myelosuppression (anemia, leukopenia, pancytopenia, thrombocytopenia), which may occur in an average of 2.4% of patients. Linezolid requires weekly blood monitoring tests. The safety of the drug has not been established beyond 28 days of use. It is classified as an FDA pregnancy category C drug.

Drug interactions
Linezolid is a weak monoamine oxidase inhibitor and should be used with caution with drugs that release catecholamines and foods containing tyramine. Linezolid may precipitate serotonin syndrome (confusion, agitation, seizures, hypertension, tachycardia, sweating, myoclonus, muscle rigidity, trismus, death),[33] but the clinical significance of this drug effect is as yet unknown.

Sulfonamides
The era of effective and safe systemic antibiotic therapy began in 1932 with the discovery by Domagk that a dye (prontosil) protected laboratory animals from streptococcal infections. Domagk determined that the active antibacterial portion of prontosil was sulfanilamide, which was subsequently first used in the United States in 1935. Trimethoprim was introduced in 1968 as a synergistic agent with sulfonamides, and the combination of sulfamethoxazole and trimethoprim is the most commonly used sulfonamide preparation today. The discovery of prontosil by Domagk ranks with the discovery of the anesthetic properties of nitrous oxide by Wells, the work on penicillin by the Oxford group, and the discovery by Jenner of vaccinations as among the greatest of all medical discoveries.

Chemistry
All the sulfonamides are derivatives of *p*-aminobenzenesulfonamide (Figure 39-12). For antibacterial activity, the sulfur must be attached directly to the benzene ring, and the *p*-amino group (N_4) must be a primary amine in vivo. Substitutions on the amino group (N_1) of the sulfonamide moiety confer differences in rates of absorption and excretion of these drugs and, to some degree, in variations of antibacterial activity. Sulfonamides are weak acids with limited water solubility, particularly in solutions of low pH. This property may present problems for the excretion of these drugs in acidic urine.

Mechanism of action and antibacterial spectrum
Sulfonamides and trimethoprim interfere with the microbial synthesis of folic acid necessary for life in some microorganisms. Mammals acquire folic acid from their diet. Sulfonamides competitively inhibit the incorporation of para-aminobenzoic acid (PABA) into tetrahydropteroic acid because the sulfas have a greater affinity for tetrahydropteroate synthetase than PABA (Figure 39-13). Trimethoprim inhibits bacterial dihydrofolate reductase with 50,000 to 100,000 times greater affinity for the bacterial than the human enzyme; this blocks the conversion of dihydrofolic acid to

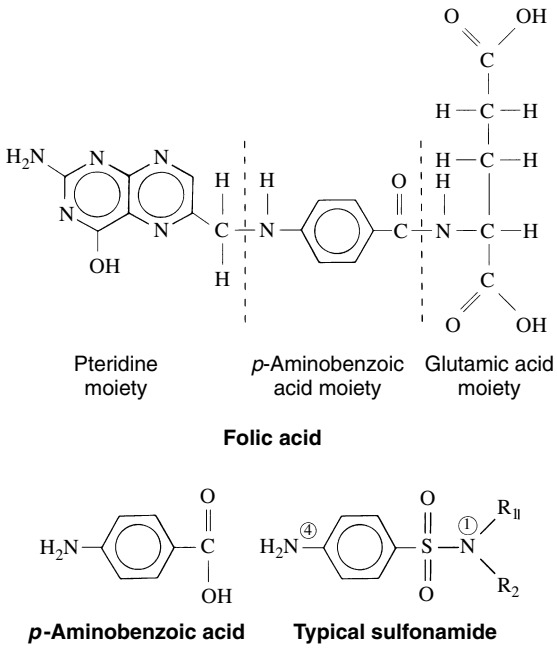

FIGURE **39-12** Structural formulas of folic acid, a sulfonamide, and *p*-aminobenzoic acid.

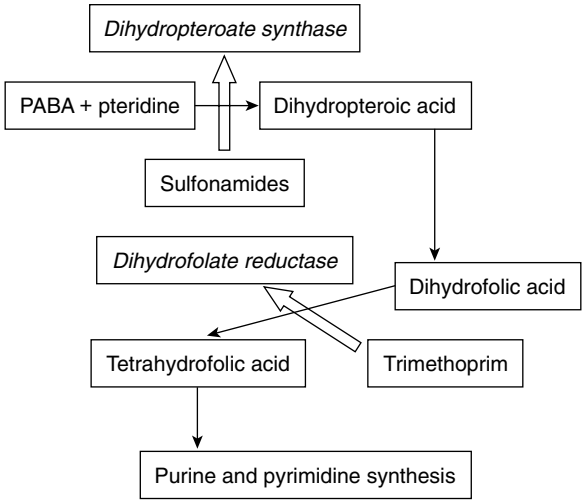

FIGURE **39-13** Sites of inhibition of folic acid synthesis by sulfonamides and trimethoprim. Note the effect of the two drugs on this common pathway and the effect on purine and pyrimidine synthesis. *PABA*, *p*-Aminobenzoic acid.

tetrahydrofolic acid, resulting in the reduced synthesis of folinic acid, purines, and DNA. Sulfonamides and trimethoprim inhibit successive steps in the synthesis of folic acid and eventually bacterial nucleotides and DNA.

Sulfonamides and trimethoprim are intended primarily for respiratory, urinary, and gastrointestinal infections.[18] *The Medical Letter* lists this combination as drugs of choice for *Y. enterocolitica*, *Aeromonas*, *Burkholderia cepacia*, *S. maltophilia*, *Nocardia*, and generally for bronchitis and upper respiratory tract infections and alternative drugs for some Enterobacteriaceae, *M. catarrhalis*, MRSA, *S. pneumoniae*, *Listeria monocytogenes*, *B. henselae*, *Brucella*, *L. pneumophila*, *V. cholerae*, *Yersinia pestis*, *M. marinum*, and *P. pseudomallei*.[18] Species that have intrinsic resistance or that can become highly resistant include enterococci, *B. anthracis*, various Enterobacteriaceae, *P. aeruginosa*, *S. pneumoniae*, and *C. diphtheriae*.

Bacterial resistance

Transferable microbial resistance to sulfonamides and trimethoprim occurs by three principal mechanisms: increased cell permeability barriers and efflux proteins, decreased sensitivity or alterations in target enzymes (dihydropteroate synthase and dihydrofolate reductase), and the acquisition of new target enzymes. Trimethoprim-sulfamethoxazole resistance in *S. pneumoniae* occurs via a single amino acid substitution in dihydrofolate reductase. Chromosomal resistance by mutations in the dihydropteroate synthetase gene occurs in *E. coli*, staphylococci, *P. carinii*, *Campylobacter*, *S. pneumoniae*, *S. pyogenes*, and *N. meningitidis*.

Despite a determined effort to reduce sulfonamide use drastically in the United Kingdom, the resistance rate in *E. coli* not only did not decline but actually increased.[30] As is now common, the resistance genes for trimethoprim-sulfamethoxazole are carried on transposable elements along with the resistance genes for other antibiotics, possibly necessitating the removal of all from the environment before resistance declines.

Absorption, fate, and excretion

Sulfonamides are classified as short-acting, medium-acting, or long-acting. Short-acting to medium-acting agents include sulfisoxazole, sulfamethoxazole, sulfamethizole, and sulfadiazine. Sulfadoxine is a long-acting agent with an elimination half-life 100 to 230 hours. (It is used in combination with pyrimethamine to treat malaria caused by *Plasmodium falciparum*.) Various other sulfonamide preparations include preparations used topically for burns (silver sulfadiazine, mafenide), vaginal preparations, ophthalmic preparations (sulfacetamide), and drugs for the management of ulcerative colitis (salicylazosulfapyridine or sulfasalazine) given orally for local gastrointestinal effects. Oral sulfonamides are 70% to 100% bioavailable (except for sulfasalazine) with a large volume of distribution and ready penetration into the CNS. The drugs are metabolized by acetylation and conjugation in the liver and excreted by glomerular filtration.

General therapeutic uses

The primary clinical uses of a sulfonamide alone or trimethoprim-sulfamethoxazole are acute bronchitis, community-acquired pneumonia, *L. pneumophila* and *P. carinii* pneumonia, uncomplicated urinary tract infections, male genitourinary tract infections, traveler's diarrhea from enterotoxigenic *E. coli*, *Shigella*, *Nocardia asteroides*, toxoplasmosis, malaria (sulfadoxine in combination with pyrimethamine), *N. meningitidis* prophylaxis, trachoma, chancroid, rheumatic fever, and Wegener's granulomatosis. Some sulfonamides are also used in special cases such as in burns and in certain cases of ophthalmic, gastrointestinal, and skin disorders (Table 39-8). There are no indications for sulfonamides and trimethoprim in the management of orofacial infections.

Adverse effects

Approximately 8% of individuals receiving sulfonamides and trimethoprim have some form of adverse reaction, such as nausea and vomiting, blood dyscrasias, and crystalluria (less soluble preparations, such as sulfadiazine, precipitate in the urine), with 3% to 5% experiencing allergy in any of its forms from skin rash and pruritus to major skin eruptions (Stevens-Johnson syndrome, epidermal necrolysis, exfoliative dermatitis, photosensitivity) to anaphylaxis.[33] Stevens-Johnson syndrome is much more likely to occur with long-acting sulfonamides. Of patients with AIDS, 70% have some form of skin rash and fever from sulfonamides and trimethoprim.

TABLE **39-8**

Classification, by Use, of Selected Sulfonamide and Trimethoprim Preparations

USE	NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME
Systemic infections	Sulfadiazine	—
	Sulfamethoxazole*	Gantanol
	Sulfisoxazole*	Gantrisin
	Erythromycin-sulfisoxazole	Eryzole, Pediazole
	Trimethoprim*	Proloprim, Trimpex
	Trimethoprim-sulfamethoxazole*†	Bactrim, Cotrim, Septra, Sulfatrim
Urinary tract infections	Sulfamethizole	Thiosulfil Forte
Dermatitis herpetiformis	Sulfapyridine	—
Local use in gastrointestinal tract	Sulfasalazine	Azulfidine
Ophthalmic use	Sulfacetamide sodium	Bleph-10, Sodium Sulamyd
Acne	Sulfacetamide sodium	Plexion
Topical use, burns	Mafenide	Sulfamylon
	Silver sulfadiazine	Silvadene

*These drugs are also used in the treatment of urinary tract infections.
†Also used in the treatment of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia in AIDS patients.

Drug interactions
Trimethoprim-sulfamethoxazole increases the clinical activity of oral anticoagulants, thiopental, methotrexate, hydantoins, sulfonylureas, and tolbutamide and decreases the activity of cyclosporine.[33] Sulfonamides are displaced from plasma protein by aspirin, other NSAIDs, and probenecid. PABA (present in some health foods) competes against the effect of sulfonamides.

Contraindications
Contraindications for the use of sulfonamides include allergy to sulfonamides and other related drugs, such as sulfonylureas and thiazide, loop, and carbonic anhydrase inhibitor diuretics. Health foods and possibly sunscreens containing PABA are contraindicated because PABA competes against the sulfonamide.

Chloramphenicol

Chloramphenicol (Chloromycetin) is a broad-spectrum antibiotic isolated in 1949 from *Streptomyces venezuelae*. It is bacteriostatic because of its inhibition of bacterial protein synthesis by reversible binding to the peptidyl transferase component of the 50S ribosomal subunit. Chloramphenicol is unique among naturally occurring antibiotics because it contains a nitrobenzene group, which is attached to a propanediol moiety linked to a dichloroacetamide side chain. Its structure is illustrated in Figure 39-14. Resistance occurs by plasmid-mediated and chromosomally mediated chloramphenicol acetyltransferase, which metabolizes chloramphenicol to an inactive form.

Chloramphenicol may be active against a wide range of microorganisms including gram-positive and gram-negative bacteria, spirochetes, *Rickettsia*, *Mycoplasma*, and *Chlamydia*. Common pathogens sensitive to chloramphenicol include *S. typhi*, other *Salmonella* species, *S. pneumoniae, H. influenzae,* and *N. meningitidis*. Enterococci are variably resistant, and MRSA, methicillin-resistant CoNS, and *P. aeruginosa* are completely resistant. Because of its propensity to induce bone marrow depression and aplasia, chloramphenicol is not the current drug of choice for any infection, but is an alternative drug for gastrointestinal *Bacteroides, C. perfringens, P. mirabilis, Brucella, S. typhi*, other *Salmonella* species, *Francisella tularensis, Fusobacterium, H. influenzae, Pseudomonas mallei, P. pseudomallei, Y. pestis, Chlamydia psittaci*, various *Ehrlichia,*

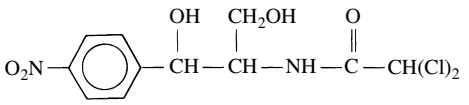

FIGURE **39-14** Structural formula of chloramphenicol.

Vibrio vulnificus, and rickettsial diseases (Rocky Mountain spotted fever, tick-bite fever, Q fever, and typhus).[33]

The most significant adverse reactions associated with chloramphenicol are reversible and irreversible bone marrow depression seen with topical, oral, and parenteral use.[93] The reversible type is dose-related (>4 g/day) and possibly caused by inhibition of mitochondrial protein synthesis resulting in anemia, leukopenia, or thrombocytopenia. "Idiosyncratic" bone marrow aplasia is not dose-related; may begin weeks or months after the drug is stopped; and is manifested by an often fatal aplastic anemia, the incidence of which seem to be 1 in 24,500 to 1 in 40,800 patients receiving chloramphenicol by any route of administration. This incidence is 13 times greater than the spontaneous random occurrence of aplastic anemia in the general population. Topical use is associated with a risk of 3 cases in 440,000 uses. The cause of this idiosyncratic aplastic anemia is unknown, but it may be due to a genetically determined liver metabolite.

The "gray baby syndrome" associated with chloramphenicol is caused by toxicity resulting from the inability of the immature liver of neonates to detoxify the drug by conjugation.[93] The signs and symptoms include abdominal distress, cyanosis, vomiting, circulatory collapse, and possibly death. There are no indications for chloramphenicol in the management of orofacial infections. The drug is rarely used because of its major adverse effects.

Bacteriophages

Bacteriophages are bacterial viruses that invade bacterial cells and can induce cell lysis by disrupting microbial metabolism.[96] Bacteriophages literally punch holes in microbial cell membranes and are among the most ubiquitous entities on earth, found in or on salt and fresh water, soil, plants, animals, and humans. Bacteriophages are composed of either RNA or DNA with a protein coat, have either a spherical or a rod shape, and contain fewer than 10 to several hundred genes.[61] Bacte-

riophages thrive when horizontal transfer of genetic material between microorganisms is common.[61] Bacteriophages came into clinical use in World Wars I and II almost exclusively in Germany, Russia (Georgia), and Eastern Europe (Poland), with claims of 75% to 100% cures of various infections from staphylococci, pseudomonads, *Shigella*, *Salmonella*, *E. coli*, and *K. pneumoniae*.[83]

The difficulties with bacteriophage therapy are lack of clinical proof of efficacy with controlled clinical studies, the potential for autoantibodies developed against bacteriophages that may decrease their efficacy, microbial resistance development, and unknown activity against intracellular pathogens. The merits of bacteriophage therapy include high, but not absolute, specificity for a single pathogenic organism, greatly reducing the risk for superinfections and resistance development; apparent safety, although this has not been studied in clinical trials; and ease of chemical manipulation to affect newly emerging pathogens.[96]

Microbial cells can mutate to resist bacteriophages or not even recognize these entities.[61] As with cationic peptides, if microorganisms develop resistance mechanisms to bacteriophages, humans will have lost another essential host defense mechanism. Proper use of bacteriophages requires very specific identification of the microbial pathogen because they are specific for each individual microbial species, making them of limited or no value in the treatment of polymicrobial disease such as pneumonia and orofacial infections.

Topical Antibiotics

Bacitracin

Bacitracin is a polypeptide antibiotic derived from *B. subtilis* that functions to block cell wall formation by interfering with the dephosphorylation of the lipid compound that carries peptidoglycans to the growing microbial cell wall.[102] The antibacterial spectrum of bacitracin is gram positive and includes staphylococci, streptococci, *Corynebacterium*, and *Clostridium*, with rare resistance seen in staphylococci. Bacitracin is too toxic to be used parenterally, whereas allergic contact dermatitis has been reported occasionally. Bacitracin is commonly combined with neomycin and polymyxin B in over-the-counter topical antibiotic preparations, but evidence for efficacy is limited.[102]

Neomycin

Neomycin is an aminoglycoside derived from *Streptomyces fradiae* and binds to the 30S ribosomal subunit to inactivate bacterial DNA polymerase and cause misreading of the genetic code to produce lethal proteins. Neomycin has a wide antibacterial spectrum against gram-positive and gram-negative bacteria, but is poorly effective against streptococci and *P. aeruginosa*.[102] It is useful as a topical antibiotic and in the management of hepatic coma by reducing nitrogen-producing bacteria in the gastrointestinal tract.[102]

Polymyxin B

Polymyxin B was isolated from *Bacillus polymyxa* and functions as a cationic detergent to disrupt the microbial cell membrane, causing a leak in cell constituents. Its spectrum is gram negative, and it is particularly useful against *P. aeruginosa*. The drug is not used parenterally because it commonly induces paresthesias, ataxia, and slurred speech.

Mupirocin

Mupirocin has a unique chemical structure composed of a short fatty acid chain linked to monic acid; it inhibits bacterial RNA and protein synthesis by binding to isoleucyl-tRNA synthetase to prevent incorporation of isoleucine into the cell wall protein chain.[102] The antimicrobial spectrum for mupirocin includes staphylococci (MRSA, MSSA, methicillin-resistant CoNS), *P. aeruginosa*, streptococci, fungi, anaerobes, and Enterobacteriaceae.[102] Irreversible resistance has been detected in *S. aureus* and CoNS either by altering the binding sites on isoleucyl-tRNA transferase or by a plasmid resistance gene, *mvp*A, which creates a modified isoleucyl tRNA synthetase.[102] Organisms that are inherently resistant include enterococci, *Corynebacterium*, and *P. acnes*. The primary use of mupirocin is as a topical application for skin infections, such as impetigo, folliculitis, burns, and leg ulcers.[102] Mupirocin is also used to reduce or eliminate nasal carriage of staphylococci, particularly MRSA.[102] Its widespread use is associated with an 11% to 63% reinfection rate from resistance development or reinfection from other body areas.[102]

Retapamulin

Retapamulin belongs to a more recently developed group of drugs called the *pleuromutilins*. The drug inhibits protein synthesis by binding to the 50S ribosomal subunit. Retapamulin inhibits *S. pyogenes* and *S. aureus*, even if methicillin-resistant. It also has activity against some gram-negative bacteria and many anaerobes. It is used to treat impetigo.

Urinary Antiseptics

Nitrofurantoin

Nitrofurantoin is prepared in various suspension forms and, as with all urinary antiseptics, has limited bioavailability, low volumes of distribution, and high urinary excretion rates. Its mechanism of action is unknown but may involve inhibition of cell wall formation or DNA synthesis after its enzymatic activation in the bacterial cell.[44] Its antibacterial spectrum includes *E. coli*, *Citrobacter*, *Staphylococcus saprophyticus*, *E. faecalis*, group B streptococci, *K. pneumoniae*, and *Enterobacter*, with inherent resistance in *Proteus*, *Providencia*, *Morganella*, *Serratia*, *Acinetobacter*, and *P. aeruginosa*.[33,44] Adverse drug reactions include severe gastrointestinal upset (nausea and vomiting, anorexia, cramping), hepatitis, pneumonitis, peripheral neuropathy, and bone marrow depression.[33,111] Pulmonary pneumonitis may be acute, subacute, or chronic with an incidence for the acute form of 1 in 100,000 users.[44] Hemolytic anemia may occur in individuals deficient in glucose-6-phosphate dehydrogenase. Nitrofurantoin and the other agents mentioned subsequently are indicated for uncomplicated urinary tract infections and cystitis.

Fosfomycin

Fosfomycin is a broad-spectrum bactericidal drug that is converted in the blood to free acid fosfomycin. Its mechanism of action is to inactivate enolpyruvyl transferase responsible for the condensation of uridine diphosphate-N-acetylglucosamine with *p*-enolpyruvate, one of the initial steps in microbial cell wall synthesis.[33] The antimicrobial spectrum for fosfomycin includes *E. coli*, *E. faecalis*, *Citrobacter*, *Enterobacter*, *K. pneumoniae*, *P. mirabilis*, and *S. marcescens*. Adverse reactions are mild and include diarrhea, vaginitis, rash, and headache. Use of fosfomycin use is commonly restricted to only a single dose because of rapid microbial resistance.[33]

Methenamine

The hydrolysis of methenamine results in the liberation of ammonia and formaldehyde as its active ingredient. The mechanism of action of methenamine is to denature proteins and amino acids.[44] Methenamine has a broad spectrum of activity against *E. coli*, staphylococci, and enterococci, with significant resistance in *E. aerogenes*, *P. vulgaris*, and *P. aeruginosa*.[33] Adverse reactions include pruritus, urticaria, nausea and vomiting, cramping, headache, dizziness, proteinuria, hematuria, and precipitation of urate crystals in the urine.[33]

Nalidixic acid

Because of its high microbial resistance rates and CNS toxicity, the quinolone nalidixic acid is presently relegated to the management of urinary tract infections from gram-negative microorganisms, including *K. pneumoniae*, *E. coli*, *P. mirabilis*, *P. vulgaris*, and *Providencia*. *P. aeruginosa* is resistant to nalidixic acid. Its mechanism of action is the same as the fluoroquinolones. More specifically, it causes the inhibition of DNA gyrase and topoisomerase IV. The major adverse effects are CNS toxicity (dizziness, weakness, headache, papilledema, and rare seizures and psychosis), blood dyscrasias, photosensitivity, and hemolytic anemia in glucose-6-phosphate dehydrogenase–deficient individuals.

Drugs Used to Treat Tuberculosis

Successful treatment of tuberculosis caused by *M. tuberculosis* became possible only with the advent of chemotherapeutic agents. Multidrug-resistant strains of *M. tuberculosis* have arisen, especially among patients with HIV/AIDS. Because of the rapid development of antimicrobial resistance in strains of *M. tuberculosis*, a combination of agents is always employed for treatment. The primary antituberculosis drugs are isoniazid, rifampin, pyrazinamide, ethambutol, and streptomycin. For recurrent infections or cases that exhibit microbial resistance, secondary drugs are available, including ethionamide, cycloserine, amikacin, kanamycin, capreomycin, ciprofloxacin, ofloxacin, and aminosalicylic acid. These agents are generally less active and often more toxic than the primary drugs.

Typical therapy consists of isoniazid, rifampin, and pyrazinamide for 2 months followed by isoniazid and rifampin for 4 months or, alternatively, isoniazid and rifampin for 9 months.[18] Until the results of sensitivity tests dictate the regimen, tuberculosis therapy should begin with four drugs—isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin—for 2 months, followed by 4 months of isoniazid and rifampin.[18] Other options are available in multidrug-resistant tuberculosis. The pharmacologic features of isoniazid, rifampin, pyrazinamide, and ethambutol are described here. Streptomycin, an aminoglycoside antibiotic, has been previously discussed.

Isoniazid

Isoniazid, the name of which derives from its chemical designation of isonicotinic acid hydrazide, is the most important drug for the treatment and prophylaxis of tuberculosis. Its spectrum of activity is limited, however, to *M. tuberculosis* and one species of atypical mycobacteria, *M. kansasii*.

Isoniazid inhibits the synthesis of mycolic acids, unique and necessary components of the cell wall of mycobacteria. The drug is bactericidal to actively growing tubercle bacilli but not to dormant organisms. Resistance to isoniazid occurs by spontaneous mutation of the bacterial chromosome (at a rate of 1 in 106 divisions), resulting in the failure of the bacterium to take up the drug, possibly as a result of an alteration in mycolic acid synthesis. Most established infections can be expected to harbor at least several resistant bacteria. There is no cross-resistance between isoniazid and other antituberculosis drugs except ethionamide.

Isoniazid is well absorbed after either oral or parenteral administration, but the oral route is preferred for reasons of convenience and maximum therapeutic effect. The drug is well distributed into all body fluids, including the caseous material of the tubercle-infected foci. Isoniazid is mainly metabolized in the liver and excreted in the urine as metabolites. Genetic differences in the rate of biotransformation are seen, but these seem to have little effect on therapeutic efficacy. The plasma half-life is prolonged in patients with hepatic dysfunction.

One important adverse reaction with isoniazid is peripheral neuritis caused by an isoniazid-induced increase in the excretion of pyridoxine. This adverse effect is more common in slow acetylators. This reaction and other symptoms of pyridoxine deficiency can be prevented by prophylactic administration of vitamin B_6 (15 to 50 mg daily). Other adverse effects include allergic reactions (fever, rashes, hepatitis), fatal hepatic necrosis (rarely), xerostomia, epigastric distress, hematologic reactions, and convulsions in seizure-prone patients (although administration of isoniazid to patients taking phenytoin has not been problematic except for the potential of pharmacokinetic effects on phenytoin metabolism). A nonallergic hepatitis of some severity has also been reported, and subsequent studies have shown that the incidence of hepatic damage increases with age and in individuals who regularly drink alcohol.

Isoniazid is effective prophylaxis against tuberculosis and approved for single-drug therapy for prophylaxis. It is also the most important drug used in tuberculosis therapy for reasons of effectiveness, expense, convenience of administration, and relative safety.

Rifampin

Rifampin is a semisynthetic derivative of one of the rifamycins, a group of macrocyclic antibiotics produced by *Streptomyces mediterranei*. Rifampin is effective against numerous gram-positive and gram-negative bacteria in addition to *M. tuberculosis* and most other species of *Mycobacterium*. Its mechanism of action involves inhibition of DNA-dependent RNA polymerase. Mammalian RNA polymerase does not bind the drug, and RNA synthesis in host cells is unaffected. Resistance can develop rapidly to rifampin, frequently in a single step, by alteration of the target enzyme.

Rifampin is generally well absorbed from the gastrointestinal tract after oral administration. The drug is distributed throughout the body and imparts an orange-red color to the urine, saliva, sweat, tears, sputum, and feces. It is secreted in the bile and undergoes enterohepatic recirculation, prolonging its half-life. Elimination occurs by hepatic deacetylation and excretion in the urine and feces.

Rifampin may be useful in prophylaxis of tuberculosis in contacts of patients infected with isoniazid-resistant organisms. The drug has proven effective in certain diseases refractory to conventional therapy, such as rifampin in combination as an option in treating resistant *S. pneumoniae* and methicillin-resistant staphylococci.

The incidence of adverse reactions to rifampin is low (4%), and the most common is liver toxicity. Gastrointestinal disturbances, suppression of T-lymphocyte function, neurologic disorders, and various allergic reactions, including soreness of the mouth and tongue, have been reported. Decreased effectiveness of oral anticoagulants, oral contraceptives, estrogens, and glucocorticoids has occurred with concomitant administration of rifampin because rifampin induces liver microsomal enzymes. If the drug is used sporadically, a flulike syndrome (possibly immune related) may develop, sometimes leading to renal failure, hepatorenal syndrome, hemolysis, and thrombocytopenia. The drug should be taken according to a prescribed regimen. Because rifampin can cause a reddish orange color in body fluids, staining of soft contact lenses may occur.

Rifabutin

Rifabutin is chemically similar to rifampin and acts by a similar mechanism. Rifabutin is not as potent an inducer of cytochrome P450 enzymes as rifampin and offers the advantage of not interacting with other drugs to the extent that rifampin does. It is useful in treating patients who have HIV/AIDS because it has less interaction with protease inhibitors and non-nucleosidase reverse transcriptase inhibitors. Adverse effects include uveitis and neutropenia but are otherwise similar to those of rifampin.

Rifapentene
Rifapentine is a long-acting rifampin-type drug that has a similar mechanism of action and similar adverse effects. It can be used twice weekly for initial treatment and once weekly during the long-term phase of treatment.

Pyrazinamide
Pyrazinamide is the pyrazine analogue of nicotinamide. It had widespread use in the 1960s but proved to be hepatotoxic in the doses used and was relegated to secondary status after the development of isoniazid and rifampin. More recently, pyrazinamide in reduced dosage has re-emerged as the third most important antituberculosis agent.

Pyrazinamide is active against various mycobacteria, including *M. tuberculosis*. It seems to function as a prodrug, relying on amidase enzymes in the mycobacteria to convert it to the active pyrazinoic acid form. Resistance to the drug in *M. tuberculosis* infection is associated with the loss of pyrazinamidase activity. The mechanism of action of pyrazinamide is inhibition of mycolic acid synthesis, most likely by inhibiting fatty acid synthase I.

Pyrazinamide is well absorbed after oral administration and is distributed throughout the body. It is metabolized primarily in the liver and excreted largely in the urine. Although pyrazinoic acid is an intermediate metabolite, it may be inactive against intracellular mycobacteria because it is not taken up intracellularly.

Pyrazinamide is administered with other antituberculosis drugs to decrease the duration of therapy required to effect a cure of uncomplicated tuberculosis. Hepatotoxicity is the most common adverse effect, but this has been less evident with the lower dosages currently used. Other toxic effects associated with current regimens are relatively benign or infrequent. Gastrointestinal disturbances, arthralgias, fever, and rash have been noted. Pyrazinamide may cause hyperuricemia, and the drug represents a risk in patients with gout.

Ethambutol
Ethambutol is a synthetic agent that inhibits arabinosyl transferases, which are important in cell wall synthesis of sensitive mycobacteria. It is active against almost all strains of *M. tuberculosis* and *M. kansasii*. Other *Mycobacterium* species show variable sensitivity, and other bacteria are not affected by the drug. Ethambutol is tuberculostatic, and resistance develops, although slowly, if it is used alone.

Ethambutol is given orally because of good absorption from the gastrointestinal tract. Distribution into various body compartments is adequate. The major route of excretion of ethambutol is by renal tubular secretion and glomerular filtration, with the drug appearing in the urine mostly as unchanged drug and as two metabolites. Dosage adjustment is required in the presence of renal impairment.

Adverse reactions to ethambutol are infrequent, the most notable being optic neuritis, with symptoms of decreased visual acuity and loss of the ability to perceive the color green. Other adverse effects include gastrointestinal upset; peripheral neuritis; allergic reactions, usually appearing as skin rashes or drug fever; and increased retention of uric acid.

Second-line drugs
A number of second-line drugs are used to treat tuberculosis. These are useful in cases of resistance to first-line drugs and include streptomycin, ethionamide, capreomycin, kanamycin, amikacin, aminosalicylic acid, cycloserine, and select members of the fluoroquinolone group of drugs.

Drugs Used to Treat Leprosy

Although leprosy is rarely seen in the United States, the World Health Organization estimates that 12 million cases exist throughout the world. Leprosy is a bacterial disease caused by the tubercle bacillus *M. leprae*. Five clinical types of leprosy are recognized, ranging from the skin lesion of tuberculoid leprosy to the neuropathies and spontaneous amputations occurring in disseminated lepromatous disease. Patients may be infectious or noninfectious, depending on the type, duration, and effectiveness of therapy. In general, this disease can be treated successfully with drugs. Treatment may be 2 to 4 years or extend throughout the patient's life, depending on the severity and type of disease.

Dapsone is the major drug used in the treatment of leprosy. It belongs to a group of drugs called *sulfones,* which are chemical relatives of sulfonamides. Dapsone is bacteriostatic against *M. leprae,* with a mechanism of action similar to that of sulfonamides. Dapsone is used orally. Other drugs, normally used in combination with dapsone, are rifampin and clofazimine. Clarithromycin, minocycline, and ofloxacin may also be beneficial.

ANTIBACTERIAL ANTIBIOTICS*

Nonproprietary (generic) name	*Proprietary (trade) name*
Aminoglycosides	
Amikacin	Amikin
Gentamicin	Garamycin, Jenamicin
Kanamycin	Kantrex
Neomycin	Mycifradin
Netilmicin	Netromycin
Paromomycin	Humatin
Streptomycin	—
Tobramycin	Nebcin
Antituberculosis drugs (not included elsewhere in this list)	
Aminosalicylate sodium	Tubasal
Capreomycin	Capastat Sulfate
Cycloserine	Seromycin
Ethambutol	Myambutol
Ethionamide	Trecator-SC
Isoniazid	Nydrazid
Pyrazinamide	—
Rifabutin	Mycobutin
Rifampin	Rifadin, Rimactane
Rifapentine	Priftin
Topical antibiotics	
Bacitracin	Baciguent
Mupirocin	Bactroban
Neomycin	Myciguent
Polymyxin B	Aerosporin
Retapamulin	Altabax
Bacitracin with neomycin and polymyxin B	Neosporin
Miscellaneous agents	
Chloramphenicol	Chloromycetin
Clofazimine	Lamprene
Colistimethate	Coly-Mycin M
Colistin	In Coly-Mycin S
Dapsone	—
Daptomycin	Cubicin

ANTIBACTERIAL ANTIBIOTICS*—cont'd

Nonproprietary (generic) name	*Proprietary (trade) name*
Fosfomycin	Monurol
Lincomycin	Lincocin
Linezolid	Zyvox
Methenamine	Hiprex, Mandelamine, Urex
Metronidazole	Flagyl
Nitrofurantoin	Furadantin, Macrodantin
Quinupristin-dalfopristin	Synercid
Spectinomycin	Trobicin
Telithromycin	Ketek
Tigecycline	Tygacil
Troleandomycin	TAO
Vancomycin	Vancocin

*Agents not shown here are listed in various tables throughout this chapter.

CHAPTER 40

Antifungal and Antiviral Agents

NO-HEE PARK AND MO K. KANG

Although the management of systemic fungal and viral diseases lies within the realm of medicine, the dentist is called on to treat localized and superficial lesions in and around the oral cavity. This chapter discusses drugs that are useful in the management of such localized lesions and drugs whose use may indicate that a patient has a potentially communicable disease, a defective immune response, or both.

ANTIFUNGAL AGENTS

Fungal diseases may take the form of superficial infestations involving the skin or mucous membranes or systemic (deep) infections involving various internal organs. Superficial mycoses are generally managed with topical drugs. Topical agents discussed in this chapter are agents with activity against mucocutaneous infections caused by *Candida albicans*, the fungus most commonly observed in oral lesions. Often these infections are benign, as in denture stomatitis, but they may indicate a serious medical condition, such as immunodeficiency.

Systemic fungal infections are subdivided into two groups according to the status of the patient and the type of infecting organism. Opportunistic mycoses occur in debilitated and immunocompromised patients, such as patients with acquired immunodeficiency syndrome (AIDS), leukemia, or lymphoma, and in patients who are receiving immunosuppressive agents or broad-spectrum antibiotics. Fungi involved include *Candida*, *Aspergillus*, and *Cryptococcus* species and various *Phycomycetes*. They are particularly dangerous and carry a high mortality rate.[59] Endemic mycoses are caused by various pathogens distributed unevenly throughout the world and have a low incidence in temperate climates. Examples of endemic mycoses that occur in the United States include blastomycosis, histoplasmosis, coccidioidomycosis, and sporotrichosis.

A number of antifungal agents have been developed (Table 40-1). Two polyene antibiotics are amphotericin B, an important drug for many deep mycoses,[1] and nystatin, an agent useful in the treatment of oral candidiasis. A third polyene, natamycin, is limited to ophthalmologic use. Miconazole, ketoconazole, and clotrimazole are representative imidazole antifungals. First introduced in 1981, ketoconazole was a major advance in systemic antifungal therapy. Clotrimazole has become a widely used topical agent. Itraconazole and fluconazole are triazole derivatives. Voriconazole and posaconazole are newer additions to the broad-spectrum triazoles that are valuable for severe fungal infections in immunocompromised patients. A new class of antifungals known as *echinocandins* comprises caspofungin, micafungin, and anidulafungin; these agents exhibit fungicidal activities against many fungal isolates.

Other antifungal drugs include flucytosine, tolnaftate, and griseofulvin. Flucytosine is a pyrimidine analogue used infrequently as a single agent but commonly used with amphotericin B for severe fungal infections. Tolnaftate is a thiocarbamate used as a topical agent for dermatophytosis. Griseofulvin is also effective against dermatophytosis and has a unique mechanism of action in binding to keratin in human skin and to microtubules of dermatophytes, inhibiting the fungal cell mitosis.

Polyene Antifungal Drugs

Polyene antifungal drugs consist primarily of amphotericin B and nystatin, which are among the earliest antifungal drugs that became available for clinical uses. These drugs show a wide spectrum of antifungal activity against common superficial and deep fungal infections, such as candidiasis, aspergillosis, zygomycosis, and cryptococcosis.[24] The primary mode of their antifungal activity results from binding to ergosterol, a component of the cell membrane of sensitive fungi.[49] This binding forms channels in the cell membrane, altering its permeability and causing leakage of Na^+, K^+, and H^+ ions. Polyenes also bind to a lesser extent to cholesterol of mammalian plasma membrane, which accounts for most of the toxicity associated with the systemic use of amphotericin B. In addition, amphotericin B may stimulate the function of host macrophages, and this immunomodulation is mediated by the oxidized form of amphotericin B.[15] Finally, amphotericin B increases the ability of *C. albicans* to induce the synthesis of tumor necrosis factor-α.[88] Resistance to polyenes is associated with a replacement of ergosterol with other sterols in the fungal plasma membrane. A parallel decline in virulence generally occurs, however, and resistance has not been a problem clinically except for rare instances involving *Candida* species other than *C. albicans*.

Amphotericin B

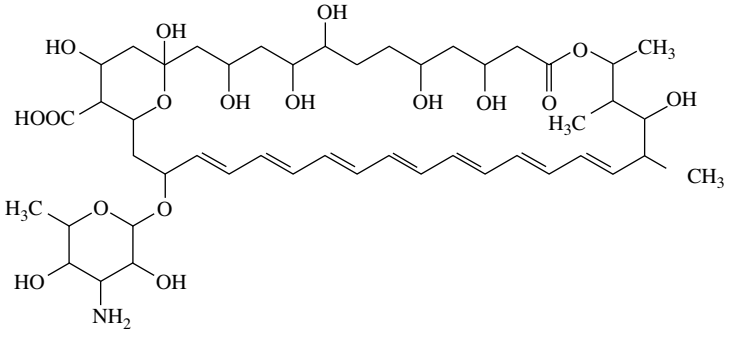
Amphotericin B is an antifungal agent obtained from *Streptomyces nodosus*, an actinomyces found in the soil. It is a member of the polyene family of antibiotics, so called because their structure contains a large lactone (macrolide) ring with numerous conjugated double bonds (Figure 40-1). The polar hydroxylated portion and the nonpolar hydrocarbon sequence lend an amphophilic character to the molecule. Polyenes are unstable in solution because of the unsaturated chromophore region, which is easily photo-oxidized. Amphotericin B exerts either fungistatic or fungicidal activity depending on the concentration of the drug, the pH, and the fungus involved. Peak activity occurs at a pH between 6.0 and 7.5. Amphotericin B

TABLE **40-1**

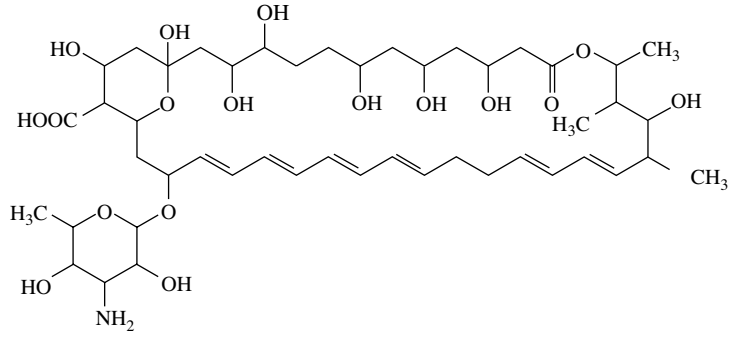
Mechanisms of Action and Clinical Uses of Some Antifungal Agents

ANTIFUNGAL AGENT	MECHANISM OF ACTION	CLINICAL USES
Amphotericin B	Binding to ergosterol of fungal membrane	*Topical:* superficial candidiasis; *intravenous:* severe, progressive systemic fungal infection*
Nystatin	Binding to ergosterol of fungal membrane	*Topical:* oral candidiasis
Clotrimazole	Inhibition of ergosterol synthesis	*Topical:* oral candidiasis, superficial fungal infections†
Fluconazole	Inhibition of ergosterol synthesis	*Oral and intravenous:* systemic and localized candidiasis, cryptococcal meningitis, systemic blastomycosis, coccidioidomycosis, and histoplasmosis
Itraconazole	Inhibition of ergosterol synthesis	*Oral:* systemic fungal infections,* dermatophyte infections and sporotrichosis
Miconazole	Inhibition of ergosterol synthesis	*Topical:* cutaneous candidiasis and vulvovaginitis, superficial fungal infections†
Flucytosine	Inhibition of nucleic acid synthesis	*Oral:* systemic candidiasis and cryptococcosis
Griseofulvin	Disruption of mitotic spindle	*Oral:* dermatophyte infections of skin, hair, and nails
Caspofungin	Inhibition of fungal cell wall synthesis	*Intravenous:* severe, invasive aspergillosis, esophageal candidiasis, candidemia
Micafungin	Inhibition of fungal cell wall synthesis	*Intravenous:* prophylactic antifungal therapy in neutropenic HSCT patients, esophageal candidiasis, candidemia
Anidulafungin	Inhibition of fungal cell wall synthesis	*Intravenous:* esophageal candidiasis, candidemia
Terbinafine	Inhibition of ergosterol synthesis	*Oral and topical:* dermatophyte infections of skin, hair, and nails, and sporotrichosis

*Systemic fungal infections include aspergillosis, blastomycosis, candidiasis, chromomycosis, cryptococcosis, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, phycomycosis, and sporotrichosis. Indications for specific drugs vary.
†Superficial fungal infections caused by pathogenic dermatophytes, yeasts, and *Malassezia furfur*.
HSCT, Hematopoietic stem cell transplantation.



Amphotericin B



Nystatin A_1

FIGURE **40-1** Structural formulas of polyene antifungal agents. Nystatin A_1 is one of three compounds found in the commercial nystatin preparation.

has a broad spectrum of antifungal activity and is effective against *Candida* species, *Histoplasma capsulatum*, *Cryptococcus neoformans,* and *Coccidioides immitis*.

Amphotericin B is not absorbed from the skin or mucous membranes and is poorly and inconsistently absorbed from the gastrointestinal tract. Because of its insolubility in an aqueous medium, the drug is reconstituted in a solution of the bile salt deoxycholate immediately before use. For systemic infections, amphotericin B is administered by slow intravenous infusion (over 2 to 6 hours each day). The drug is bound in plasma to various lipoproteins and in tissues to cholesterol-containing membranes. More recent studies

showed that amphotericin B lipid complex or liposomal amphotericin B preparations could be used for systemic infections, particularly in premature infants and other immunocompromised patients.[50] Amphotericin B can also be prepared in colloidal dispersion with sodium cholesteryl sulfate in a 1 : 1 discoidal complex. Colloidal amphotericin B showed reduced peak plasma levels, prolonged residence time, and reduced renal toxicity and hepatotoxicity compared with conventional amphotericin B preparations.[41]

The exact metabolic pathway of amphotericin B is unknown, but most of the drug is biotransformed and slowly excreted by the kidney over the next 2 months. The plasma concentration of amphotericin B is unaffected by renal disease; no dosage adjustment needs to be made in patients with compromised renal function. Amphotericin B applied topically as a 3% cream, ointment, or lotion is useful in the treatment of superficial *Candida* infections. Because *C. albicans* infection can readily occur in patients receiving broad-spectrum antibiotics, these agents are sometimes administered with amphotericin B or nystatin. The efficacy of fixed-ratio combinations has not been proven, however, and does not reflect sound therapy.

The only adverse effects accompanying the topical application or oral administration of amphotericin B are local irritation and mild gastrointestinal disturbances. As an intravenous agent, however, amphotericin B is the most toxic antibiotic in current use. Intravenous amphotericin B causes many side effects, including hypotension, delirium, fever, nausea, vomiting, abdominal pain, anorexia, headache, and thrombophlebitis. Hypochromic, normocytic anemia is induced by amphotericin B, and leukopenia and thrombocytopenia occur rarely. Allergic reactions of all types have been reported, including anaphylaxis. All patients receiving intravenous amphotericin B show some degree of nephrotoxicity, which may lead to discontinuation of therapy. Permanent damage of the kidneys does not occur, however, in patients receiving a cumulative dosage of less than 4 g during a normal therapeutic interval of several weeks. Great caution should be exercised when amphotericin B is used with other nephrotoxic drugs. Because amphotericin B can cause hypokalemia, it can increase digitalis toxicity. The toxic effects of cyclosporine may also be increased.

Nystatin

Nystatin is a polyene antibiotic obtained from *Streptomyces noursei*. Its structure is similar to the structure of amphotericin B (see Figure 40-1). Nystatin is relatively insoluble in water and unstable except as a dry powder.

Nystatin has a spectrum of activity slightly narrower than that of amphotericin B, but is nevertheless active against many species of *Candida*; *Histoplasma*; *Cryptococcus*; *Blastomyces*; and the dermatophytes *Epidermophyton*, *Trichophyton*, and *Microsporum*. Similar to amphotericin B, nystatin is either fungistatic or fungicidal depending on the concentration of the drug present, the pH of the surrounding medium, and the nature of the infecting organism. The mechanism of action of nystatin is also similar to that of amphotericin B. In vitro, some species of *Candida*, such as *Candida tropicalis*, can develop resistance to nystatin, but resistance is rarely observed clinically.

Nystatin is not appreciably absorbed from the skin, mucous membranes, or gastrointestinal tract. After oral administration, the bulk of the administered dose appears unchanged in the feces. Because of unacceptable systemic toxicity, nystatin is never given parenterally. A newer form of nystatin encapsulated in liposomes showed reduced systemic cytotoxicity, however, making it an active systemic antifungal agent.[38] Also, liposomal nystatin has been suggested to target *Candida* species that are resistant to amphotericin B.[10]

Nystatin is used primarily to treat candidal infections of the mucosa, skin, intestinal tract, and vagina. Although the efficacy of oral nystatin for enteric candidiasis has been questioned, topical nystatin remains a drug of choice for the treatment of candidal infections of the oral cavity (oral moniliasis, thrush, denture stomatitis). It has also been used prophylactically in immunocompromised patients.[64] To treat oral candidiasis, 2 to 3 mL of a suspension containing 100,000 U/mL of nystatin is placed in the mouth, swished, and held for at least 5 minutes before swallowing. This regimen is repeated every 6 hours for at least 10 days or for 48 hours after remission of symptoms. Alternatively, 1 to 2 lozenges (200,000 U per each) may be used four to five times per day. For denture stomatitis, nystatin ointment (100,000 U/g) can be applied topically every 6 hours to the tissue surface of the denture.

Nystatin is well tolerated. Only mild and transient gastrointestinal disturbances, such as nausea, vomiting, and diarrhea, have occurred after oral ingestion. The major complaint associated with nystatin is its bitter, foul taste.

Imidazole and Triazole Antifungal Drugs

Imidazoles and triazoles (together called *azoles*) are synthetic compounds that belong to the azole class of antifungal drugs. The antifungal spectrum of azole antifungal drugs is broad, including yeasts, dermatophytes, and various species of *Histoplasma*, *Coccidioides*, *Paracoccidioides*, *Cladosporium*, *Phialophora*, *Blastomyces*, and *Aspergillus*. Although the mode of action is not fully established, it is known that azoles inhibit an enzyme involved in the synthesis of fungal ergosterol. More specifically, one of the nitrogen atoms of the azole ring binds to the heme moiety of the fungal cytochrome P450 enzyme lanosterol 14-α-demethylase, inhibiting the conversion of lanosterol to ergosterol.[25] The addition of ergosterol fails to reverse the antifungal effect in vitro, however, and other mechanisms must be invoked to explain the activity of these compounds against several protozoa and bacteria in which ergosterol is not an important membrane constituent. The addition of 14-α-methyl sterols such as lanosterol, whose concentrations increase as a result of azole therapy, may disrupt cell membranes even in the presence of ergosterol.

Other antifungal actions ascribed to ketoconazole and similar drugs, perhaps related to the changes caused by lanosterol, include inhibition of purine transport, interference with mitochondrial respiration, and alteration of the composition of nonsterol membrane lipids. Acquired resistance to imidazoles has not been a significant problem clinically; however, it can develop in *C. albicans*.[82] Refractory mucosal candidiasis in immunocompromised patients has been ascribed to the *Candida* species with cross-resistance to clotrimazole and other azole compounds.[65]

Ketoconazole

Ketoconazole (Figure 40-2) is rarely used because of its toxicity and the availability of other azoles. Ketoconazole was the first oral antifungal agent to be approved for the treatment of deep systemic mycoses. It is well absorbed from the gastrointestinal tract, provided that the stomach content is acidic. Drugs that increase gastric pH, such as antacids and H_2 antihistamines, markedly reduce its absorption.[54] It should be reserved for cases refractory to other therapy.[11,66,80]

The drug should be used cautiously because severe hepatotoxicity occurs in approximately 0.01% of individuals. Ketoconazole markedly inhibits the synthesis of testosterone and estradiol, which may lead to gynecomastia and menstrual irregularities. Alterations of adrenal steroid synthesis may also occur. Ketoconazole inhibits the metabolism of cyclosporine, phenytoin, sulfonylureas, warfarin, and several other drugs. Isoniazid increases the metabolism of ketoconazole.

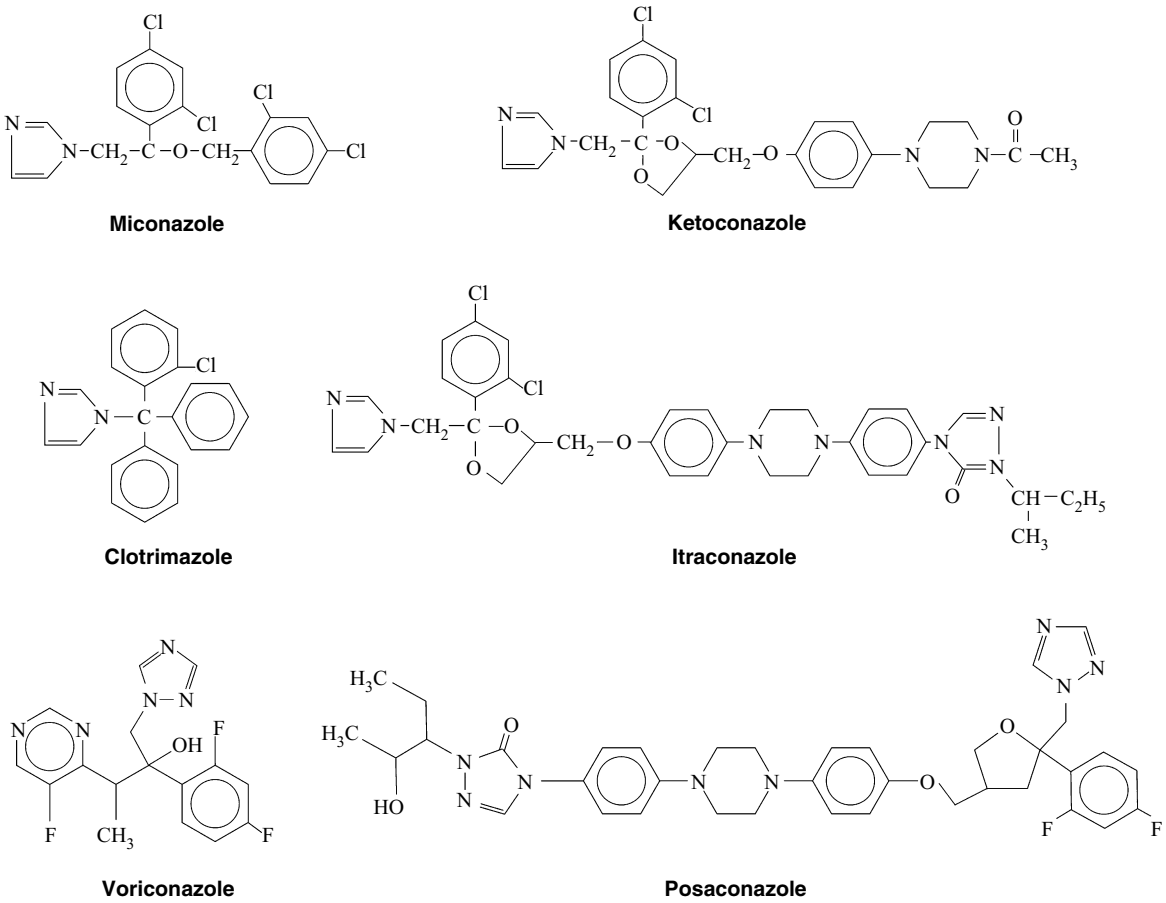


FIGURE **40-2** Structural formulas of several imidazole and triazole antifungal agents.

Miconazole

Miconazole (see Figure 40-2) was the first imidazole antifungal drug to be approved for topical and parenteral use. It is no longer used systemically. Cutaneous candidiasis and vulvovaginitis caused by *C. albicans* respond rapidly and reliably to 2% miconazole nitrate cream. Oral candidiasis is also effectively treated; however, a specific formulation for intraoral use is unavailable. Other topical uses of miconazole are treatment of cutaneous dermatophyte infections caused by *Epidermophyton*, *Microsporum*, and *Trichophyton*. Untoward effects after topical administration of miconazole are rare, but burning, skin maceration, itching, and redness can develop.

Clotrimazole

Clotrimazole is an imidazole antifungal drug used for various mucosal and cutaneous infections. The antifungal spectrum and mechanism of action are similar to other azoles. Clotrimazole is restricted to topical use. A preparation specifically suited for intraoral application is marketed.

For treatment of oral candidiasis, clotrimazole is available as a 10-mg troche. Slow dissolution in the mouth results in the binding of clotrimazole to the oral mucosa, from which it is gradually released to maintain at least fungistatic concentrations for several hours. The swallowed drug is variably but poorly absorbed. It is metabolized in the liver and eliminated in the feces along with the unabsorbed drug.

One troche dissolved in the mouth five times a day for 2 weeks is the standard regimen for oropharyngeal candidiasis. Patient compliance is believed to be enhanced by the more pleasant taste of clotrimazole compared with nystatin. Clotrimazole also seems to be useful for the topical treatment of oral candidiasis in patients with AIDS.[80,88,89] For cutaneous candidiasis and dermatophytoses, a 1% cream or lotion is equivalent to topical miconazole.

Irritation associated with topical clotrimazole, although unlikely, is qualitatively similar to the irritation described in association with miconazole. Occasionally, minor gastrointestinal upset may follow oral ingestion of the drug.

Itraconazole

Itraconazole is a water-insoluble triazole compound that shows a broader spectrum of antifungal activity and a faster clinical effect compared with some other azoles. Similar to ketoconazole, itraconazole is well absorbed from the gastrointestinal tract when it is given with meals. It is highly bound to plasma proteins (>99%) and has a long half-life (approximately 20 hours after a single dose, ≤60 hours at steady state). Although the concentrations of itraconazole in saliva and cerebrospinal fluid are negligible, tissue concentrations are two to five times higher than that of plasma. The drug is mostly metabolized in the liver and partially eliminated in the bile.

When given in therapeutic doses, itraconazole exerts effective antifungal activity against paracoccidioidomycosis, blastomycosis, aspergillosis, histoplasmosis, sporotrichosis, candidiasis, and various dermatophytoses. Previous studies show that itraconazole is effective for suppressive therapy and primary treatment of histoplasmosis in patients seropositive for human immunodeficiency virus (HIV).[55,83] Drug interactions are qualitatively similar to those noted for ketoconazole, but occur less frequently. Itraconazole and related triazoles are more specific for fungal 14-α-demethylase, however, and

do not affect mammalian steroid metabolism as greatly.[23] Adverse effects include rashes, hepatotoxicity, hypokalemia, hypertension, and heart failure in susceptible patients.

Fluconazole

Fluconazole is a water-insoluble, fluorine-substituted bistriazole with effective antifungal activity in immunocompetent and immunocompromised patients. Fluconazole is significantly less potent as an inhibitor of mammalian steroid synthesis, indicating more specific antifungal actions than ketoconazole. It is well absorbed from the gastrointestinal tract (the drug is also available for intravenous injection), weakly bound to plasma proteins (12%), and well distributed throughout the body. Peak plasma concentrations are reached within 2 hours after oral administration; concentrations in the cerebrospinal fluid are generally more than 50% of the corresponding plasma values. Fluconazole has a long plasma half-life of 20 to 50 hours in adults and approximately 17 hours in children. Fluconazole is excreted largely unchanged in the kidney.

Fluconazole is active in suppressive therapy and primary treatment of cryptococcal meningitis, which may occur in patients with AIDS.[46] It is effective in the treatment of mucosal candidiasis, including oropharyngeal and esophageal candidiasis.[11] Weekly use of fluconazole was suggested to have prophylactic value against mucosal candidiasis in HIV-seropositive patients.[71] It is also used in the primary treatment of coccidioidal meningitis and treatment of blastomycosis and histoplasmosis. In one study, fluconazole was found to be more effective against oral candidiasis than nystatin in immunocompromised children.[37] It may also be effective in candidiasis resistant to polyenes and imidazoles.[57]

Nausea, vomiting, gastric pain, headache, and rashes are the most common adverse effects. Increases in serum transaminases have been reported in less than 5% of individuals receiving fluconazole. Seizures, anaphylaxis, and exfoliative dermatitis occur rarely. The drug interactions generally resemble those of itraconazole, but to a lesser degree. Gastric pH has little effect on the oral absorption of fluconazole (antacids and H_2 antihistamines do not interact).

Other imidazoles and triazoles

Terconazole, a member of the triazole antifungal drugs, is supplied in a vaginal suppository for vaginal candidiasis. Butoconazole and tioconazole are imidazoles that are also used topically for vulvovaginitis. Oxiconazole and sulconazole are used topically for infections caused by dermatophytes. Econazole is another imidazole derivative that is used topically for the treatment of dermatophyte and *Candida* infections.

Voriconazole and posaconazole have been developed more recently and represent a new generation of triazole antifungals with enhanced pharmacologic properties. These drugs show broad-spectrum fungicidal activity against molds and fungistatic activity against *Candida* and other yeasts.[48] Voriconazole is a derivative of fluconazole exhibiting increased antifungal activity and specificity. It is the drug of choice for the treatment of invasive aspergillosis caused by *Aspergillus terreus*, which is increasingly observed as a pathogen in immunocompromised patients.[74] Voriconazole is also effective against dimorphic fungi (*Histoplasma*, *Coccidioides*, and *Blastomyces* species), yeasts (*Candida krusei*, *Candida glabrata*, *C. neoformans*, and *Tricosporon asahii*), and pathogenic molds (*Fusarium* and *Scedosporium* species).[40] Adverse side effects of voriconazole include erythematous rash, visual disturbances, hepatotoxicity, and headache.[47] Voriconazole is considered a safer alternative to other antifungals such as amphotericin B for patients at risk of renal dysfunction or receiving concurrent administration of nephrotoxic drugs.[81]

Posaconazole is a newer addition to the antifungal triazoles that structurally resembles itraconazole (see Figure 40-2). The antifungal spectrum of posaconazole is similar to that of voriconazole except that its potential therapeutic efficacy has also been shown against Zygomycetes (e.g., *Rhizopus*, *Absidia*, and *Mucor* species).[27] Voriconazole and posaconazole are effective against a wide variety of *Candida* species. In particular, voriconazole administration led to a higher success rate against *C. tropicalis* compared with amphotericin B and fluconazole.[52] Posaconazole was found to be as effective as fluconazole for the treatment of oropharyngeal candidiasis in patients infected with HIV and led to fewer incidences of clinical relapse.[79] Posaconazole may have extensive uses in dentistry in the future.

Echinocandin Antifungal Drugs

Echinocandins are a new class of antifungal drugs approved recently by the U.S. Food and Drug Administration (FDA) (Figure 40-3). Their unique mechanism of drug action involves noncompetitive inhibition of synthesis of 1,3-β-D-glucan linkages in fungal cell walls.[14] The 1,3-β-D-glucan linkages are crucial for fungal cell wall synthesis and maintaining the osmotic balance. Echinocandins currently available for clinical uses include caspofungin, micafungin, and anidulafungin. Echinocandins are especially useful for treating candidal esophagitis and candidemia and *Aspergillus* infections, for empiric treatments of febrile neutropenia, and for antifungal prophylaxis in hematopoietic stem cell transplant (HSCT) recipients.[60] Caspofungin is also approved for treatment of invasive aspergillosis in patients who are refractory to other antifungal drugs. No echinocandins are approved for pediatric patients.

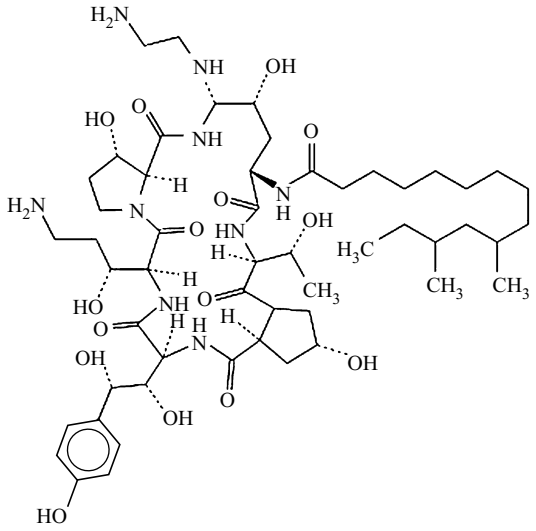
Caspofungin

Caspofungin (see Figure 40-3) is derived from the fermented by-product of *Glarea lozoyenisi*. It is the first echinocandin approved by the FDA for clinical use. It is an echinocandin with antifungal activity against a wide variety of fungal pathogens, including *Candida*,[8] *Pneumocystis*, *Aspergillus*, and *Histoplasma* species. Caspofungin disrupts the formation of the fungal cell wall by inhibiting the enzyme 1,3-β-D-glucan synthase, which is necessary for β(1,3)-D-glucan polymerization in filamentous fungi. Because this mechanism of action differs from those of amphotericin B and the azole compounds, combination therapy using caspofungin with other antifungal agents has been suggested and has yielded synergistic effects against cryptococcal species.[30] Caspofungin showed higher therapeutic efficacy against candidal infections compared with amphotericin B in immunocompromised patients.[15,44]

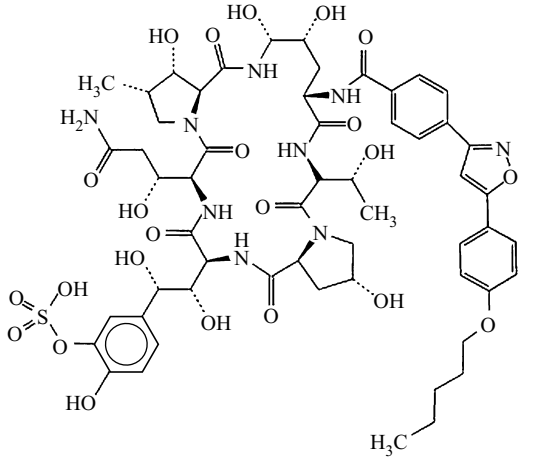
Caspofungin is of particular importance in patients with life-threatening systemic fungal infection who cannot tolerate amphotericin B or azole therapy; it is generally well tolerated when administered parenterally. The manufacturer recommends intravenous infusion of 70 mg of caspofungin acetate for the first day, followed by 50 mg/day thereafter. Common adverse effects resemble histamine-mediated symptoms, such as rash, facial swelling, pruritus, or sensation of warmth. One case of anaphylaxis was also reported with the initial administration of the drug.

Micafungin

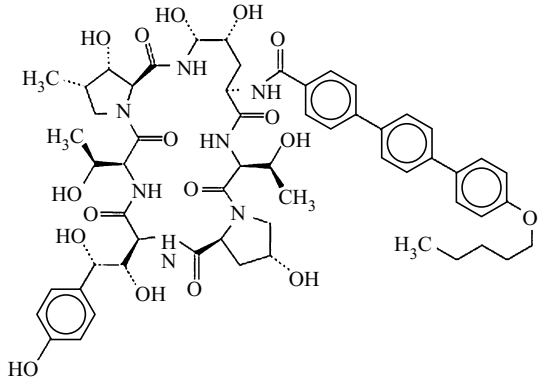
Micafungin is a synthetic derivative of lipopeptides isolated from *Coleophoma empetri*. It is approved for therapeutic use against esophageal candidiasis and for chemoprophylaxis against candidiasis in neutropenic patients undergoing HSCT.[60] Fluconazole has been the primary drug of choice for chemoprophylaxis against candidiasis and aspergillosis in HSCT patients. A comparative phase III clinical trial of antifungal prophylactic efficacy showed superior results, however, with micafungin compared with fluconazole.[77] Among 889 adult and pediatric patients enrolled for HSCT, 50 mg of



caspofungin



micafungin



anidulafungin

FIGURE **40-3** Structural formula of echinocandin antifungals.

micafungin administered daily to patients yielded an 80% success rate versus 73.5% in patients who received 400 mg daily dose of fluconazole. Also, the patients receiving micafungin prophylaxis reported fewer side effects and fewer incidences of discontinued therapy compared with patients receiving fluconazole prophylaxis.

Micafungin was found to be as effective as fluconazole against esophageal candidiasis with a similar spectrum of adverse effects in HIV patients.[29] A more recent study also showed a comparable level of therapeutic efficacy of micafungin against candidemia and invasive candidiasis as liposomal amphotericin B when both drugs were delivered as an intravenous infusion.[53] Compared with amphotericin B, micafungin treatment led to significantly fewer adverse effects, such as hypokalemia, rigors, back pain, infusion-related reactions, and nephrotoxicity. Micafungin is considered a well-tolerated addition to the antifungal armamentarium. Micafungin is given at a daily infusion dose of 150 mg for esophageal candidiasis and 50 mg for antifungal prophylaxis.

Anidulafungin

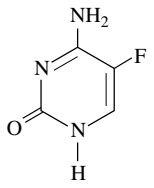
Anidulafungin is derived from *Aspergillus nidulans*. It is the newest addition to echinocandin antifungals approved for esophageal candidiasis, candidemia, and invasive candidiasis. Anidulafungin showed potent and broad antifungal activity against *Candida* and *Aspergillus* species, including species resistant to fluconazole.[67] Compared with azole antifungals, anidulafungin was more effective in vitro against *C. albicans*, *C. tropicalis*, *C. glabrata*, and *C. krusei*, but not *Candida famata* and *Candida parapsilosis*.[9] Anidulafungin was also more effective than caspofungin against *Aspergillus*.[68] Large-scale clinical trials confirmed the therapeutic efficacy of anidulafungin against invasive candidiasis compared with fluconazole.[69] Anidulafungin is given by intravenous infusion as a 100-mg daily maintenance dose for invasive candidiasis and 50-mg daily dose for esophageal candidiasis. A loading dose is also recommended for the first day of treatment.

Other Antifungal Drugs

In addition to the aforementioned antifungal drugs, several other antifungal drugs with different and unique mechanisms of action are discussed next: flucytosine, thiocarbamates (tolnaftate and tolciclate), allylamines (naftifine and terbinafine), and griseofulvin. Flucytosine is used in combination therapy for severe systemic mycosis. Thiocarbamates, allylamines, and griseofulvin are primarily indicated for dermatophytosis as topical or systemic agents.

Flucytosine

Flucytosine, a fluorinated analogue of cytosine (5-fluorocytosine) (Figure 40-4), is a synthetic antimycotic agent orally effective in the treatment of systemic fungal infections, in particular infections caused by yeasts. Flucytosine has a limited antifungal spectrum compared with amphotericin B and is mainly effective against *Candida* and *Cryptococcus*. It is also active against some species of *Cladosporium*



Flucytosine

FIGURE **40-4** Structural formula of flucytosine.

and *Phialophora*, the latter being etiologic agents for chromoblastomycosis.

Flucytosine is taken up into sensitive fungal cells by cytosine permease, where it is converted to 5-fluorouracil by cytosine deaminase. The 5-fluorouracil is metabolized further to yield 5-fluorodeoxyuridine monophosphate, a competitive inhibitor of thymidylate synthetase. The formation of thymidine monophosphate from deoxyuridine monophosphate is blocked, and the synthesis of DNA is impaired; 5-fluorouridine triphosphate is also formed in fungal cells, leading to the synthesis of defective RNA. Selective toxicity against fungi is achieved with flucytosine because mammalian cells do not readily take up the drug or convert it to 5-fluorouracil.

Flucytosine is indicated for the treatment of systemic candidiasis and cryptococcosis; however, resistance to flucytosine frequently develops during therapy of these infections. Mechanisms of resistance include decreased flucytosine uptake by fungal cells (altered permease) and decreased synthesis of active nucleotide metabolites (decreased deaminase and other enzyme activities). Flucytosine is normally used in combination with amphotericin B, which seems to increase fungal uptake of flucytosine and to result in synergistic effects against certain fungal diseases. Perhaps more important, coadministration permits reduction in the dose of amphotericin B.

Flucytosine is well absorbed from the gastrointestinal tract, and the peak plasma concentration is attained within 1 to 2 hours after oral administration. The drug is widely distributed throughout the body; it attains a concentration in cerebrospinal fluid approximately 65% to 90% that of the plasma. Flucytosine has a half-life of 3 to 6 hours and is excreted unchanged in the urine.

The major toxicity of flucytosine is depression of the bone marrow, resulting in anemia, leukopenia, and thrombocytopenia. This effect is dose-related and is reversible. Because flucytosine is excreted mainly through the kidneys, it is advisable to measure the plasma concentration of the drug periodically, especially because it is normally given with the highly nephrotoxic amphotericin B. An elevation of hepatic enzymes in plasma and hepatomegaly occurs in approximately 5% of patients receiving flucytosine. Lastly, flucytosine may cause nausea, vomiting, diarrhea, and (rarely) severe enterocolitis. These toxic effects may result from the formation and release of 5-fluorouracil by fungi and intestinal microbes.

Tolnaftate and allylamine antifungal drugs

Tolnaftate is a thiocarbamate that is commonly used as a topical antifungal agent against mild-moderate superficial fungal infection in skin and toenails, such as tinea pedis, tinea cruris, tinea corporis, tinea manuum, and tinea versicolor. Susceptible dermatophytes include *Malassezia furfur, Epidermophyton floccosum, Trichophyton mentagrophytes, Trichophyton tonsurans,* and *Microsporum canis*. However, tolnaftate is generally ineffective against yeasts, however, such as C. *albicans*.[12] Adverse effects associated with the topical use of tolnaftate are generally mild and could involve allergic contact dermatitis. Possible teratogenic effects of tolnaftate spray use during pregnancy have been suggested[26] and need further investigation for conclusive results.

The mechanism of action of tolnaftate involves noncompetitive inhibition of fungal squalene epoxidase, which is a membrane-bound enzyme necessary for conversion of acetate to sterols and biosynthesis of ergosterol. This mechanism of drug action is shared by another class of antifungals known as *allylamines,* which include naftifine and terbinafine. Terbinafine is effective against dermatophytes (*Microsporum*, *Trichophyton*, and *Epidermophyton* species) and molds (*Aspergillus* and *Scopulariopsis* species).[39] Terbinafine is highly lipophilic and keratophilic and accumulates in the stratum corneum of skin and nails. Similar to thiocarbamate antifungals, allylamine agents are used effectively for dermatophytosis of skin and nails. The adverse effects of terbinafine include mild and transient forms of gastrointestinal symptoms, rash, urticaria, pruritus, and neutropenia, but the drug is generally well tolerated. Terbinafine is used orally and topically, whereas naftifine is used only topically.

Griseofulvin

Griseofulvin was first isolated from *Penicillium griseofulvum dierckx* in 1939, but its antifungal activity was unknown until 1946. It exerts a fungistatic effect against *Microsporum*, *Epidermophyton*, and *Trichophyton* species that infect skin, hair, and nails. Griseofulvin interacts with polymerized microtubules, causing the disruption of the mitotic spindle and eventually fungal mitosis.

Griseofulvin is variably absorbed from the gastrointestinal tract; micronization of the primary drug particles (see Chapter 2) and ingestion with a fatty meal improve bioavailability. Although most of the absorbed drug is inactivated in the liver by dealkylation, the plasma half-life is fairly long (approximately 20 hours), and griseofulvin readily reaches the skin, hair, and nails, where it binds avidly to newly synthesized keratin and inhibits fungal invasion through surface keratin. Serious side effects are uncommon, but griseofulvin may induce nausea, vomiting, diarrhea, fatigue, headache, and mental confusion. The drug may also cause hematologic and dermatologic reactions. As an inducer of cytochrome P450 enzymes, griseofulvin is contraindicated in patients with acute intermittent porphyria and may participate many drug interactions, potentially decreasing the effectiveness of drugs such as warfarin and oral contraceptives. Its use has waned as a result of marketing of newer drugs for treating superficial fungal infections.

Treatment of Oral Candidiasis

Candidiasis is the most common type of oral fungal infection. Regardless of which drug is used, therapy for 2 weeks is required, and more extended treatment may be necessary. Clotrimazole, in the form of oral troches, is highly effective in most cases. On swallowing, clotrimazole can cause an increase in plasma concentrations of hepatic enzymes, which and may rarely lead to hepatitis. If patients have liver disease or are at greater risk of liver toxicity (e.g., alcoholics), nystatin oral pastilles or rinses are preferred. For more extensive disease or difficult cases, such as patients with AIDS, systemic antifungal therapy may be indicated.[64,89]

Oral fluconazole (100 to 200 mg/day) is a major systemic drug useful for oral candidiasis. The risk of causing liver abnormalities is less with fluconazole than the outmoded ketoconazole.[23] If the infection is resistant to fluconazole, oral itraconazole (200 mg/day) is another alternative.[31] Posaconazole can be administered orally at 400 mg twice daily for oral candidiasis resistant to itraconazole or fluconazole. The use of caspofungin, 50 mg intravenously, is an option in more advanced cases, as are micafungin and anidulafungin. In extreme cases, intravenous amphotericin B may be considered.[31] The toxicity of this drug must be carefully weighed, and consultation with a specialist in infectious disease is essential. Surgery may be helpful to remove a condensed lesion after medical therapy. The occurrence of oral candidiasis with lichen planus is common. In these cases, a topical antifungal drug may be applied with a topical corticosteroid. It has been suggested that clotrimazole be given with a topical steroid in patients with oral lichen planus for prophylaxis against candidiasis.[89] Chlorhexidine oral rinses may also be useful in treating oral candidiasis.

ANTIVIRAL AGENTS

Advances in the pharmacologic control of viral infections have lagged behind achievements in the chemotherapy of other microbial diseases. The reason for this delay, which also applies to the therapeutic management of neoplastic disorders (see Chapter 42), has been the difficulty in attaining an antiviral agent with an adequate degree of selective toxicity. When the First Conference on Antiviral Agents, sponsored by the New York Academy of Sciences, was held in 1965, there were no more than a half-dozen scientists in the United States who believed that safe and effective antiviral agents could be identified. Because the replication of viruses was known to use metabolic machinery essential for the function of normal cells, it seemed to be nearly impossible to find antiviral agents that would inhibit viral growth without killing the host.

Since the First Conference on Antiviral Agents many molecular events unique to viral replication have been identified and exploited in the development of selective antiviral agents. Potential points of attack include virus-encoded enzymes and other proteins that appear during viral replication and are different from corresponding cellular enzymes in noninfected cells. Endogenous mediators of antiviral immunity are another potential source of antiviral compounds. Although the issue of selective toxicity of antiviral agents still remains a major challenge, there is now considerable optimism for the future of viral therapeutics, and many safe and effective antiviral agents have been introduced.

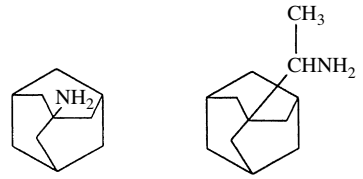
The FDA has approved more than 40 antiviral agents for clinical use. These drugs are reviewed in Table 40-2 and include (1) amantadine and rimantadine for prophylaxis and treatment of influenza A infections and oseltamivir and zanamivir for prophylaxis and treatment of influenza A and B infections; (2) idoxuridine, vidarabine, and trifluridine for treatment of ocular herpetic diseases; (3) acyclovir, valacyclovir, famciclovir, penciclovir, ganciclovir, and foscarnet for treatment of various systemic and localized herpes group infections; (4) ribavirin, a broad-spectrum agent for treatment of respiratory syncytial viral bronchitis and pneumonia; (5) interferons for the treatment of human papillomavirus and chronic hepatitis infections; and (6) three classes of antiviral agents for the control of HIV infection (two groups belong to the reverse transcriptase inhibitors).

Anti–Influenza Virus Agents

Replicative cycles of influenza virus, a representative RNA virus, have been extensively studied during the past two decades. After penetrating into the cytoplasm of cells through endocytosis, the M2 protein virus allows an influx of hydrogen ion into the virion interior, resulting in uncoating of virion. This uncoating process induces the release of the ribonucleoprotein (RNP) complex into the cytoplasm. Then viral RNAs (vRNAs) enter nuclei of cells and begin to make more progeny vRNAs expressing structural and nonstructural proteins of the virus. These vRNAs and proteins are assembled to be virions, which are eventually released from the infected cells. Several antiviral drugs were developed to disrupt this replicative cycle and have been used for the treatment and prophylaxis of influenza caused by influenza virus type A or B. Amantadine and rimantadine inhibit the function of M2 protein and in doing so prevent the uncoating process of the virus. Oseltamivir and zanamivir are known to inhibit the activity of viral neuraminidase, resulting in blockade of the release of progeny virus from the infected cells.

Amantadine and rimantadine

Amantadine and rimantadine are synthetic tricyclic amines (Figure 40-5). In 1966, amantadine became the first antiviral agent to be licensed for general use in the United States.



Amantadine **Rimantadine**

FIGURE **40-5** Structural formulas of amantadine and rimantadine.

Rimantadine is a close structural analogue of amantadine in which the amino moiety is replaced with an α-aminoethyl group. It also shares a similar pharmacologic profile.

Amantadine inhibits the replication of influenza A virus, influenza C virus, Sendai virus, and pseudorabies virus. No inhibition is observed, however, with influenza B virus, parainfluenza virus types 1 through 3, mumps virus, and Newcastle disease virus. Different strains of influenza A virus display sensitivities to amantadine that vary by 100-fold.[51]

Although the mechanism by which amantadine inhibits virus replication has not been fully determined, it has been suggested that amantadine inhibits or delays the uncoating process that precedes primary transcription. Specifically, it blocks the action of the M2 viral protein that facilitates dissociation of the ribonucleoprotein complex preceding replication and the conformational changes in viral hemagglutinin that follow translation. Amantadine has no effect on the virus-specific, RNA-dependent RNA polymerase activity of influenza A virus.

Amantadine hydrochloride is a water-soluble compound and is rapidly absorbed from the gastrointestinal tract. Peak plasma concentrations are reached within 2 to 4 hours; the pulmonary concentration is approximately two thirds that of the plasma. Amantadine is excreted in the urine with an elimination half-life of approximately 15 hours.

Amantadine is available in capsules or syrup and is administered orally for the prevention of influenza A virus infection. Amantadine prophylaxis reduces infection rates by at least 50% and illness rates by at least 60%. The effectiveness of amantadine after the onset of influenza symptoms is not as convincing as its effectiveness with prophylactic use. More recently, an aerosol mist of amantadine has been used for the treatment of influenza virus. Although such use significantly reduces certain respiratory symptoms of influenza, no effect is observed on fever, other constitutional symptoms, or pulmonary function measurements.

Dose-dependent side effects of amantadine are observed in 3% to 30% of patients, including nervousness, drowsiness, difficulty in concentration, insomnia, and depression. Symptoms usually appear within 48 hours after the initiation of drug use and disappear quickly after drug administration is terminated. The ability of amantadine to affect central nervous system (CNS) dopaminergic transmission (see Chapter 15) is largely responsible for the CNS disturbances. During the 2005-2006 influenza season, influenza A virus acquired resistance against amantadine and rimantadine. These agents are not presently recommended for prophylaxis or treatment of influenza. Amantadine and rimantadine have shown moderate activity against some strains of avian influenza virus, but not against most of the H5N1 subtype strains that have caused the outbreaks in Asia.

Oseltamivir and zanamivir

Oseltamivir and zanamivir are neuraminidase inhibitors effective against symptoms related to infection with influenza A

TABLE **40-2**

Antiviral Spectrum, Mechanisms of Action, and Clinical Uses of Some Antiviral Agents

AGENT	ANTIVIRAL SPECTRUM	MECHANISM OF ACTION	CLINICAL USES
Anti—Influenza Virus Agents			
Amantadine, rimantadine	Influenza A virus	Blockade of uncoating process	Prophylaxis of influenza A infection
Oseltamivir, zanamivir	Influenza A and B virus	Inhibition of viral neuraminidase activity	Prophylaxis and treatment of influenza A and B virus infection
Influenza vaccine	Influenza A and B	Production of antibody	Prophylaxis of influenza A and B virus infection
Antiherpesvirus Agents			
Idoxuridine	HSV	Inhibition of DNA synthesis	Topical use for herpetic keratitis and keratoconjunctivitis
Vidarabine	HSV	Inhibition of DNA synthesis	Topical use for herpetic keratitis and keratoconjunctivitis; treatment of herpes encephalitis
Trifluridine	HSV	Inhibition of DNA synthesis	Topical use for herpetic keratitis and keratouveitis
Acyclovir, valacyclovir	HSV and VZV	Inhibition of DNA synthesis	Treatment of primary and recurrent herpes genitalis, herpetic encephalitis, mucocutaneous herpetic infections in immunocompromised patients, neonatal herpetic infection, VZV infection, and CMV prophylaxis
Famciclovir	HSV and VZV	Inhibition of DNA synthesis	Oral use for VZV infection and recurrent herpes infections
Penciclovir	HSV	Inhibition of DNA synthesis	Topical use for recurrent herpes labialis
Foscarnet	HSV, VZV, and CMV	Inhibition of DNA synthesis	Treatment of CMV retinitis and acyclovir-resistant HSV and VZV infections
Ganciclovir	CMV	Inhibition of DNA synthesis	Treatment of CMV retinitis and prevention of CMV colitis and esophagitis
Cidofovir	CMV and HSV	Inhibition of DNA synthesis	Treatment of CMV keratitis and HSV lesions
Fomivirsen	CMV	Inhibition of viral mRNA function	CMV retinitis in AIDS patients
Anti—Viral Hepatitis Agents			
Interferon alfa and alfa-2b	HCV and HPV	Stimulation of synthesis of antiviral proteins	Treatment of HBV and HCV and refractory genital warts
Anti—Respiratory Syncytial Virus Agent			
Ribavirin	RSV	Inhibition of mRNA synthesis and purine synthesis	Treatment of RSV pneumonia and bronchitis
Anti-HIV Agents			
Reverse transcriptase inhibitors*	HIV	Inhibition of viral DNA synthesis	Treatment of HIV infection and AIDS
Protease inhibitors†	HIV	Blockade of HIV protease	Treatment of HIV infection and AIDS
Fusion inhibitor—enfuvirtide	HIV	Blocks fusion of viral envelope with host plasma membrane	Treatment of HIV infection and AIDS
Papillomavirus Vaccine			
Human papillomavirus quadrivalent vaccine, recombinant	HPV	Production of antibody against HPV	Prevention of diseases (e.g., genital warts; precancerous cervical, vaginal, or vulval lesions; and cervical cancer) associated with HPV infection

*Includes nucleoside (e.g., zidovudine, 2′,3′-dideoxyinosine, didanosine, stavudine, and lamivudine) and non-nucleoside (e.g., nevirapine and efavirenz) inhibitors.

†Includes such drugs as saquinavir, indinavir, ritonavir, indinavir, nelfinavir, and amprenavir.

AIDS, Acquired immunodeficiency syndrome; *CMV,* cytomegalovirus; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *HPV,* human papillomavirus; *HSV,* herpes simplex virus; *RSV,* respiratory syncytial virus; *VZV,* varicella-zoster virus.

or B. Taken orally, oseltamivir can reduce the severity and duration of the symptoms caused by influenza viruses and can decrease the incidence of upper respiratory complications. Zanamivir can be orally inhaled and is used for treatment of acute uncomplicated influenza A or B infection. These drugs are effective when taken within 48 hours after the onset of symptoms. The earlier they are started, however, the more effective they are. Oseltamivir or zanamivir taken once or twice daily for prophylaxis seems to be effective against influenza-related illnesses. Viral resistance can occur, but viral resistance to oseltamivir and zanamivir has rarely been reported in immunocompetent individuals. Common side effects include nausea and vomiting with oseltamivir and nasal discomfort and bronchospasm with zanamivir.

Because oseltamivir and zanamivir reduce the clinical efficacy of live attenuated intranasal influenza vaccines, such as FluMist, they should be stopped at least 48 hours before and should not be started for 2 weeks after the use of such vaccines.[5,16] Both these drugs are effective against subtype strains of avian influenza virus and can be used for prophylaxis and early treatment of H5N1 infection.

Influenza vaccine

The most effective way to prevent infection from influenza A and B is annual immunization. There are two types of influenza vaccine in the United States: trivalent inactivated vaccine and live attenuated intranasal vaccine. In general, the vaccines are recommended for pregnant women, individuals older than 50 years, individuals older than 5 years with chronic medical conditions, caregivers of children younger than 6 years, and health care workers.[4]

Approximately 2 weeks after immunization, antibodies against influenza virus reach protective levels and persist for 6 months.[62] The immunization can cause soreness at the injection site; other side effects are uncommon. One study showed, however, that a significant proportion of patients receiving the live attenuated vaccine shed vaccine-strain viruses, but the peak titer was below the infectious dose.[75]

Antiherpetic Agents

Many different herpesviruses cause diseases in humans. Among them, herpes simplex virus (HSV), herpes zoster virus (HZV), and cytomegalovirus (CMV) are major herpesviruses that cause various infections. These are DNA viruses. The viral replication and reproduction in cells are very well known as depicted in Figure 40-6. Most anti-HSV agents inhibit viral DNA replication. HSV causes diseases in the orofacial area, eyes, skin, genital organs, and brain, resulting in primary herpes stomatitis, recurrent herpes labialis, herpes keratitis, cutaneous herpetic infections, herpes genitalis, and herpetic encephalitis. Primary infection with varicella-zoster virus (VZV) causes varicella (chickenpox), which may induce zoster (shingles) in individuals older than 60 years. CMV infection can cause retinitis in 20% to 25% of patients with AIDS and may cause CMV colitis and esophagitis in AIDS patients.

With the exception of foscarnet and vaccines, drugs effective against herpesviruses are purine or pyrimidine analogues that are converted to active nucleotides by cellular or virus-specific enzymes. Drugs that are activated by virus-encoded enzymes and inhibit a specific molecular event in viral replication, such as acyclovir, valacyclovir, and penciclovir, are the most selective agents currently available.

Anti–herpes simplex virus agents

Idoxuridine. Idoxuridine was synthesized in 1959 as part of an anticancer program and was soon found to possess antiviral activity against HSV. Idoxuridine is a thymidine analogue with an iodine atom replacing the methyl group on the carbon

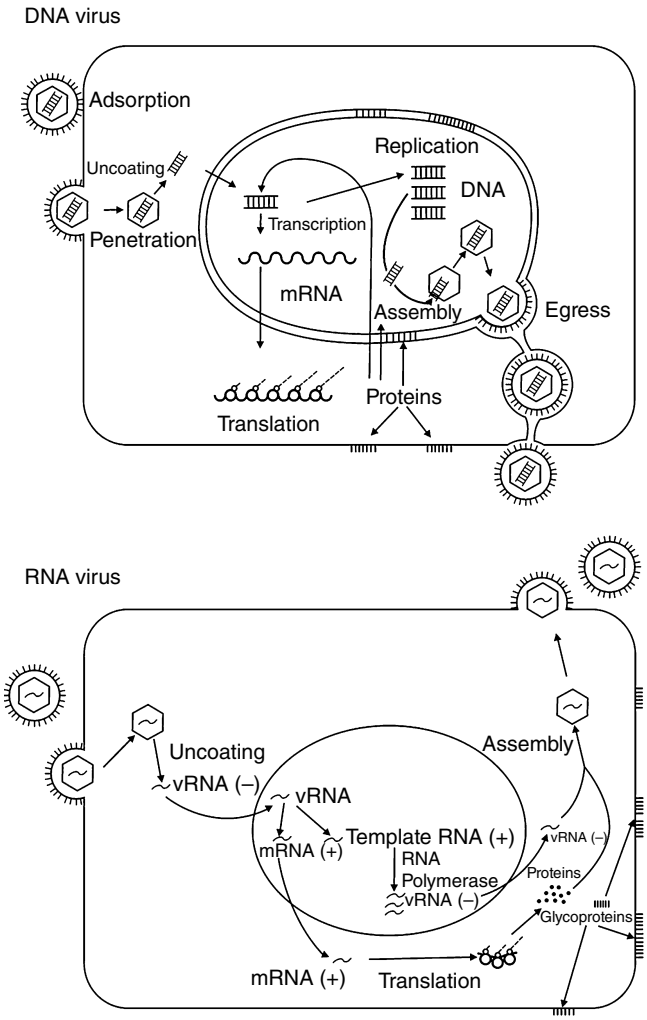


FIGURE **40-6** Viral replication and reproduction of DNA and RNA viruses. *mRNA*, Messenger RNA; *vRNA*, viral RNA.

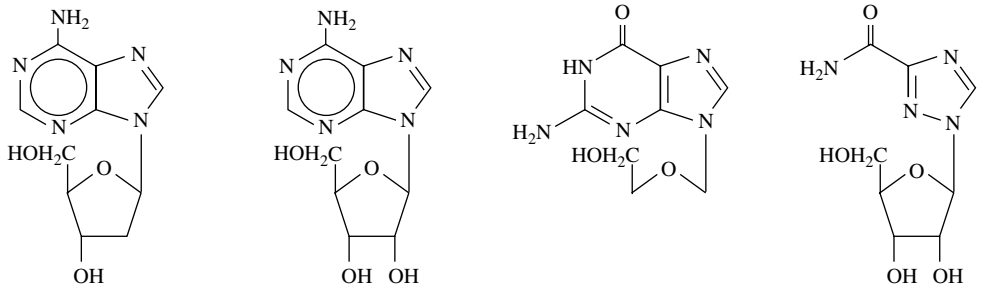
5 atom (Figure 40-7). Because iodine has almost the same radius as the methyl moiety, idoxuridine is readily phosphorylated to idoxuridine monophosphate by thymidine kinase. Idoxuridine monophosphate is metabolized further to the triphosphate form and is incorporated into viral and cellular DNA. Several enzymes involved in the biosynthesis of DNA, such as thymidine kinase, thymidylate kinase, and DNA polymerase, are inhibited by idoxuridine and its phosphorylated forms. The antiviral effect of idoxuridine is most likely related, however, to the adverse biologic consequences of incorporating idoxuridine into viral DNA: chromosomal breakage and altered synthesis of viral proteins. The incorporation of idoxuridine into the DNA of normal uninfected cells is similarly responsible for the drug's toxicity.

Idoxuridine in vitro shows antiviral activity against various DNA-dependent viruses, but the clinical use of idoxuridine solution and ointment is limited to the treatment of keratitis caused by HSV and vaccinia virus (the latter without specific FDA approval). Viral resistance commonly develops during therapy; idoxuridine is rapidly inactivated by deaminase or nucleotidase enzymes.

Topical application of idoxuridine to the conjunctiva can cause local irritation, contact dermatitis, punctate keratopathy (which may be more closely associated with the disease process than the drug), corneal clouding, photophobia, and lacrimation. In addition to these undesirable effects, idoxuri-

PURINES



PYRIMIDINES

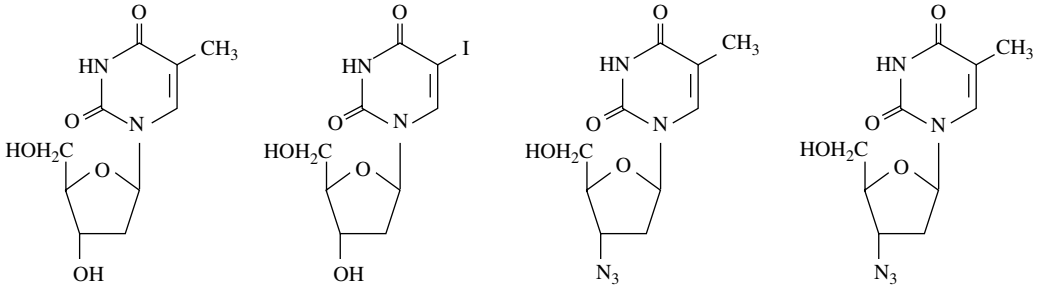


FIGURE **40-7** Structural formulas of deoxyadenosine, thymidine, and several nucleoside antiviral drugs.

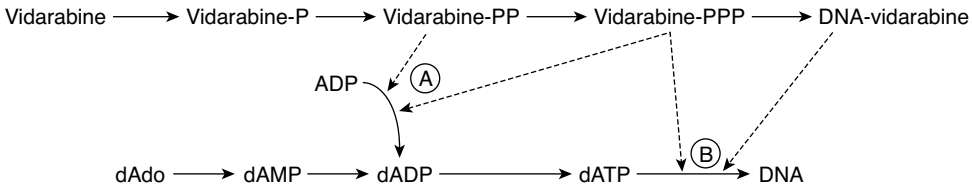

FIGURE **40-8** Mechanisms of action of vidarabine. *Top,* Sequential phosphorylation of vidarabine by cellular enzymes and its incorporation into viral DNA. *Bottom*, Conversion of deoxyadenosine *(dAdo)* to deoxyadenosine monophosphate *(dAMP)*, diphosphate *(dADP)*, and triphosphate (*dATP*) and the synthesis of normal viral DNA. *A*, Vidarabine diphosphates *(-PP)* and triphosphates *(-PPP)* inhibit ribonucleotide reductase–dependent production of dADP. *B*, Vidarabine triphosphate and vidarabine incorporated into DNA block further DNA synthesis by inhibiting the activity of DNA polymerases and terminal deoxynucleotidyl transferase.

dine causes chromosomal damage in cell culture and has disturbed embryonic development in animals after topical administration to the eye.

Vidarabine. Vidarabine (adenosine arabinoside) is an analogue of adenosine originally synthesized but subsequently found in cultures of *Streptomyces antibioticus*. In vidarabine, the D-ribose moiety is replaced with arabinose (see Figure 40-7). Vidarabine exhibits a spectrum of antiviral activity in vitro against many DNA viruses (e.g., herpesvirus group and poxviruses) and some oncogenic RNA viruses (oncornaviruses). Studies indicate that the biologic activity of vidarabine can be attributed to phosphorylated derivatives, as shown in Figure 40-8, which inhibit viral DNA polymerases. The percentage of phosphorylated vidarabine is limited after intravenous infusion, however, and most of the drug is rapidly metabolized (the average plasma half-life is 3.5 hours) by adenosine deaminase to arabinosyl hypoxanthine, which is 60 times less potent than vidarabine. Because of the compound's low water solubility and poor gastrointestinal absorption, vidarabine must be administered by prolonged intravenous infusion of dilute solutions.

Topical treatment with vidarabine ointment is useful for keratitis caused by HSV and is the drug's main use.[85] It seems to be superior to idoxuridine in that it is at least as effective and is less allergenic, less irritating to the eye, and less likely to encounter viral resistance. Intravenous infusion of vidarabine is effective for the treatment of herpes encephalitis and useful for the control of VZV infections in immunocompromised patients; however, acyclovir has essentially replaced

vidarabine for these uses. Topical application of vidarabine for recurrent herpes labialis and herpes genitalis has been reported to have no significant therapeutic effect.

Major toxic effects of vidarabine are mostly associated with the phosphorylated derivatives and their effects on DNA synthesis. Adverse responses to parenteral vidarabine include gastrointestinal disturbance (nausea, vomiting, diarrhea), CNS manifestations (dizziness, confusion, ataxia), and hematologic disorders (hyperbilirubinemia, leukopenia). As with other drugs affecting DNA synthesis, vidarabine is potentially teratogenic and carcinogenic. The side effects of topical application are similar to the side effects described for idoxuridine.

Trifluridine. Trifluridine (trifluorothymidine) is a derivative of idoxuridine in which the iodine atom is replaced with a trifluoromethyl group. Trifluridine exhibits antiviral activity against numerous DNA viruses, including HSV, vaccinia, and adenoviruses. The advantages of trifluridine over idoxuridine are its 10-fold greater potency against herpetic keratitis and 10-fold greater solubility in aqueous solution. More recent studies also suggest that trifluridine is often effective in patients who have previously not responded to idoxuridine or vidarabine.

The mechanism of antiviral action of trifluridine has primarily been studied regarding its effects against vaccinia virus. Trifluridine is phosphorylated to trifluridine monophosphate, diphosphate, and triphosphate by viral or cellular thymidine kinase and thymidylate kinase. Trifluridine triphosphate is preferentially incorporated into viral DNA and produces effects similar to those of idoxuridine. Major cytotoxic reactions are more closely associated with the inhibition of cellular thymidine synthetase by trifluridine monophosphate.[43]

Trifluridine, marketed as a 1% ophthalmic solution, is the drug of choice for superficial herpes keratitis. Toxic reactions to trifluridine are infrequent and generally mild, consisting of a burning sensation on instillation and palpebral edema. Allergic reactions are rare. Trifluridine is potentially mutagenic and carcinogenic; however, the risk from conjunctival application is minute.

Acyclovir and valacyclovir. Acyclovir is a product of research revolving around the synthesis of compounds designed to mimic substrates for adenosine deaminase, an enzyme essential to nucleic acid metabolism. (Although acyclovir proved not to act through inhibition of this enzyme, experimental drugs have been devised that do.) Acyclovir is an analogue of guanosine, or deoxyguanosine, in which two carbon atoms are missing from the ribose constituent (see Figure 40-7). Acyclovir is effective against herpesviruses such as HSV, VZV, and CMV. As an antiherpetic agent, acyclovir is 160 times as potent as vidarabine and 10 times as potent as idoxuridine.

Valacyclovir is the L-valyl ester of acyclovir. A prodrug, valacyclovir is rapidly absorbed after oral ingestion and converted to acyclovir during its first pass through the intestine and liver. The pharmacologic actions and effects of valacyclovir and acyclovir are essentially identical.

The mechanisms of antiviral action of acyclovir are well known (Figure 40-9). The nucleoside analogue is phosphorylated to form acyclovir monophosphate by herpesvirus-encoded thymidine kinase and phosphorylated further by other enzymes to acyclovir diphosphate and triphosphate. Acyclovir triphosphate acts to inhibit viral DNA polymerase and to terminate elongation of the viral DNA chain as spurious nucleotide is incorporated into DNA. In the noninfected host cell, phosphorylation of acyclovir occurs to a limited extent. Acyclovir triphosphate inhibits HSV DNA polymerase 10 to 30 times more effectively than it does mammalian cell DNA polymerase.[33]

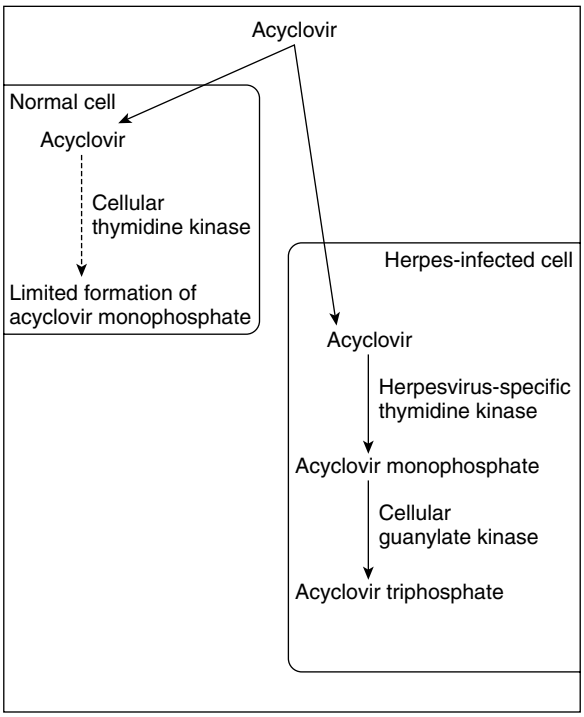

FIGURE **40-9** Selective phosphorylation of acyclovir by herpesvirus-specific thymidine kinase and subsequent phosphorylation to acyclovir triphosphate by cellular guanylate kinase. The preferential phosphorylation of acyclovir in herpesvirus-infected cells and selective inhibition of viral DNA polymerase by acyclovir triphosphate provide for the drug's selectivity; inhibition of the growth of uninfected cells can require a 3000-fold greater concentration of drug than inhibition of viral multiplication.

The bioavailability of acyclovir after oral administration is only approximately 20%. Peak plasma concentrations, which occur 2 hours after ingestion, are sufficient only for prophylaxis and treatment of highly susceptible infections such as genital herpes. Intravenous infusion can produce the much higher blood titers required for more resistant infections. The plasma half-life of acyclovir ranges from 2 to 5 hours in normal individuals but is approximately 20 hours in patients with renal failure. Acyclovir is mostly eliminated through glomerular filtration and tubular secretion, with 90% of the excreted dose recovered as the parent molecule.

The FDA has approved the use of acyclovir ointment for treatment of primary herpes genitalis and for treatment of initial and recurrent mucocutaneous herpetic lesions that are not life-threatening in immunocompromised patients. Although physicians and dentists have used topical acyclovir for symptomatic relief of recurrent herpes labialis in patients with normal immune systems, there is little evidence of this practice providing real benefits.[73] Oral acyclovir is used for the prevention of recurrent herpes genitalis and treatment of primary and recurrent herpes genitalis and VZV infections. Oral therapy has also been shown to be effective in preventing reactivation of HSV in immunosuppressed patients.[6] Parenteral acyclovir has proved to be effective in the treatment of chronic and recurrent mucocutaneous HSV infections in immunocompromised patients, VZV infections (chickenpox and shingles), and herpes encephalitis.[28,84,87,88] Valacyclovir is currently indicated for treatment of VZV infections and recurrent genital herpes.

Because acyclovir is in extensive clinical use, reports concerning the facile emergence of acyclovir-resistant HSV

mutants have received much attention.[21,36] The specific mechanisms of viral resistance against acyclovir include (1) loss of viral thymidine kinase activity, (2) elaboration of a viral thymidine kinase with altered substrate specificity, and (3) expression of altered DNA polymerase activity. The first two mechanisms account for most resistant strains isolated in the laboratory; however, virulence is decreased by alterations in thymidine kinase activity. Full infectivity seems to be retained by mutant strains with DNA polymerase resistant to acyclovir binding.

No serious toxicity has been reported with topical or oral acyclovir therapy. The most frequent side effects during 3 to 6 months of oral use are headache, diarrhea, nausea and vomiting, arthralgias, and vertigo. Intravenous injection of acyclovir can induce local phlebitis, nausea and vomiting, diaphoresis, rash, and hypotension. Serious adverse effects, such as nephrotoxicity or encephalopathy, occasionally occur after intravenous administration of acyclovir.

Penciclovir. Penciclovir is a guanine nucleoside analogue structurally related to acyclovir. It is less potent than acyclovir as an inhibitor of DNA polymerase, but the triphosphate form attains much higher concentrations than those of acyclovir and persists intracellularly for a longer time (half-life 7 to 20 hours). The spectrum of action is similar to acyclovir. Herpesviruses that are resistant to acyclovir because of reduced thymidine kinase activity are also resistant to penciclovir. For recurrent herpes labialis, 1% penciclovir cream is available as a topical agent. It can be topically applied to recurrent herpetic lesions every 2 hours while awake for 4 days. Clinical trials involving additional uses of penciclovir are under way.[86]

Foscarnet. Foscarnet is a phosphonoformate analogue of pyrophosphate. It is strongly active against HSV, CMV, other herpesviruses, and HIV-1. The drug inhibits herpetic DNA polymerase activity by blocking the pyrophosphate binding site on the enzyme. It inhibits the synthesis of DNA complementary to HIV-1 RNA by similarly suppressing the activity of reverse transcriptase. Foscarnet is approximately 100 times more selective for herpesvirus DNA polymerase than for mammalian DNA polymerase.

Foscarnet has been approved by the FDA for the treatment of acyclovir-resistant HSV infections in AIDS patients and CMV retinitis in immunocompromised patients.[31] The drug is also effective clinically against acyclovir-resistant VZV infection and against HIV-1 infection. The drug is highly ionized and must be given by slow (1 hour minimum) intravenous infusion every 8 hours.

Foscarnet has two major problems: renal toxicity and electrolyte disturbances. Nephrotoxicity occurs to some degree in most patients receiving foscarnet. Renal impairment is often reversible, but nephritis and necrosis may lead to permanent loss of renal function. Foscarnet binds divalent cations and causes a dose-dependent hypocalcemia, with possible paresthesias, muscle spasms, tetany, and seizures. Hypomagnesemia and disturbances in phosphate concentrations also occur. Malaise, nausea and vomiting, fatigue, headache, genital ulcers, CNS disturbances, anemia, leukopenia, and liver dysfunction are additional manifestations of foscarnet toxicity.

Docosanol. Docosanol is a long-chain saturated alcohol and has been approved by the FDA for over-the-counter treatment of herpes labialis. In vitro, it prevents infection by lipid-enveloped viruses by inhibiting fusion between the viral envelope and the plasma membrane of the host cells. In clinical trials, docosanol, available in 10% cream, allowed for faster healing from recurrent herpes labialis compared with placebo when docosanol was placed topically at the first sign of recurrence.

Anticytomegalovirus agents

Many drugs have been approved by the FDA for the control of CMV infections, including ganciclovir, valganciclovir, foscarnet, cidofovir, and Fomivirsen.

Ganciclovir and valganciclovir. Ganciclovir (9-[1,3-dihydroxy-2-propoxymethyl]-guanine) is a hydroxymethylated analogue of acyclovir. Valganciclovir is a prodrug of ganciclovir. Similar to acyclovir, ganciclovir is phosphorylated to the monophosphate form by herpesvirus-specific thymidine kinase and phosphorylated further to the triphosphate form.[20,72] Ganciclovir triphosphate inhibits viral DNA polymerase. The agent is more potent than acyclovir against HSV, CMV, and VZV, but the cytotoxicity of ganciclovir is also much greater.

Systemic ganciclovir is indicated for the treatment of life-threatening and sight-threatening CMV infections, especially CMV retinitis in immunocompromised patients.[58] Ganciclovir is also effective for the treatment of some acyclovir-resistant HSV (DNA polymerase mutant) infections. The drug can cause aspermatogenesis in animals and is potentially carcinogenic and teratogenic. The most common serious side effects of ganciclovir are granulocytopenia and thrombocytopenia, and these toxicities are not always reversible after the cessation of drug administration.

Because of its poor oral bioavailability (<10%), ganciclovir is administered intravenously for treatment of active disease; oral administration may be used to prevent relapse after the infection has been suppressed. More recent studies showed that valganciclovir exhibited greater than 10-fold oral bioavailability compared with ganciclovir, making it possible to replace intravenous ganciclovir with this drug.[70] The plasma half-life of ganciclovir is approximately 3 hours, with renal excretion of unchanged drug as the primary method of elimination.

Cidofovir. Cidofovir is an analogue of cytidine that gets converted to cidofovir diphosphate, resulting in the inhibition of DNA polymerase. The diphosphate form of the drug persists in the cell. This permits infrequent dosing intervals. Cidofovir is poorly absorbed orally and is given topically or intravenously. It is used to treat CMV retinitis and HSV mucocutaneous lesions.

Formivirsen. Formivirsen is a phosphothioate antisense oligonucleotide. It binds to specific viral RNA and inhibits viral protein synthesis. It is used topically to treat CMV retinitis in AIDS patients.

Anti–varicella-zoster virus agents

Acyclovir, valacyclovir, famciclovir, and foscarnet are available for the control of VZV infections.

Famciclovir. Famciclovir is an ester prodrug that is converted to penciclovir during its passage from the gut to the systemic circulation. The spectrum of action is similar to acyclovir; herpesviruses that are resistant to acyclovir because of reduced thymidine kinase activity are also resistant to penciclovir. Famciclovir is currently approved for the treatment of acute, localized VZV and HSV infections.

Herpes zoster vaccine. The FDA more recently approved a live attenuated varicella-zoster vaccine (Zostavax) for prevention of herpes zoster (shingles) in individuals older than 60 years. VZV persists in a latent form in sensory ganglia after primary infection. The latent VZV can be reactivated and induce varicella. In the United States, more than 90% of adults have had varicella and are at risk of the development of herpes zoster, and more than 1 million new cases of herpes

zoster are reported in the United States each year. The vaccine enhances VZV-specific cell-mediated immunity, which inhibits the reactivation of latent VZV.[56] The vaccine reduces the severity and duration of discomfort and pain caused by herpes zoster by 61%.[63]

Anti–respiratory syncytial virus agents

Ribavirin. Ribavirin is a synthetic triazole nucleoside analogue of guanosine with a broad spectrum of antiviral activity (including DNA viruses and RNA viruses). Ribavirin exerts multiple actions. It directly inhibits guanine deaminase, and its metabolite, ribavirin 5′-phosphate, inhibits inosine monophosphate dehydrogenase and the formation of guanosine 5′-triphosphate. The triphosphate form of ribavirin, which is the predominant form intracellularly, interferes with viral messenger RNA transcriptase activity.

Although ribavirin has a broad antiviral spectrum in vitro, its approval in the United States is presently limited to use as an aerosol for the treatment of respiratory syncytial virus bronchitis and pneumonia in children and use in combination with interferon alfa-2a for certain adult patients with hepatitis C. Ribavirin administered by aerosolization to hospitalized infants and young children with respiratory syncytial virus infections produces significant reductions in fever and severity of systemic illness. It holds promise as an aerosol and oral medication for treatment of influenza, measles, acute and chronic hepatitis, Lassa fever, and various RNA viral infections not commonly seen in the United States.[32]

The pharmacokinetics of ribavirin are complex. Systemic absorption occurs after inhalation, and plasma concentrations increase with long-term therapy. Ribavirin has a terminal half-life of 18 to 36 hours; however, the triphosphate derivative in red blood cells persists for several months after cessation of therapy.

Various serious toxic reactions have been attributed to use of ribavirin, particularly in severely ill patients. Respiration may be worsened after inhalation, especially if the patient has preexisting chronic obstructive pulmonary disease. Anemia, hypotension, and cardiac arrest are possible side effects. Because ribavirin is a nucleoside analogue and nonselective antiviral agent, it is potentially mutagenic, carcinogenic, and teratogenic.

Palivizumab. Palivizumab is a monoclonal antibody directed against the A antigen site of RSV. It is used in high-risk infants and children. The adverse effects of palivizumab include gastrointestinal symptoms, rash, and respiratory tract infections.

Anti—Viral Hepatitis Agents

Human interferons

Interferons are glycoproteins secreted by virus-infected cells that promote the establishment of an antiviral state in uninfected cells. In addition to their antiviral activity, interferons regulate cellular functions dealing with cell proliferation and immunologic responses. Although all tissues seem to be capable of synthesizing interferons, cells that are derived from the hematopoietic system (e.g., lymphocytes and macrophages) may be the most significant in contributing to the total interferon synthesis of the body. All DNA and RNA viruses—single or double-stranded, enveloped or not, with or without virion-associated polymerase, and replicating in the cytoplasm or in the nucleus—are sensitive to interferons to a greater or lesser degree.

Interferons can be classified according to three major groups: α, β, and γ. These are produced by induction of synthesis in human leukocytes, fibroblasts, or lymphoblastoid cells and, in larger amounts, by recombinant DNA techniques in bacteria. The mechanisms of action of interferons are complex; two important responses to interferon are reviewed in Figure 40-10. After binding to specific plasma-membrane receptors and being taken up by infected cells, interferon induces the synthesis of two enzymes: an oligonucleotide polymerase that synthesizes from adenosine 5′-triphosphate a series of oligonucleotides containing 2′,5′-phosphodiester bonds and a protein kinase that phosphorylates and inactivates eukaryotic initiation factor. Oligonucleotides stimulate cellular endonucleases to cleave viral messenger RNA, whereas the inactivated eukaryotic initiation factor no longer supports protein synthesis.[35,45] Additional antiviral effects may result

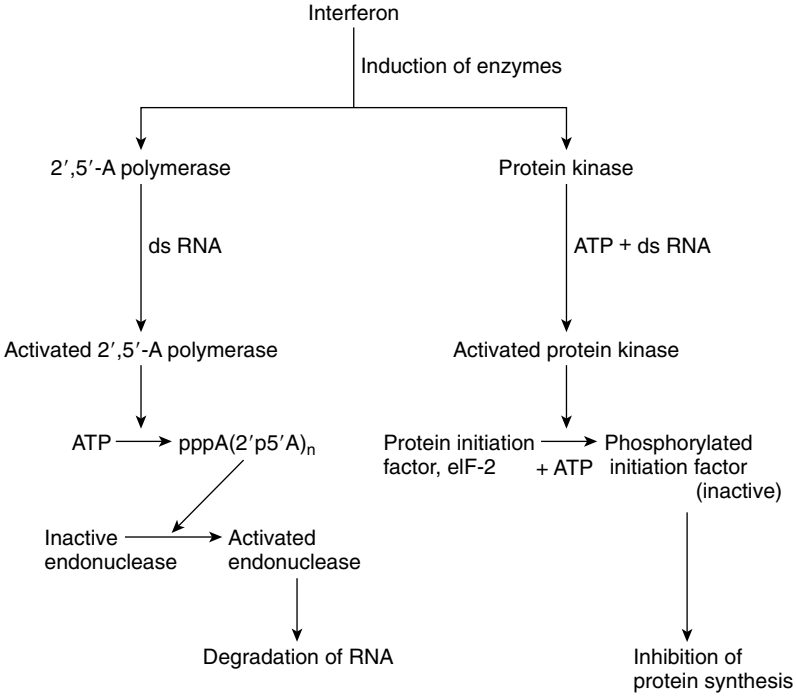

FIGURE **40-10** Mechanisms of action of interferon. After incorporation into the cell, interferon induces the synthesis of two enzymes, an oligonucleotide polymerase (2′,5′-A polymerase) and a protein kinase, which in the presence of double-stranded RNA *(ds RNA)* lead to a cascade of reactions that inhibit viral replication. *ATP,* Adenosine 5′-triphosphate; *ds,* double strand.

from activation of macrophages and natural killer cells and modulation of cell surface proteins to facilitate immune recognition.

For prophylaxis of viral infection or for early treatment, interferons may have certain advantages over more narrow-spectrum antiviral agents. In other circumstances, a specific antiviral agent may be preferable to interferons on the grounds of convenience of administration, a quicker onset of antiviral action, or a lack of side effects. Interferons can cause increases in pulse rate and temperature; decreases in white blood cell counts; and headache, somnolence, and malaise. Interferons are currently undergoing clinical trials for various viral diseases, including AIDS. Interferon alfa-2b and mixed interferon-α preparations are currently approved for use against chronic hepatitis B and C infections, condylomata acuminata (anogenital warts) caused by human papillomavirus infection, multiple sclerosis, and Kaposi's sarcoma in patients with HIV infection. The approved uses of interferons in the treatment of cancer are reviewed in Chapter 42. Interferon beta-1a and interferon beta-1b have been approved for the management of multiple sclerosis, and interferon gamma-1b has been approved for chronic granulomatous disease.

Hepatitis B virus DNA polymerase inhibitors

Lamivudine inhibits reverse transcriptase (discussed subsequently in the section on anti-HIV drugs). As a result of its action, it inhibits HBV DNA polymerase. The drug is a cytosine analogue and is used orally. Entecavir is a guanosine analogue that inhibits HBV DNA polymerase. The drug is well absorbed when taken orally; however, it should be taken on an empty stomach. Adverse effects are usually mild and include headache and dizziness. Some animal studies indicate a potential for carcinogenesis. Adefovir dipivoxil is an adenine nucleotide analogue prodrug that inhibits HBV DNA polymerase. At the lower doses used to treat HBV, it is generally well tolerated. Adverse effects include gastrointestinal symptoms and nephrotoxicity.

Anti–Human Immunodeficiency Virus Agents

Since AIDS was first characterized in the early 1980s and attributed to HIV, a retrovirus, tremendous efforts have been made to develop effective therapies against the disease. Although numerous anti-AIDS drugs have been tested, many have proved to be of dubious worth. Four groups of drugs—nucleoside reverse transcriptase inhibitors, non-nucleoside reverse transcriptase inhibitors, HIV protease inhibitors, and fusion inhibitors—are now available for clinical use. Because of the rapidity with which some of these drugs have been developed and approved for marketing, research is ongoing regarding the therapeutic uses and toxic profiles of these agents. An especially promising development from these studies has been the dramatic therapeutic benefits obtained with multiple-drug therapy. Adverse effects of nucleoside reverse transcriptase inhibitors include lactic acidosis, headaches, gastrointestinal disorders such as nausea and vomiting, and hepatomegaly. Adverse effects of other anti-HIV drugs are discussed subsequently.

Reverse transcriptase inhibitors

Zidovudine. Zidovudine (azidothymidine) was the first antiviral agent to be sufficiently safe and effective to receive FDA approval for treatment of AIDS. Zidovudine is a thymidine analogue in which the 3′-hydroxyl group is replaced by an azido group ($-N_3$) (see Figure 40-7). Zidovudine is phosphorylated by cellular enzymes to zidovudine triphosphate, which is incorporated into viral complementary DNA (cDNA) by the reverse transcription of HIV RNA. The 3′ substitution of zidovudine prevents further 5′-3′-phosphodiester linkages and terminates chain elongation. HIV-1 reverse transcriptase is approximately 100 times more susceptible to inhibition by zidovudine than DNA polymerase of mammalian cells. Zidovudine not only seems to block replication of the virus, but also promotes regeneration of $CD4^+$ lymphocytes. The agent also delays progression of AIDS in HIV-infected individuals with $CD4^+$ lymphocyte counts less than 500 cells/mm^3 and in individuals with no symptoms or early symptoms of AIDS-related illness.

Zidovudine provides palliative treatment only; it does not cure AIDS and cannot eliminate HIV from the body. As a preventive measure, however, zidovudine significantly reduces the incidence of neonatal infection when an HIV-infected mother begins taking the drug orally after 14 weeks of gestation and continues until birth (at which time intravenous zidovudine is administered). The efficacy of zidovudine for postexposure prophylaxis is controversial. A case-controlled study indicated that zidovudine reduced the risk of HIV infection in exposed health care workers by 79%.[19] Preliminary guidelines at this time recommend the basic 4-week regimen of two drugs (zidovudine and lamivudine or didanosine and stavudine) for most HIV exposures.[76] For HIV exposures that pose an increased risk for transmission, an expanded regimen that includes the addition of a third drug is recommended.

Many HIV strains resistant to zidovudine have been isolated from clinical specimens. Although HIV strains from individuals not receiving zidovudine are very susceptible to zidovudine, the sensitivity of HIV from patients receiving zidovudine for 6 months is significantly decreased. Zidovudine-resistant strains are susceptible to other anti-HIV agents such as didanosine, zalcitabine, and foscarnet in vitro.

Zidovudine is given orally on a rigid 4-hour schedule. The drug is rapidly absorbed, quickly metabolized in the liver, and excreted in the urine. The mean elimination half-life is approximately 1 hour. Intracellular zidovudine triphosphate persists for several hours. Common side effects are nausea, headache, and bone marrow depression.[31] Occasionally, transfusion may be required to correct granulocytopenia and anemia. Other side effects of zidovudine include asthenia, dizziness, insomnia, malaise, and myalgia. Long-term use of this drug is infrequently associated with a toxic myopathy. Although zidovudine can induce cell transformation in vitro and tumors in animals, the teratogenic potential in humans is unknown.

Didanosine. Didanosine (dideoxyinosine) is active against HIV, including zidovudine-resistant strains, and was approved for human use in 1991. Similar to zidovudine, didanosine, when converted to the triphosphate form, inhibits the activity of reverse transcriptase and by so doing blocks the synthesis of HIV cDNA. Oral didanosine increases the number of $CD4^+$ lymphocytes, decreases viral antigen titers, and decreases symptoms of AIDS-related illness. Cross-resistance between didanosine and zidovudine has not been reported so far. Major side effects include peripheral neuropathy and potentially fatal pancreatitis.

Didanosine is well absorbed at neutral pH and should be taken on an empty stomach. The chewable didanosine tablet contains an antacid to neutralize the pH of the stomach. It should not be taken with medications that require an acidic pH for absorption, such as itraconazole and quinolone antibiotics. Although the drug is quickly eliminated in the urine (elimination half-life of approximately 1 hour), persistence of intracellular didanosine triphosphate permits twice-daily dosing.

Didanosine was originally reserved for patients with advanced HIV infection who were intolerant to zidovudine or showed clinical or immunologic deterioration. It is now commonly used in combination with zidovudine and a prote-

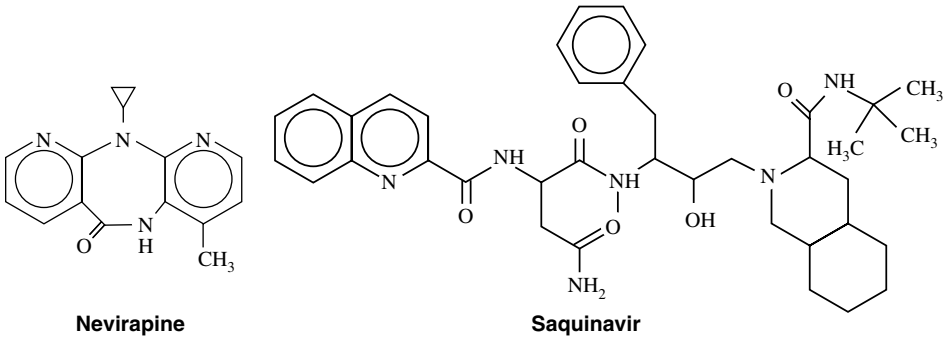

FIGURE **40-11** Structural formulas of nevirapine and saquinavir.

ase inhibitor. Resistance to didanosine is progressive, with resistant strains appearing in most patients after 6 months of monotherapy.

Zalcitabine. Zalcitabine is the 2′-3′-dideoxy analogue of cytidine. Its mechanism of action and pharmacologic profile are similar to zidovudine. Zalcitabine was initially approved for the control of HIV infection in 1992, but it is inferior to zidovudine for monotherapy when used as the initial treatment modality. Zalcitabine shows therapeutic efficacy in patients who are resistant to zidovudine and is comparable to didanosine in patients intolerant to zidovudine.[2,3] Cross-resistance is common between didanosine and zalcitabine. The drug is often administered in combination with zidovudine and a protease inhibitor.

Stavudine. Stavudine, approved in 1994, is the 2′-3′-dideoxy analogue of thymidine. Its mechanism of action and clinical pharmacologic features are similar to those of the previously discussed antiretroviral agents. Studies have shown that stavudine therapy increases the number of $CD4^+$ cells in patients who did not respond to zidovudine therapy. Occasionally, development of resistance to stavudine also confers resistance to zidovudine and didanosine. As with other antiretrovirals, stavudine is used in combination drug therapy.

Abacavir. Abacavir is a nucleoside analogue reverse transcriptase inhibitor that is useful in combination for treating HIV infections. It was approved for clinical use in 1998. Abacavir can cause adverse effects common to other nucleoside reverse transcriptase inhibitors and has been associated with fatal hypersensitivity reactions.

Lamivudine and emtricitabine. Lamivudine is another nucleoside analogue introduced into clinical practice in 1995. It is the (–) enantiomer of 2′-deoxy-3′-thiacytidine. Conversion intracellularly to the triphosphate form inhibits chain elongation of the viral cDNA by inhibiting reverse transcriptase. Poorly effective as monotherapy, lamivudine is approved for the control of infection in combination with zidovudine. Clinical studies indicate that the combination synergistically inhibits HIV replication and strongly enhances $CD4^+$ cell counts.[23] As with other retroviral agents, the persistence of lamivudine triphosphate intracellularly effectively counteracts the rapid elimination of the parent drug. Side effects of lamivudine are generally mild and include nausea and headache. Emtricitabine is a fluoro derivative of lamivudine. It has a longer half-life than lamivudine and is given once a day. Its adverse effects are similar to lamivudine.

Trizivir is a single-tablet combination regimen of lamivudine, zidovudine, and abacavir for treatment of HIV. Trizivir should be used only for patients whose treatment regimens would otherwise include all three of the nucleoside analogues. It is not recommended for patients weighing less than 40 kg because it is a fixed-dose tablet. Because Trizivir combines three drugs in a single tablet, it may help patients with compliance. The most notable side effect of Trizivir is associated with the hypersensitivity reaction to abacavir, which has been observed in 5% of HIV patients.

Nevirapine, efavirenz, delavirdine, and etravirine. Nevirapine, a dipyridodiazepinone (Figure 40-11), is the first non-nucleoside inhibitor of reverse transcriptase. The drug requires no activation; it binds directly to reverse transcriptase of HIV-1 and noncompetitively inhibits cDNA synthesis. Rapid development of drug resistance is the major limitation of this compound, which should never be used as monotherapy.

In contrast to nucleoside analogues, nevirapine is lipid-soluble, very well absorbed, and extensively metabolized by cytochrome P450 (CYP3A family). The elimination half-life decreases from 2 days to 1 day as nevirapine induces its own metabolism. The drug also induces the breakdown of estrogens and HIV protease inhibitors (described later). Nevirapine may cause rash, diarrhea, and drug fever.

Other non-nucleoside inhibitors of reverse transcriptase are efavirenz, delavirdine, and etravirine. These drugs are used to treat HIV-1 infections. Gastrointestinal symptoms can occur with these drugs. Rash, including Stevens-Johnson syndrome, may occur with delavirdine and less commonly with etravirine; CNS adverse effects and mild skin rash are common with efavirenz.

Protease inhibitors

HIV protease is a viral enzyme responsible for the cleavage of the Gag and Gag-Pol polyproteins into the enzymes and structural proteins that are required for the final assembly of new infectious virions.[13] In patients with advanced HIV infection, use of a protease inhibitor in combination therapy with other classes of antiretroviral agents significantly improved the survival of patients. After sustained exposure to antiviral agents, viral isolates may develop resistance to one class of drugs and remain susceptible to others. It is preferred to use new protease inhibitors combined with other drugs when drug resistance has occurred. All protease inhibitors exhibit similar side effects after prolonged exposure. Most commonly, patients may experience hyperglycemia, increased aminotransferase activity, and gastrointestinal dysfunction.[18] Fat redistribution and hyperlipidemia have also been noted.

Saquinavir. Saquinavir (see Figure 40-11) was the first drug approved by the FDA to inhibit HIV protease. Saquinavir has shown selective and potent anti-HIV activity; however, saquinavir monotherapy rapidly induces viral resistance. Similar to combination therapy involving nucleoside and non-nucleoside antiretrovirals, the use of protease inhibitors in conjunction with nucleoside analogues has shown improved clinical efficacy over single drugs or two-drug combinations. The combination of saquinavir, zidovudine, and zalcitabine greatly reduced the viral load without causing any increased toxicity compared with two-drug therapy.[22] The side effects of saquinavir include gastrointestinal disturbances such as nausea and vomiting. Because saquinavir is metabolized by

and is an inhibitor of hepatic CYP3A isoenzymes, interactions are possible with other drugs that rely on the same P450 enzymes for inactivation. Saquinavir may accumulate in patients taking drugs that inhibit CYP3A, and saquinavir may inhibit the metabolism of drugs such as verapamil and triazolam. Drugs that induce CYP3A enzymes, such as rifampin and nevirapine, may reduce the effectiveness of saquinavir.

Indinavir and ritonavir. Indinavir and ritonavir are HIV protease inhibitors. They were released for use in 1996 by the FDA under a special program for drugs with promising anti-HIV activity (as have several other drugs discussed in this chapter).[17] The triple-drug combination of ritonavir and two nucleoside analogues significantly increased the number of $CD4^+$ lymphocytes and reduced the mortality rate of patients with advanced AIDS,[34] and the combination of indinavir with zidovudine and lamivudine resulted in sustained undetectable viral titers for 1 year in more than 80% of patients receiving the therapy. A more recent study evaluated the therapeutic efficacy of combination therapy with indinavir for pediatric patients seropositive for HIV-1.[78] The initial 2-year therapy showed HIV-1 RNA load below the detectable limit and increase in $CD4^+$ cell counts to 94% of the age-matched normal value in most treated patients.

Major side effects of indinavir include hyperbilirubinemia and nephrolithiasis. Because 3% of patients receiving indinavir develop kidney stones, drinking at least 48 oz of water per day is recommended. Ritonavir induces gastrointestinal disturbances, altered taste, and perioral paresthesia. Potential drug interactions for both drugs are similar to interactions mentioned for saquinavir.

Nelfinavir and lopinavir. Nelfinavir is probably the most commonly used protease inhibitor because of its relatively low toxicity. Its side effects include hyperglycemia, abnormal fat distribution, and diarrhea, often controllable with loperamide. Lopinavir shows high potency in vitro, especially when given in combination with ritonavir. The combination of lopinavir and ritonavir causes mild gastrointestinal side effects and headache.

Amprenavir and fosamprenavir. Amprenavir can be used for HIV-infected adults and children older than 4 years. Amprenavir is available in large capsules (150 mg and 50 mg) and in oral solution (15 mg/mL). Amprenavir capsules contain vitamin E. The vitamin E facilitates drug absorption. Each 150-mg capsule contains 109 IU of vitamin E, which exceeds the recommended daily allowance, so patients taking amprenavir should not take additional vitamin E supplements. In a 24-week study, combination therapy with amprenavir, zidovudine, and lamivudine reduced the viral load to less than 500 copies/mL.[61] The side effects of amprenavir include nausea, vomiting, diarrhea, oral and perioral paresthesias, and rash. Similar to other protease inhibitors, altered body fat distribution, hyperglycemia, and increased aminotransferase activity have been reported with amprenavir. Fosamprenavir is a prodrug of amprenavir that has the advantage of being better absorbed, which reduces the required daily dose.

Darunavir, tipranavir, and atazanavir. Darunavir is a protease inhibitor and effective against many HIV strains resistant to other protease inhibitors. This drug should be given with ritonavir, which increases the bioavailability of darunavir by 14 times. Side effects of this drug are similar to other protease inhibitors and include diarrhea, nausea, headache, and increased aminotransferase activity. Darunavir may also worsen diabetes.[7]

Tipranavir is similar to darunavir in that ritonavir increases it plasma levels. The drug can cause gastrointestinal symptoms and rash. More serious adverse effects include liver toxicity and intracranial hemorrhage.

Atazanavir is a protease inhibitor whose plasma half-life is increased by ritonavir. The drug should not be taken with drugs that increase stomach pH. Adverse effects include gastrointestinal symptoms, rash, and peripheral neuropathy. There are several drug-drug interactions involving atazanavir.

Fusion inhibitor

Enfuvirtide. Enfuvirtide is a fusion inhibitor that is effective against HIV. Enfuvirtide binds to a viral envelope glycoprotein (gp),[41] which prevents the fusion between the viral envelope with the host plasma membrane. It is given by the subcutaneous route. Adverse effects include eosinophilia.

Other anti–human immunodeficiency virus agents

Once-daily combination tablet for human immunodeficiency virus. The drug Atripla is the combination of efavirenz, a non-nucleoside reverse transcriptase inhibitor (600 mg); emtricitabine, a nucleoside reverse transcriptase inhibitor (200 mg); and tenofovir, a nucleoside reverse transcriptase inhibitor (300 mg). This is the first once-daily, single-tablet combination for HIV. Side effects are similar to the side effects of the individual drugs taken separately, including rash, dizziness, headache, insomnia, dreams, and inability to concentrate. It is also contraindicated in pregnant women because of its teratogenicity.[42]

Human immunodeficiency virus vaccine

More recently, a vaccine (AIDSVax) was introduced for the prevention of HIV infection; this vaccine is HIV glycoprotein 120–like protein, which induces HIV glycoprotein 120 antibody formation in humans. It has shown modest success in Asians and blacks, but failed to show clinical efficacy in whites. The reason for the difference in vaccine efficacy in various ethnic groups remains to be investigated.

ANTIVIRAL THERAPY IN THE ORAL CAVITY

HSV causes various oral mucosal lesions, including herpetic gingivostomatitis, recurrent intraoral herpes simplex, herpes labialis, and the life-threatening eczema herpeticum. Herpetic gingivostomatitis can also manifest in weakened hosts as aphthoid of Pospischill-Feyrter, characterized by rapid expansion of the lesion to the throat and perioral skin. Most HSV-associated viral lesions are routinely treated by oral acyclovir, with intravenous administration in some severe cases.

Acyclovir is best used as soon as symptoms begin to appear. The intravenous dosage is based on body weight and the type of the lesion. In general, 5 to 10 mg/kg of body weight is administered intravenously for 1 hour and repeated every 8 hours for 5 to 10 days. Long-term suppressive acyclovir therapy is recommended for patients with eczema herpeticum at 200 to 400 mg orally two to three times per day. In addition, supportive therapies for herpetic lesions include antipyretic analgesics, antibacterial antibiotics, and antifungals that help control secondary infections.

Topical 1% penciclovir cream is the drug of choice for the control of recurrent herpes labialis, and it may be applied to the lesion every 2 hours while awake for 4 days. It reduces the uncomfortableness of the infection and can shorten the period of lesions by 1 to 2 days.

HSV infection can develop into a more severe and generalized form in AIDS patients. Recurrent herpetic lesions become chronic in these patients, and HSV strains resistant to acyclovir could arise, in which case other antiherpetic agents, such as ganciclovir and foscarnet, may be effective. In AIDS patients, numerous concomitant oral lesions of different

viral origins are common. Human papillomavirus infection is almost always noted in these patients, resulting in variants of papillomas, condylomata, and focal epithelial hyperplasia in the oral cavity. Also, CMV is associated with aphthae-like ulcerations in the oral mucosa. Oral hairy leukoplakia is an early sign of HIV infection, presumably caused by Epstein-Barr virus in immunocompromised patients. Treatment of oral hairy leukoplakia is reserved for symptomatic patients and usually involves topical application of a solution of podophyllin resin 25% and oral acyclovir 800 mg five times daily. Valacyclovir (1000 mg) and famciclovir (500 mg), given orally three times a day, can be used as alternatives. Systemic antiretroviral therapy is also provided as described earlier. Oral hairy leukoplakia disappears after drug therapy but normally recurs when the medication is discontinued.

ANTIFUNGAL AND ANTIVIRAL AGENTS

Nonproprietary (generic) name	*Proprietary (trade) name*
Antifungal agents	
Amphotericin B	Abelcet, Amphotec, Fungizone
Anidulafungin	Eraxis
Butenafine	Mentax
Butoconazole	Femstat
Caspofungin	Cancidas
Ciclopirox	Loprox
Clioquinol	Vioform
Clotrimazole	Lotrimin, Mycelex
Econazole	Spectazole
Fluconazole	Diflucan
Flucytosine	Ancobon
Gentian violet	—
Griseofulvin	Fulvicin, Grifulvin V, Grisactin
Haloprogin	Halotex
Itraconazole	Sporanox
Ketoconazole	Nizoral
Miconazole	Micatin, Monistat-Derm, Monistat i.v.
Micafungin	Mycamine
Naftifine	Naftin
Natamycin	Natacyn
Nystatin	Mycostatin, Nilstat, Nystex
Oxiconazole	Oxistat
Posaconazole	Noxafil
Sulconazole	Exelderm
Terbinafine	Lamisil
Terconazole	Terazol
Tioconazole	Vagistat-1
Tolnaftate	Aftate, Tinactin
Triacetin	In Fungoid
Undecylenic acid (and derivatives)	Crex, Desenex, Fungoid AF
Voriconazole	Vfend
Antiviral agents	
Abacavir	Ziagen
Abacavir, zidovudine, and lamivudine (combination)	Trizivir
Acyclovir	Zovirax
Adefovir dipivoxil	Hepsera
Amantadine	Symmetrel
Amprenavir	Agenerase
Atazanavir	Reyataz
Cidofovir	Vistide
Darunavir	Prezista
Delavirdine	Rescriptor
Didanosine	Videx
Docosanol	Abreva
Efavirenz	Sustiva
Emtricitabine	Emtriva, in Truvada
Enfuvirtide	Fuzeon
Entecavir	Baraclude
Etravirine	Intelence
Famciclovir	Famvir
Fomivirsen	Vitravene
Fosamprenavir	Lexiva
Foscarnet	Foscavir
Ganciclovir	Cytovene
Herpes zoster vaccine	Zostavax
Human papillomavirus quadrivalent vaccine, recombinant	Gardasil
Idoxuridine	Herplex
Imiquimod	Aldara
Indinavir	Crixivan
Interferon alfa-2a	Referon-A
Interferon alfa-2b	Intron A
Interferon alfa-n3	Alferon
Lamivudine	Epivir
Lopinavir	Kaletra
Nelfinavir	Viracept
Nevirapine	Viramune
Once-daily combination tablet for HIV	Atripla
Oseltamivir	Tamiflu
Palivizumab	Synagis
Penciclovir	Denavir
Ribavirin	Virazole
Rimantadine	Flumadine
Ritonavir	Norvir
Saquinavir	Invirase, Fortovase
Stavudine	Zerit
Tenofovir disoproxil fumarate	Viread
Tipranavir	Aptivus
Trifluridine	Viroptic
Valacyclovir	Valtrex
Valganciclovir	Cymeval, Valcyte
Vidarabine	Vira-A
Zalcitabine	Hivid
Zanamivir	Relenza
Zidovudine	Retrovir

CHAPTER 41

Immunotherapy

JOHN A. YAGIELA AND ANAHID JEWETT*

Immunopharmacology is the study of the interaction between drugs and the immune system. Immunotherapy is the application of clinical strategies to modulate the activities of certain components of the immune system in order to improve immune function and to prevent or treat disease. This chapter reviews the immune system with regard to the pathways used toward adaptive, specific immunity that are or can be targeted for immunotherapy and discusses immunotherapeutic strategies that are of clinical importance today or show promise for the future. The pharmacologic manipulation of innate immune mechanisms involved in inflammation is covered in Chapters 21 and 35.

OVERVIEW OF SPECIFIC IMMUNITY

Components of the Immune System

Research in immunology has progressed rapidly over the last three decades. Spanning this period, major technologic feats (e.g., the development of hybridomas for the production of monoclonal antibodies) and major strides in our understanding of the immune system (including elucidation of cytokines and intracellular signaling) have resulted in significant advances in immunotherapeutics. Today immunopharmacologists use these new insights to pinpoint therapeutic targets among (1) a constellation of cytokines and other factors that influence cellular growth, differentiation, and function and (2) myriad receptors responsive to these mediators, specific antigens, or ligands found on other cells.

Cells

The immune system is composed of two major arms, innate immunity and adaptive immunity. These two components of the immune system differ in the types of effectors, their specificity for antigens, speed of action, and induction of memory. Innate immune cells are the primary initiators of the immune response and support functional activation of adaptive immune effectors. They differ from the adaptive immune effectors by their lack of antigen specificity and their fast acting capabilities. Unlike the adaptive immune effectors, the innate immune effectors do not generate memory. The main effectors of innate immune system are granulocytes, macrophages, and natural killer (NK) cells, whereas T and B lymphocytes are the main effectors of adaptive immunity.

All the effectors of the immune system are derived from the bone marrow. Pluripotent hematopoietic stem cells in bone marrow give rise to either myeloid progenitor cells or lymphoid progenitor cells (Figure 41-1). Myeloid progenitor cells are the precursors of red blood cells, platelets, granulocytes (polymorphonuclear leukocytes [PMNs]: neutrophils, eosinophils, and basophils), monocyte-macrophages, dendritic cells (DCs), and mast cells. Lymphoid progenitor cells give rise to the T, B, and NK cells. Lymphocytes are generated and mature in the bone marrow and thymus, which are considered to be the primary or central lymphoid organs. From there, they travel to reside in secondary or peripheral lymphoid organs, such as lymph nodes, spleen, mucosa-associated lymphoid tissues (MALT), gut-associated lymphoid tissues (GALT), and bronchus-associated lymphoid tissues (BALT).

The various cell types exit the bone marrow at different levels of maturation, circulate through the bloodstream, and may take up residence in specific tissues. Certain cells involved in the body's defense system provide rapid responses, whereas others support slower, adaptive responses. Neutrophils and NK cells exit the bone marrow in a relatively mature state and require very little time to become activated. In contrast, monocytes, dendritic cells, and most lymphoid cells leave the bone marrow in a relatively immature state and complete their maturation at some other tissue site, where they can be activated to respond to local cues.

Lymphocytes circulate between blood and lymphatics continuously. Lymphocytes that have not encountered antigen are called naïve lymphocytes; those that have encountered antigen and have become mature are effector lymphocytes. Activation of antigen-presenting cells (APCs)—monocytes, B cells and dendritic cells—is the necessary first step for the induction of adaptive immunity. In adaptive immunity, lymphocytes activated by antigens give rise to clones of antigen-specific cells, which are then selected either positively or negatively. Clonal selection is the central principle of adaptive immunity. The four basic postulates of clonal selection are that (1) each lymphocyte bears a single type of receptor with a unique specificity to self and nonself; (2) lymphocytes expressing receptors for specificity for self-antigens are deleted at an early stage and therefore are absent from the pool of mature lymphocytes; (3) interaction between a foreign antigen and the receptor capable of binding to it leads to lymphocyte activation; and (4) the differentiated effector cells derived from an activated lymphocyte will bear receptors of identical specificity to those of the parental cells. In adaptive immunity, unique antigen receptors are generated by gene rearrangement, and signals received through antigen receptors determine the development and survival of lymphocytes. Binding of antigen activates lymphocytes, resulting in the generation of effector cells and the establishment of immunologic memory.

T cells exit the bone marrow as CD3-CD4-CD8–null cells according to the cluster of differentiation (CD) classification of leukocyte antigens before entering the thymus. In young individuals, the thymus contains large numbers of developing T-cell precursors embedded in a network of epithelia known

*The authors wish to recognize Dr. Kenneth T. Miyasaki for his past contributions to this chapter.

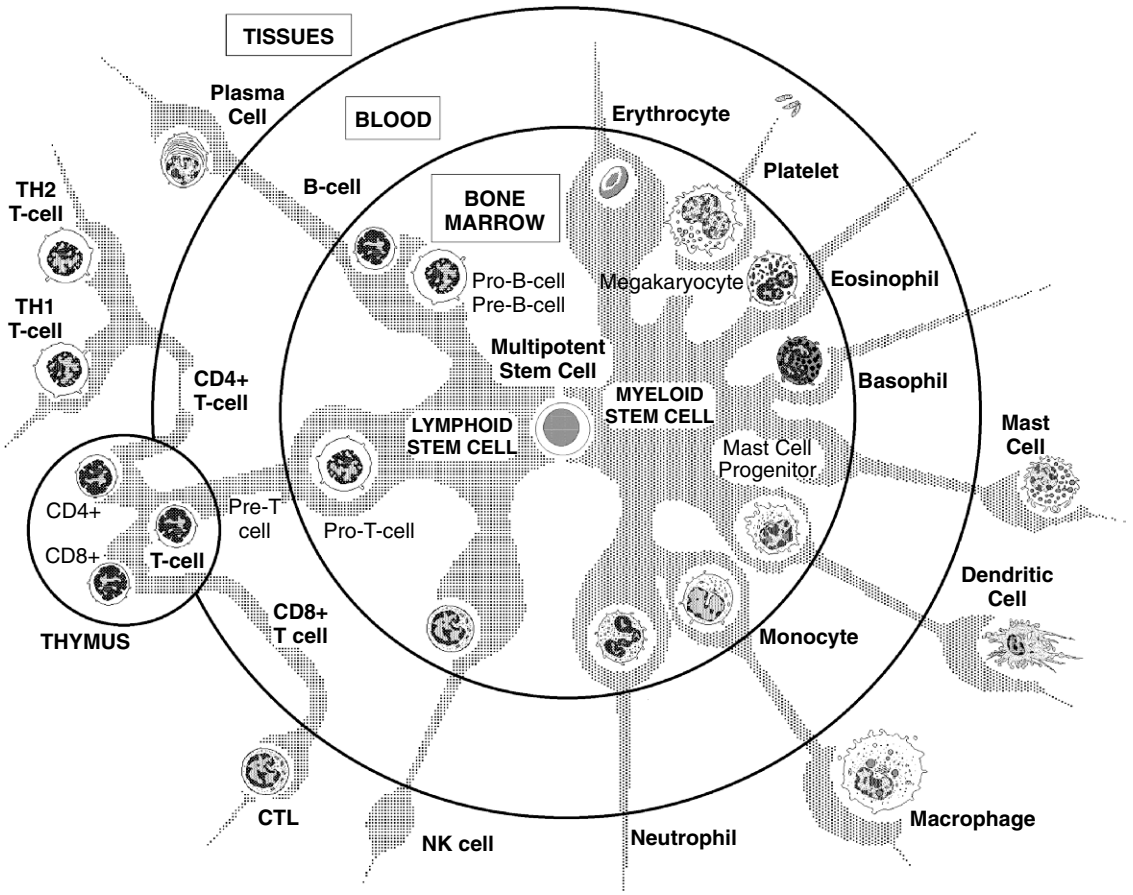

FIGURE **41-1** Lineage and location of blood cells and other cells involved in the immune response. Differentiative and proliferative events are indicated by shading. Not shown are the regulatory T cell and the T helper cell TH17. *Pre-T cell*, precursor T cell.

as the thymic stroma, which provides a supportive environment for the developing T cells. T-cell precursors proliferate extensively in the thymus, but most eventually are eliminated there. The thymus of a young adult mouse contains $1\text{-}2 \times 10^8$ thymocytes. Although 50 million new cells are generated each day, only 2 million of these cells survive to leave the thymus. The developmental pathway of T cells in the thymus is the following. Early on, CD3-CD4-CD8-null cells develop into CD3+pTαCD4+CD8+ (triple–positive) thymocytes. About 95% of triple-positive thymocytes will be eliminated by apoptosis, and the remaining 5% will exit thymus as either CD3+CD4+ or CD3+CD8+ double-positive T cells.

Once T cells have completed their developmental stages in the thymus, they enter the bloodstream and then are carried to the secondary lymphoid tissues, such as the lymph nodes or spleen. If they encounter their specific antigen, they will become activated, proliferate, and differentiate to armed effector T cells. Otherwise, they will continue to travel back and forth from the blood to the secondary lymphoid tissues. Meanwhile, these naïve T cells will receive survival signals from self-peptide-self-MHC complexes.

Immature dendritic cells also travel from the tissues to secondary lymphoid tissues where they mature to activate T cells. The first encounter of a naïve T cell with the antigen on a mature dendritic cell is called *priming*, to distinguish it from the response of an armed effector T cell to antigen.

The sampling of different peptide-MHC complexes by naïve T cells on dendritic cells is important for the specific encounter of antigen-specific T cells, since only 0.0001% to 0.01% of T cells are specific for any particular antigen. Once they encounter the antigen they cease migration, proliferate, and differentiate to effector T cells. This process may take several days. At the end of that time, they leave the lymphoid tissues and re-enter the bloodstream to migrate to the site of the infection.

CD4+ T cells differentiate further outside the thymus into four distinct subsets. T helper (TH)1 cells primarily secrete interleukin (IL)-2 and interferon (IFN)-γ and activate monocytes and B cells, whereas TH2 cells primarily secrete IL-4, IL-5, IL-6, and IL-10 and activate B cells. TH17 cells secrete IL-17 and activate neutrophil responses to extracellular bacteria; T regulatory (Treg) cells function to suppress T cell responses.

TH1 cells upon activation produce IL-2 and IL-2 receptors, both of which are important in the induction of cell proliferation. The IL-2 receptor is composed of three different chains; α, β, and γ chains. Resting T cells express the β and γ chains, which together form the intermediate affinity IL-2 receptor and can respond to high concentrations of IL-2. The high affinity IL-2 receptor is formed when all three chains associate; it responds to low concentrations of IL-2 in activated T cells.

CD8+ T cells differentiate into cytotoxic cells. CD8+ cytotoxic T cells kill virally infected cells or tumor-target cells via two different mechanisms, namely apoptosis and necrosis. Apoptosis is distinguished from necrosis by the intact plasma membrane at the initial stages of programming for cell death, nuclear membrane blebbing, and DNA fragmentation.

Receptors and other cell-surface proteins

Cells involved in specific immunity express various surface glycoproteins to help coordinate their functions and interac-

tions. These glycoproteins include adhesion molecules, cytokine receptors, and receptors that bind and respond to specific antigens and to co-receptors and costimulatory receptors expressed on other cells.

Clonally distributed antigen-specific receptors. As mentioned above, T cells and B cells possess receptors that specifically recognize the antigen and are distributed in a clonal manner. These receptors, both members of the immunoglobulin superfamily, are the T cell receptor (TCR) mentioned previously and the B-cell antigen receptor (BCR). Secreted forms of the BCR constitute the immunoglobulins found in plasma, extracellular fluid, and secretions. The BCR and TCR recognize short oligomeric sequences of a molecule and exhibit primary sequence specificity. In addition, the BCR (but not the TCR), which is designed to react with unprocessed antigen, may recognize secondary, tertiary, and quaternary structural features. The diversity of the TCR/BCR repertoire is generated by four main mechanisms: (1) somatic recombination, in which variable regions of the receptor chains, which are encoded in several pieces called *gene segments*, are assembled in the developing lymphocytes by somatic DNA recombination (a process known as *gene rearrangement*); (2) pairing of heavy and light chains of the BCR, or α and β chains of the TCR; (3) junctional diversity; and (4) somatic hypermutation. In both BCRs and TCRs the diversity is significantly increased by the addition and subtraction of nucleotides at the junction between the gene segments. Because the total number of nucleotides added by junctional diversity is random, the added nucleotides may disrupt the reading frame of the coding sequences, causing frameshifts that will lead to a nonfunctional protein. This outcome is called nonproductive rearrangement. Since two out of three rearrangements are nonproductive, many B cell progenitors never succeed in producing BCRs and never mature (into plasma cells and memory cells). Junctional diversity is achieved only at the expense of considerable cellular waste.

Rearranged genes in B cells (but not T cells) are further diversified by somatic hypermutation. Somatic hypermutation is the process of introducing point mutations into the variable region of the rearranged heavy and light chain genes at a very high rate. Somatic hypermutation occurs only when the B cells respond to the antigen along with the signals from activated T cells. Mutations that are deleterious and cannot bind antigen will remove the B cells (*negative selection*). Those that are positive will select for B cells with an even more improved antigen binding capacity (*affinity maturation*) causing the clonal expansion of these B cells.

Nonclonally distributed antigen-binding receptors. Most cells possess receptors that bind and present antigen specifically, but are not clonally distributed. These receptors are members of the immunoglobulin superfamily and include two classes of proteins encoded within the major histocompatibility gene complex (MHC) named MHC I and MHC II. T cells recognize self- and non–self-antigens as peptide fragments bound to MHC antigens. The MHC I and MHC II molecules recognize peptides derived from proteins that have been processed internally. MHC I proteins deliver peptides originating from cytosolic compartments, whereas MHC II proteins deliver peptides from vesicular compartments. The MHC I and II molecules do not discriminate the entire primary structure of the peptide, but instead recognize two (or more) "anchor" positions in the peptide separated by a short sequence of amino acids of virtually any composition or sequence. Peptide fragments presented through MHC I activate CD8+ T cells to kill; peptide fragments presented by MHC II activate the function of CD4+ T cells to aid B cells and macrophages to become activated.

Polygenic and polymorphic properties of the MHC make it difficult for pathogens to evade immune responses. Polygenic refers to the fact that the MHC contains several different MHC I and II genes; polymorphic indicates there are multiple variants of each gene.

The MHC is located on chromosome 6 in humans. There are three class I genes in humans named *HLA-A*, *HLA-B*, and *HLA-C* (classical MHC I genes). There are also three pairs of class II genes named *HLA-DR*, *HLA-DP*, and *HLA-DQ*. The HLA-DR cluster contains an extra β chain gene, where its product can pair with the DRα chain, giving rise to four types of MHC II proteins. Expression of MHC II genes is induced by IFN-γ via the production of a transcriptional activator known as *MHC class II transactivator* (CIITA). The absence of CIITA causes severe immunodeficiency.

MHC restriction refers to the recognition of the antigen by the T cells in the context of self- MHC. Thus a non–self-MHC I presenting the same peptide would not be recognized and would not activate T cells. Non–self-MHC molecules are recognized by 1% to10% of T cells, an event termed *alloreactivity*. In alloreactivity, recognition of either the peptide antigen (peptide-dominant binding) or the foreign MHC molecule irrespective of the peptide with which it is complexed (MHC-dominant binding) leads to T-cell activation.

Other genes that map to the MHC locus include components of the complement cascade, such as C2, C4, and factor B, and cytokines including tumor necrosis factor (TNF)-α. These genes are referred to as *MHC class III genes*. In addition to highly polymorphic MHC I and II genes, there are many genes encoding MHC I–like molecules that show little polymorphism termed *MHC class Ib*. Some MHC Ib genes (e.g., the MIC gene family) are induced during cellular stress and regulate NK function.

Most individuals are heterozygous at each MHC locus. MHC polymorphism affects T-cell recognition of antigen by influencing both the peptide binding and the contact between the TCR and MHC molecule.

Mediators

Numerous water-soluble proteins affect or create specific immune reactions. Two principal groups of interest in immunotherapy are the cytokines and humoral antibodies.

Cytokines. Cytokines are produced by a wide variety of cells. They play crucial roles in stimulating the production of blood cells of all types and in regulating the differentiation, activation, and suppression of cells involved in specific immunity. Some cytokines are referred to as *interleukins*; cytokines also include interferons, and colony-stimulating factors. Cytokines have local and distant effects and activate cells in an autocrine (causing a self-response) and paracrine (affecting other cells) fashion.

An important feature of cytokine action is that multiple cytokines often work in concert to foster a particular change in cellular activity. The proliferation and differentiation of effector T cells important in cell-mediated immunity (CMI) depend on the interplay of TH1 cytokines such as IL-2, IL-12, and IFN-γ. Activation of B cells for humoral immunity is based on the release of several interleukins (IL-4, IL-5, IL-10, and IL-13) by TH2 cells. TH1 cytokines are important in stimulating B-cell differentiation leading to the production of immunoglobulins IgG1, IgG2, and IgG3. TH2 cytokines stimulate IgE and IgG4 production. The actions of selected cytokines are summarized in Table 41-1.

Humoral antibodies. Antibodies synthesized and released by plasma cells directly mediate humoral immunity. As shown in Figure 41-2, the basic immunoglobulin structure consists of two heavy chains and two light chains covalently linked by

TABLE **41-1**

Selected Cytokines and Their Functional Relationships

CYTOKINE	SECRETED BY	FUNCTIONS
Lymphoid Hematopoiesis		
IL-7	SC	Lymphopoietin-1 Growth of pro-B and pre-B cells Growth of $CD4^-$ and $CD8^-$ T cells
T-Cell—Stimulating Factors		
IL-1 (α and β)	APC, B, Ep, En	Upregulation of IL-2 receptors on T cells Fever (endogenous pyrogen) Bone resorption (OAF)
IFN-α	B, Ma	Death of virus-infected cells Isotype switching Upregulation of MHC class II Ag
IFN-β	Fb, Ep	Same as for IFN-α
IFN-γ	T	Same as for IFN-α Upregulation of IL-2 receptors
IL-2	T	T-cell proliferation and formation of cytotoxic T lymphocytes
IL-10	T, B	T-cell proliferation Inhibition of cytokine synthesis by TH1 cells Cofactor for mast cell growth Increased B-cell expression of MHC class II molecules
B-Cell—Stimulating Factors		
IL-4	T	Activation of resting B cells Isotype switching (IgG1 and IgE)
IL-5	T	B-cell proliferation Isotype switching (IgA, IgM) Eosinophil differentiation factor
IL-6	T, M, Fb	B-cell proliferation Death of virus-infected cells
IL-13	$CD4^+$ T	Monocytes assume dendritic features Stimulation of B-cell differentiation
Tumor Killers and Cell-Mediated Immunity		
TNF-α	Ma	Death of tumor cells Related to IFN-γ and TNF-β Promotion of healing Angiogenesis
TNF-β	T	Death of tumor cells (lymphotoxin)
IL-12	Ma	Stimulation of TH1 cells and CMI Inhibition of TH2 cells and IgE production
Myeloid Factors		
IL-3	L, My	Multiple granulocytic cell type CSF
IL-8	Ma, En	Neutrophil (and lymphocyte) chemotaxis Granulocyte differentiation cofactor
IL-9	T	Erythroid cell precursor growth Mast cell growth
IL-11	SC	Megakaryocyte growth and differentiation
GM-CSF	L, My	Granulocyte/monocyte CSF
M-CSF	L, My	Monocyte CSF
G-CSF	L, My	Granulocyte/erythroid cell CSF
Erythropoietin	RC	Erythroid growth and differentiation

This summary table is not intended to provide a complete listing of all the biologic functions of the cytokines, but rather to point out the relationships among them.

Ag, Antigen; *APC,* antigen-presenting cell; *B,* B cell; *CMI,* cell-mediated immunity; *CSF,* colony-stimulating factor; *En,* endothelial cell; *Ep,* epithelial cell; *Fb,* fibroblast; *G,* granulocyte; *L,* lymphoid cell; *M,* monocyte; *Ma,* macrophage; *My,* myeloid cell; *OAF,* osteoclast-activating factor; *RC,* renal cortex; *SC,* stromal cell; *T,* T cell; *TNF,* tumor necrosis factor.

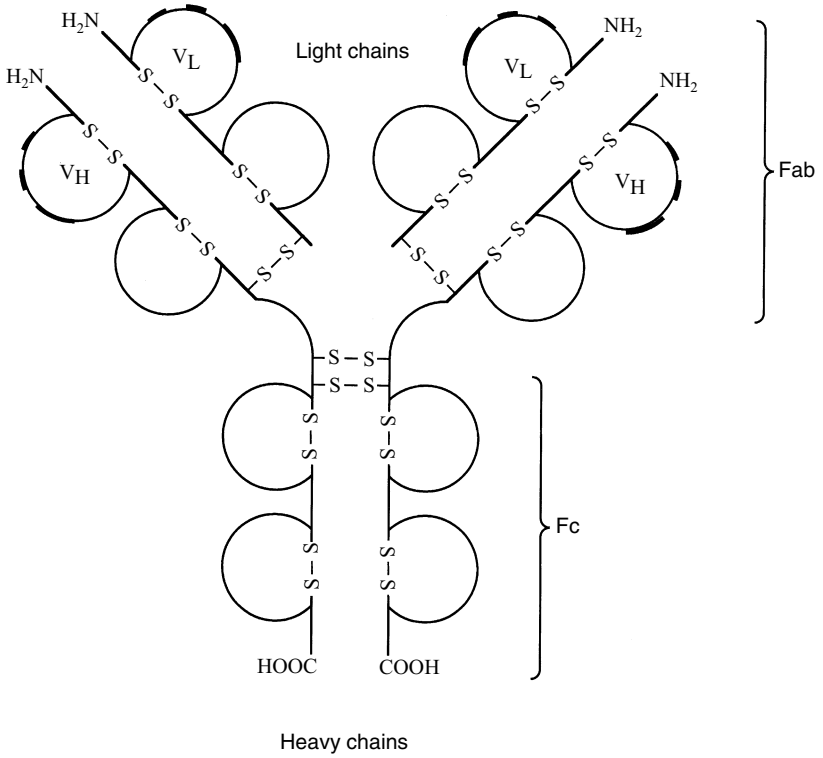

FIGURE **41-2** Diagram of an IgG antibody, including disulfide linkages. The "crystallization fragment" *(Fc)* of the molecule, formed by portions of the two heavy chains, contains the binding sites for specific cells and for complement; each remaining "antibody fragment" *(Fab)*, which consists of one light chain and the remaining portion of one heavy chain, includes the variable regions (*VL* and *VH*) that participate in antibody binding. The hypervariable sequences of the variable regions are shown as thickened segments.

interchain disulfide bonds. Both chains consist of two or more domains, each defined by a single intrachain disulfide bond. The heavy chain is composed of three or four constant domains and one variable domain. The light chain incorporates one constant and one variable domain. The relatively flexible hinge regions found in certain immunoglobulins are believed to be remnants of primordial constant domains. Terminal sequences on the amino end of each chain make up the variable regions of the molecule. Within each variable region are hypervariable sequences that are responsible for specific antigen binding. There are two types of light chains, λ and κ. The ratio of λ and κ chains differs in various species, being 1:20 in mice and 1:2 in humans. Sometimes the ratio of λ to κ is used to identify multiple myeloma.

The class of an antibody is determined by its heavy chain. There are five heavy chains or isotypes: IgM, IgG, IgD, IgA, and IgE. IgG is the most abundant subtype and has several subclasses: IgG1, IgG2 (IgG2a and IgG2b), IgG3; and IgG4. The amino terminal region in the variable domain (v domain) of the heavy and light chains (V_H and V_L) binds to antigen, whereas constant domain (C domain) of the heavy and light chains (C_H, C_L) makes up the constant regions.

These domains form the Fc region of the molecule (Fc is the "crystallizable fragment" of a polyclonal immunoglobulin). The Fc region dictates the specific binding of each isotype to different Fc receptors on phagocytes, mast cells, and other cells involved in inflammatory reactions. The Fc region also dictates complement activation by IgG and IgM.

There are three discrete regions in the V_H and V_L domains of the antibodies named HV1 (hypervariable 1), HV2, and HV3 (HV3 is the most variable site of each domain). These are separated by structural framework regions (FRs), namely FR1, FR2, FR3, and FR4. The six hypervariable regions in each arm of the antibody that form the antigen binding site when brought together are complementary to the antigen, thus they are called *complementarity determining regions* or CDRs. There are three CDRs, CDR1, CDR2 and CDR3. Antigen molecules contact antibody over a broad area of its surface and binds noncovalently through electrostatic forces, hydrogen bonds, van der Waals forces, and hydrophobic interactions.

Transmembrane and secreted forms of Igs are generated through alternative splicing of heavy chain domains. There are two polyadenylated sites that dictate the generation of transmembrane or secreted forms of Igs. All B cells initially express IgM in its transmembrane form, but upon contact with antigen they generate the secreted forms and undergo isotype switching to generate other antibodies.

Sequence differences between Ig heavy chains cause the various isotypes to differ in the number and location of their disulfide bonds, the number of attached oligosaccharide moieties, the number of C domains, and the length of the hinge region.

IgM, which is co-expressed with IgD on the surface of cells, predominates in neonates and during initial, or primary, immune responses to antigenic challenges. IgG, IgA, and IgE are important in responses to antigens on secondary exposure. Because of an extended half-life (approximately 21 days), IgG constitutes approximately 75% of circulating immunoglobulins. IgG is the principal opsonic antibody important for phagocytosis; it plays a central role in immune responses against submucosal antigens. Fc receptors for IgG are found on neutrophils, monocytes, and dendritic cells.

On a daily basis, approximately three times more IgA is produced than all other immunoglobulins combined. IgA has two subclasses, IgA1 and IgA2. The IgA2 isotype is found in most mucous secretions and constitutes about 40% of total salivary IgA. It is important in mucosal immunity and caries immunology. Both IgA and IgM are bound by the polymeric immunoglobulin receptor (pIgR), which is not within the Fc receptor family. Found on the basolateral surface of ductal epithelial and intestinal epithelial cells, the pIgR enables the two immunoglobulins to be transported by transcytosis across the epithelium and into secretions. IgA is important in specific immunity against supramucosal antigens and in anti-inflammatory reactions below the mucosa. Although circulatory IgA production (mostly IgA1) is equal to that of IgG,

it has a shorter half-life (approximately 7 days) than IgG and a lower plasma concentration.

IgE is evolutionarily related to IgG in that both their ancestries can be traced back to IgY, the predominate inflammatory immunoglobulin found in nonmammalian vertebrates. IgE is bound with extremely high affinity by Fc receptors found on mast cells and basophils; it promotes immediate inflammation (which is important in initiating acute and chronic inflammation). IgE is also bound by low-affinity receptors present on eosinophils and enables these cells to exert anthelmintic and antiparasitic effects. IgE production is tightly controlled.

The role of IgD is less clear; it is not a secondary response antibody because it can be co-expressed with IgM on a single B cell. IgD and IgM mRNA is produced as a single transcript. Post-transcriptional modifications dictate whether IgM or IgD will be translated. IgD is believed to prevent the induction of B-cell tolerance, which can occur in B cells expressing IgM alone. Fc receptors for IgD have been found on T cells.

Each plasma cell produces a unique antibody because of the clonal distribution of the BCR. Initially, the differentiation of B cells to plasma cells results in the production of IgM antibodies. If antigen has also been presented to CD4+ T cells by B cells, the T cells can guide B-cell differentiation along the memory pathway as opposed to the plasma cell differentiation pathway. In the memory pathway, the isotype may change. Secondary antigen exposure can elicit IgA, IgG, or IgE production. This process of isotype switching promotes a more appropriate interplay of antibodies with complement and with myeloid immune cells (e.g., neutrophils, monocytes, mast cells, and eosinophils).

Initiation, Progression, and Termination of Specific Immune Responses

The immune system is normally engaged in the homeostatic regulation of host-derived antigens. Once an antigen receptor is formed it has to be rigorously tested against self peptides. Given the incredible number of receptors formed it is important that those lymphocytes which reach maturity are likely to be useful in recognizing foreign antigens. In general, developing lymphocytes whose receptors interact weakly with self-antigens, or bind antigen in a particular fashion, receive a survival signal. In contrast, lymphocytes with strongly self-reactive receptors must be deleted to prevent auto-immunity through negative selection. The fate of lymphocytes in the absence of any signal is death. In addition, the immune system participates in its more widely appreciated inflammatory function known as the *immune response*.

Immune responses are the measurable alterations in immune system activity after an antigenic perturbation. They are usually initiated by an immediate inflammatory reaction resulting from the activation of soluble factors (e.g., complement) found within the extracellular fluid or mediators released by resident leukocytes, especially the mast cell. The immediate inflammatory response signals postcapillary venule endothelial cells to recruit the appropriate acute-phase or chronic-phase leukocytes from the blood. Initially recruited are cells that do not need to progress through proliferation or differentiation to exert an effect, such as neutrophils. Neutrophils are the predominant cell in acute inflammation. Acute inflammation may be followed by slower, chronic inflammation involving less mature cells capable of adaptive cellular differentiation (with or without proliferation). The proliferation and differentiation of clones of cells that recognize the antigen specifically constitute the specific immune response.

Specific immune responses involve a series of events (Figure 41-3), each of which offers a potential site for immunotherapeutic intervention. Included in this series are antigen processing and presentation, T-cell selection, lymphocyte differentiation, effector function, and termination. These events occur in response to changes in the concentrations of antigens intracellularly and extracellularly.

Antigen processing

Antigen processing is the partial degradation of polymeric antigens into oligomeric units (especially the degradation of a protein into small peptides), which are subsequently bound by MHC I or II molecules. Various hydrophobic peptides and glycolipids can be bound by CD1 antigens, which are related to the MHC I and II molecules.

Intracellular antigens. Processing of intracellular antigens generated within the endoplasmic reticulum or cytosol occurs continuously in all cells. Proteins in the cells become degraded and are replaced by newly synthesized proteins. Degradation of protein occurs in a large, multi-subunit protease-like structure called the *proteasome*. Peptides can further be trimmed in the endoplasmic reticulum (ER) by the help of aminopeptidases. Some proteasomes accept proteins for degradation only if they are tagged by small polypeptides called *ubiquitin*. The peptides generated in the cytosol are transported into the ER where they are bound by nascent MHC I molecules.

Viruses and certain types of bacteria are degraded in the cytosol or in the nuclear compartments before they are presented in the context of MHC I. Structurally, MHC I consists of two polypeptide chains, α and β. The α chain is the larger of the two and has three domains, α1, α2 and α3. The smaller, nonpolymorphic β chain, termed *β_2 microglobulin*, is noncovalently attached to the α3 domain. Only the α chain spans the membrane. The α1 and α2 domains form the cleft that binds to the peptide fragment and are highly polymorphic. Peptides that bind to MHC I molecules are transported from the cytosol to the ER. The peptide-binding site of MHC I is formed in the lumen of the ER and is never exposed to the cytosol. Expression of MHC I on the surface of the cells is unstable unless it is bound to peptide. Mutations at a site where peptides bind to the MHC I protein cause significant decreases in the expression of MHC I on the surface of the cells. Mutations in transporters associated with antigen processing (TAPs) may also not allow for the transport of the peptides from the cytosol to the lumen of the ER.

Newly synthesized MHC I α chains bind to a chaperone protein called *calnexin*, which retains MHC I in a partly folded structure in the ER. When β_2 microglobulin binds the α chain the complex dissociates from calnexin and then binds to another chaperone, *calreticulin*. A third protein, tapasin, forms a bridge between MHC I molecules and TAP, allowing the transport of the suitable peptide from the cytosol. Most of the chaperon proteins play a role in selecting peptides with higher binding affinity.

Viruses have evolved several means of evading recognition by preventing the appearance of peptide:MHC I complexes at the cell surface. For example, the herpes simplex virus prevents the transport of viral peptides into the ER by producing proteins that bind and inhibit TAP, whereas adenoviruses produce a protein that binds MHC I molecules and retains them in the ER. Cytomegaloviruses accelerate retrograde translocation of MHC I back into the cytosol, where they are degraded.

Extracellular antigens. The majority of pathogenic bacteria and some eukaryotic parasites replicate in the endosomes and lysosomes that form the vesicular system. Pathogens such as Leishmania and Mycobacteria are picked up by macrophages through endocytosis. The resultant endocytic vesicles gradually become acidified and finally fuse with lysosomes, forming phagolysosomes. These organelles contain acid proteases that become activated at low pH, resulting in degradation of the protein antigen. Among acid proteases are the cysteine proteases cathepsin B, D, S, and L. Cathepsin L is the most active of the family. Disulfide bonds also need to be cleaved for

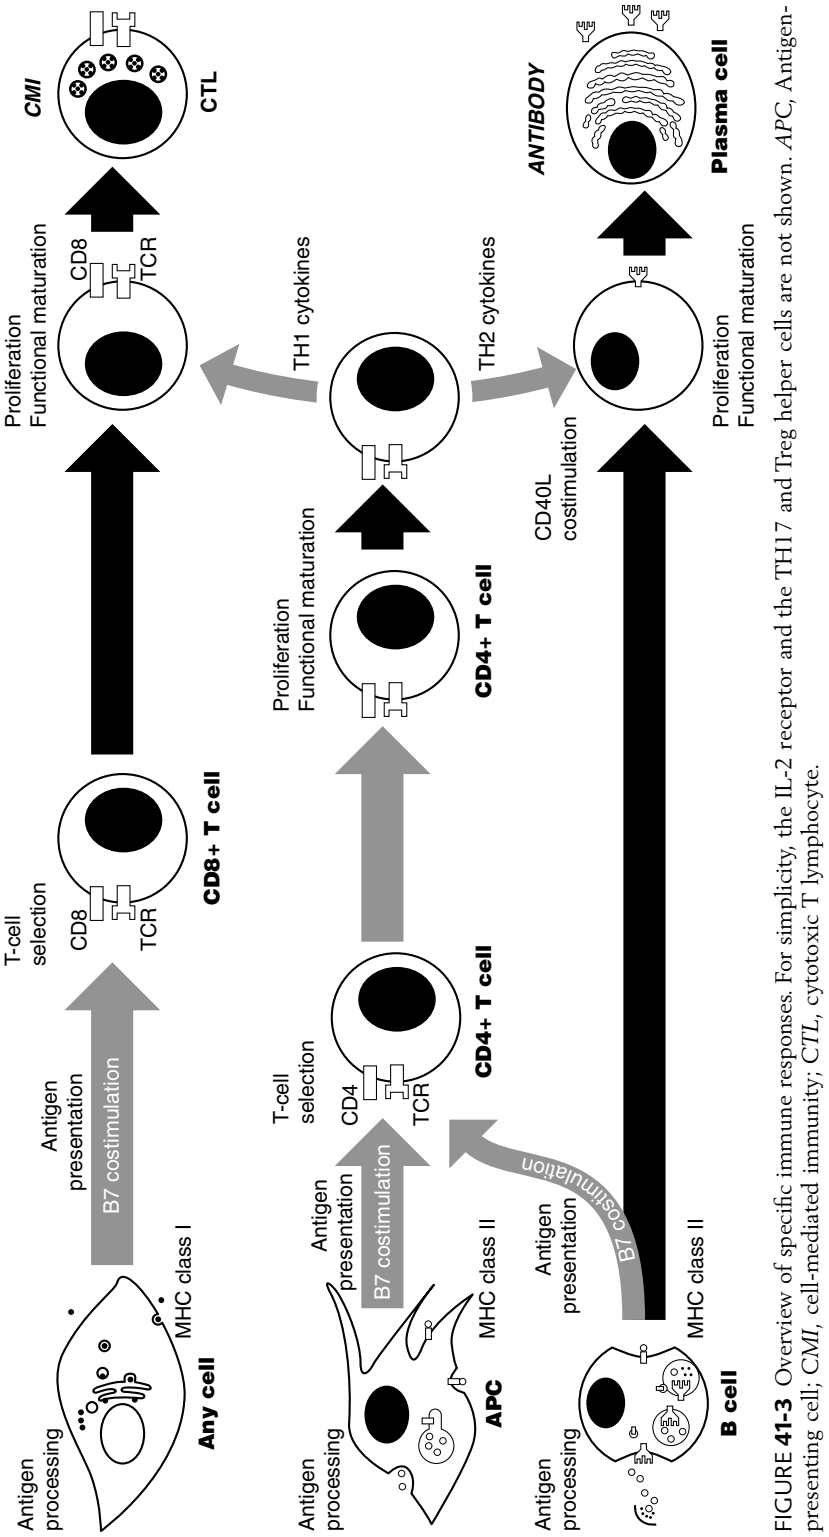

FIGURE **41-3** Overview of specific immune responses. For simplicity, the IL-2 receptor and the TH17 and Treg helper cells are not shown. *APC*, Antigen-presenting cell; *CMI*, cell-mediated immunity; *CTL*, cytotoxic T lymphocyte.

peptide processing. Degraded peptides from pathogens are then presented in the context of MHC II molecules to T cells.

Each MHC II protein comprises two noncovalently bound chains, α and β, both of which span the membrane. There are two α domains, α1 and α2, and two β domains, β1 and β2. The α1 and β1 domains are very polymorphic and form the peptide-binding locus. The folding of α1 and β1 is more open than the α1 and α2 domain of MHC I, thus the ends of the peptide fragments are exposed.

Binding of nonspecific peptides to MHC II is prevented by the association of MHC II in the ER with a third polypeptide termed the *invariant chain*. The invariant chain, by forming a trimer with MHC II, covers the antigen-binding groove. Invariant chains also target MHC II to low-pH endosomal compartments where peptide loading can occur. The invariant chain is then cleaved by acid proteases, such as Cathepsin S, to generate a truncated form. The subsequent cleavage releases the MHC II molecule leaving a fragment called C*LIP* bound to the MHC II.

Most MHC II molecules are brought to the cell surface in vesicles, which at some point fuse with incoming endosomes where they encounter and bind peptides derived from self- or non–self-proteins. HLA-DM assists in the process by stabilizing MHC II molecules, which would otherwise aggregate. It also catalyzes the removal of CLIP and the loading of the peptide into the groove of the MHC II. HLA-DM, closely related to the MHC II molecule, does not bind to the peptide because its groove is closed. HLA-DM also removes weakly bound peptides, allowing for the binding of high affinity peptides. Peptides bound to MHC can remain several days in case the APC does not encounter the target; therefore, increased binding affinity of the peptide to the groove is important.

A second atypical MHC II molecule, called HLA-DO is produced in thymic epithelial cells and B cells. Unlike HLA-DM, which aids in releasing CLIP and binding peptide, HLA-DO inhibits HLA-DM function and subsequently inhibits antigen loading. The activating capacity of HLA-DM is higher than the inhibiting capacity of HLA-DO because secreted IFN-γ can upregulate HLA-DM but not HLA-DO.

T-cell activation

T-cell recognition, activation, and effector function depend on cell-cell contact mediated by cell adhesion molecules. T cells enter the lymph nodes through binding to specialized postcapillary swellings called *high endothelial venules*. The main classes of adhesion molecules involved in lymphocyte interaction are the selectins, integrins, members of the Ig superfamily, and mucin-like molecules. Selectins are important for leukocyte homing to particular tissues and can be expressed either on leukocytes (L selectin) or on endothelial cells (P and E selectins). Selectins are cell-surface molecules with a common core structure, but different lectin-like domains in their extracellular portions. The lectin domain binds to particular sugar groups on a carbohydrate backbone. L selectin binds to the carbohydrate moiety of mucin-like molecules called vascular addressins, which are expressed in the surface of endothelial cells. The interaction between L selectin and vascular addressins is responsible for the specific homing of naïve T cells to lymphoid tissues, whereas the integrins and the Ig superfamily are involved in their crossing through the endothelial barrier.

Just as binding of neutrophils to endothelial cells is guided by chemokines, migration of naïve T cells into lymphoid tissues is directed by similar molecules, such as secondary lymphoid tissue chemokine. This interaction increases both the affinity and surface expression of integrins on the T cell membranes, which arrests the cells and causes them to move through the endothelial layer to enter the lymphoid parenchyma. The integrin LFA-1, for example, is expressed on all T cells. It binds to Ig superfamily adhesion molecules, such as ICAM-1 and ICAM-2, which are expressed on endothelium and APCs. Binding to LFA-1 allows the leukocytes to migrate through the blood vessel wall in lymph nodes and be able to sample antigen on the surface of APCs. ICAM-3, another adhesion molecule, is expressed only on leukocytes and binds to its partner (DC-sign) on dendritic cells. The binding of CD58 (LFA3) on APCs to CD2 on T cells is yet another example of adhesion molecule interactions.

The initial association of T cells with APCs is mediated by the interplay of multiple adhesion molecules. Binding of LFA-1, ICAM-3 and CD2 on T cells to ICAM-1, ICAM-2, DC-sign and CD-58 on APCs provides enough redundancy that if one pairing is missing the T cells can still bind and recognize the specific antigen on the APCs. The transient binding to APCs allows the T cells to sample a large number of MHC:peptide sequences on APCs, and if it recognizes the antigen, signaling through the TCR will significantl increase the affinity of LFA-1 for ICAM-1.

Both signals for specific antigen and costimulatory molecules are required for the clonal expansion of T cells. In the absence of costimulatory signals, activation of T cells through antigen receptor will lead to anergy or unresponsiveness. Anergic cells are deleted by cell death. The most highly characterized costimulatory molecules are structurally related glycoproteins belonging to the B7 family. The best known are B7.1 (CD80) and B7.2 (CD86). They bind to the CD28 receptor on the surface of naïve T cells and costimulate in the presence of antigen receptor. Once a naïve T cell is activated, it up-regulates CD40 ligand, which binds to the CD40 receptor on APCs and further activates both the T cells and the APCs. Activated T cells will then upregulate cytotoxic T-lymphocyte–associated antigen-4 (CTLA-4 or CD152), which is similar in structure to CD28 and limits further activation by binding to B7 family costimulatory molecules. This way activation and proliferation of T cells are regulated.

Resident dendritic cells such as Langerhans cells are able to pick up antigen by phagocytosis or macropinocytosis. They can travel and take the antigen to the secondary lymphoid tissues where they lose the capability to phagocytize but gain the ability to present antigen to T and B cells. Both dendritic cells and B cells can bind soluble antigens and present them as peptide: MHC II complexes to T cells. B cells do not express costimulatory molecules constitutively; they need to be activated by bacteria to express B7.1 and B7.2.

The actual recognition of antigen by the TCR is a low-affinity reaction. This characteristic enables many TCRs of a given T cell to interact with the few specific antigens presented by the antigen-presenting cell. Multiple interactions are important because T-cell activation depends on the number of TCRs that interact with antigen over time.[42] The factors that influence T-cell activation include the number of antigen molecules presented by the antigen-presenting cell, the affinity of the TCR for the antigen, and the number of TCRs. If the interaction with peptide antigen by TCRs is sufficient, the TCRs cluster on the T-cell surface and downregulate (the TCRs are probably internalized). With costimulation, downregulation of approximately 4250 TCRs leads to T-cell activation.

In early stages of exposure to antigen, costimulatory signals permit T cells to become receptive to differentiative signals, allowing them to proliferate or mature in function. These signals also block apoptosis. At later stages, the same signals can permit T cells to differentiate terminally, even to the point of death.

Differentiation

After antigen recognition by TCR and BCR, intracellular signaling events allow the T cell to differentiate into functionally mature cells (Figure 41-4). Much present-day immunother-

apy is aimed at this stage of the specific immune response. Binding of antigen to its receptor leads to the clustering of antigen receptor on lymphocytes, which is the first step in signal transduction, Clustering of antigen receptor leads to activation of intracellular signaling molecules. Protein tyrosine kinases are enzymes that affect the function of other proteins by adding a phosphate group to certain tyrosine residues. Specific growth factors such as c-kit have cytoplasmic domains that contain intrinsic tyrosine kinase activity. T- and B-cell signaling is different from c-kit signaling since the TCR and BCR do not have intrinsic kinase domains; rather they rely on the interaction with other tyrosine kinases known as receptor-associated tyrosine kinases.

There are specialized areas within the membrane lipid bilayer that contain high quantities of sphingolipids and cholesterol. These areas are called *lipid rafts*. Signaling molecules associate with lipid rafts. Disruption of the lipid rafts inhibits T- and B-cell signaling.

Signaling through T and B cells is governed by a complex array of intracellular signaling elements, which can phosphorylate and activate other elements to transduce the signal from the receptor. The receptor-associated protein kinases are localized in the inner surface of the cell membrane and cannot activate their cytosolic targets efficiently unless they themselves are activated. Their activation and subsequent phosphorylation of tyrosines on receptor-associated chains recruits other protein tyrosine kinases, which then transduce the signal. The Src family kinases involved in T and B cell receptor signaling provide an example of this kind of signaling element.

The variant chains of the lymphocyte antigen receptor are associated with invariant accessory chains that mediate the signaling function of the receptor. The BCR is associated with Igα and Igβ invariant chains. The TCR is associated with multiple invariant accessory chains (ε, γ, δ, and ζ). Accessory chains have a structure termed the *immunotyrosine activation motif* (ITAM), which enables them to signal when the BCR or TCR is bound to the antigen. ITAMs are phosphorylated by src family receptor–associated tyrosine kinases, which gives them the ability to bind to the members of a second family of tyrosine kinases (Syk in B cells and Zap 70 in T cells). The enzyme activity of each src family kinase is regulated by the phosphorylation status of its kinase domain and its carboxy terminal region, each having a regulatory tyrosine residue. Phosphorylation of tyrosine in the kinase domain activates the enzyme, whereas phosphorylation at the carboxy terminal tyrosine is inhibitory. Src family kinases are kept inactive by a tyrosine kinase called C*SK* (c-terminal src kinase), which phosphorylates the inhibitory domain. Since the function of CSK is constitutive in resting cells, src-family proteins remain quiescent until antigen recognition, which then activates a protein tyrosine phosphatase (CD45 that removes the phosphate block from the inhibitory tyrosine and permits activation of the src-family kinases.

Antigen receptor signaling is enhanced by coreceptors that bind to the same ligand. B cell co-receptors are formed by a complex of CD19, CD21, and CD81 proteins. Src family kinases phosphorylate the ITAMs on Igα and Igβ, and these subsequently recruit Syk to Igβ. Trans-phosphorylation of each kinase by the other occurs, and the activated kinases in turn activate phospholipase C-γ (PLC-γ), guanine exchange factors (GEFs), and Tec kinases.

Similar to BCRs, clustering of TCRs and the co-receptors activates CD45, which removes a phosphate from Src family kinases (e.g., Lck) and activates their function, resulting in the phosphorylation of ITAMs. After phosphorylation, ZAP-70 is able to bind and become activated by Lck, which will initiate a signaling cascade leading to the activation of PLC-γ, GEF, and Tec kinases.

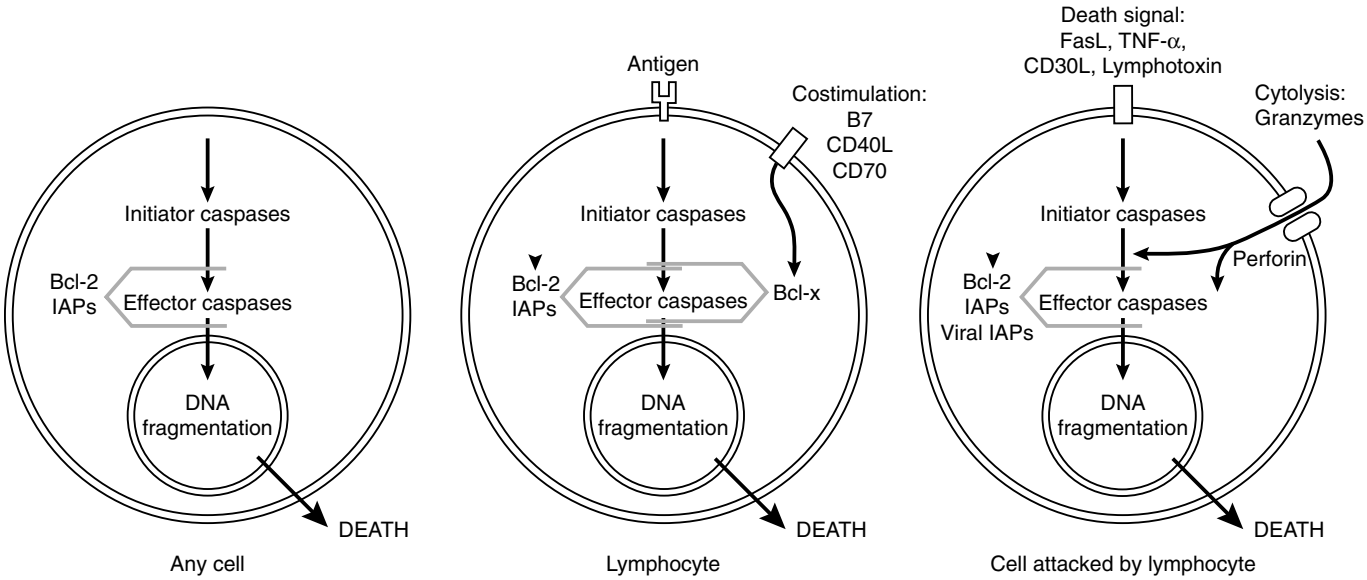

FIGURE **41-5** Apoptosis and lymphocyte-induced cytolysis. Apoptosis, indicated by the sequence of *arrows,* involves the activation of initiator caspases (e.g., caspase 8), which promotes proteolytic activation of other effector caspases involved in apoptosis. Environmental cues help prevent programmed cellular death by invoking the blocking action *(shaded lines)* of Bcl-2 or specific inhibitor of apoptosis proteins (IAPs) or both. Similar molecules (e.g., Bcl-x) inhibit apoptosis in lymphocytes co-stimulated by members of the tumor necrosis factor family (B7, CD40L, and CD70) and in virally infected cells. Cytotoxic lymphocytes destroy targeted cells either by (1) signaling for apoptosis to occur or (2) releasing perforins and granzymes that activate proteolysis directly. *FasL,* Fas ligand.

PLC-γ is known to cleave membrane phosphatidylinositol bisphosphate (PIP_2), yielding diacylglycerol (DAG) and inositol triphosphate (IP_3). DAG activates protein kinase C (PKC), which in turn stimulates nerve factor-κB (NF-κB). NF-κB usually is complexed with inhibitor proteins collectively called I-κB, which prevent its translocation to the nucleus. NF-κB is an important transcription factor for various inflammatory cytokines, and supports inflammatory aspects of the specific immune response. TNF-α, one of the cytokines whose synthesis is stimulated in part by NF-κB, increases the transcription of NF-κB and its dissociation from I-κB.

IP_3 increases the intracellular Ca^{++} concentration, activating calcineurin, a phosphatase that frees NF-AT (nuclear factor of activated T cells) from a phosphate block. GEFs activate Ras, an important GTPase that activates MAP kinases. The Ras-induced MAP kinases then activate Fos and Jun kinases, which are components of the transcription factor AP-1.

In unstimulated cells, NF-AT is rendered inactive and remains in the cytoplasm by phosphorylation on serine/threonine residues. Ca^{++}-activated calcineurin removes the phosphate block and unmasks the nuclear localization signal, which then directs NF-AT to enter the nucleus of the cell and activate transcription. For NF-AT to remain in the nucleus, however, the function of glycogen synthase kinase (GSK3) must be inhibited. GSK3 can phosphorylate NF-AT, exporting it back to the cytoplasm. Cyclosporin A and tacrolimus are inhibitors of NF-AT.

Signals from the antigen receptor alter the cytoskeleton to produce changes in cell shape, motility, and secretion. Antigen receptor signaling can be inhibited by interactions with inhibitory receptors expressed on the surface of cells such as NK cells and other lymphocytes.

Effector aspects of cell-mediated immunity

In specific CMI, CD4+ and CD8+ T cells play important roles. CD4+ T cells receive antigen stimulation and co-stimulation from dendritic cells (e.g., the Langerhans cells) to secrete key cytokines and growth factors. CD8+ T cells receive antigen stimulation and co-stimulation from infected or neoplastic cells and become primed to receive proliferative and differentiative signals from CD4+ T cells. CD8+ T cells proliferate and differentiate into cytotoxic T lymphocytes in the presence of TH1 cytokines, such as IL-2, IL-12, and IFN-γ.

Apoptosis. When a cytotoxic T lymphocyte recognizes antigen in association with MHC I molecules on virally infected cells or transformed tumor targets, it may induce *apoptosis* or programmed cell death. The cytotoxic T lymphocyte does this by presenting the target cell with specific membrane-bound signals delivered by Fas ligand, TNF-α and APO2 ligand.[22] If the signals are effective, the target cell is induced to die. Target cells express specific TNF-family receptors (TNFRs) for these ligands. Apoptosis, as summarized in Figure 41-5, involves several steps that may be targeted for therapeutic intervention.

Cells possess mechanisms for preventing death by using proteins, such as Bcl-2, and several inhibitor of apoptosis proteins (IAPs).[23] Bcl-2 is expressed on the membranes of intracellular organelles, including the mitochondria, nucleus, and smooth endoplasmic reticulum. Bcl-2 and IAPs delay or prevent apoptosis by inhibiting proteolysis mediated by cysteine proteases, termed *caspases,* that are responsive to apoptotic signals.[31] Several viruses (including Epstein-Barr virus, adenovirus, African swine fever virus, and cowpox) produce substances similar to Bcl-2 and IAP, which may help them evade host defenses by preventing apoptosis. Also, B-cell lymphomas have been associated with Bcl-2 overexpression. Co-stimulation of T cells and B cells induces the expression of apoptosis-inhibiting molecules after antigen stimulation.[7]

Cytolytic activities. A target cell may become resistant to apoptotic signaling mediated by the above-mentioned surface ligands, especially if the cell is infected by a virus that produces apoptotic inhibitors. In this case, the NK cells and the cytotoxic T lymphocytes must depend on cytolytic factors to kill the damaged cell. Within the vesicular components and

dense cores of these granules are numerous potentially cytocidal proteins. The vesicles and dense cores are discharged when the cytotoxic granules fuse with the plasma membrane of the NK cell or cytotoxic T lymphocyte.

Granule exocytosis can provide additional death-inducing factors. One factor is perforin. Perforin can form polymeric channels in cell membranes.[26] Affected membranes lose their structural integrity, and lysis of the cell soon follows. The second factor is granzyme B. Granzymes may gain access to the target cell, either directly by fusion of the granule vesicles or dense core with the membrane of the target cell, or because of a sublytic quantity of perforin that allows granzymes to gain access to the cytosol of the target cell.[26] When in the cytosol, granzyme B can activate apoptotic proteolysis.

Humoral immunity

Humoral immune responses protect the extracellular spaces of the body from being colonized by pathogenic bacteria and guard against the spread of intracellular pathogens from cell to cell. The activation of B cells and their differentiation into antibody-producing plasma cells and memory cells are triggered by the antigen, processes that usually require the assistance of T helper cells.

Antibodies play important roles in active immunity. Antibodies can neutralize the pathogen. Neutralization prevents viruses and intracellular bacteria from binding to specific receptors on the surface of the cells. It also blocks bacterial toxins from gaining access to the cells. Even without neutralization, antibodies can coat the surface of pathogens, thereby enhancing phagocytosis through the process known as *opsonization*. Antibodies support phagocytosis in two ways. First, antibodies bound to the pathogen are recognized by the Fc receptor on phagocytes; second, antibodies activate the complement system, which results in complement binding to the pathogens and recognition by complement receptor on phagocytes.

The BCR binds and delivers antigens to the intracellular compartments where they dissociate. The protein is degraded and returned to the cell surface as peptide bound to MHC II. The MHC II antigen complex stimulates antigen-specific T cells to secrete cytokines and provide co-stimulatory signals directing mature B cells to become plasma cells and memory B cells.

B cells require two simultaneous signals to become activated. The first signal is the binding of antigen to the BCR. The second signal can occur in either of two ways. In T helper cell–dependent pathway, the signal is generated by the binding of the T helper cell to the MHC II antigen complex as assisted by CD40/CD40L co-stimulation. In the T cell–independent pathway, the second signal is caused by the reaction of membrane IgM with a polymeric antigen or by exposure to large concentrations of lipopolysaccharide. In the latter case, the polyclonal activation can activate large numbers of B cells rather indiscriminately.

The B cell co-receptor complex CD19/CD21/CD81 greatly enhances B-cell responsiveness to antigen. B cells and T helper cells must recognize epitopes of the same molecular complex in order to interact. This requirement is termed *liked recognition*. Antigenic peptides bound to self-MHC II molecules trigger armed T helper cells to make CD40L and cytokine IL4/IL5/IL6. Isotype switching is decreased in individuals who lack CD40L. Individuals with CD40L deficiency have hyperimmunoglobulinemia M, a disease characterized by an elevation of IgM and a severe deficiency of almost all other isotypes.

In secondary lymphoid tissues antigen-binding B cells are trapped in the T-cell zones and are activated by armed helper T cells. The second phase of the primary B cell immune response occurs when activated B cells migrate to follicles and proliferate to form germinal centers (GCs). GCs are composed largel of proliferating B cells, with antigen-specific T cells making up 10% of the lymphocytes. Somatic hypermutation, affinity maturation, and isotype switching occurs in GC B cells. Negative selection of B cells in GCs keeps the size of the lymphoid tissues manageable.

Antibodies of the IgA subclass are particularly important in conferring protection to the mucosa and in preventing potentially deleterious "overkill" responses mediated by IgG or IgE. IgG and IgM are important in antibacterial and antifungal host defense, but can also lead to type II (cytotoxic) and type III (immune complex) immunopathologic reactions (see Chapter 3). Antibodies of the IgE subclass not only provide host defense against parasites and worms, but also can lead to type I immunopathologic reactions (anaphylaxis). Rarely, IgA has been associated with type II immunopathologic conditions. The distinct functional and immunopathogenic attributes of the immunoglobulin isotypes provide another area of potential immunotherapeutic intervention.

Shutdown

Mechanisms exist to terminate immune responses when they are no longer required. These mechanisms involve the removal of effector cells that are no longer needed and the suppression of activity of remaining cells.

Propriocidal apoptosis. In the later stages of antigen exposure, when the concentrations of proinflammatory cytokines are high, T cells may undergo a form of antigen-induced cell death known as *propriocidal apoptosis*. It may occur as a result of T-cell expression of different co-stimulatory receptors for factors such as B7 proteins. As previously mentioned, the interaction between B7 and CD28 may serve to prepare a cell for early differentiative events in the immune response (resulting in proliferation and functional maturation), but the interaction between B7 and CTLA-4 may prepare a cell for more terminal events (e.g., differentiation leading to death).

Immune regulation and suppression. Suppression is involved in regulating the balance between humoral and CMI responses and in terminating these responses altogether. Regulating the degree of humoral immune response versus CMI seems related to the activities of CD4+ T cells, whereas terminating responses involves CD8+ T cells. CD4+ T cells of the TH1 phenotype suppress CD4+ T cells of the TH2 phenotype and directly inhibit B-cell activity. CD4+ T cells of the TH2 phenotype suppress TH1 activities. CD4+ TH1 T cells also stimulate CD8+ T cells, an event which has been referred to as *suppressor induction*. CD4+CD25+ Treg cells are key regulators that suppress the function of T cells.

Classically, the CD8+ phenotype has been associated with cytotoxicity and suppressor activity. It is becoming apparent that the suppression mechanism of the CD8+ T cell can resemble its cytotoxic action. CD8+ T-cell suppression of specific humoral immunity and the termination of CMI may be accomplished with the CD30 ligand (CD30L). CD30L is a member of the TNF family recognized by CD30 (a member of the TNFR family) found on T cells. In this case, suppression results from the programmed death of the CD4+ T cell.

If there is an imbalance between TH1 and TH2 activities, or if CD8+ T-cell suppression is excessively active, immunodeficiency may occur. If suppression is insufficient, immunopathologic reactions, including autoimmunity, may ensue. Suppression pathways thus play a role in two widely differing defective immune states often considered for immunotherapy: immunodeficiency and autoimmunity.

Mucosal Immunity

The vast majority of infectious agents invade the human body by one of the mucosal routes. Diarrheal diseases, respiratory

infections, parasitic infestations, and diseases such as tuberculosis, measles, hepatitis B, whooping cough, and HIV infection are widespread and continue to cause significant public health problems throughout the world. Another important point regarding the mucosal surfaces is that they are the portal of entry for a great majority of foreign antigens such as food antigens, dusts, pollens, and other materials. In addition, the gastrointestinal tract is colonized by a great number of commensal bacteria, which normally live within their host symbiotically without causing any pathology.

Traditionally, the mucosal immune system has been considered a minor component of the immune system, and to this date little is known regarding the function of immune cells in mucosa. Because of its size and exposure to a wide variety of foreign antigens, the mucosal immune system perhaps forms the largest and the most important part of the immune system. It contains significant numbers of lymphocytes and produces high amounts of Igs in healthy individuals. It also has many distinctive features. In mucosa there is an intimate interaction between mucosal epithelia and the lymphoid tissues. Mucosal epithelial cells contain specialized antigen-uptake mechanisms, and most of the lymphocytes have the activated/memory phenotype even in the absence of infection. The mucosa contains large numbers of regulatory T cells and they have inhibitory macrophages and tolerance-inducing dendritic cells. Finally, there is constitutive down-modulation of immune responses to food and other nonpathogenic antigens.

Mucosal-associated lymphoid tissues are located in anatomically defined compartments of the gut. Lymphocytes, macrophages, and dendritic cells are found throughout the mucosa in organized tissues as well as scattered throughout the surface epithelium and an underlying compartment of the connective tissue called the *lamina propria*. Another important feature of the gut mucosa is the existence specialized epithelial cells called *microfold* (M) cells . These cells are different from the other epithelial cells (e.g., enterocytes in intestines) in that they do not secrete mucus and are the route of entry of foreign antigens. Antigens are engulfed by the M cells and transcytosed via membrane bound vesicles to the basal cell membrane where they are released into the extracellular compartment. The dendritic cells can then take up the antigen, process it, and present it to naïve, antigen-specific T lymphocytes in Peyer's patches, or they migrate through draining lymphatics to present antigen to naïve antigen specific T cells in mesenteric lymph nodes. Dendritic cells are recruited to the epithelial layer through the action of chemokines.

The mucosal immune system contains large numbers of effector lymphocytes even in the absence of disease. In addition to the organized lymphoid organs in the mucosa, there are other immune effectors that are scattered throughout the mucosa. The majority of those that are in the epithelial layer are mainly CD8+ T cells, whereas in the lamina propria large numbers of CD4+ as well as CD8+ T cells, plasma cells, dendritic cells, and macrophages can be found. Neutrophils are rare in healthy intestines, but their numbers increase rapidly upon infection. Therefore, healthy intestinal mucosa displays characteristics that are similar to chronic inflammation in response to the intimate interaction between foreign antigens, commensal bacteria, and mucosal immune cells. Because of the function of regulatory immune effectors, a balance is maintained between inflammation and homeostasis during health and disease.

The trafficking of the lymphocytes within the mucosa is controlled by the actions of specific sets of chemokines and integrins. Gut-specific homing is determined by the expression of $\alpha4{:}\beta7$ integrin on the lymphocytes, which binds to mucosal vascular addressin MADCAM-1 on the endothelial cells. In addition the expression of the CCR9 chemokine receptor on lymphocytes is important for attracting lymphocytes to mucosa. Indeed, local production of CCL25 by the gut epithelium, which binds to CCR9, is required for the homing of the lymphocytes to the gut. Only lymphocytes that first encounter antigen in the gut are induced to express gut-specific homing receptors and integrins. This action is mediated by the gut dendritic cells, which impart to lymphocytes the ability to express the $\alpha4{:}\beta7$ integrin and CCR9 receptor. These tissue-specific responses explain why vaccination against intestinal infections requires immunization through the mucosal route and not through parenteral routes.

As mentioned previously, IgA is by far the most abundant antibody in mucosal tissues. The ratio of IgA1 to IgA2 in blood is 10:1, whereas in mucosa it is 3:2. Class switching for IgA is under the control of the TGF-β cytokine. IgA2 is resistant to proteolytic cleavage. After secretion of IgA, it will bind to the poly-Ig receptor on epithelial cells and be transported through transcytosis to the apical surface of the epithelial cells. The main function of IgA in mucosa is to prevent the access of pathogen to the mucosal surfaces. Selective IgA deficiency in humans is a common primary immune deficiency in Caucasians, and atopic and auto-immune diseases have been reported in people with IgA deficiency. Most people with IgA deficiency are normal, however, which might result from the fact that IgA can be replaced by IgM.

There are two types of intraepithelial lymphocytes. One has the conventional αβ T-cell receptor and co-receptor CD8 (αβ homodimer). These *type a* conventional T cells recognize antigen within the context of MHC I. The second group of lymphocytes has either the αβ or γδ T cell receptor and the CD8αα homodimer. These *type b* T cells do not recognize antigen in the context of MHC I, but rather bind to other ligands, such as MHC Ib. Another nonclassical MHC I molecule is the thymus leukemia (TL) antigen, which can bind to the CD8αα homodimer with high affinity. The type b T lymphoctes mediate cytotoxicity; they do not undergo positive or negative selection in the thymus.

IMMUNOTHERAPEUTIC AGENTS

Therapies designed to stimulate or replicate endogenous immune reactions have long been used to prevent infectious disease and treat immunodeficiencies. More recently, attempts have been made to provoke immune responses to cancer, and specific antibodies have been developed for a wide range of applications.

In certain clinical situations, it is advantageous to suppress the inflammatory activities of the specific immune system temporarily. Organ transplantation is the best example of an instance in which immunosuppression is beneficial. Immunosuppression is also helpful in the treatment of autoimmune diseases and other immunopathologic conditions.

Vaccination

The most successful area of immunotherapy has been vaccination, or "active immunization." It was first introduced to Western culture by Jenner in the 18th century, who injected individuals with the cowpox virus to protect them against smallpox. Vaccination is a procedure in which the immune system is exposed to an antigen, such as an inactivated toxin or attenuated pathogen, to elicit antigen-specific clonal expansion (i.e., the proliferation of T cells and B cells that recognize the antigen). Active immunization uses the host's immune system itself to generate antigen-specific immunotherapeutic agents (e.g., antibodies). On subsequent exposure to the actual pathogen, the immune response is of sufficient speed, magnitude, duration, and specificity to prevent the pathogen from causing disease (the secondary or anamnestic response).

Clinically, most success has been observed with vaccination designed to elicit humoral immunity rather than CMI. The composition, recommended dosage, and schedule of administration of standard vaccines may be found in several references.[6,14]

Caries vaccines

A disease of special interest to dentistry is dental caries. Vaccines directed against *Streptococcus mutans* and *Streptococcus sobrinus*—lactic acid bacteria long suspected of being the major cause of dental caries—have been investigated by several laboratories.[29] The purpose of these investigations was to induce an immune response that would prevent the adherence or metabolism by these bacteria on the tooth surface. Several types of vaccines have been considered, including (1) oral immunization by whole bacteria or live enteric bacteria that bear antigens of *S. mutans* as a result of recombinant DNA procedures, and (2) immunization by various routes using "subunit" vaccines containing isolated antigens (adhesins, glucosyltransferases, dextranases) believed to be involved in cell adherence and plaque formation. Whole-cell vaccines are anticariogenic in many laboratory animals, including primates.

In humans, oral immunization results in the generation of secretory IgA antibodies in salivary secretions. Ingested antigens are subjected to partial breakdown within the stomach and small intestine. As described previously specialized M cell enterocytes in the gut transcytose macromolecular antigens to unencapsulated lymphoid structures known as *Peyer's patches*. Here, in the presence of TH3 T cells, antigen-specific B cells are selected to undergo IgA isotype switching. They eventually migrate to the regional lymph nodes, where they proliferate. IgA-committed progeny enter the blood and are distributed to effector sites, such as the salivary glands, where they produce IgA antibodies for secretion.

Parenteral routes of administration usually lead to IgG antibodies that can gain access to the tooth by way of the gingival crevicular fluid. For parenteral administration, subunit vaccines are preferred because antibodies directed against lipoteichoic acid in the cell wall of *S. mutans* may cross-react with human heart muscle. Although purified antigens are effective in preventing caries in gnotobiotic rodents and lower primates, the actual antigenic components; dosage; route of administration; and potential benefits, costs, and adverse effects in humans must be determined before a vaccine can be considered for routine use.

Several modifications to the subunit vaccine approach embellish traditional methods with purified bacterial antigens. Synthetic pieces of a larger antigen, such as glucosyltransferase, have been used as an immunogen.[37,38] Synthetic peptides derived from a glucan-binding domain of glucosyltransferase or from the amino terminus have also been used. Antisera or monoclonal antibodies raised in laboratory animals against these synthetic domains inhibit glucosyltransferase by 30% to 80%.

Antigen-delivery strategies. Local immune responses can be elicited within the gingiva. The swabbing of gingiva with a 3800 Da component of *S. mutans* in monkeys elicits increases in IgG in the crevicular fluid and secretory IgA in the saliva.[24] From a theoretic point of view, it is difficult to ascribe the IgA response to local (gingival) immunization rather than systemic (enteric) because some antigen must be ingested. From a therapeutic point of view, the method itself may be useful because the swabbing was administered only 10 times over the course of 1 year and resulted in a reduction in *S. mutans* and caries activity.

Liposomes are artificial membrane vesicles that can be prepared to contain hydrophilic solutes internally and hydrophobic molecules within the membrane. One method of increasing antibody responses by gingival immunization has been the sequestration of candidate antigens (i.e., glucosyltransferase) into liposomes, permitting the liposomes to desiccate, and administering the dehydrated liposomes to humans. This technique resulted in salivary IgA2 antibodies against glucosyltransferase, suggesting that dehydrated liposomes may be useful in generating specific salivary immunity against target antigens in the oral cavity.[8]

Genetic engineering provides an especially efficient possibility for delivering a subunit vaccine. A major problem with subunit vaccines has been the inability to maintain sufficiently high amounts of antigen in the gut to stimulate antibody production in a cost-effective manner. Genes for candidate antigens of *S. mutans* have been introduced into "harmless" enteric bacteria. These bacteria can proliferate in the gut, elaborating antigen for a prolonged time compared with a conventional dosage form (e.g., gelatin capsules).

Anti-idiotypic antibodies. During an infection, the body commonly produces antibodies to its own immunoglobulins used to ward off the offending organism. These antibodies, called *anti-idiotypic antibodies*, contain in their hypervariable regions a peptide sequence (idiotope) that is identical with or structurally analogous to an antigenic determinant (epitope) of the infecting microorganism. Injection of these antibodies into a host generates a second set of anti-idiotypic antibodies directed against them. If the injected antibodies are the same allotype as the host, the host forms anti-idiotypic antibodies against only the idiotope. These antibodies also bind to the bacterial epitope. This method can be used to elicit antibodies against virtually any antigenic target. A vaccine containing anti-idiotypic antibodies with idiotopes equivalent to epitopes of streptococcal antigens has reduced caries in the gnotobiotic rat model.[21]

Adjuvants

The effects of a vaccine may be enhanced by incorporation of adjuvants, substances that increase the immune response. The mechanism of action of some adjuvants, such as alum (aluminum-containing hydroxides or phosphates), is simply to retard removal of the antigen and to attract lymphoid cells by increasing the inflammatory response (often quite severely) in the immediate area of the vaccine. Many adjuvants, such as complete Freund's adjuvant, that are effective in laboratory tests have not been cleared for routine use in humans because they induce long-lasting necrotic lesions in the area of injection. Alum is the only adjuvant currently approved for use with vaccines (e.g., diphtheria and tetanus toxoids) in humans; however, it is not active with all antigens, and it elicits only humoral responses. In mice, alum adjuvants selectively activate TH2 CD4+ T cells; one of the problems facing immunostimulant therapy has been devising methods to stimulate TH1 and CMI responses.

Bacillus Calmette-Guérin (BCG) is a live attenuated strain of *Mycobacterium bovis* that has been used as a vaccine against tuberculosis since the early part of the 20th century. Similar to complete Freund's adjuvant, it contains mycobacterial derivatives and seems to stimulate CMI. BCG has been shown to stimulate specific tumor immunity in experimental animals, to induce responses in immunodeficient individuals, and to reverse the effects of immunosuppressive drugs. It activates macrophages that produce IL-1. IL-1 stimulates the maturation of CD4+ T cells. BCG has been used experimentally in the treatment of melanoma, hepatoma, leukemia, and bladder cancer; it may also have potential against chronic infections involving immunodeficiency. Severe allergic reactions and shock have occurred infrequently during BCG treatments. Other microbially derived immunostimulants that activate macrophages and should help trigger TH1 responses include extracts of pathogenic bacteria and fungal polysaccharides.

Quil-A is a partially purified saponin extract from plants. It forms immunostimulating complexes with cholesterol and various antigens. The complex may intercalate into the membranes of cells, introducing antigen into the cell cytosol. Humoral immunity and CMI are stimulated by increased MHC presentation.

Enhancement of Co-stimulation

Because the presentation and recognition of antigen alone is insufficient to initiate an immune response, immunotherapy has also focused on enhancement of costimulation. One method includes the antibody-mediated cross-linking of co-stimulatory receptors (e.g., CD28 and CTLA-4). It has been shown to enhance T-cell activity against tumor targets as measured by increased cytokine output. A second method involves immunization of an individual with tumor cells that have been transfected with a B7 gene plus an MHC II gene, causing the cells to express these protein products constitutively. Such immunization has led to rejection of the tumor at a site distant from the immunization site.[5]

Immunostimulants

Thymic extracts

Primary CMI deficiencies may result from absence of the thymus gland or a defect in its function. Treatment has been directed toward inducing maturation of T cells by using thymic tissue or extracts. In several cases, thymus transplants in humans have corrected CMI deficiencies, with subsequent development of immunocompetence. Immunologically immature fetal thymic tissues are used to prevent graft-versus-host reactions.

Thymic extracts have been used nonspecifically to induce CMI competence.[3] These extracts, including thymosin, are usually extracted from calf thymus glands. They consist of a family of nonimmunogenic polypeptide hormones. Certain tumors, chronic mucocutaneous candidiasis, and several other diseases caused by primary CMI immunodeficiency have responded favorably to thymosin therapy. Thymic extracts must be administered continually. Although thymosin administration has been found to be of therapeutic benefit, it is still experimental, and routine use awaits further development.

In Europe, several peptides have been purified or synthesized for experimental use in humans,[17] including thymostimulin, which has proved beneficial in the treatment of hepatocellular carcinoma and chronic obstructive pulmonary disease. These hormones function at different stages of CMI development, inducing the maturation of T cells or differentiation of T cells into functional effectors, such as cytotoxic or suppressor cells.

Levamisole

Levamisole is an anthelmintic drug that possesses nonspecific immunostimulatory properties. In deficient animals and humans, it restores many different immunologic functions, suggesting that it acts on multiple populations of cells, including neutrophils, macrophages, and T cells (but not B cells). Its effects on the immune response and its pharmacologic activity indicate that levamisole is a thymomimetic agent.

Levamisole has been used in the treatment of tumors and other diseases in which there are manifestations of immune dysfunction, including rheumatoid arthritis and Crohn's disease. Several investigators have used it successfully in the treatment of recurrent aphthous stomatitis and herpes labialis. It has been suggested that the therapeutic effect of levamisole in aphthous stomatitis, which may have an autoimmune etiology, results from enhancement of suppressor T cells that normally prevent autoimmune responses.[25] It is currently approved for use in the United States as an adjunct to fluorouracil in the treatment of colorectal carcinoma.

Polyclonal Antibody Preparations

Human immunoglobulins

Deficiencies in humoral immunity may result from congenital defects in the production of all or selected immunoglobulin classes, or they may be acquired, as occurs with multiple myeloma. Severe deficiencies in humoral immunity, or hypogammaglobulinemias, require "replacement therapy" consisting of weekly or monthly injections of pooled human immunoglobulins, the dose and frequency depending on the patient's status. These treatments are often accompanied by antibiotics. Selective isotype deficiencies involving individual classes of immunoglobulins are usually less severe because the body may compensate by increased production of other immunoglobulin classes. Selective isotype deficiencies also can be treated with immunoglobulins.

Human immunoglobulin is effective against many common diseases, such as measles and infectious hepatitis, because it is derived from the pooled sera of many individuals, including some who would have contracted these infections in the past and produced protective antibodies against them. Although immunopathologic reactions are possible with allogeneic human immunoglobulins, they are much less a problem than with xenogeneic immunoglobulins, and the risk is greatly minimized by using purified or partially purified IgG. In contrast to most other pooled blood products, human immunoglobulin carries no known risk of human immunodeficiency virus (HIV) or hepatitis B transmission. Intravenous, rather than intramuscular, administration of immunoglobulins is preferable because much larger doses can be infused.[34]

Antisera or purified immunoglobulins may be administered to prevent or treat specific diseases. In some cases, this is referred to as *passive immunization*, a classic term in immunology used to indicate that a donor was immunized with an antigen, and that a recipient host was then injected with the protective antibodies generated by the donor. The injection of antibody obtained from an immune donor into a nonimmune recipient has the advantage of conferring almost instantaneous protection, as opposed to vaccines, which require days or weeks to stimulate a sufficient protective effect. The effects of passive immunization last only 4 to 6 weeks (equivalent to one to two half-lives of IgG in vivo), however. Human immunoglobulin preparations specifically directed against hepatitis B, cytomegalovirus, rabies, tetanus, infant botulism, respiratory syncytial virus, and varicella-zoster virus are available.

Rh_o(D) immunoglobulin

Rh_o(D) immunoglobulin represents a special case in which passive immunization is used to induce specific immunosuppression for the prevention of Rh disease. Rh disease occurs when an Rh-negative woman—one whose red blood cells do not contain the Rh_o(D) antigen—becomes sensitized to the antigen by exposure to the blood of her Rh-positive fetus. On subsequent pregnancies, the mother's anti-Rh antibody passes through the placenta and causes massive destruction of fetal erythrocytes, resulting in hemolytic disease of the newborn.

The injection of anti-Rh antibody into Rh-negative mothers who will give birth to Rh-positive infants is effective in preventing the disorder. The goal of treatment is to prevent mothers from generating anti-Rh_o(D) antibodies. High titers of specific antibody against an antigen specifically inhibit the immune response to that antigen, but the mechanism may be more involved than simple binding of the antigenic stimulus. The injection of anti-Rh_o(D) antibodies may induce the mother to generate a set of antibodies against the variable domains of the injected antibodies. This second set of anti-idiotypic antibodies may impede the interaction of B cells with Rh antigen, cause B-cell inactivation or death, or neutralize anti-Rh_o(D)–specific antibodies as they are generated. Such idiotypic–anti-idiotypic inhibitory effects have been

shown in laboratory animals. Alternatively, anti-Rh_o(D) antibody may lead to rapid clearance of fetal red blood cells from the mother's circulation by liver macrophages, which would prevent the elicitation of chronic inflammatory reactions necessary for antibody responses.

Antiserum to the Rh antigen is produced in Rh-negative male volunteers. The γ-globulin fraction containing anti-Rh antibody, in the form of Rh_o(D) immunoglobulin (human), must be given within hours of parturition because the fetal erythrocytes carrying the Rh antigen enter the mother's body at this time and induce the immune response that would cause problems in subsequent pregnancies. This specific immunosuppressive treatment has been very successful in preventing Rh disease, and it is now used routinely.

Antitoxins and antivenins

Immunoglobulin preparations that neutralize toxic compounds, such as rattlesnake venom and diphtheria toxin, are commonly derived from the sera of horses actively immunized against the noxious substances. The regional availability of these xenogeneic antibody products varies widely depending on the perceived risk of exposure. Being bitten by a poisonous animal outside its normal geographic range can delay the administration of the immunoglobulin antidote and increase the risk of injury or death.

If administered parenterally, xenogeneic (or even allogeneic) sera or immunoglobulins may induce immunity in the recipient against animal (or human) serum antigens. Not only would this response lead to rapid clearance of the antibodies—and circumvent their therapeutic effect—but also it can induce type III immunopathologic reactions such as serum sickness or immune complex disease.

Oral administration of xenogeneic antibodies

The oral administration of xenogeneic antibodies offers one possible strategy for highly precise, cost-effective immunotherapeutics. Cows immunized against cariogenic bacteria exhibit antibodies against those bacteria in their milk. The milk (or whey) can confer protection to individuals consuming that milk in a passive manner. In cows' milk and colostrum, the antibodies are of the IgG1 subclass. *S. mutans* and caries scores can be reduced in this manner in gnotobiotic animals.[29] Whey from immunized cows also seems to decrease *S. mutans* in human volunteers when it is used as a mouth rinse.

Antithymocyte globulin

Antithymocyte globulin is produced in rabbits and horses by immunization with human thymocytes. It lyses or agglutinates human lymphocytes in vitro and produces lymphocytopenia in vivo. CMI responses are decreased, and allograft survival is prolonged. Antithymocyte globulin is rich in cytotoxic antibodies directed against numerous antigens expressed by T cells, including CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA (human MHC) class I and II molecules. The immunosuppressive effects are transient, and antithymocyte globulin must be given repeatedly. Because the preparation is itself antigenic, however, it can induce an immune response leading to serum sickness. The agent's primary indication is suppression of acute transplant rejection reactions.

Monoclonal Antibody Preparations

A monoclonal antibody (MAb) is an antibody of a single specificity produced by cells derived from a single B-cell clone. In most cases, the MAb is derived from mice (and is xenogeneic). Fusion of a normal mouse plasma cell and a myeloma cell results in the formation of a hybridoma with the antibody-forming properties of the plasma cell and the proliferative properties of the myeloma cell.[16] When grown in tissue culture, hybridomas are capable of almost unlimited production of MAb. MAbs are increasingly being used diagnostically to assess immunocompetence, to identify infectious diseases, and to monitor the concentrations of hormones and chemotherapeutic agents in the plasma. Some are used as immunosuppressive agents. Their exquisite specificity also makes them ideal guidance systems as carriers for cytotoxic agents (described subsequently). Table 41-2 lists clinically available MAbs and derivatives, their target antigens, and their principal therapeutic indications.

Muromonab-CD3, the first monoclonal antibody to be approved for human use (in 1986), is a mouse MAb that reacts with CD3, a component of the TCR complex (see Figure 41-4). Antibody binding induces internalization of the TCR. Sensitive T cells die in response to complement activation; other T cells redistribute to nonlymphoid tissues and become significantly less responsive to antigenic challenge. Muromonab-CD3 is highly effective in terminating acute cellular rejection episodes. The major adverse effect of therapy, known as the *cytokine release syndrome*, develops from the stimulation of Fc receptors by CD3-bound MAb. Affected T cells release TNF-α, IL-2, and other cytokines, causing high fever, chills, nausea and vomiting, malaise, weakness, and generalized pain. The syndrome usually begins within 30 minutes of drug injection, lasts for hours, and rarely may produce life-threatening cardiovascular and pulmonary disturbances. Repeated MAb treatment may lead to the development of human antimouse antibodies that block the therapeutic effect or sensitize the patient to the drug.

Chimeric antibodies

The most important factor that limits the therapeutic potential of MAbs as a group is their xenogeneic origin, and clinical testing of these reagents has led to some disappointment. One approach to circumvent this problem has been to combine the antigen-specific portions of mouse MAbs with human constant or framework domains. Chimeric MAbs, which represent the second generation of MAbs, are produced by the grafting of the variable regions of rodent immunoglobulin to the constant regions of human immunoglobulin (see Figure 41-2). Because the constant region of an immunoglobulin also confers function to an antibody, chimeric MAb engineering permits the selection of functional attributes. A chimeric MAb possessing an IgG1 isotype constant region would be most effective in complement activation and antibody-dependent cell-mediated cytotoxicity, whereas a chimeric antibody of the IgA subclass may exhibit anti-inflammatory effects.

Basiliximab is a chimeric MAb (60% human, 40% mouse) used to prevent allograft rejection in patients receiving other immunosuppressants. It is directed against the α subunit of the IL-2 receptor on activated T cells (see Figure 41-4). IL-2 is a major cytokine supporting CMI and organ rejection. In general, the drug is administered only twice; the first dose is infused intravenously within 2 hours before transplantation surgery, and the second is given 4 days later. The only adverse events attributable to basiliximab used in this manner are rare cases of allergic reactions and cytokine release syndrome.

Complementarity-defining region-grafted (humanized) antibodies

Although chimeric MAbs may seem exotic, they have been superseded by a third-generation MAb, the complementarity-defining region (CDR)-grafted MAb, more simply known as the "humanized" MAb. As described previously, CDR refers to the hypervariable peptide sequences of an antibody that actually bind to an antigen. These hypervariable regions are joined by intervening framework sequences. A CDR-grafted MAb contains rodent hypervariable sequences, human frame-

TABLE **41-2**

Monoclonal Antibodies and Related Agents in Clinical Use

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	RECEPTOR/TARGET	THERAPEUTIC INDICATION
Abciximab	ReoPro	GPIIb/IIIa	Prevent platelet aggregation in unstable angina or percutaneous cutaneous intervention
Adalimumab	Humira	TNF-α	Ankylosing spondylitis Moderate-severe arthritidies Moderate-severe Crohn's disease Moderate-severe plaque psoriasis
Alefacept	Amevive	CD2	Chronic plaque psoriasis (moderate-severe)
Alemtuzumab	Campath	CD52	B-cell chronic lymphocytic leukemia
Basiliximab	Simulect	IL-2	Prevention of renal allograft rejection
Bevacizumab	Avastin	VEGF	Breast cancer Colorectal cancer Glioblastoma Non-small cell lung cancer Renal cancer
Certolizumab	Cimza	TNF-α	Moderate-severe rheumatoid arthritis Moderate-severe Crohn's disease
Cetuximab	Erbitux	EGFR	Colorectal and head and neck cancers
Daclizumab	Zenapax	IL-2	Prevention of renal allograft rejection
Digoxin immune Fab	Digibind	Digoxin	Serious digoxin toxicity
Efalizumab	Raptiva	CD11a	Plaque psoriasis (moderate-severe)
Etanercept	Enbrel	TNF	Ankylosing spondylitis Moderate-severe arthritidies Moderate-severe plaque psoriasis
Gemtuzumab ozogamicin	Mylotarg	CD33	Relapsed acute myeloid leukemia
Golimumab	Simponi	TNF-α	Ankylosing spondylitis Moderate-severe rheumatoid arthritis Psoriatic arthritis
Ibritumomab tiuxetan	Zevalin	CD20	Non-Hodgkin's lymphoma
Infliximab	Remicade	TNF-α	Ankylosing spondylitis Moderate-severe rheumatoid arthritis Moderate-severe Crohn's disease Moderate-severe plaque psoriasis Ulcerative colitis
Muromonab-CD3	Orthoclone OKT3	CD3	Acute graft rejection
Natalizumab	Tysabri	α4-integrin	Relapsing multiple sclerosis
Nimotuzumab*		EGFR	Squamous cell cancer Glioma
Ofatumumab	Arzerra	CD20	Chronic lymphocytic leukemia
Palivizumab	Synagis	RSV F protein	Prevention of RSV disease
Panitumumab	Vectibixc	EGFR	Colorectal cancer
Rituximab	Rituxan	CD20	Non-Hodgkin's lymphoma
Tositumomab and iodine I 131 tositumomab	Bexxar	CD20	Non-Hodgkin's lymphoma
Trastuzumab	Herceptin	HER2	Metastatic breast cancer

*Not currently available in the United States.
CD, Cluster of differentiation (protein); *EGFR*, epidermal growth factor receptor; *HER2*, human epidermal growth factor receptor 2; *IL*, interleukin; *RSV F protein*, respiratory syncytial virus fusion protein; *TNF*, tumor necrosis factor.

work sequences, and human constant regions. There is some loss of affinity in humanized MAbs, but it is usually an acceptable tradeoff for the reduced allergenicity. Humanized MAbs are used clinically to prevent rejection of organ transplants. Other diseases in which CDR-grafted MAbs have been used include rheumatoid arthritis, Crohn's disease, systemic vasculitis, septic shock, various neoplasms, and viral infections.[44]

Daclizumab is a humanized variant of basiliximab in which the murine (mouse) content of the antibody has been reduced to 10%. As expected, daclizumab is less potent than basiliximab in binding to the α subunit of the IL-2 receptor. A one-time five-dose regimen is used, with the first dose given within 24 hours before transplantation surgery and subsequent doses every 14 days thereafter. Few adverse reactions have been reported for this use of daclizumab; it apparently does not cause cytokine-release syndrome.

Conjugated monoclonal antibodies

Immunotoxins are antibodies coupled with a poison (toxin). Toxins may be derived from many sources, including plants and microbes (e.g., the lectin ricin, *Pseudomonas* exotoxin, diphtheria toxin). The therapeutic strategy is to have the antibody selectively deliver the toxin to undesirable cells, such as those infected by HIV-1, or participate in immunopathologic reactions. Immunotoxins have also been explored for their potential in cancer immunotherapy (including metastatic melanoma; colorectal, ovarian, and breast carcinomas; non-Hodgkin's lymphoma; Hodgkin's disease; B-cell leukemia; and

T-cell lymphoma) and immunosuppression in steroid-resistant graft-versus-host disease. Although immunotoxins have been called "magic bullets" capable of pinpoint target destruction, it has become clear that most of these "bullets" are not as accurate as desired and have significant side effects, including vascular leak syndrome, myalgia, aphasia, paresthesia, encephalopathy, neuropathy, thrombocytopenia, liver destruction, renal insufficiency, proteinuria, hypoalbuminemia, dyspnea, hematuria, and tremors. The toxins themselves have proved quite antigenic, eliciting immune reactions in most cases. Gemtuzumab ozogamicin is the first immunotoxin to be approved for clinical use. It combines the anti-CD33 antibody gemtuzumab with the anticancer agent ozogamicin.[1] When the agent binds its antigen receptor, it is internalized. The active agent is released to kill the cell. The drug is approved for treatment of acute myeloid leukemia.

Immunotoxins have not been explored aggressively as therapeutic agents delivered locally in the oral cavity. Such a strategy might be used to eliminate pathogens selectively or reduce inflammatory activities of the host immune system, and may not result in the same degree of toxicity observed in systemic administration.

Radioimmunotherapy relies on a similar strategy to deliver radioactive substances in a selective manner for diagnostic or therapeutic purposes. In this case, the potential for tissue damage by the toxin has been replaced by the potential for radiation injury. Inasmuch as several radioimmunotherapeutic agents have been approved for human use, the tradeoff seems favorable.

Ibritumomab tiuxetan, approved in 2002, is a covalently linked conjugate of the MAb ibritumomab and the linker-chelater tiuxetan. Ibritumomab is selective for CD20, a cell-surface antigen expressed by normal B cells and more than 90% of B-cell non-Hodgkin's lymphomas. Tiuxetan contains a high-affinity binding site that can accommodate either indium-111 (used for diagnostic imaging) or yttrium-90 (used for target cell destruction). A complex administration schedule involving the prior administration of radiation-free MAb is used to limit damage of healthy lymphoid tissue and maximize destruction of lymphoma cells.[19] Common adverse effects include neutropenia and thrombocytopenia. Infection, hemorrhage, allergic reactions, and new malignancies are potentially life-threatening reactions.

Future developments

Contemporary medicine is witnessing an explosive increase in the development of monoclonal antibodies to diagnose and treat disease. Already, monoclonal antibodies constitute the most widely used form of cancer immunotherapy. In the quarter century since the introduction of muromonab-CD3 into clinical practice, slightly more than 20 monoclonal antibodies have been approved for use. Two hundred more are now in clinical trials or awaiting approval. Among these agents are "fully" human monoclonal antibodies (fourth generation monoclonal antibodies) harvested from mice genetically engineered to produce human antibodies from laboratory bacteria using phage display technology.

Chemolabeled monoclonal antibodies constitute a third strategy for targeting therapeutic agents using monoclonal antibodies. In this case a substance that is not inherently toxic is directed to a specific site where it can produce the desired therapeutic effect. It now seems likely that the early promise to therapeutics represented by the concept of monoclonal antibodies will soon be realized.

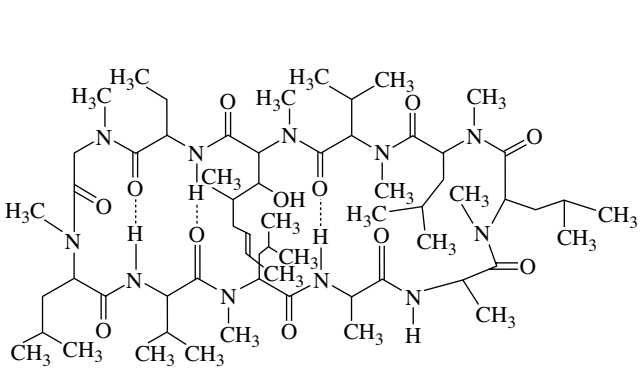
Immunophilin Ligands

Cyclosporine (cyclosporin A), tacrolimus (FK506), and sirolimus (rapamycin) are microbial derivatives now classified as immunophilin ligands because they all initially form a complex with cytosolic receptors of the immunophilin family. These drugs seem to have similar but not identical mechanisms of action. Cyclosporine, the first of these agents to gain approval for human use, revolutionized the field of organ transplantation.

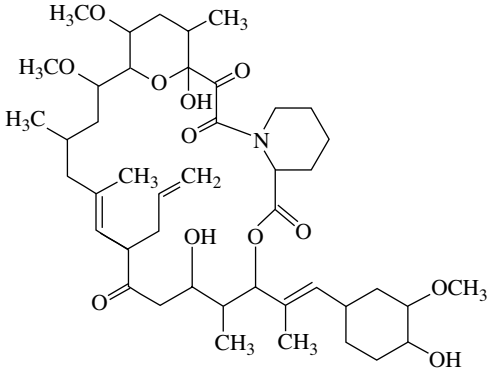
Cyclosporine

Cyclosporine was originally isolated from a fungus, *Beauveria nivea*. It is a neutral hydrophobic macrocyclic undecapeptide (Figure 41-6). Cyclosporine binds immunophilins called *cyclophylins*. The cyclosporine-cyclophylin complex interacts with calcineurin, a Ca^{++}-dependent protein phosphatase (see Figure 41-4).[27] The calcineurin complex is inhibited from dephosphorylating NF-AT, impeding its translocation into the nucleus and impairing transcription important in the earlier phases of immune responses. The immunosuppressive activity of cyclosporine is usually ascribed to its ability to block IL-2 synthesis, but the drug also suppresses macrophage activation and the release of IL-1, prevents the formation of IL-1 receptors on CD4+ T cells, and blocks the expression of IL-2 receptors on naïve T cells.[11] Increased synthesis of TGF-β inhibits IL-2 activity. The primary outcome is that CD4+ T cells are not stimulated to proliferate in response to an antigenic challenge. B-cell function is also impaired by the reduced synthesis of TNF-α, and mast cell degranulation is blocked.

Cyclosporine is commonly used as an immunosuppressive agent to promote graft survival. It has proved successful in preventing rejections of nonmatched kidney, liver, heart, heart-lung, bone marrow, and pancreas transplants. The first-year survival of liver transplants increased from 35% to 70% after the introduction of cyclosporine. Cyclosporine is also effective as a topical agent in the treatment of oral lichen planus,[15] and it has been used systemically to treat other



Cyclosporine



Tacrolimus

FIGURE **41-6** Structural formulas of cyclosporine and tacrolimus.

autoimmune diseases that may affect oral (bullous pemphigoid, pemphigus) and nonoral (psoriasis, rheumatoid arthritis) tissues. Lastly, cyclosporine has proved effective in the treatment of Behçet's syndrome (a vasculitis that almost always includes oral aphthous ulcers and uveitis), nephrotic syndrome, inflammatory bowel disease, atopic dermatitis, and endogenous uveitis. Cyclosporine is better tolerated than less selective immunosuppressant drugs. The drug is potentially dangerous, however. The two major adverse side effects associated with long-term use are (1) dose-related renal toxicity, which, including mild forms, may occur in 75% of patients, and (2) hypertension, which is not apparently dose related, and occurs in 50% of all renal transplant patients (and is especially common in children). Other side effects include central nervous system toxicity (headache, confusion, depression, seizures), gingival hyperplasia, hirsutism, mild tremor, and hepatotoxicity. The risk of lymphoma and other neoplasias is increased.

The precise mechanism of cyclosporine-induced gingival hyperplasia is unknown; corrective procedures involve mainly drug titration and surgical intervention. Some studies indicate that cyclosporine therapy results in the selection of fibroblasts with cyclosporine receptors, and it has been proposed that there is an associated immunologic cytokine imbalance.[18]

The absorption of cyclosporine is incomplete and variable among patients. Because interstitial fibrosis of the kidney has been associated with sustained high concentrations of cyclosporine, monitoring of plasma cyclosporine concentrations is necessary. A microemulsion form offers higher and more reliable absorption than the original product. Cyclosporine is metabolized by CYP3A enzymes; drugs that induce these enzymes (e.g., carbamazepine, phenobarbital, rifampin) reduce plasma concentrations of cyclosporine, whereas drugs that inhibit them (e.g., erythromycin, ketoconazole, prednisolone) have the opposite effect. Nonsteroidal anti-inflammatory drugs, aminoglycosides, and other drugs that cause nephrotoxicity are contraindicated in patients receiving cyclosporine.

Tacrolimus

Tacrolimus is a macrolide antibiotic originally isolated from *Streptomyces tsukubaensis*. Tacrolimus binds to immunophilins known as FK506-binding proteins (FKBPs). The resulting tacrolimus-immunophilin complex produces the same action and effects as described for cyclosporine. Tacrolimus is approximately 100 times more potent than cyclosporine, however. Tacrolimus is approved for prophylaxis against rejection of allogeneic liver transplants. The drug is also potentially as useful as cyclosporine for other conditions. Tacrolimus has been shown to exert profound antipsoriatic effects, probably by direct interaction with keratinocytes.[30] Adverse effects of tacrolimus are qualitatively similar to those of cyclosporine except that gingival overgrowth and hirsutism are not observed. Drug interactions are also similar because tacrolimus is metabolized by CYP3A.

Sirolimus

Sirolimus, originally known as rapamycin, was originally detected in the fermentation broth of *Streptomyces hygroscopicus*. A structural analogue of tacrolimus, sirolimus binds to the same FKBP receptors (see Figure 41-4) and is approved for a similar therapeutic indication. The sirolimus-immunophilin complex binds not to calcineurin, but to a serine-threonine kinase often referred to as FKBP-rapamycin-associated protein (FRAP).[9] The FRAP-sirolimus-FKBP complex cannot phosphorylate a set of proteins involved in protein translation important in later stages of the T cell's immune response (i.e., its response to growth factors, IL-2 in particular).[43] It is believed that sirolimus interferes with signals from growth factor receptors, such as the IL-2 receptor (IL-2R), rather than with signals generated by the TCR. In addition to blocking proliferation of T cells, sirolimus affects nonhematopoietic cells, and may find applications different from those of cyclosporine or tacrolimus.

Sirolimus is free of nephrotoxicity and neurotoxicity, and it does not promote hypertension. Hyperlipidemia is a common dose-dependent side effect. Anemia, thrombocytopenia, and leukopenia may occur. Combined use of sirolimus with cyclosporine significantly worsens renal function, but a positive drug interaction permits use of reduced cyclosporine doses.

Glucocorticoids

Glucocorticoids such as prednisone and dexamethasone have long been used as immunosuppressive agents, but their mechanism of action has been defined only more recently. As discussed in Chapters 32 and 35, glucocorticoids bind to a soluble intracellular receptor and then enter the nucleus of the cell. Specific glucocorticoid response elements on DNA interact with the glucocorticoid receptor, and transcription of specific genes is promoted or inhibited. Several cytokines and other proteins involved in inflammatory reactions are affected. Dexamethasone has also been shown to induce transcription of the I-κB gene. The subsequent increased synthesis of I-κB prevents the translocation of NF-κB from the cytosol to the nucleus.[33] Because NF-κB promotes IL-6 and IL-8 transcription, glucocorticoids are important as anti-inflammatory agents and as immunosuppressants. Apoptosis contributes to the rapid decline in peripheral lymphocytes.

Corticosteroids alone or with other immunosuppressive agents that inhibit antibody production and phagocytosis are often used to treat severe type II autoimmune reactions. Corticosteroids are also useful in the treatment of type III immune complex immunopathologic conditions, primarily because of their anti-inflammatory properties. In severe cases, another immunosuppressant may be added to block the immune response and allow use of reduced quantities of steroids. The steroids mainly act on CMI. In addition to their lympholytic effects, steroids may interfere with macrophage processing by stabilization of macrophage cell membranes.

Thalidomide and Lenalidomide

Thalidomide, a sedative agent briefly available in Europe more than four decades ago but quickly withdrawn because of its powerful teratogenic effects (see Chapter 3), was approved in 1998 for restricted use by the U.S. Food and Drug Administration (FDA) in the treatment of erythema nodosum leprosum. Although its mechanism of action is unknown, thalidomide decreases excessive production of TNF-α in target patients and downregulates certain surface adhesion molecules involved in leukocyte migration. TH2 cell responses are favored over TH1, yielding increases in IL-4 and IL-5. The drug can be sold only by registered pharmacies, which must obtain informed consent about its use from all patients. Thalidomide should never be used by women who are or may become pregnant; it is also contraindicated in men who are sexually mature and do not agree in writing to the need for using latex condoms when having sexual intercourse with women of childbearing potential. Peripheral neuropathy is an important side effect of the drug.

Lenalidomide is an analogue of thalidomide approved for use in the treatment of certain patients with multiple myeloma or myelodysplastic syndrome. It carries the same prescribing restrictions as thalidomide and is likely to cause neutropenia and thrombocytopenia

Cytotoxic Drugs

Cytotoxic drugs are of two classes: the first kills lymphocytes, and the second interferes with the proliferative stage of the

immune response. The lympholytic drugs are most effective if given before antigen administration. They include the alkylating agents such as cyclophosphamide and phenylalanine mustard. Drugs that impede cellular proliferation include various metabolite analogues that inhibit DNA synthesis. The general pharmacologic characteristics of most of these drugs are discussed in Chapter 42.

Cyclophosphamide

Cyclophosphamide was originally developed for cancer chemotherapy and has been adapted for immunotherapy in the prevention of allograft rejection, control of autoimmune and rheumatoid diseases mediated by antibody, and control of T-cell–mediated diseases. Although considered an alkylating agent, cyclophosphamide is inactive until it is metabolized within the liver microsomes (the phosphamide ring is hydrolyzed). Cyclophosphamide metabolites are eliminated by the kidney. Liver and kidney function should be considered in the use of this drug. The metabolites of cyclophosphamide exert their effect by alkylating and cross-linking cellular macromolecules, including DNA, ribonucleic acid (RNA), and proteins. Damage to DNA can occur at all stages of the cell cycle, but lethal hits occur mainly in the S phase.

The daily, long-term administration of cyclophosphamide at low therapeutic doses leads to a progressive reduction in circulating lymphocytes, with minimal effect on myeloid cell populations. Within 7 days, B cells, CD4+ T cells, and CD8+ T cells show a 30% to 40% reduction in numbers. Cessation of cyclophosphamide therapy results in a differential rate of recovery of lymphocyte populations. CD8+ T cells recover first, followed by B cells and, finally, CD4+ T cells. Intermittent low-dose administration seems to affect antibody production, but long-term low-dose administration diminishes CMI as assessed by decreased delayed-type allergic reactions. Paradoxic increases in immune activity have also been observed after low-dose cyclophosphamide therapy, attributable to selective depression of T-suppressor cell activity. Cyclophosphamide also depresses myeloid hematopoiesis in the bone marrow, and has been associated with neutropenia and thrombocytopenia.

Metabolite analogues

The purine, pyrimidine, and folate antagonists represent a second group of cytotoxic drugs active against rapidly dividing or metabolizing cells. Included among these are the purine antagonists azathioprine and 6-mercaptopurine, the pyrimidine antagonist floxuridine, and the folate antagonist methotrexate. These agents are given with, or within 48 hours of, antigen administration and inhibit cellular proliferation and initial differentiation, usually through inhibition of DNA or RNA synthesis. They all seem to impair CMI and humoral immunity. Originally developed for cancer therapy, these drugs can affect any group of rapidly proliferating cells. Because they are particularly toxic to hematopoietic tissues, they may induce leukopenia (especially neutropenia), thrombocytopenia, and anemia.

Azathioprine. Azathioprine warrants special mention because it is used solely as an immunosuppressant. Azathioprine is a prodrug that yields 6-mercaptopurine on intracellular exposure to glutathione and other nucleophilic reactants. Although the pharmacologic features of azathioprine are essentially identical to those of 6-mercaptopurine (see Chapter 42), azathioprine is believed to be a more selective immunosuppressant. This advantage may stem from an enhanced uptake or metabolic activation of azathioprine in T cells.

Mycophenolate. Mycophenolate mofetil is an ester that is rapidly hydrolyzed to mycophenolic acid, the active form of the drug. The active metabolite is now also available for use. Mycophenolate is an inhibitor of inosine monophosphate dehydrogenase, an important enzyme in purine synthesis. Because lymphocytes depend more on the de novo synthesis of purines than other cells, which can reclaim purines by the salvage pathway, mycophenolate is a more selective immunosuppressant than other cytotoxic agents. CMI and humoral immunity are suppressed, and leukocyte recruitment to inflammatory sites is inhibited.

Slow-Acting, Disease-Modifying Antirheumatic Drugs

One potential immunosuppressive strategy involves the inhibition of selected aspects of antigen processing within the endolysosome or by the proteasome. The antimalarial disease-modifying antirheumatic drugs (DMARDs) chloroquine and hydrochloroquine seem to have several effects on the immune system, including inhibition of endolysosomal antigen processing. It has been suggested that these weak bases may impair endolysosomal acidification. As a result, individuals treated with chloroquine or hydrochloroquine exhibit diminished antibody formation (including decreased formation of rheumatoid factor, decreased autoantibodies, and decreased total serum IgG and IgA), which is one of the main rationales for their use in Sjögren's syndrome and other autoimmune rheumatic diseases.

Gold compounds—gold sodium thiomalate, aurothioglucose, and auranofin—function in part by inhibiting transcription activation. Gold compounds may be active against protein kinase C. As a result, not only are various lymphocyte functions diminished, but also the induction of immune function in nonhematopoietic cells is impaired. In the latter situation, it has been shown that the expression of MHC II molecules by endothelial cells can be inhibited by gold compounds.

Penicillamine and sulfasalazine are DMARDs that inhibit proliferation through unknown mechanisms. Penicillamine blocks T-cell proliferation in response to IL-1 and blocks IL-1 production by monocytes; sulfasalazine blocks T-mitogen–induced and B-mitogen–induced proliferation of peripheral blood lymphocytes.[10]

Cytokine Therapy

Therapeutics based on the administration of hormones is not new. As more is learned about the activities of immunologic hormones, loosely referred to as *cytokines*, new therapies to increase or decrease immunologic activities will be developed. Currently, over a dozen cytokines have been approved for human use, and others are in clinical trials. In the following discussion, cytokines and soluble cytokine receptors are reviewed in accordance with their principal biologic activities (see Table 41-1).

Hematopoietic growth factors

The hematopoietic growth factors, also referred to as *colony-stimulating factors*, include granulocyte colony-stimulating factor, granulocyte/macrophage colony-stimulating factor, monocyte/macrophage colony-stimulating factor, stem cell factor, erythropoietin, and a number of interleukins. Although it is beyond the scope of this chapter to discuss these growth factors, they are used clinically in the treatment of various hematopoietic deficiencies, including neutropenia, anemia, and thrombocytopenia, and are reviewed in Chapter 30.

Interleukin-1 family

IL-1 occupies the borderland between adaptive, nonspecific immune responses and adaptive, specific immune responses. Several related molecules, including IL-1α, IL-1β, IL-1 receptor antagonist (IL-1Ra), and their receptors in soluble form, are under consideration for use in immunotherapeutics.[13] IL-1 is

TABLE **41-3**

Effects of Interleukin-1 on Immune Cells

TARGET CELLS	EFFECTS
Lymphoid Cells	
T cells	Growth factor (primarily owing to its ability to stimulate IL-2)
	Increased IL-2 receptors
	Induction of cytokine synthesis (IL-2, IL-3, others)
	Induction of IFN-γ synthesis
	Chemoattractant
B cells	Growth factor for transformed B cells (B blasts)
	Potentiates B-cell growth and differentiation factors (IL-4, IL-6)
	Chemoattractant
NK cells	Facilitates IL-2 and IFN enhancement of tumor cell lysis
	Increases binding of NK cells to targets
	Induces cytokine synthesis (IL-1)
Myeloid Cells	
Neutrophils	Thromboxane synthesis
	Degranulation (secretion)
Monocytes/ macrophages	Induces synthesis of PGE_2, IL-1, and other cytokines
	Induces cytotoxicity
	Colony-stimulating factors
	Stimulates migration

IFN, Interferon; *IL,* interleukin; *NK,* natural killer; *PGE_2,* prostaglandin E_2.

produced by many cells, but mainly monocytes/macrophages, in the form of precursor molecules lacking a signal sequence. A large fraction of IL-1α remains inactive in the cytosol of the cell. In contrast, IL-1β is rapidly converted to its active form and released extracellularly in large quantities.

IL-1 can exist in soluble and membrane-associated forms. As a soluble molecule, IL-1 is a hormone with wide-ranging systemic effects involving the central nervous system, liver, kidney, hematopoietic system (including neutrophilia and lymphopenia), and vascular system (e.g., promotes leukocyte adherence). The membrane-associated form may be a partially degraded version of IL-1α, which can function as a costimulatory factor for naïve T cells. Some immunologic effects of IL-1 are listed in Table 41-3. In addition, IL-1β is important as an osteoclast-activating factor and is believed to be involved in periodontal bone destruction. IL-1 has cytotoxic activities; it kills melanoma cells, thyrocytes, and β-islet (insulin-producing) cells. IL-1 also induces fever, and as such it is one of the more important endogenous pyrogens. The pyrogenic effect of IL-1 is blocked by nonsteroidal anti-inflammatory drugs, suggesting that it depends on the elaboration of cyclooxygenase products.

IL-1Ra, a protein with structural homology to IL-1α and IL-1β, is secreted by monocytes. It is found in the urine of patients with fever or monocytic leukemia. The molecule binds to the IL-1 receptor in competition with IL-1α and IL-1β, but it does not trigger the cellular responses typical of IL-1. IL-1Ra is considered a natural means of blocking excessive IL-1 inflammatory events, which can lead to shock, arthritis, osteoporosis, colitis, leukemia, diabetes, wasting, and atherosclerosis. IL-1Ra has potential therapeutic application in humans, and clinical trials have shown some efficacy in septic shock syndrome and more consistent benefits in rheumatoid arthritis.[12]

Interleukin-1 receptors

The IL-1 receptor (IL-1R) is a member of the immunoglobulin superfamily. There are two subtypes of IL-1R. Subtype 1 (IL-1RI) binds IL-1α preferentially and is found on T cells, endothelial cells, keratinocytes, hepatocytes, and fibroblasts. Subtype 2 (IL-1RII) is expressed by neutrophils, monocytes, B cells, and bone marrow cells, and it binds IL-1β preferentially. IL-1RI is more sensitive to inhibition by IL-1Ra than IL-1RII. IL-RII exhibits a very short cytoplasmic domain compared with IL-1RI, suggesting that it may serve as a "decoy" receptor. IL-1R can exist in either a transmembranous form or a soluble form. Soluble receptors exert an antagonistic effect by binding to IL-1. (Because IL-1 and IL-1R can be either membrane-bound or soluble, the distinction between ligand and receptor blurs.) Experiments in mice have shown that recombinant soluble IL-1RI can prolong the survival of cardiac allografts. Much of this survival is attributable to decreased inflammation, rather than to specific immunosuppression. Anakinra, a recombinant form of IL-1RI, has been marketed for the treatment of rheumatoid arthritis not responding to more traditional DMARDs.

Interleukin-2

Lymphocytotrophic hormone, or IL-2, is a glycoprotein produced by naïve and TH1 T cells in the presence of antigen-presenting cells. IL-2 abrogates suppressor T-cell activity and is required for IFN-γ production. In specific immune responses, the main function of IL-2 is to induce T-cell proliferative differentiation; as such, IL-2 enhances the growth of naïve CD4+ T cells, TH1 CD4+ T cells, and CD8+ T cells. In nonspecific, innate responses, IL-2 can activate NK cells to form more aggressive lymphokine-activated killer (LAK) cells. Most immunotherapies involving IL-2 are based on its ability to alter NK cell activity.

The IL-2 receptor is a collection of isoforms designated by their relative affinities for IL-2. These isoforms result from unique combinations of three different IL-2R subunits.[40] The high-affinity form is usually present on less than 1% of the circulating mononuclear cells.

IL-2 therapy has been explored in various immunodeficiency diseases and cancer, and IL-2 replacement has been effective in treating patients with IL-2 deficiency. The cytokine has been given the nonproprietary name of aldesleukin and has been marketed for the treatment of metastatic renal cell carcinoma (see Chapter 42).
