Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

HOW TO APPROACH PHARMACOLOGY

Although pharmacology can be considered a basic science, the ultimate purpose of pharmacology in the health science setting is to apply basic principles to clinical practice. This book, which is targeted to the dental student and dental practitioner, is designed to meet that need. Pharmacology is important to the dentist not only because of the drugs that he or she prescribes or uses in the dental office, but also because of other drugs that the patient takes. Every drug can affect the entire body. Moreover, when more than one drug is given concurrently, there is a potential for drug interactions that could have adverse consequences.

This book is designed to make specific dental applications to each drug class. Included in this information are the benefits and risks associated with those drug classes.

In the study of pharmacology it is important to learn drugs by their class on the basis of similarity of mechanism of action, not as individual stand-alone medications. Thus armed with the knowledge of the properties of a class of drugs and examples of drugs within that class, one can streamline the learning process. Organization of drug information can then be arranged around the following subcategories. (These will be useful in studying most drugs.)

1. Name of drug class and examples
2. Mechanism of action
3. Pharmacokinetics
4. Indications
5. Adverse effects
6. Contraindications
7. Miscellaneous information, including drug interactions
8. Implications for dentistry

Some devices can help in the learning of drug names. The nonproprietary (generic) names for drugs within a given class often have similarities. Being familiar with a list of suffixes of generic drug names can be helpful in identifying an individual drug. Such a list is given below.

SUFFIXES AS CUES FOR REMEMBERING DRUG CLASSES

SUFFIX	DRUG CLASS	EXAMPLE
"azole"	Azole-type antifungal drug or Antibacterial-antiparasitic drug	Fluconazole Metronidazole
"caine"	Local anesthetic	Lidocaine
"coxib"	Cyclooxygenase-2 (COX-2) inhibitor	Celecoxib
"dipine"	Dihydropyridine Ca^{++} channel blocker	Nifedipine
"ilol" or "alol"	β-Adrenergic receptor blocker that also the blocks the α_1-adrenergic receptor	Carvedilol, labetalol
"mab"	Monoclonal antibody	Infliximab
"olol"	β-Adrenergic receptor blocker	Propranolol
"onium" or "urium"	Quaternary ammonium compound, usually used as a peripheral competitive skeletal muscle relaxer	Pancuronium, atracurium
"osin"	α_1-Adrenergic receptor blocker	Prazosin
"pam" or "lam"	Benzodiazepine antiaxiety agent or sedative hypnotic	Diazepam, triazolam
"pril" or "prilat"	Angiotensin-converting enzyme (ACE) inhibitor	Captopril
"sartan"	Angiotensin II receptor blocker	Losartan
"statin"	HMG CoA reductase inhibitor anti-lipid drug	Lovastatin
"triptan"	Serotonin 5-$HT_{1B/1D}$ agonist antimigraine drug	Sumatriptan
"vir"	Antiviral drug	Acyclovir

Application of information to clinical cases can increase retention and appreciation of pharmacology. For instance, suppose that a dental patient has been prescribed darifenacin by his or her physician to treat urinary urgency. One should know that drugs such as darifenacin are likely to cause xerostomia (dry mouth), and one should know why. Therefore it is reasonable to assume that xerostomia would be a likely complaint that a patient would have after taking such a drug. Moreover, it would also be well to consider how a dentist can help relieve symptoms of xerostomia without compromising the treatment for urinary urgency. This thought process requires knowledge of how these drugs act, including the receptors involved, and what responses are linked to these receptors.

The landscape of pharmacology is ever expanding with the constant development of new drugs, new drug classes, and new information on older drugs. Furthermore, the growth in our knowledge in areas such as pharmacogenetics and pharmacogenomics promises to lead to the practice of tailoring drug therapy to the individual.

All in all, pharmacology is an exciting and dynamic discipline. This book covers the major areas of pharmacology and provides an intellectual framework on which to use drugs in a rational manner.

ACKNOWLEDGMENTS

The competing demands of academia in the modern health science setting make the writing of textbooks such as *Pharmacology and Therapeutics for Dentistry* a challenging task. In this effort, we have been aided greatly by our contributing authors, past and present, who have given their time and expertise to ensure that the information provided herein is both accurate and current. We wish to acknowledge especially Dr. Enid Neidle, who was the lead editor for the first three editions of this book and Dr. Tom Pallasch, who died shortly after completing his revisions for this edition. We also must express gratitude to our families and colleagues for their forbearance in dealing with our distractions and preoccupations pharmacologic.

We wish to thank several individuals who made special contributions to this work. Mr. John Dolan, Acquisitions Editor; Ms. Joslyn Dumas, Developmental Editor; and Ms. Claire Kramer, Project Manager, of Elsevier played crucial roles in the completion of this edition. We wish to acknowledge Pat Dowd, Mare Akers, Jolene Winterfeld, Andrew Waters, Elizabeth Reese, Karen Bishop, Kristen Koseluk, and Leanne Tapper for their help with manuscript preparation.

and Enid A. Neidle

Contents

Introduction

Pharmacology may be defined as the science of drugs, their preparation, their uses, and their effects. The term derives from *pharmakon*, the Greek word for drug or medicine, and *logia*, the Latin suffix traditionally used to designate a body of knowledge and its study. As an organized discipline, pharmacology is of recent origin, but the study of medicinal substances is as old as civilization itself.

HISTORY

Sir William Osler once said, "The desire to take medicine is perhaps the greatest feature which distinguishes man from animals." Although this argument has been vitiated by experiments involving self-medication in rats and other laboratory species, it nevertheless serves to illustrate the historical relationship between drugs and human beings. The use of natural products to cure disease and alter mentation dates back to the dawn of time. By the writing of the Ebers papyrus (circa 1550 BC), more than 700 prescriptions for various ailments were known. Many of the ingredients incorporated in these preparations—lizard's blood, virgin's hair, fly excreta—are humorous by modern standards, but also included were many compounds recognized today as pharmacologically active. A summary of folk remedies and other medicinals that have withstood scientific scrutiny would list such substances as opium (morphine), belladonna (atropine), squill and foxglove (digitalis), cinchona bark (quinine and quinidine), coca leaves (cocaine), and ma huang (ephedrine). The empirical study of plant derivatives and animal products must have been extensive to have been so fruitful.

A major hindrance to the effective use of these drugs, however, was the large number of materials usually present in apothecary formulations. For example, the most popular drug of the fifteenth century, triaca, contained more than 100 separate components. Aureolus Paracelsus (1493-1541) was the first to recognize that the indiscriminate mixing of numerous substances did little but dilute whatever effective compounds may have been present initially. The focus of Paracelsus on single agents was refined by Felice Fontana (1720-1805), who deduced from his own experiments that each crude drug contains an "active principle" that, when administered, yields a characteristic effect on the body. One of the greatest scientific achievements of the nineteenth century was the isolation and objective evaluation of such active principles.

In 1803, a young German pharmacist, Frederick Sertürner (1780-1841), extracted the alkaloid morphine from opium. This singular achievement not only marked the beginning of pharmaceutical chemistry, but also led to a revolution in experimental biology. The availability of newly purified drugs and the standardization of existing biologic preparations encouraged pioneers like Francois Magendie (1783-1855) and Claude Bernard (1813-1878) to use pharmacologic agents as probes in the study of physiologic processes. The use of curare by Bernard for the elucidation of the neuromuscular junction is but one example of the successes obtained with this approach. Perhaps because drugs became associated with several biologic sciences and were, of course, considered under the domain of the various medical specialties, the development of pharmacology as a separate discipline was delayed.

Rudolf Buchheim (1820-1879) and Oswald Schmiedeberg (1838-1921) were the two individuals most responsible for establishing pharmacology as a science in its own right. Buchheim organized the first laboratory exclusively devoted to pharmacology and became the first professor of his discipline. A student of Buchheim's, Schmiedeberg founded the first scientific journal of pharmacology. More important, through his tutelage Schmiedeberg helped spread acceptance of pharmacology throughout the world. One protégé of Schmiedeberg was John Abel (1857-1938), generally regarded as the father of American pharmacology.

Once an obscure experimental science, pharmacology has expanded its purview to such an extent that the subject has become an important area of study for all health professionals and holds certain interests for the lay public as well. In dentistry, the impact of pharmacology was formally recognized by the American Dental Association in 1934 with publication of the first edition of *Accepted Dental Remedies*.

SCOPE OF PHARMACOLOGY

Pharmacology is one of the few medical sciences that straddles the division between the basic and the clinical. The scope of pharmacology is so extensive that several subdivisions have come to be recognized. *Pharmacodynamics* is the study of the biologic activity that a drug has on a living system. It includes a study of the mechanisms of action of the drug and the exact processes that are affected by it. The influence of chemical structure on drug action (the structure-activity relationship) is also a concern of this branch of pharmacology. *Pharmacokinetics* deals with the magnitude and time course of drug effect, and it attempts to explain these aspects of drug action through a consideration of dosage and the absorption, distribution, and fate of chemicals in living systems. *Pharmacotherapeutics* is the proper selection of an agent whose biologic effect on a living organism is most appropriate to treat a particular disease state. It requires a consideration of, among many other things, dose, duration of therapy, and side effects of drug treatment. The practice of *pharmacy* involves the preparation and dispensing of medicines. Although pharmacists today are rarely called on to actually prepare drug products, they can serve as a useful source of drug information for both the clinician and the patient. *Toxicology* is that aspect of pharmacology dealing with poisons, their actions, their detection, and the treatment of conditions produced by them. The importance of toxicology to modern life is continually underscored by new discoveries of chemical hazards in the environment. As the various disciplines of science and medicine have continued to evolve, fruitful areas of inquiry have emerged from the union of fields with overlapping interest. For example, study

of the interrelationships between drugs and heredity, aging, and the immune system has led to the respective development of *pharmacogenetics*, *geriatric pharmacology*, and *immunopharmacology*. A final subdivision of pharmacology, *pharmacognosy*, is now a somewhat vestigial science. Essential at a time when most drugs were derived from plants, it literally means "drug recognition" and deals with the characteristics of plants and how to identify those with pharmacologic activity. Most drugs today are synthesized chemically, but phytochemistry, especially the synthesis of complex chemical structures by plants, remains of interest. On the other hand, herbal medicine as a discipline has gained in importance since 1994. The use of products in this area has spurred interest in the active components of herbal medicines, their clinical efficacy, and their potential liabilities.

After a description of how the study of drugs is classified, it is appropriate to discuss what is meant by the word *drug*. To the pharmacologist, a drug is any chemical agent that has an effect on the processes associated with life. This definition is obviously broad and ill suited for many parties who define the term more restrictively to better serve their particular needs. The therapist, for example, considers as drugs those chemicals that are effective in treating disease states. To the lay public, drugs generally connote those substances that cause mental and psychological alterations. Finally, governmental agencies are concerned with the revenue derived from the taxes levied against the sale of certain substances or with public health problems associated with their use. Some of these agents, such as tobacco and alcohol, are legally sequestered; that is, by law they are considered "nondrugs." Although pharmacologists have long recognized these agents as potent drugs, they are exempted from the usual governmental restraints and are not subject to normal scrutiny by the U.S. Food and Drug Administration. There are other substances that have gained such special status not by historical accident, as did some of those previously mentioned, but by considerations of public health. Examples of these include chlorine and fluoride added to community water supplies and iodides mixed with table salt. Lawsuits over the question of whether these public measures constitute an illegal form of "mass medication" have been resolved by the courts, at least in part through the categorization of these chemicals as legal nondrugs when they are used in a specific manner for the public good.

Drugs to be covered in this book include almost exclusively only those substances with a known therapeutic application. Even so, the potential number of agents for consideration is large—several thousand drugs marketed in a multiplicity of dosage forms and, in some instances, in a bewildering variety of combinations. To limit confusion, emphasis is placed on single, prototypical agents that are representative of their respective drug classes. By this approach, an understanding of the properties of related agents can be more readily achieved; at the same time, differences that may exist between them can be highlighted. Finally, it is important to recognize that there are certain generalizations that apply to all drugs. These principles of drug action are the subject of the first four chapters in this book. A mastery of the concepts presented in these chapters is necessary for a thorough understanding of pharmacology, for the rational use of therapeutic agents, and for the objective evaluation of new drugs.

PHARMACOLOGY AND THERAPEUTICS FOR DENTISTRY

PART I

Principles of Pharmacology

CHAPTER 1

Pharmacodynamics: Mechanisms of Drug Action

JOHN A. YAGIELA

DRUG-RECEPTOR INTERACTIONS

The actions of most therapeutic agents are imbued with a certain degree of specificity. In conventional doses, drugs are generally selective in action; that is, they influence a narrow spectrum of biologic events. In addition, the pharmacologic profile of such agents is often markedly dependent on chemical structure; simple molecular modifications may drastically alter drug activity. These attributes of drug action suggest that the tissue components with which drugs interact to cause observable effects are uniquely individualized. Such tissue elements must have highly ordered physicochemical properties to permit particular compounds to combine with them, while prohibiting all others from doing so. They must also be intimately involved with discrete processes of life for drug interactions to exert specific physiologic influences. These "biologic partners" of drug action are given the term *receptors*.

The existence of receptors for exogenously administered drugs implies that drugs often mimic or inhibit the actions of endogenous ligands for these receptors. Drugs rarely produce novel effects; instead, they modify existing physiologic functions.

Receptor Classification

For many years after their postulation a century ago, receptors remained an enigma to pharmacologists. Little was known about them other than the probability that they were complex macromolecules possessing a ligand-binding site to interact with specific drugs and an effector site to initiate the pharmacologic response. With the development of biochemical methods for the isolation, solubilization, and characterization of proteins, however, enzymes became available as model systems for the study of drug-receptor interactions. Enzymes exhibit many of the properties that are ascribed to receptors. They are macromolecules having measurable biologic functions and possessing specific reactive sites for selected substrates. The close association between enzymes and receptors was underscored in the early 1940s when it became apparent that some enzymes are drug receptors. The list of drugs that alter known enzymatic activities is extensive and includes angiotensin-converting enzyme inhibitors, allopurinol, anticholinesterases, carbidopa, carbonic anhydrase inhibitors, disulfiram, entacapone, monoamine oxidase inhibitors, protease inhibitors, reverse transcriptase inhibitors, statin cholesterol synthesis inhibitors, sulfonamides, trimethoprim, and various antimetabolites used in cancer chemotherapy.

Besides enzymes (including coenzymes) and other easily solubilized proteins, at least two additional classes of receptors have been identified and are of clinical significance: nucleic acids and membrane-linked proteins. Nucleic acids serve as receptors for a limited number of agents. Certain antibiotics and antineoplastic compounds interfere with replication, transcription, or translation of genetic material by binding, sometimes irreversibly, to the nucleic acids involved. Other drugs, including thyroid hormones, vitamin D analogues, sex steroids, and adrenal corticosteroids, also modify transcription, but here the affected DNA becomes activated or inhibited as a consequence of drug interaction with a separate receptor protein in the cytosol or nucleus of the cell, as described subsequently. The most common receptors of drugs are those located on or within the various membranes of the cell. Their study has been greatly aided in recent years by developments in genomics, proteomics, and informatics. Membrane transporter proteins and metabolic enzymes, described in Chapter 2 for their influence on drug disposition, are themselves targets of drug action. Of greater significance are the many integral membrane proteins that function as receptors for endogenous regulatory ligands, such as neurotransmitters, hormones, and other signaling molecules.

Receptors involved in physiologic regulation can be grouped by molecular structure and functional characteristics into several superfamilies. Most of these receptors have one or more extracellular ligand-binding domains linked by one or more lipophilic membrane-spanning segments to an effector domain often, but not always, located on the cytoplasmic side of the membrane. This arrangement is ideal for the translation of an extracellular signal into an intracellular response. Usually, the endogenous ligand "signal" is hydrophilic and incapable of passive diffusion through the cell membrane. For lipophilic regulatory ligands, such as for thyroid hormone and various steroids, a separate superfamily of intracellular receptors exists. Commonly, drug binding exposes a DNA-binding site on the receptor protein, allowing the receptor to interact with DNA and alter transcription. These major classes of receptors are illustrated in Figure 1-1 and described subsequently.

Ion channel–linked receptors

There are two general classes of ion channels: voltage gated and ligand gated. Voltage-gated ion channels are activated by alterations in membrane voltage. Voltage-gated Na^+ channels open when the membrane is depolarized to a threshold potential and contribute to further membrane depolarization by allowing Na^+ influx into the cell. As described in Chapter 16, local anesthetics such as lidocaine bind to voltage-gated Na^+ channels, leading to blockade of neuronal depolarization. Specific voltage-gated ion channels also exist for K^+, Ca^{++}, H^+, and Cl^-.

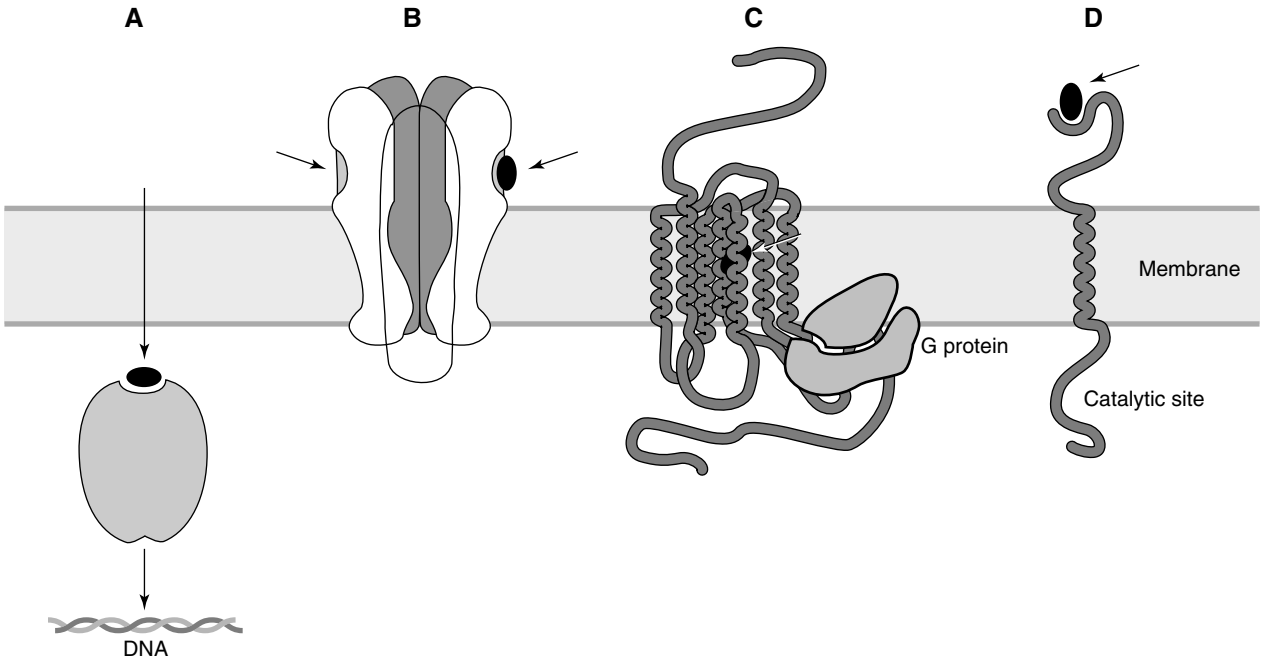

FIGURE **1-1** Examples of four major classes of receptors and signal transduction mechanisms. *Arrows* denote the receptor ligand-binding sites. **A,** Intracellular receptors. Lipophilic substances such as steroids can cross the plasma membrane and activate intracellular receptors, which, after translocation to the nucleus, alter gene transcription and, ultimately, synthesis of new protein. **B,** Ion channel–linked receptors. Drugs such as nicotine can activate ligand-gated ion channels, leading to depolarization (or hyperpolarization) of the plasma membrane. **C,** G protein–linked receptors. Many drugs can activate G protein–linked receptors, causing release of the α and βγ subunits of associated G proteins. **D,** Enzyme-linked receptors. Drugs such as insulin promote dimerization of its receptor and activation of the catalytic site on the intracellular end of the receptor.

In contrast, ligand-gated ion channels are activated in response to the binding of specific ligands or drugs. Many neurotransmitters and drugs and some cytoplasmic ligands activate membrane-bound ligand-gated ion channels, including several types of glutamate receptors and one 5-hydroxytryptamine ($5\text{-}HT_3$) receptor promoting Na^+, K^+, or Ca^{++} movements, and certain γ-aminobutyric acid and glycine receptors promoting Cl^- influx. Depending on the ionic charge and the direction of flow, ligand-gated ion channels can either depolarize or hyperpolarize the cell membrane.

The nicotinic receptor (Figure 1-2), the first membrane-bound drug receptor to be fully characterized,[12,22] is an important example of a ligand-gated ion channel. An oligomeric structure, the polypeptide constituents of the nicotinic receptor are arranged concentrically to form a channel through which small ions can traverse the plasma membrane when the receptor is activated by the binding of two acetylcholine (ACh) molecules. As is the case with other ion channels, numerous subtypes of nicotinic receptors exist expressing differing affinities for specific ligands.

G protein–linked receptors

G protein–linked receptors, sometimes referred to as metabotropic receptors, constitute the largest superfamily of integral membrane proteins, and collectively serve as targets for approximately half of all nonantimicrobial prescription drugs.[9,11] The basic structure of these receptors includes a common seven-membered transmembrane domain. Generally, metabotropic receptors greatly amplify extracellular biologic signals because they activate G proteins, which activate ion channels or, more commonly, other enzymes (e.g., adenylyl

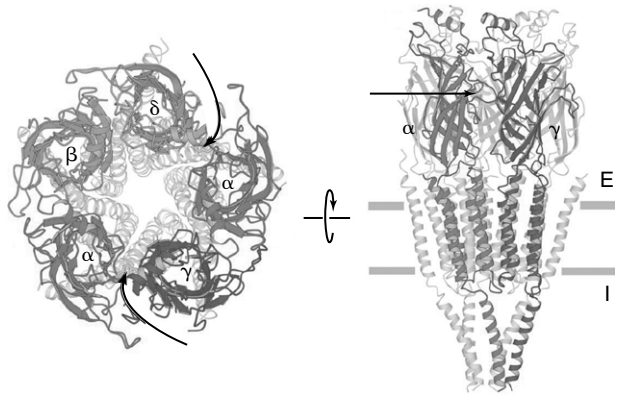

FIGURE **1-2** Ribbon structural model of the nicotinic ACh receptor from the electric organ of *Torpedo marmorata*. *Left*, View from the synaptic cleft. Five polypeptide units consisting of four different types (*α*, *β*, *γ*, and *δ*) form a rosette with a hydrophilic pore spanning the center of the oligomer. External regions, which include the ACh binding sites, are highlighted. *Arrows* indicate the α-subunit tryptophan (W149) that constitutes part of each ligand-binding site. *Right*, View parallel to the plasma membrane. Each polypeptide subunit includes four α-helical sequences that traverse the plasma membrane; the front two subunits are highlighted. *Arrow* indicates the same W149 residue. *E*, External surface (interstitial space); *I*, internal surface (cytoplasmic space). (Adapted from Unwin N: Refined structure of the nicotinic acetylcholine receptor at 4 Å resolution, *J Mol Biol* 346:967-989, 2005.)

cyclase), leading to the introduction or formation of a host of internal second messengers for each extracellular signal molecule detected. This amplification system, which also usually involves an extended duration of activation of G proteins relative to the binding of drug to the receptor, may explain why maximal pharmacologic effects are often observed when only a small proportion of receptors are activated.

G proteins are heterotrimers consisting of α, β, and γ subunits. After receptor activation, guanosine diphosphate attached to the α subunit is replaced by guanosine triphosphate, and the heterotrimer splits into the α monomer and βγ dimer. Many, but not all, of the observed cellular actions are caused by the α subunit (see Figure 5-7). $G_{\alpha s}$, the specific α subunit for the G protein associated with β-adrenergic receptors, activates adenylyl cyclase, which catalyzes the synthesis of cyclic adenosine 3′,5′-monophosphate (cAMP).[9] cAMP activates protein kinase A, which catalyzes the phosphorylation of serine and threonine residues of certain intracellular proteins, leading to altered cellular function.

The G protein system is complex and still incompletely understood. One receptor subtype may activate different G proteins, several receptor subtypes may activate the same G protein, and the ultimate target proteins can exist in tissue-specific isoforms with differing susceptibilities to secondary effector systems. The different G protein pathways can also interact with one another. The complexity of G protein signal transduction provides a sophisticated regulatory system by which cellular responses can vary, depending on the combination of receptors activated and the cell-specific expression of distinct regulatory and target proteins. Several specific membrane-bound G proteins are discussed in Chapter 5.

Figure 1-3 depicts the structure of the mammalian β_2 receptor based on x-ray crystallography studies and how it is believed to be arranged within the plasma membrane.[11]

Enzyme-linked receptors

Enzyme-linked receptors have only one transmembrane domain per protein subunit, with an enzymatic catalytic site on the cytoplasmic side of the receptor. Dimerization of activated receptors usually provides the conformational change required for expression of enzymatic activity. The catalytic sites are commonly protein kinases that phosphorylate tyrosine or, less commonly, serine or threonine residues on target proteins. Autophosphorylation of the receptor also occurs. Some catalytic receptors have guanylyl cyclase or tyrosine phosphatase activity. Insulin, atrial natriuretic peptide, and various growth factors (e.g., epidermal growth factor) activate catalytic receptors. A closely related group of receptors responsible for the action of numerous peptides—including various neurotrophic peptides, growth hormone, and cytokines—lacks enzymatic activity. In such cases, the catalytic site is supplied by a separate nonreceptor protein kinase that interacts with the dimerized receptor.

Many forms of cancer seem to involve mutant variants of enzyme-linked receptors in which the catalytic site or associated nonreceptor protein kinase is continuously activated.[4] Approximately half of all oncogenes discovered to date encode for continuously activated protein kinases.

Intracellular receptors

Lipophilic substances capable of crossing the plasma membrane may activate intracellular receptors. Sex steroids, mineralocorticoids, glucocorticoids, thyroid hormones, and vitamin D derivatives all activate specific nuclear receptors that influence DNA transcription.[8,20] The typical nuclear receptor is composed of three major subunits: the carboxyl end of the receptor forms the ligand-binding domain, the adjacent segment includes the DNA-binding region, and the amino terminus constitutes the transcription-modulating domain. When a drug (or hormone) binds to the receptor, it

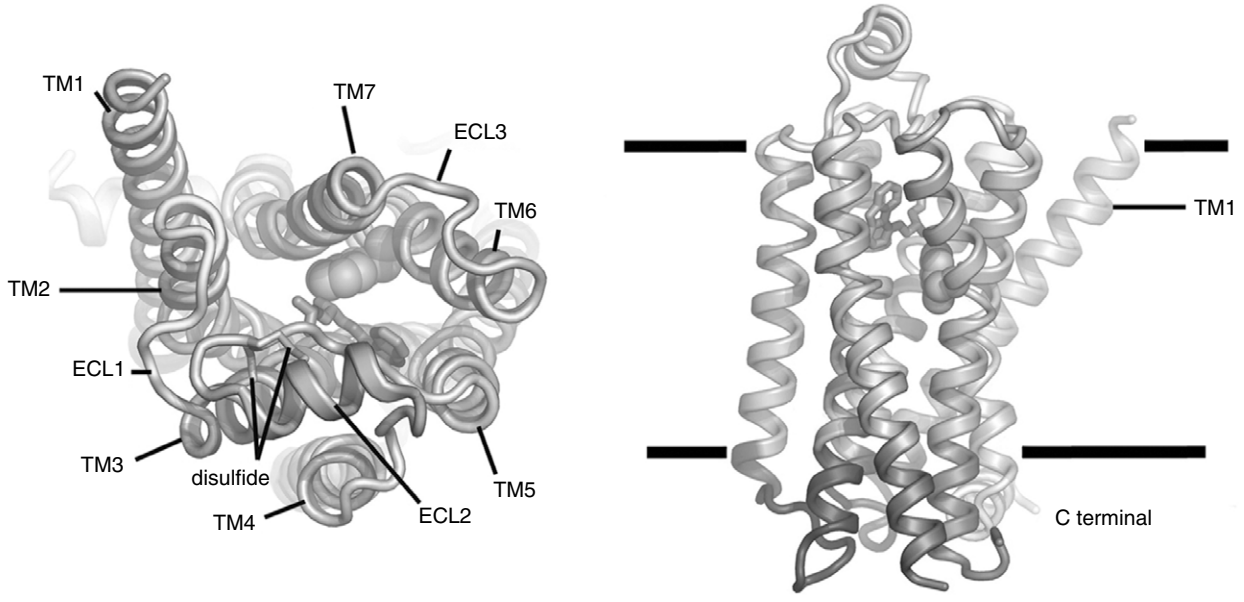

FIGURE **1-3** Ribbon structural model of the β_2-adrenergic receptor. *Left*, View from the synaptic cleft; *right*, view parallel to the plasma membrane. For technical reasons, it was not possible to visualize the extracellular N-terminal amino acid chain attached to transmembrane helix 1 *(TM1)*, the intracellular connector between *TM5* and *TM6*, and a major portion of the intracellular C terminal. Binding of a drug ligand (in this case, the β-adrenergic receptor antagonist carazolol) is represented as a stick figure. The rotamer toggle switch tryptophan (W293), which allows TM6 to move in response to drug agonists, is indicated by the space-filling spheres. *ECL*, Extracellular loop. (Adapted from Hanson MA, Stevens RC: Discovery of new GPCR biology: one receptor structure at a time, *Structure* 17:8-14, 2009.)

folds into the active configuration and dimerizes with a partner receptor. The conformational change results in a dramatic increase in binding to specific DNA sequences. Binding of thyroid hormone to its receptor produces more than a 10-fold increase in receptor affinity for binding to DNA.[20] DNA binding of the activated receptor often initiates transcription, leading to increased production of specific proteins. Because this type of signal transduction requires protein synthesis, drugs that activate intracellular receptors typically have a delay of several hours before the onset of their pharmacologic effect. (For this reason, glucocorticoids cannot be used as primary drugs for the management of anaphylaxis.) In some systems, the binding of the drug-receptor complex inhibits transcription. Regardless of the specific mechanism involved, however, the intensity and duration of drug effect is temporally independent of the plasma concentration.

In addition to these intracellular receptors, other enzymes and proteins involved in cellular metabolism and gene expression are receiving increasing scrutiny as potential targets for drug therapy. Nitric oxide, which stimulates guanylyl cyclase directly to form cyclic guanosine 3′,5′-monophosphate (cGMP), and sildenafil, which inhibits the breakdown of cGMP by cGMP-specific phosphodiesterase-5, are two examples of currently available agents acting intracellularly on regulatory enzymes. Finally, structural proteins such as tubulin, which are assembled to form microtubules, are targets for several drugs used in the treatment of cancer, gout, and fungal infections.

Drug-Binding Forces

Implicit in the interaction of a drug with its receptor is the chemical binding of that drug to one or more specific sites on the receptor molecule. Five basic types of binding may be involved (Figure 1-4).

Covalent bonds

Covalent bonds arise from the sharing of electrons by a pair of atoms. Although covalent bonds are required for the structural integrity of molecules, they are generally not involved in drug-receptor interactions. Most drugs reversibly associate with their receptors. As described in Chapter 2, the duration of action of these agents is related to how long an effective drug concentration remains in the vicinity of the drug receptors. This time may vary from a few minutes to many days, but usually is on the order of several hours. With bond energies of 250 to 500 kJ/mol, the stabilities of covalent linkages are so great that, when formed, drug-receptor complexes are often irreversible. In these instances, the duration of action is not influenced by the concentration of unbound drug surrounding the receptors. Instead, it may depend on the synthesis of new receptors or on the turnover of the affected cells, processes that often take days to weeks. When the receptors happen to compose or influence the genetic material of a cell, drug effects may be permanent.

Ionic bonds

Ionic bonds result from the electrostatic attraction between ions of opposite charge. Such associations are relatively weak in an aqueous environment, having bond energies of approximately 20 kJ/mol. Nevertheless, many drugs have a formal charge at physiologic pH, and it is likely that ionic bonds are commonly made with ionized groups located at receptor sites. Because the attraction between ions is inversely proportional to the square of the distance separating them, ionic influences operate over much greater distances than do other interatomic forces. It is reasonable to assume that ionic bonds initiate many drug-receptor combinations.

Cation-π interactions

Although benzene and similar aromatic compounds are hydrophobic solvents, their π electron clouds are capable of interacting with positively charged ions.[5] Phenylalanine, tyrosine, and tryptophan—amino acids with aromatic side groups—retain this ability. These amino acids are common constituents at receptor sites for such positively charged drugs as ACh, dopamine, epinephrine, and 5-HT. Individual bond energies are similar to those of hydrogen bonds described subsequently; however, interactions between multiple aromatic amino acids and a single cationic moiety commonly strengthen the overall interaction.

Hydrogen bonds

The hydrogen bond represents a special type of interaction between polar molecules. When a hydrogen atom is cova-

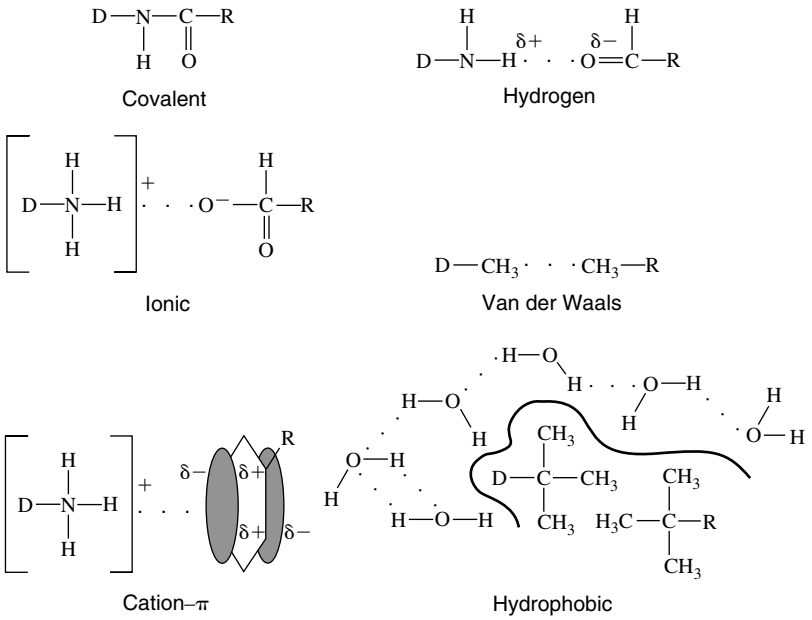

FIGURE **1-4** Major chemical bonds associated with drug-receptor interactions, where *D* is drug and *R* is receptor.

lently attached to a strongly electronegative atom such as oxygen or nitrogen, it becomes partially stripped of its electron and takes on some of the characteristics of a bare proton. Strongly electropositive and with an exceedingly small atomic radius, the hydrogen nucleus is able to associate closely with additional electronegative atoms. Hydrogen linkages are generally weaker than ionic bonds (approximately 5 kJ/mol) and are more sensitive to interatomic separation. Functional groups capable of forming hydrogen bonds are common to drugs and receptor sites, however, and if multiple unions occur, the resultant stabilizing force can far outweigh that of a single ionic bond.

Van der Waals forces

Van der Waals forces collectively describe the weak interactions that develop when two atoms are placed in close proximity. The electrostatic attractions that constitute these forces result from reciprocal perturbations in the electron clouds of the atoms involved. These "bonds" are the weakest of the five types described (approximately 0.5 kJ/mol); in addition, they decrease in strength according to the seventh power of the interatomic distance. Paradoxic as it may seem, van der Waals forces are of primary importance in conferring specificity to drug-receptor interactions. Because even electroneutral carbon atoms can participate in such associations, the number of these bonds that connect a drug to its receptor may be large, and the total binding force may be considerable. When minor steric influences prevent an exact fit between a drug and its receptor, the sensitivity of van der Waals forces to interatomic separation forestalls their development, and drug-receptor stability markedly declines.

Hydrophobic interactions

In addition to the bonding forces already described, hydrophobic interactions between the drug, its receptor, and the aqueous environment can play a major role in stabilizing drug-receptor binding. Water is an unusual liquid with respect to its ability to form hydrogen bonds with itself and with various solutes. The association of a drug with its receptor is enhanced if the drug is hydrophobic or if the surface area of a nonpolar region of the receptor is reduced by drug binding. In either case, stability occurs because of the reduced perturbation of the normal water structure.

Cooperation of binding forces

The binding of a drug to its receptor is generally not related to a particular attractive force but results from the conjoint action of ionic, cation-π, hydrogen, van der Waals, and (rarely) covalent linkages, often in synchrony with hydrophobic interactions. Each type of association contributes differently to the drug-receptor complex. When random movement causes a drug molecule to approach or collide with the receptor surface, ionic attractions, closely followed by cation-π interactions, are the first to develop. Unable to convey specificity or stability to a drug-receptor union by themselves, these forces nevertheless serve to draw in and partially orient the drug to its receptor. As the intermolecular separation diminishes, hydrophobic influences, hydrogen bonding, and subsequently van der Waals forces become prominent. In concert, these interactions provide for the specificity of drug action; without an exact fit, binding is impaired, and the drug cannot adhere well enough to influence receptor function. Covalent linkage confers a high degree of permanency to the drug-receptor complex. Fortunately, though, irreversible binding is uncommon in therapeutics. Many agents are used to produce a single, temporary effect; covalent attachment would preclude such use. In many instances, covalent bonding would make drug regimens more difficult to administer and adverse reactions more troublesome to treat.

Structure-Activity Relationships

Examination of structure-activity relationships (SARs) is a time-honored method of studying drug-receptor interactions. In SAR investigations, specific features of the structure of a drug molecule are identified and then altered systematically to determine their influence on pharmacologic activity. The chemical features that are most often involved in these considerations are the presence and type of ionic charge; the effect of neighboring groups on the degree of ionization; hydrogen-bonding capability; and steric factors such as the size of alkyl side chains, the distance between reactive groups, and the three-dimensional configuration of such groups. SAR studies of closely related agents (congeners) have led to an understanding of the chemical prerequisites for pharmacologic activity and, on a practical level, made possible the molecular modification of drugs to provide enhanced or even novel therapeutic effects, while reducing the incidence and severity of toxic reactions. In addition, SAR studies serve to illustrate how the combined action of the various binding forces described earlier are necessary for maximal drug activity, which yields certain clues concerning the physicochemical properties of the receptor sites involved that are of value to investigators seeking to unravel the exact structure of these sites.

A recent example of SARs is provided by the study of the binding of norepinephrine and related drugs to the β_2-adrenergic receptor (Figure 1-5).[2] The norepinephrine molecule is composed of a catechol residue (a benzene ring with two hydroxyl groups in the meta and para positions) connected by a two-carbon intermediate chain to a nitrogen terminus that is positively charged at physiologic pH. The presence of a cationic nitrogen locus is essential for full activity; loss of the ionic charge by removing the nitrogen moiety or replacing it with a nonionic carbon group virtually eliminates drug action, as does replacement of the receptor's aspartate residue (D113) with a neutral amino acid. Hydrogen bonds involving both ring hydroxyl groups with correspond-

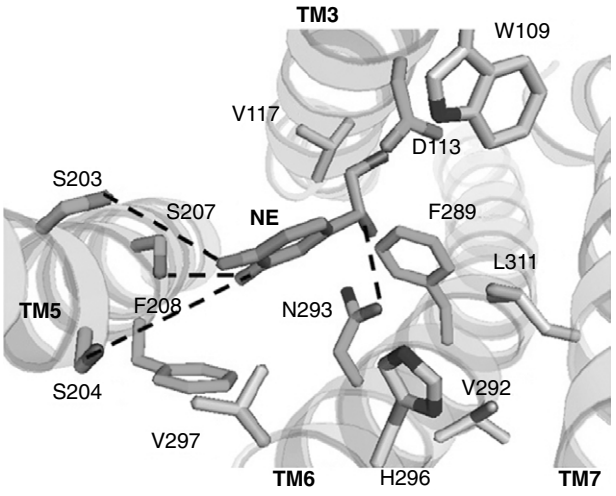

FIGURE **1-5** Ribbon model of the interaction of norepinephrine *(NE)* with the β_2-adrenergic receptor. The transmembrane segments involved in agonist binding *(TM3, TM5, TM6, TM7)* are shown along with their serine and asparagine residues (*S203, S204, S207,* and *N293*), involved in hydrogen binding (*dashed lines*), and the aspartate residue *(D113)* that forms an ionic bond. Other amino acids involved in agonist binding are also identified. (Adapted from Bhattacharya S, Hall SE, Li H, et al: Ligand-stabilized conformational states of human β2 adrenergic receptor: insight into G-protein-coupled receptor activation, *Biophys J* 94:2027-2042, 2008.)

ing serine residues (S203, S204, and S207) greatly increase potency (by 25-fold, 33-fold, and 39-fold, respectively) but preclude entry of the drug into the central nervous system (CNS). Replacement of a hydroxyl with a larger group generally eliminates agonist activity at β receptors but may result in antagonistic effects. Another hydrogen bond between the β-hydroxyl group and its asparagine counterpart (N293) increases binding affinity 38 times. The distance separating the catechol and nitrogen moieties of the molecule is likewise crucial for full activity. Electrostatic interactions involving the benzene ring and aromatic amino acid residues of the receptor protein (e.g., F290) also contribute to the binding of norepinephrine.

Although norepinephrine can fully activate the β_2 receptor in vitro, it requires higher concentrations than those achieved physiologically. Epinephrine, the natural β_2 receptor ligand, has a nitrogen-bound methyl group that increases β_2 activity by 10 to 50 times. Increasing the size of the alkyl moiety on the nitrogen further increases β-adrenergic selectivity. Because alkyl moieties do not form hydrogen or ionic bonds, this finding implies that van der Waals forces or hydrophobic interactions, or both, contribute significantly to the binding of epinephrine and congeners with selective β_2-adrenergic properties.

An important source of support for the concept of specificity in drug-receptor interactions comes from the differences so often observed in the activity of optical isomers, such as *d*-norepinephrine and *l*-norepinephrine. It is common for virtually all the activity in a racemic mixture to reside in one of the two stereoisomers. In the case of norepinephrine, the levorotatory isomer is highly active, whereas the other member of the pair is almost devoid of activity. This difference, at least with regard to the β_2 receptor, stems from the inability of the *d*-isomer to make the hydrogen bond between its β-hydroxyl group and the receptor's N293 residue. The presence of only a single atom with an opposite configuration is apparently sufficient to bring about dramatic differences in binding efficiency. Such critical sensitivity can occur only if the drug and receptor fit together with some degree of precision. The optical isomers quinine and quinidine are of interest because both have been used therapeutically but for different purposes. Quinidine (dextro) and quinine (levo) differ from each other only in the configuration of a single secondary alcohol group that serves as the connector of the two halves of the molecule. Both isomers are approximately equal in antimalarial activity, a property that depends on the drug reacting with the DNA of the plasmodial parasites responsible for the disease. The antiarrhythmic action on cardiac muscle is greater, however, for quinidine than for quinine. The enantiomers of D-mannose are another example of two molecules that differ only in the spatial arrangement of a single hydroxyl group, and yet vary in their biologic activity. α-D-Mannose is sweet when applied to chemoreceptors of the tongue, whereas β-D-mannose is bitter.

Consequences of Drug Binding

The combination of a drug with its receptor represents the incipient event in a series of reactions that culminate in a pharmacologic effect. Of prime importance is the second step in this chain—the receptor response to drug binding. Drugs generally are not highly reactive compounds in the chemical sense; they exert their influences indirectly by altering, through receptor attachment, the activity of an important regulator of a biologic process. The mechanism of action of a drug refers to this initial perturbation of normal function.

Ligand competition

Of the various receptor-based mechanisms of drug action, perhaps the most readily observed are those involving enzymes. Certain drugs are analogues of natural enzyme substrates. These antimetabolites compete with the substrate for the same catalytic site on the enzyme molecule, causing a decrease in the rate of product formation. As a general rule, however, such inhibitions are likely to be of little biologic consequence unless the magnitude of inhibition at least approaches 50%. This phenomenon seems to be explained best by the concept that the number of enzyme molecules present usually exceeds what is necessary for adequate catalysis. A 20% inhibition might produce no observable response because the remaining fraction of uninhibited enzyme is still capable of providing enough product. The enzyme carbonic anhydrase represents an extreme example of this situation. To reduce by half the enzymatic hydration of carbon dioxide, 99.7% of the carbonic anhydrase activity must be abolished.[17]

Another consideration related to antimetabolites is the often greater affinity of the reactive site for the natural substrate. This difference may be 1000-fold and carries some significance for pharmacology. If the substrate to be interfered with is abundant, such as glucose, the dose of inhibitor needed to obtain a body fluid concentration 1000 times that of the metabolite would be formidable. Substrates that are in more limited supply, such as vitamin derivatives or chemical mediators, are more reasonable targets for therapy based on this form of inhibition.

Ligand competition may also be invoked for drugs that compete with natural ligands for binding to regulatory proteins. In this case, the drug binds to the ligand-binding site of the receptor, preventing the activating signal to be recognized.

Conformational induction

Many drugs that influence enzyme activity are not structurally related to native substrates. These drugs affect catalysis by serving as allosteric regulators; that is, by binding elsewhere on the enzyme, they induce conformational changes at the active center. These disturbances may lead to an increased affinity for the substrate, but it is more likely for the effect to be one of inhibition. Although the basis of drug-induced allosteric change in enzymes is poorly understood, hydrophobic interactions involving the surrounding hydration layer may be involved. As with other macromolecules, enzymes are covered by a surface film of water. When a drug is bound to its receptor, it upsets the microenvironment around the binding site. Alkyl groups common to many drugs are especially proficient at disturbing the hydration layer; as a result, they promote conformational changes in the drug-receptor complex that minimize their impact. The quaternary structure of proteins is greatly influenced by the state of the surrounding water molecules, and enzymes subject to allosteric regulation have quaternary structures of exceptional conformational sensitivity. The requirement described previously that a certain percentage of enzyme be affected before an observable effect is achieved also holds for allosteric regulation, but the need for the drug concentration to be greater than the substrate does not hold because the two compounds are not in direct competition for binding.

The concept of conformational induction may be of particular relevance to the regulatory receptors previously described. The allosteric concept suggests that a receptor, whether stimulated by its natural effector or by a drug substitute, becomes morphologically distorted. This disturbance causes a change in a particular enzyme activity or transport mechanism or an alteration of membrane permeability. Recent studies of the β_2-adrenergic receptor (and other G protein receptors[6]) suggest that conformational induction is a common phenomenon.[2,11] When a ligand such as epinephrine or norepinephrine approaches its binding site, it begins to form ionic and hydrogen bonds, as described previously (see

Figure 1-5). These developing associations cause distortions of the surrounding transmembrane helices (TMs). Rotation of the TM5 helix brings serine residues in closer association with the catechol hydroxyl groups. An ionic bond between TM3 and TM6 is broken as both helices rotate in response to the ligand's strengthening ionic bond with TM3. In particular, rotation of the TM6 helix at a specific tryptophan amino acid (see Figure 1-3) promotes this action and increases van der Waals stabilization of the active receptor configuration. As a result of TM3 rotation, additional amino acid residues move into close association with the ligand. Increased stability of the active conformation of the receptor also occurs as new hydrogen bonds and other attractions develop between the repositioned TM helices.

Drugs can directly alter processes controlled by membrane-bound receptors without resorting to mimicry of natural messengers. As is the case with enzymes, drugs can adjust receptor affinity for ligands through allosteric mechanisms at sites separate from the ligand-binding site.

Conformational selection

Most early attempts to study drug action assumed the receptor was in a quiescent state until activated by an agonist. As has been shown for ion channels and increasingly for other receptor families, however, receptors may exist individually in more than one configuration with or without the presence of a ligand. When this situation exists, drugs may work by selectively binding to a particular conformation of the receptor, stabilizing that arrangement, and altering the relative proportion of receptors existing in active versus inactive states.

Conformational selection provides a particularly credible explanation for the action of drugs that lack polar functional groups capable of strongly interacting with protein constituents to cause allosteric distortions. Inhalation anesthetics are representative in that they are uncharged and weakly interactive. It has been suggested that such anesthetics bind to preformed cavities on ligand-gated ion channels in neurons, causing little structural change themselves, but stabilizing (by occupying space) conformations that result in loss of consciousness.[7]

Subsequent events

Although drug inhibition may simply prevent the formation of an enzyme substrate or the reading of an endogenous signal by a regulatory protein, drug activation of a receptor generally leads to a cascade of events that eventually results in an observable pharmacologic effect. Epinephrine provides a useful illustration of the consequences of drug binding.[19] Incorporated into local anesthetic solutions to prolong the duration of pain relief, epinephrine mimics the action of the neurotransmitter norepinephrine. As a result of epinephrine attachment to α_1-adrenergic receptors on vascular smooth muscle cells, the G protein known as G_q is activated, phospholipase C_β activity is stimulated, and the membrane lipid phosphatidylinositol-4,5-bisphosphate is broken down to yield the second messengers diacylglycerol and inositol-1,4,5-trisphosphate (IP_3). Diacylglycerol initiates a cascade of metabolic events that support muscle contraction. IP_3 causes the release of Ca^{++} from intracellular storage sites, which induces the activation of actomyosin and initiates vasoconstriction.

DOSE-RESPONSE RELATIONSHIPS

A fundamental aspect of drug action is the relationship between the dose administered and the effect obtained. Common experience dictates that the magnitude of a chemical's effect on a system is positively correlated with the quantity or concentration of that chemical present. To increase the saltiness of a food, for example, more salt must be added. Within certain limits, the addition of salt yields a graded response, but very small increments have no effect on taste, and if the food is salty to begin with, further additions, no matter how great, will have no effect either. There is reason to expect that the dose-effect relationship of a drug is not a linear function throughout the entire dose range. Below a minimum threshold, there can be no incremental effect from a dose because there is no observable effect to begin with. Above a certain ceiling, even a large dose would exert no demonstrable influence because the maximal effect has already been reached.

Occupation Theory

Clark attempted in the 1920s to quantify drug effects through application of the law of mass action. Out of his efforts and the contributions of others emerged the occupation theory of drug action.[16] The occupation theory holds that the magnitude of a pharmacologic response elicited by a drug that reversibly combines with its receptor is directly proportional to the number (or fraction) of receptors occupied by the drug. The relationship can be written as follows:

$$D + R \underset{k_2}{\overset{k_1}{\rightleftharpoons}} DR \rightarrow \text{Effect}$$

where D is the drug, R is the receptor, and k_1 and k_2 are rate constants. This reaction is analogous to the interaction of an enzyme with a single substrate yielding a single product. A derivative of the Michaelis-Menton equation can be used to quantify drug effects as follows:

$$\text{Effect} = \frac{\text{Maximal effect} \times [D]}{K_D + [D]}$$

where K_D (the dissociation constant) = k_2/k_1.

This mathematic relationship between the dose (or concentration) of a drug and its response may be shown visually by an experiment in which an isolated muscle is exposed to increasing concentrations of a drug while the force of contraction is measured (Figure 1-6). When a drug is introduced into a tissue, it binds to its receptor in accordance with the K_D. For various reasons, very small quantities will not elicit a measurable response. Each muscle cell may require a minimal number of receptors to be occupied before it contracts, or technical difficulties in detecting small contractions may make such determinations inaccurate or impossible to obtain. The lowest concentration to elicit a measurable response is termed the *threshold concentration*. As higher concentrations are used, the number of receptors occupied increases, as does the intensity of response. An increase in the fraction of receptors occupied necessarily reduces the number available for subsequent binding so that at high concentrations each increment produces progressively smaller additions to the magnitude of contraction. At very high concentrations, the receptor population becomes saturated, and further drug administration no longer influences contraction. A maximal muscle response for the drug, termed the *ceiling effect*, is achieved.

The useful concentration range for a drug falls between the threshold and the ceiling. By expressing data as the logarithm of the concentration versus the degree of response, this important and normally hyperbolic segment of the concentration-effect relationship becomes a sigmoid curve with the linear central portion extending over a 10-fold concentration range. The advantage of plotting with the log scale instead of the arithmetic scale is that it greatly simplifies drug study. The concentration of a drug that produces a half-maximal response (EC_{50}) is often used in comparisons with similar agents. (In classic occupation theory, the EC_{50} equals

the K_D). When data from several experiments are expressed on a single graph with the log dose, this value can be accurately determined for each drug from the linear portion of the respective curve. If the concentration data were not logarithmically transformed, statistical analysis would become more complex. Figure 1-7 illustrates the difficulties encountered if two drugs differing only in receptor affinity are examined on an arithmetic scale. The curve for drug A is so compressed that the concentration yielding the EC_{50} cannot be easily ascertained; for drug B, it cannot even be represented on the same page.

Agonists

Drugs that elicit a response from a tissue are known as *agonists*. Agonists that produce ceiling effects—effects that are not exceeded by other drugs—are called *full agonists*, and drugs whose maximal effects are less than those of full agonists are referred to as *partial agonists*. The distinction between full and partial agonists is unrelated to variances in receptor affinity; the relatively low ceiling effect of a partial agonist cannot be elevated by increasing its dose. The difference between these two classes of agonists lies in their unequal intrinsic activities. *Intrinsic activity* is an empiric term used in classic occupation theory to describe the ability of a drug to activate a receptor after the drug-receptor complex has formed. Incorporating intrinsic activity into the concentration-effect equation yields:

$$\text{Effect} = \frac{a \times [D]}{K_D + [D]}$$

where a is the intrinsic activity. Drugs with a low intrinsic activity not only have a relatively low ceiling effect, but each fraction of receptors occupied elicits a response that is smaller than that produced by a similar degree of receptor binding by a full agonist. In other words, the log dose-response curve of a partial agonist has a lower maximum and a smaller slope than does that of a full agonist.

These precepts of occupation theory are shown in Figure 1-8, which presents data from a study of four agonists of muscle contraction.[1] The muscle to be investigated was removed from the animal, placed in a bath containing an oxygenated physiologic salt solution, and attached to a strain gauge to measure isometric contractions. In such experiments, conditions can be manipulated to ensure that each drug tested has equal access to the receptor in question. (This condition, which greatly simplifies the interpretation of experimental

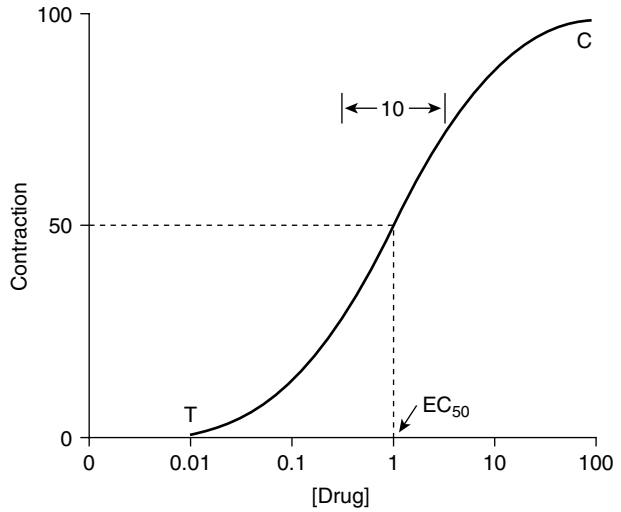

FIGURE **1-6** Theoretic dose-response curve (log scale) for a smooth muscle stimulant. The threshold and ceiling effects are represented by *T* and C. As shown, the linear portion of the sigmoid curve, extending from approximately 25% to 75% of the maximal effect, is encompassed by a 10-fold concentration range. A range of 10,000 times is required, however, to depict the curve in its entirety (from 1% to 99% of the maximal effect). The concentration yielding 50% of the maximal response *(EC_{50})* is also shown.

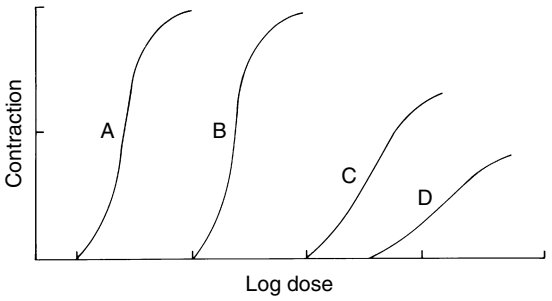

FIGURE **1-8** Effects of four catecholamines on muscle contraction in the vas deferens of the rat. Drugs *A* and *B* differ in affinity, but not in intrinsic activity. Drugs C and *D* differ from each other and from A and B in affinity and intrinsic activity. (Adapted from Ariëns EJ, Simonis AM, van Rossum JM: Drug-receptor interactions: interaction of one or more drugs with one receptor system. In Ariëns EJ, editor: *Molecular pharmacology: the mode of action of biologically active compounds,* New York, 1964, Academic Press.)

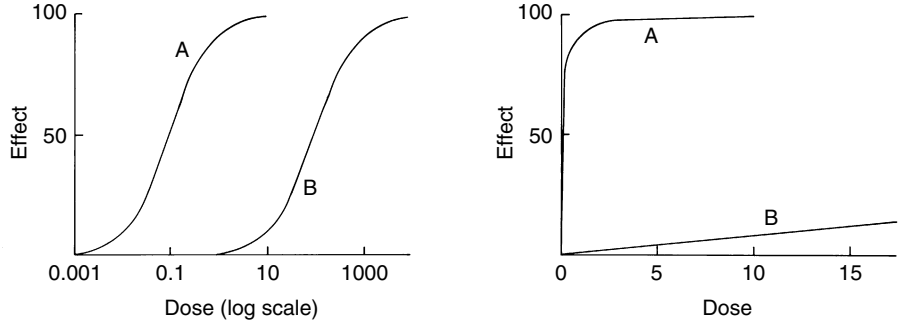

FIGURE **1-7** Dose-effect curves for two drugs differing in receptor affinity by a factor of 1000. *Left,* A log scale. Note the identical shapes of the two dose-effect relationships. *Right,* An arithmetic scale. The lack of correspondence between the two curves hinders drug comparison.

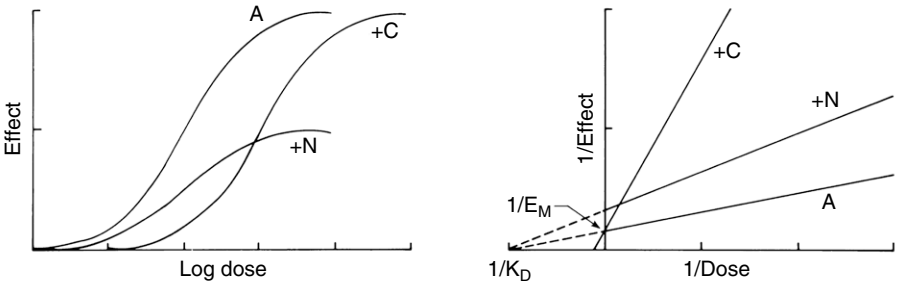

FIGURE **1-9** Modification of a pharmacologic effect by drug antagonism. *Left*, Curve *A* depicts the dose-effect relationship of a full agonist; curves +*C* and +*N* represent the influences of a competitive (C) and noncompetitive (N) antagonist. Note the shift to the right of the agonist dose-response curve by the competitive inhibitor and its downward displacement by the noncompetitive variety. *Right*, Double-reciprocal plot of the same curves; the competitive antagonist increases the apparent dissociation constant (K_D) without influencing the maximum effect obtainable by the agonist (E_M). The noncompetitive inhibitor selectively decreases E_M.

results, cannot be duplicated in whole-animal investigations.) The most potent drug shown is A, with drugs B, C, and D exhibiting progressively decreasing potencies. The potency of a drug is the dose required to elicit an arbitrarily determined level of response (commonly the EC_{50}). Potency is usually a matter of little importance because a drug that is very potent regarding its desirable effects is often equally potent regarding undesirable effects. In the intact animal (or patient), potency is influenced by the drug's ability to reach the receptor (determined by the rate of absorption and the patterns of distribution and elimination) in addition to the agent's intrinsic activity and receptor affinity. A very active drug will seem to have low potency if it is not well absorbed, becomes bound to nonspecific sites, or cannot reach the target organ.

Drugs A and B are full agonists (assuming no other drug with an affinity for this particular receptor can produce a greater ceiling effect), and drugs C and D are partial agonists. Drug D has the smallest intrinsic activity. The consequences of the low potency of drug B can be completely overcome by increasing its dose. According to classic receptor theory, drug B exhibits a lower potency than drug A solely because it has a weaker affinity for its receptor. Drugs C and D represent a more complex problem. These agents are less potent than drugs A and B, which suggests that they possess lesser affinities. Part of their reduced potency, however, is a consequence of their lower intrinsic activities.

Antagonists

Drugs that bind reversibly to a receptor at the same site as the agonist but have an intrinsic activity of zero (no receptor activation; $a = 0$) are competitive antagonists. By making receptors less available for agonist binding, a competitive antagonist depresses the response to a given dose or concentration of agonist. The result is a parallel shift to the right of the agonist dose-response curve. The most important aspect of this type of inhibition is that it is completely surmountable by a sufficiently high dose of agonist. As in enzymology, the presence of a competitive antagonist produces an apparent reduction in the affinity of an agonist for its receptor. Competitive antagonisms are common in pharmacology, and numerous examples are cited in succeeding chapters: histamine versus antihistamines, morphine versus naloxone, ACh versus atropine, epinephrine versus propranolol, diazepam versus flumazenil. By virtue of its small intrinsic activity, a partial agonist can also serve as a competitive antagonist of a full agonist. The aggregate receptor stimulation from the combination depends on the relative concentrations, receptor affinities, and intrinsic activities of the two agents.

Another type of antagonism commonly encountered is the noncompetitive variety. The noncompetitive blockade is insurmountable in that the ceiling effect of an agonist can never be reattained, regardless of the dose administered. A noncompetitive antagonist may decrease the effective number of receptors by irreversibly binding to the receptor site or binding with such affinity that the agonist cannot successfully compete with it for binding. The result is a downward displacement of the agonist log dose-response curve. Figure 1-9 reviews the dissimilarities between the two classic types of drug blockade as represented in occupation theory.

A third type of antagonism involves allosteric modulation of the receptor. Binding of the modulating drug at a site separate from the agonist binding site can result in changes in agonist affinity, intrinsic activity, or both. Complex dose-response relationships may occur.[13] If the sole effect of the modulator is to decrease, but not eliminate, agonist affinity, the antagonism resembles that of classic competition because larger doses of the agonist can restore maximum activity. When all of the receptors have bound modulator molecules, however, increasing the concentration of modulator further will have no additional effect because the modulator and agonist are not in direct competition for the ligand-binding site. It is unnecessary to continue escalating the concentration of agonist to overcome the blockade. When the modulator alters, but does not eliminate, intrinsic activity of the agonist, the resulting antagonist resembles that of a noncompetitive antagonist. When all of the allosteric sites are bound by modulator, however, there can be no further depression of the agonist dose-response curve. Should the modulator completely eliminate either agonist affinity or intrinsic activity, the effect will resemble that of a noncompetitive antagonist completely except that the blockade is usually reversible in time because most modulators bind noncovalently with the receptor. Further complexities arise because the modulator may variably influence different agonists. The relative potencies of several agonists for the muscarinic M2 receptor are as follows: pilocarpine>ACh>carbachol. In the presence of the M2 receptor modulator eburnamonine, the order becomes carbachol>ACh>pilocarpine.[13] Because modulators may also increase agonist affinity or intrinsic activity or both, potentiation of agonist action is also a possible outcome of modulator binding.

Limitations of occupation theory

The occupation theory provides a good conceptual framework to understand receptor-mediated drug effects. Basic to the foregoing discussion, however, are several assumptions about the interactions between a drug and its receptor, as follows:

1. One drug molecule reversibly combines with a single receptor.
2. This binding is independent of other drug-receptor interactions.
3. The receptors are identical and equally accessible to the drug.
4. Only a small portion of the total drug is involved in forming complexes with the receptor.
5. The biologic response is proportional to the degree of receptor occupancy and independent of time.

Research findings over the last four decades have made obvious the fact that all these assumptions are usually not valid regarding individual dose-response relationships. It has already been mentioned that equal access of receptors to drugs is unlikely in vivo based on uneven drug distribution. As illustrated for the nicotinic receptor in Figure 1-2, some receptors require the binding of more than one drug molecule to become active. Systematic exploration of these assumptions has led to a fuller understanding of the complexities involved in dose-response relationships and improved models of drug action.

Stimulus-Response Coupling

One representative failure of classic occupation theory is its inability to account for the inhibition of ACh by atropine. Atropine is typically classified as a competitive antagonist of ACh. It binds to the ACh receptor and causes an inhibition that can be surmounted by increasing the concentration of agonist present. Nevertheless, the association of atropine with its receptor in some tissues is practically irreversible; neither ACh nor extensive washing will remove the drug when it is bound. Atropine should therefore behave as a noncompetitive antagonist of ACh. To explain the paradox presented by atropine, pharmacologists borrowed from the phenomenon of enzyme excess described earlier in this chapter to postulate the existence of spare receptors. This amendment to the occupation theory states that for many agonists there are more receptors available than are required to yield a maximal response. Although atropine completely blocks some receptors from binding ACh, a sufficient quantity remains to produce a ceiling effect, albeit at a higher agonist concentration. As one might predict, the competitive inhibition obtained with a conventional dose of an antagonist such as atropine gradually takes on the characteristics of a noncompetitive block as larger doses of the antagonist deplete the spare receptor pool.

Another observation that cannot be reconciled with classic occupation theory is the finding that various ligands for the same receptor can behave as full agonists in one tissue but not in another expressing the same receptor. The α-adrenergic agonists norepinephrine and oxymetazoline display essentially identical potencies and ceiling effects in contracting the anococcygeus muscle in the rat. In the vas deferens, norepinephrine remains a full agonist, albeit with less potency, whereas oxymetazoline decreases in potency and ceiling effect to become a weak partial agonist.[15]

These two examples give only a taste of the complexities that can arise from the gulf that often separates the binding of a drug by its receptor and the resultant development of a biologic effect. Even if the assumptions basic to the occupation theory hold for the initial action of a drug, they often do not apply to an observed effect that is removed from drug binding by several intermediate events and where the magnitude of drug effect holds a complex relationship to the degree of receptor occupancy. One useful approach to resolving these findings with classic occupation theory is to consider the binding of a drug to its receptor as an initial stimulus, which is translated by the affected tissue into a response, as illustrated by the following equation[14]:

$$\text{Response} = f\left[\frac{\varepsilon \times R_t \times [D]}{K_D + [D]}\right]$$

Here, the "effect" of classic occupation theory (see the Equation on p. 9) becomes the stimulus (in brackets), with the intrinsic activity replaced by the product of the intrinsic efficacy (ε) and the total number of receptors available for binding the drug (R_t). The function *f* couples the stimulus to the response. Intrinsic efficacy refers to the number of receptors that must be activated to yield a maximal response. A drug with high efficacy needs to stimulate only a small percentage of receptors, whereas a drug with lesser efficacy (but still considered to be a full agonist) must activate a larger proportion. In the case of a partial agonist, insufficient receptors exist even when fully occupied to yield a maximal response.

Because full agonists can differ in efficacy and in receptor affinity, potency differences between drugs such as A and B in Figure 1-8 cannot simply be ascribed to unequal affinities for the receptor. Curves similar to those in Figure 1-8 can be generated by drugs that differ from each other solely in intrinsic efficacy, and affinity constants calculated according to classic occupation theory would be grossly in error.

Figure 1-10 depicts the influence of stimulus-response coupling on three drugs that have identical dissociation constants (K_D) for the same receptor but differ significantly in intrinsic efficacy. In a highly coupled system (Tissue 1), all three drugs behave essentially as full agonists. In systems with less efficient coupling (Tissues 2 and 3), drugs B and C are revealed as partial agonists. Finally, in a system with inefficient coupling (Tissue 4), drug A remains a full agonist, drug B is a weak partial agonist, and drug C exhibits no agonistic effect at all but instead serves as a purely competitive antagonist. The selective estrogen receptor modulator tamoxifen illustrates how differences in tissue response elements can greatly alter drug activity. Tamoxifen behaves as a full estrogen receptor agonist in some tissues (e.g., mouse uterus), a partial agonist in others (e.g., rat uterus), and a competitive antagonist in still others (e.g., mouse and rat pituitary gland). Figure 1-10 helps explain these diverse responses to tamoxifen.[18] Clinically, selective estrogen receptor modulators are used to block estrogen receptors in breast tumors and to stimulate estrogen receptors in managing osteoporosis.

A further complication in describing stimulus-response coupling arises from findings that the intrinsic efficacy of an agonist may not be an inherent, invariant attribute with regard to a given receptor.[23] Instead, it seems that an agonist may exhibit higher efficacy than another agonist with respect to a given receptor in one tissue yet be less effective in eliciting a pharmacologic response when stimulating the same receptor in another tissue that expresses a different response system. An explanation for this phenomenon is that the two agonists yield different versions of the active receptor that are unequally active in stimulating the response systems expressed in the two tissues.

Competitive antagonists always act in stimulus-response systems by decreasing the apparent affinity of an agonist for its receptor without altering the maximal effect that the agonist can generate. Noncompetitive antagonists, however, can present different patterns of action based on the coupling function. Figure 1-11 displays the influence of increasing concentrations of a noncompetitive antagonist in a highly coupled stimulus-response system. As previously described for atropine, low concentrations of the antagonist cause a rightward shift of the agonist's dose-response curve, whereas higher concentrations also depress the maximal effect. For noncompetitive antagonists that essentially remove receptors from the system (i.e., reduce R_t in the Equation above) by irreversibly associating with the ligand-binding site, a complete loss

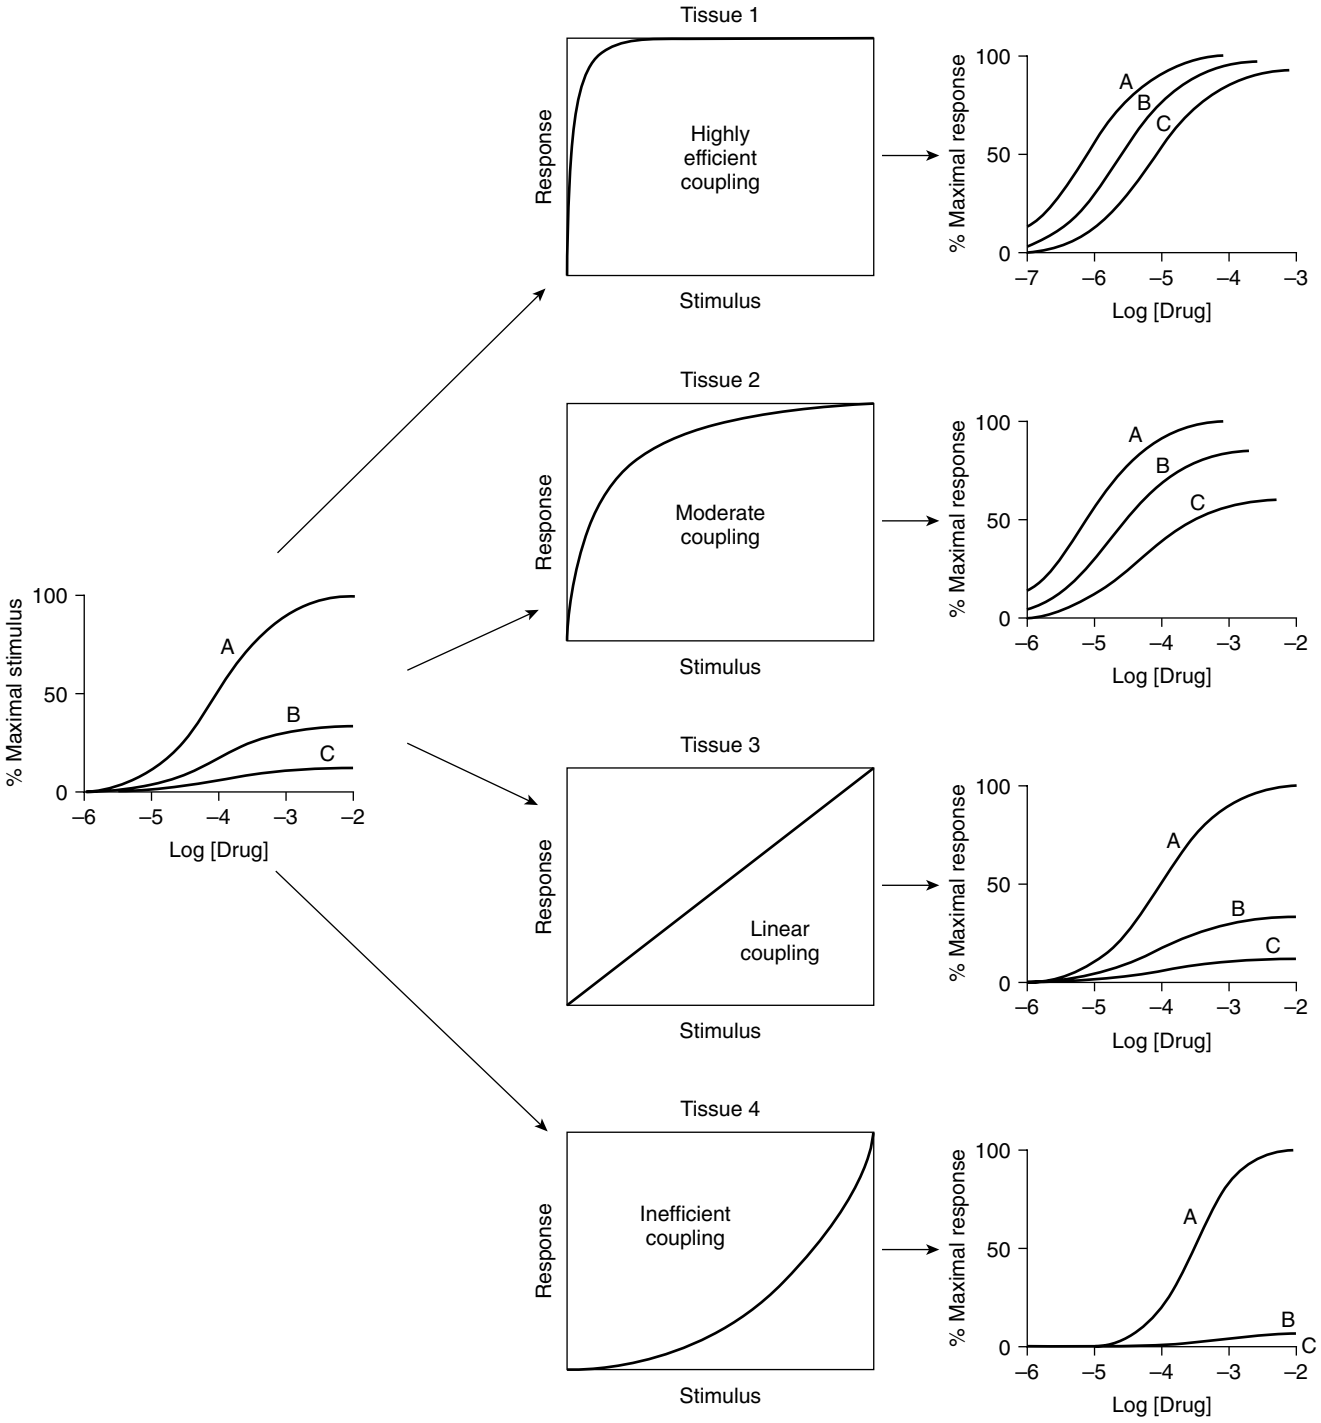

FIGURE **1-10** Stimulus-response coupling. *Left*, The dose-stimulus curves (representing the initial effect of receptor binding) for three drugs with identical receptor affinity but differing sequentially in relative efficacy by a factor of 3 (*A*>*B*>C). *Middle*, The tissue-dependent coupling between the initial stimulus and the evoked response in four different tissues. *Right*, The dose-response curves for the three drugs in each tissue. Note the different abscissa for *Tissue 1*, reflecting the increased potency of drugs in a highly coupled stimulus-response system. (Adapted from Ross EM, Kenakin TP: Pharmacodynamics: mechanisms of drug action and the relationship between drug concentration and effect. In Hardman JG, Limbird LE, Gilman AG, editors: *Goodman and Gilman's the pharmacological basis of therapeutics,* ed 10, New York, 2001, McGraw-Hill.)

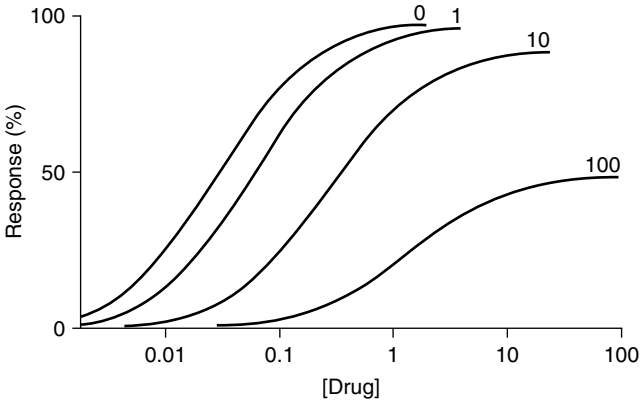

FIGURE **1-11** Noncompetitive antagonism in a highly coupled stimulus-response system. The relative concentration of the noncompetitive antagonist for each agonist dose-response curve is shown at right. Low concentrations of antagonist (*1* and *10*) cause a rightward shift in the agonist dose-response curve with little or no effect on the agonist-induced maximal response. Higher concentrations *(100)* increasingly depress the maximal agonist response, however.

of drug effect can be obtained by giving enough antagonist. For modulators that reduce intrinsic efficacy (i.e., reduce ε in the Equation on p. 11) to some value other than zero through an allosteric mechanism, some agonist activity may be retained in highly coupled systems despite massive doses of the agent but is completely lost in poorly coupled systems.

Receptor Diversity

In addition to the fact that pharmacologic responses are usually not linearly related to receptor occupancy, situations exist in which the receptors for a drug are not identical to one another. A repeating theme in the elucidation of the autonomic nervous system has been the division of receptor classes into an increasing array of subtypes with differing drug sensitivities. Part of the explanation for the unusual pharmacology of tamoxifen was made clear by the discovery that there were two subtypes of estrogen receptors in various tissues that responded differently to the agent.[18] Individuals may even harbor differences in receptor structure based on single point mutations. An important example is the β_2-adrenergic receptor, for which numerous single nucleotide polymorphisms have been identified that may alter drug responsiveness in diseases such as bronchial asthma.[21] As more refined techniques are developed to study drug-receptor interactions, it is possible that subtle differences in configuration or membrane location or both will be found to negate generally the assumption that all receptors are identical and equally accessible to a drug.

Receptors with Multiple Ligand-Binding Sites

The aforementioned isolation of the nicotinic receptor for ACh provides an important exception to the assumption of the occupation theory that a single drug molecule binds to a single receptor. To activate the nicotinic receptor, two ACh molecules must be bound at the same time, although at different sites on the molecule.[12] Evidence suggests that positive cooperativity occurs (the binding of one ACh molecule improves the binding of the second). The requirement for more than one agonist to bind the receptor before a response can occur is not uncommon; other ligand-gated ion channels commonly share this characteristic, as does the insulin receptor and various receptors that must dimerize to become active (e.g., estrogen receptors).[8,24]

Pharmacodynamic Tolerance

The preceding discussion of dose-response relationships was predicated on the often erroneous assumption that the intensity of drug effect is not influenced by the passage of time. *Pharmacodynamic tolerance* is a general term for situations in which drug effects dissipate with time despite the continued presence of the agonist at a fixed concentration. At the receptor level, various processes in addition to the primary drug effect are often invoked that subsequently limit pharmacologic responses. In the case of the β-adrenergic receptor (Figure 1-12), phosphorylation of specific amino acid constituents leads to a loss of drug action, a process termed *desensitization*.[3] The effect is temporary; removal of the agonist for a certain interval re-establishes tissue responsiveness to receptor activation. A longer lasting loss of drug effect, known as *downregulation*, may also occur. In this process, membrane-bound receptors are internalized by the cell, where they may be sequestered for later use or destroyed by lysosomal enzymes. Pharmacodynamic tolerance may also occur independently of any change in the drug receptor or stimulus-response system. As an illustration of this point, consider a drug that increases blood pressure by causing vasoconstriction in selected vascular beds. In response to the hypertensive effect of the drug, various cardiovascular reflexes are evoked that tend to reduce blood pressure, including activation of the parasympathetic nervous system, which leads to bradycardia. The buildup of lactate and other metabolites in the affected tissues also limits vasoconstriction. Eventually, additional changes, such as decreased salt and water retention, may reduce drug responses further. These and other mechanisms of drug tolerance are described more fully in Chapter 3.

MULTISTATE MODEL OF DRUG ACTION

As mentioned in the discussion on conformational selection, receptors may exist constitutively in more than one conformation. According to the multistate model of drug action, these forms of receptors are in equilibrium, and drugs act by altering their relative distributions.[16] Figure 1-13 illustrates a simple two-state version in which the receptor can exist in an active or inactive configuration. In this model, full and partial agonists increase the proportion of receptors that exist in the active state. The model does not distinguish between agonists whose binding tends to force a conformational change in the receptor to the active form and agonists that bind preferentially to active receptors, stabilizing their configuration and altering their number through the law of mass action. Drugs with high efficacy would produce the highest ratios of active to inactive species; partial agonist binding would produce an insufficient active form to yield a maximal response (Figure 1-14). Competitive antagonists would associate with receptors regardless of—and without influencing—their conformational state. Noncompetitive antagonists would limit the ability of agonist binding to elevate the number of receptors in the active state by reducing the total number of available receptors. Allosteric inhibitors would reflect aspects of either or both forms of antagonism.

The major attractions of the multistate model are that it gives a physical solution for differences in efficacy between congeners, and that it affords a simple mechanism for the pharmacologic response elicited by drug binding. It also provides an excellent explanation for drugs known as *inverse agonists*. An inverse agonist causes an effect opposite to that of the agonist, in contrast to a competitive antagonist, which simply blocks the agonist (or the inverse agonist) but has no inherent effect by itself. In a tonically active pathway, a drug that preferentially binds to the inactive configuration or

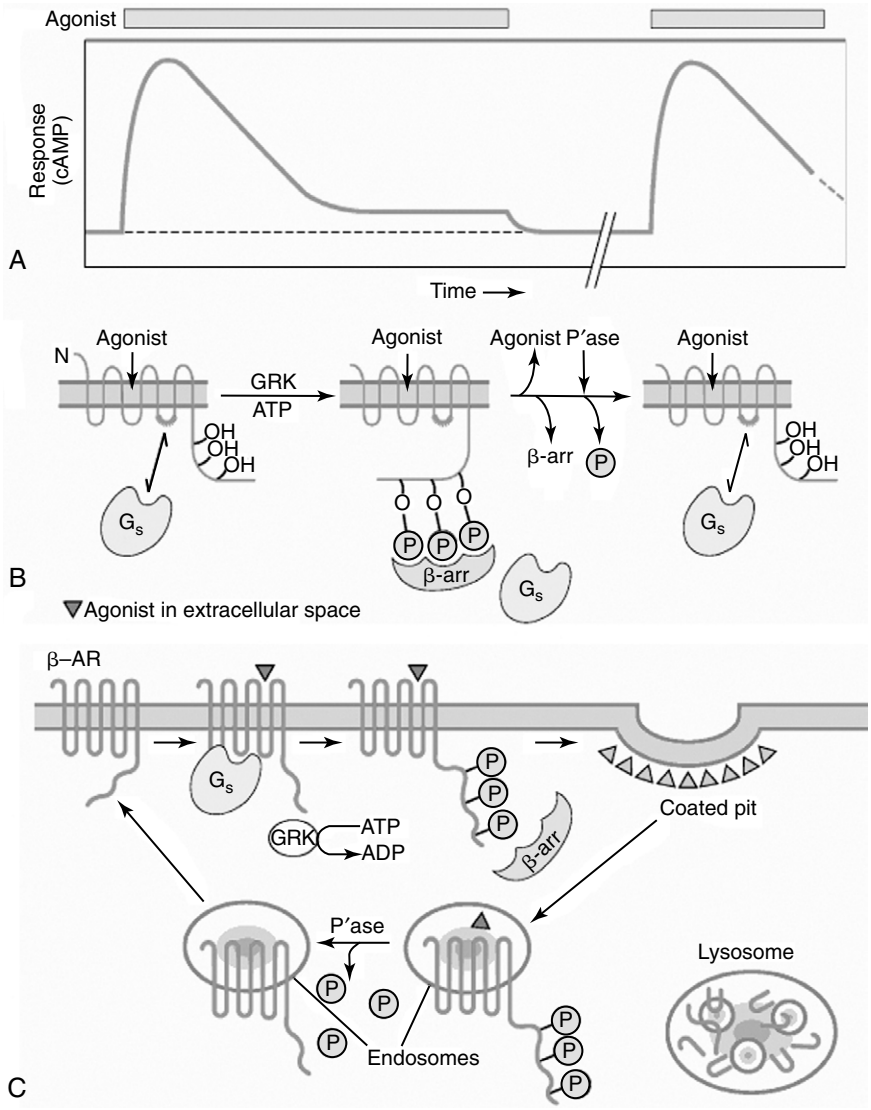

FIGURE **1-12** Rapid desensitization and longer term downregulation of the β-adrenergic receptor. **A,** Response to a β-adrenoceptor agonist (ordinate) versus time (abscissa). Temporal exposure to a constant concentration of agonist is indicated by the shaded bars. The break in the time axis indicates passage of time in the absence of agonist. Desensitization refers to the reduced cAMP production after several minutes in the continued presence of agonist; restored response is observed after a brief period (typically several more minutes in the absence of agonist). **B,** Agonist-induced phosphorylation by a G protein–coupled receptor kinase *(GRK)* of carboxyl terminal hydroxyl groups (—*OH*) of the β adrenoceptor. This phosphorylation induces binding of a protein, β-arrestin (β-arr), which prevents the receptor from interacting with G_s. Removal of agonist for a short time (e.g., several minutes) allows dissociation of β-arr, removal of phosphate (Ⓟ) from the receptor by phosphatase *(P′ase)*, and restoration of the receptor's normal responsiveness to agonist. **C,** Agonist-induced endocytosis and endocytotic membrane trafficking of receptors. β-Arrestin promotes receptor binding to an endocytotic structure in the plasma membrane called a coated pit. After short-term agonist exposure, receptors primarily undergo dephosphorylation by P′ase and recycling, promoting rapid recovery of signaling responsiveness. After longer term agonist exposure, receptors that have undergone endocytosis are degraded by lysosomes, promoting the process of receptor downregulation. (From Bourne HR, von Zastrow M: Drug receptors and pharmacodynamics. In Katzung BG: *Basic and clinical pharmacology*, ed 10, New York, 2007, McGraw-Hill Professional.)

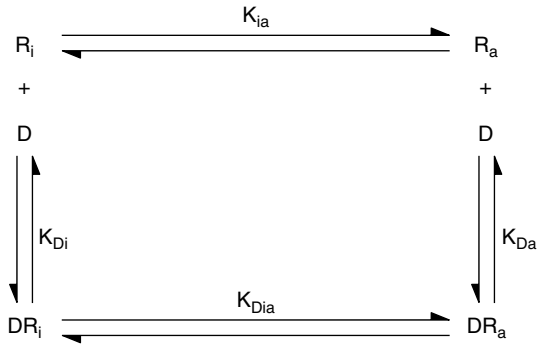

FIGURE **1-13** Two-state model of drug-receptor interaction. The receptor can exist in an active (R_a) or inactive (R_i) state, as governed by the equilibrium constant K_{ia}. Unless the receptor mediates a tonically active process, K_{ia} greatly favors the inactive form. Drugs (D) may bind to R_a, R_i, or both. Agonist binding alters the proportion of active ($R_a + DR_a$) to inactive ($R_i + DR_i$) receptors.

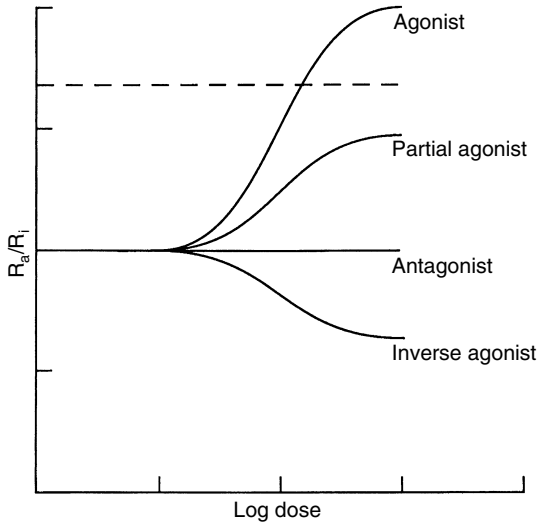

FIGURE **1-14** Dose-effect relationships according to the two-state model. In this example, a tonically active process is depicted. Full agonists can increase the ratio of active to inactive receptors (R_a/R_i) above that which causes the ceiling effect (*dotted line*); partial agonists also increase the ratio, but to a lesser maximal degree. Antagonists bind without disturbing the existing R_a/R_i ratio, and inverse agonists exert an opposite effect by reducing the R_a/R_i ratio and inhibiting a normally active pathway. In this example, all the drugs are assumed to have the same receptor affinity.

induces its formation would behave as an inverse agonist. Such agents (e.g., β-carboline) have been described for the benzodiazepine receptor. In contrast to sedative benzodiazepines such as diazepam, these experimental drugs cause anxiety and CNS arousal. Flumazenil, a competitive antagonist of the benzodiazepine receptor, reverses the effects of agonists and inverse agonists.[10] Additional examples of inverse agonism have been shown for various G protein receptors overexpressed in cells experimentally or after neoplastic transformation. Inhibition of constitutionally active oncogenes by inverse agonists may provide a new strategy for cancer chemotherapy.

A final advantage of the multistate model is that it can accommodate desensitization and time-dependent actions of drugs such as nicotine. Nicotine exhibits a complex pharmacologic profile. Initially, this natural alkaloid acts like an agonist: it stimulates ACh receptors at autonomic ganglia and in skeletal muscle. The stimulation is temporary, however, and in minutes the action of nicotine transforms from that of excitation to one of antagonism. This metamorphosis can be adequately explained if one assumes that a third, or "desensitized," configuration of the receptor exists to which active receptors are slowly converted and from which they even more slowly recover. Nicotine, by increasing the proportion of active receptors, causes an initial stimulation and a subsequent prolonged loss of activity as receptors are progressively trapped in the desensitized state.

RECEPTOR-INDEPENDENT DRUG ACTIONS

No description of drug action would be complete without a consideration of agents that exert pharmacologic effects through receptor-independent mechanisms. Aside from the fact that these drugs act without the benefit of receptor intermediaries, there are no common traits serving to link this miscellaneous array of compounds. It has also proved impossible to derive a quantitative description of drug responses akin to that presented for receptor-based agents. The very diversity of these drugs precludes any unifying relationship between dose and effect. Nevertheless, concentration-effect curves similar to those previously discussed are often obtained with these drugs, and general concepts such as potency and efficacy still apply. For the sake of discussion, these drugs are grouped arbitrarily into three categories: chemically reactive agents, physically active agents, and counterfeit biochemical constituents.

Chemically Reactive Agents

Chemically reactive drugs include a wide variety of compounds, some of which interact with small molecules or ions, whereas others attack proteins and other macromolecules. Gastric antacids and metallic ion chelators are two kinds of drugs that combine with inorganic substances within the body. Of particular importance to dentistry are the systemic and topical fluorides used to increase tooth resistance against dental caries. Also of interest is dimercaprol, a chelating agent capable of forming coordination complexes with mercury and other heavy metals. Drugs affecting macromolecules include most germicides and the antineoplastic alkylating agents. Sodium hypochlorite solutions provide antisepsis and facilitate canal debridement during endodontic therapy because they release hypochlorous acid, a potent chemical disrupter of biologic matter. Generally, these compounds can be readily distinguished from drugs that are receptor mediated. With the exception of certain chelating agents, they lack specificity and may individually react with various substances, organic or otherwise. Minor structural modifications also do not usually influence drug activity. Finally, the reactions of these drugs rely heavily on covalent bonding or on strong ionic attachments; they do not usually depend on hydrophobic or weak electrostatic interactions.

Physically Active Agents

Physically active agents, in contrast, are often useful therapeutically because they are chemically inert and can safely be used for their colligative properties. Magnesium sulfate is an effective cathartic because it is not absorbed from the gastrointestinal tract and exerts an osmotic effect, causing retention of large amounts of water within the intestinal lumen. The colon becomes distended and is stimulated to undergo expulsive contraction. Through a similar osmotic mechanism, mannitol helps reverse cerebral edema in a patient with traumatic brain injury. A totally unrelated physical mechanism is evoked by

hydrogen peroxide. Although highly reactive, hydrogen peroxide is useful in wound debridement because of its effervescent action. The release of gas bubbles promotes the physical removal of debris from injured tissues.

The physically active agents generally exhibit a surprising lack of structural specificity. For many agents, the major requirements for activity seem to be a certain pharmacologic inertness coupled with the ability to be administered in high concentrations (compared with most other drugs) without causing undue toxicity.

Counterfeit Biochemical Constituents

The counterfeit biochemical constituents resemble antimetabolite drugs inasmuch as they are artificial analogues of natural substrates. They have to meet the same rigid structural requirements as do their receptor-based counterparts. Counterfeit agents do not inhibit enzymes, however; they are instead incorporated into specific macromolecules by the cell. The resulting drug effects arise from an altered biologic activity of the affected macromolecules or from their increased susceptibility to destruction. The 2′-deoxycytidine analogue cytarabine is representative of this group. When incorporated into a cell's DNA, cytarabine inhibits the reparative and replicative functions of DNA polymerase. Affected cells may undergo apoptosis or terminal differentiation. Agents of this type are used therapeutically in the treatment of several neoplasias and microbial infections.

CHAPTER 2

Pharmacokinetics: The Absorption, Distribution, and Fate of Drugs

JOHN A. YAGIELA

When the magnitude of a drug's pharmacologic effect is quantified as a function of dose, the tacit assumption is that the drug concentration vicinal to the site of action is linearly related to the amount administered. Although this assumption may strictly apply to an in vitro test, it ignores the temporal factors that modify drug effects in vivo. Drug concentrations are rarely static; they increase and decrease as dictated by the processes of absorption, distribution, metabolism, and excretion. This chapter examines these processes (Figure 2-1) and how they influence the passage of drugs through the body.

PASSAGE OF DRUGS ACROSS MEMBRANES

For a drug to be absorbed, reach its site of action, and eventually be eliminated, it must cross one or more biologic membrane barriers. These may consist of a single plasma membrane or constitute a layer of closely packed cells. Because such barriers to drugs behave similarly, the cell membrane can serve as a prototype for all. The plasma membrane is composed of a bimolecular sheet of lipids (primarily phospholipids and cholesterol) with proteins interspersed throughout and extending beyond the lipid phase of the membrane (Figure 2-2).[8,51] The presence of protein molecules spanning the entire thickness of the membrane provides a necessary link between the extracellular environment and the cell interior, which is consistent with the concept that drug activation of a membrane-bound receptor on the external surface of a cell can be directly translated into an intracellular response. Specific transmembrane proteins also provide important pathways for the uptake and extrusion of drugs.

Passive Diffusion

The passage of drugs across biologic membranes can involve several different mechanisms. Of these, passive diffusion is the most commonly encountered. The defining characteristic of passive diffusion is that the drug moves down its electrochemical gradient when crossing the membrane.

Simple diffusion

Studies by Overton and Meyer more than a century ago showed that the cell membrane acts for the most part as a lipoid barrier. As shown by Collander (Figure 2-3), the rate of transfer of nonelectrolytes across a membrane is directly proportional to the lipid/water partition coefficient. (The partition coefficient is a measure of the relative solubility of an agent in a fat solvent, such as olive oil or octanol, versus its solubility in water.) A drug with a high partition coefficient (i.e., a *lipophilic* drug) readily enters the lipid phase of the membrane and passes down its concentration gradient to the aqueous phase on the other side. More molecules are then free to enter the membrane and continue the transfer process. With poorly lipid-soluble compounds, however, few molecules enter the membrane per unit of time, and the rate of passage is depressed.

The absence of an ionic charge is one major factor favoring lipid solubility. Drugs with a fixed charge, such as drugs containing a quaternary nitrogen atom, permeate membranes slowly if at all. The reason for the relative solubility of nonionized molecules in lipids relates to their exclusion from polar media. Simple ions and charged molecules are stabilized in water by the hydration shells that surround them, a consequence of the tendency of charged species to orient polar molecules. This process excludes nonpolar substances, and the resulting segregation causes them to coalesce in a manner analogous to the formation of oil droplets on the surface of water. The term *hydrophobic bonding,* introduced in Chapter 1, refers to the tendency for water-insoluble molecules to be drawn together; this behavior is responsible for the preferential tendency of lipid-soluble drugs to penetrate cell membranes by way of the lipid components. Ionized compounds are so stabilized by their interaction with water that movement into a lipid phase is markedly restricted. Many therapeutic agents are weak electrolytes; depending on the pH of their aqueous environment, they can exist in ionized and neutral forms. Because charged molecules penetrate membranes with considerable difficulty, the rate of movement of these drugs is governed by the partition coefficient of the neutral species and the degree of ionization. As illustrated in Figure 2-4, acidic conditions favor the transport of weak acids, and the opposite holds true for basic compounds.

The same concept of water interaction used to explain the aqueous solubility of ions also applies to many nonionic molecules. Although unsubstituted aliphatic and aromatic hydrocarbons have little or no tendency to react with water, affinity for water molecules is not restricted to structures with a formal charge. Organic residues possessing electronegative atoms such as oxygen, nitrogen, and sulfur can interact with water through the formation of hydrogen bonds to provide some degree of aqueous solubility.

Figure 2-3 shows that lipid solubility is not the only factor influencing the simple diffusion of uncharged drugs across cell membranes; molecular size is also important. Water, glycerol, and some other small molecules permeate much more readily than would be predicted from their respective partition coefficients. Figure 2-3 also shows that some large organic molecules diffuse more slowly than expected. Nonelectrolytes containing numerous hydrophobic groups are often so insoluble in water that their transit across the lipid/water interface may be retarded despite a favorable partition coefficient.[26] This finding suggests that some degree of water solubility is necessary for the passive diffusion of drugs across membranes.

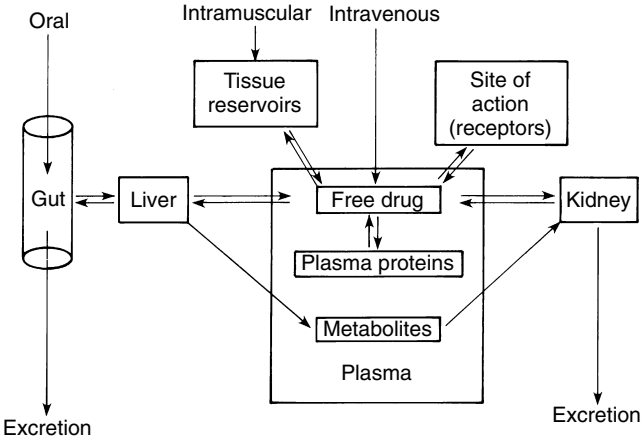

FIGURE **2-1** Outline of the major pathways of absorption, distribution, metabolism, and excretion of drugs. Compounds taken orally must pass through the liver before reaching the systemic circulation. When in the bloodstream, agents are distributed throughout the body and come in contact with their respective sites of action. Drugs are filtered by the kidney, only to be reabsorbed if lipid soluble. Metabolism of many drugs occurs primarily in the liver, after which the metabolites are excreted in bile or urine. Some agents eliminated in the bile are subject to reabsorption and may participate in an enterohepatic cycle.

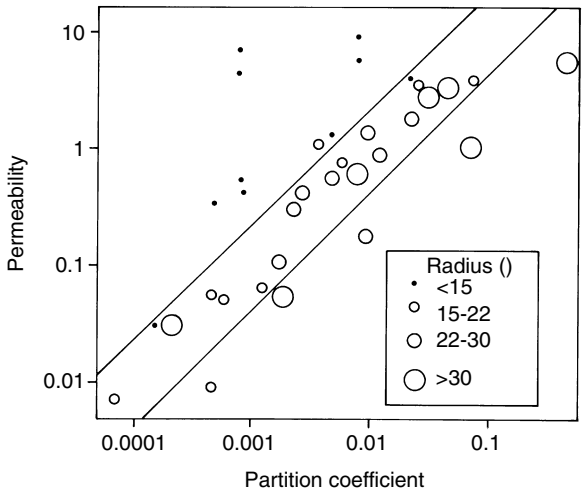

FIGURE **2-3** Relationship between membrane permeability and lipid (olive oil)/water partition coefficient in *Chara certatophylla*. Each *circle* represents a single nonelectrolyte with a molecular radius as indicated in the key. Small compounds permeate more readily than their partition coefficient would indicate; the reverse is true for large molecules. (Adapted from Collander R: The permeability of plant protoplasts to small molecules, *Physiol Plantarum* 2:300-311, 1949.)

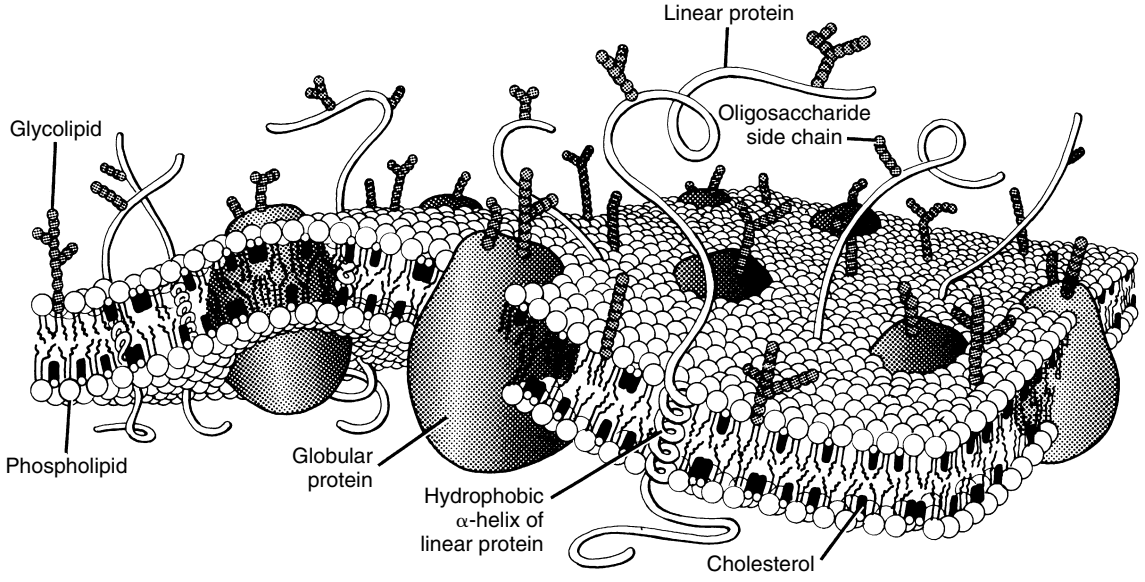

FIGURE **2-2** The plasma membrane depicting the lipid bilayer, composed of phospholipids and cholesterol, and the globular and linear proteins, which are anchored within the membrane by α-helical segments and extend beyond the 40-Å thick bilayer on the extracellular and cytoplasmic surfaces. For clarity, the ratio of lipid to protein is much larger than exists in natural membranes. Glycolipid components of the membrane and saccharide polymers attached to proteins are also shown. (Redrawn from Bretscher MS: The molecules of the cell membrane, *Sci Am* 253:100-108, 1985.)

No matter how lipid soluble an agent is, it will never cross a membrane if it cannot first dissolve in the extracellular fluid and be carried to the structure. Benzocaine, an active local anesthetic when applied directly to nerves, is ineffective after injection because its water insolubility precludes significant diffusion away from the administration site and toward its locus of action within the neuronal membrane. When inside the membrane, a drug with an extremely high partition coefficient may be so soluble in the lipid phase that it has little tendency, despite moderate solubility in water, to diffuse out of the membrane down its concentration gradient.[38] A review of human clinical data involving more than 2400 compounds suggests that simple diffusion will be poor if a drug has two or more of the following characteristics: (1) more than five H-bonding donor groups, (2) more than five H-bonding acceptor groups, (3) more than 10 N and O atoms, (4) a molecular weight greater than 500 Da, and (5) a partition coefficient greater than 10,000:1.[28]

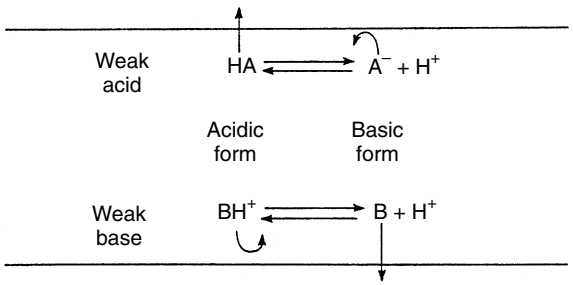

FIGURE **2-4** Membrane penetration by weak electrolytes. The nonionic species of drugs *(HA, B)* permeate membranes much more efficiently than do the charged forms *(A^-, BH^+)*. Acidic conditions shift the dissociation curves to the left, favoring the diffusion of weak acids. An increase in pH favors the loss of hydrogen *(H^+)* and the diffusion of weak bases.

Simple diffusion across capillary walls warrants special comment. In addition to the transcellular pathway of drug diffusion just described for lipid-soluble agents, an aqueous paracellular pathway formed by 10-nm to 15-nm clefts between the endothelial cells of most capillaries permits the aqueous diffusion of water-soluble drugs between the plasma and extracellular space. Hydrophilic molecules up to small proteins in size can use this route; fixed negative charges along the diffusion pathway tend to promote the movement of positively charged macromolecules while restricting movement of those with net negative charges.

Adding to the paracellular movement of drugs across capillaries is the bulk flow of water that moves in relation to the net balance of hydrostatic and osmotic forces between the vascular and interstitial compartments. This net transfer of fluid, termed *convection*, carries with it dissolved drugs and other solutes. Convective movement of most drugs is quantitatively inconsequential; however, it may play a major role in the movement of proteins and other macromolecules that avoid filtration by the endothelium, especially in inflamed tissues. The small amounts of albumin and other plasma proteins that reach the extracellular space (4% per hour for albumin) are largely returned to the circulation by lymphatic convection.

Facilitated diffusion

Water, small electrolytes, and hydrophilic molecules of biologic importance generally move across plasma membranes much more readily than would be predicted by simple diffusion. In these instances, transmembrane proteins that circumvent the lipid bilayer facilitate diffusion. The simplest mechanism involves a transmembrane pore, such as aquaporin 1. Discovered in 1991, aquaporin 1 is a 28-kDa polypeptide that forms a 3-Å channel through which water can enter or leave cells. More than 10 aquaporins have been discovered in mammalian tissues and are especially prominent in cells and organs involved with the transcellular movement of water: kidneys, capillaries, secretory glands, red blood cells, choroid plexus, brain glia, eyes, and lungs.[1,24] Some aquaporins are selective for water only, increasing its membrane permeability by a factor of 10 to 100; others permit the passage of glycerol and several other molecules in addition to water.

The movement of specific ions (e.g., Na^+, K^+, and Ca^{++}) across the cell membrane is facilitated by the presence of transmembrane channels, such as the nicotinic receptor described in Figure 1-2 and the Na^+ channel illustrated in Figure 16-4. The opening of these gated channels (in contrast to porins, which are always open) is regulated by the electric potential across the membrane or by the presence of specific ligands, such as neurotransmitters. When a channel is open, passive diffusion of an ion capable of traversing it depends on the electric potential across the membrane and the ion's own chemical gradient. Boosting the electrochemical gradient by manipulating the voltage across the cell membrane is an effective method of increasing ionic flow. Even in the absence of specific ion channels, the transport of fixed ions and weak electrolytes across tissue barriers can be facilitated by the appropriate use of electric current (as in iontophoresis, discussed subsequently).

Numerous lipid-insoluble substances are shuttled across plasma membranes by forming complexes with specific membrane constituents called *carriers* or *transporters*. Carriers are similar to receptors in many ways; they are proteins, often quite selective in the agents with which they combine, and subject to competitive inhibition. Because the number of transporter molecules is finite, carrier-mediated diffusion can be saturated at high drug concentrations. The GLUT family of glucose transporters is representative of carrier proteins that facilitate the movement of hydrophilic solutes across cell membranes. The initial step in the facilitated diffusion of glucose is its binding to the exposed active site of the transporter protein. This binding sequentially causes an external barrier or gate to close and interior gate to open, after which the glucose is released into the cell. The loss of glucose causes the internal gate to close and the external gate to open, exposing the active site and completing the cycle.

Active Transport

Active transport is the term given to the carrier-mediated transfer of a drug against its electrochemical gradient. In addition to exhibiting selectivity and saturability, active transport requires the expenditure of energy and may be blocked by inhibitors of cellular metabolism. Active transport permits the efficient absorption of substances vital for cellular function (and certain drugs that resemble them structurally) and the selective elimination of waste products and foreign chemicals, including many drugs. Approximately 2000 genes—7% of the total human genome—code for transporters and associated proteins. Two superfamilies of transporters are of special significance to pharmacokinetics: ATP-binding cassette (ABC) transporters, and solute carrier (SLC) transporters.

Approximately 49 ABC transporters hydrolyze adenosine triphosphate (ATP) to provide the energy directly needed for molecular transport and are referred to as *primary active transporters*. P-glycoprotein (P for altered permeability), also known as *multidrug resistance protein-1 (MDR-1)* and given the designation *ABCB1* by the Human Gene Nomenclature Committee, is the most extensively researched representative. Originally identified in 1976 for its ability to expel numerous antineoplastic drugs from mutated cells that overexpress it, P-glycoprotein is a 170-kDa glycoprotein composed of two subunits in a head-to-tail arrangement (Figure 2-5).[44,48] Each subunit contains a transmembrane domain of six α-helices that span the plasma membrane and help form the pump itself, and a nucleotide-binding domain (also known as the ABC cassette) that hydrolyzes ATP to power the transport. Many ABC transporters are referred to as half transporters because they consist of only a single subunit and must dimerize to create the active pump. P-glycoprotein preferentially promotes the cellular extrusion of large (300 Da to 2000 Da) hydrophobic substances and neutral or positively charged amphiphilic molecules. Transported drugs include numerous anticancer agents (e.g., doxorubicin, vinblastine, and paclitaxel), antiviral compounds (e.g., ritonavir), Ca^{++}-channel blockers (e.g., diltiazem), digoxin, antibiotic and antifungal drugs (e.g., erythromycin and ketoconazole), hormones (e.g., testosterone), and immunosuppressants (e.g., cyclosporine).

Drug binding occurs within the plasma membrane near the cytoplasmic surface, limiting transport to drugs with good lipid solubility or sufficient length to reach the active site.

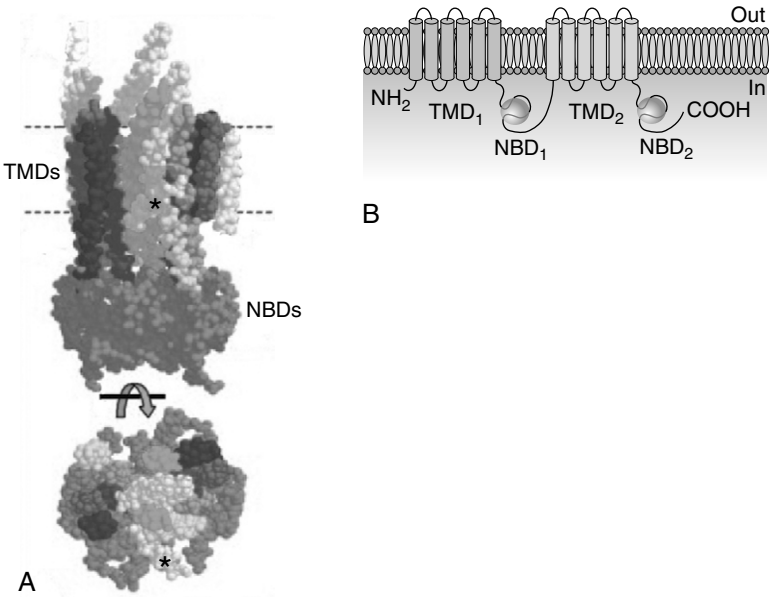

FIGURE **2-5** Structure of P-glycoprotein. Two transmembrane domains *(TMDs)* provide the transport mechanism and are powered by the nucleotide-binding domains *(NBDs)* that hydrolyze ATP. **A,** Three-dimensional model. *Top,* Lateral view. The transmembrane helices are darkened; four α-helical structures that do not traverse the membrane are lightly shaded, including one (*) that is partially intracellular in location. *Dashed lines* delimit the lipid bilayer. *Bottom,* View from the extracellular space illustrating the pseudosymmetric arrangement of the transmembrane helices. **B,** Two-dimensional topology. (**A,** Adapted from Rosenberg MF, Callaghan R, Modok S, et al: Three-dimensional structure of P-glycoprotein, *J Biol Chem* 280:2857-2862, 2005; **B,** adapted from Sarkadi B, Homolya L, Szakács G, et al: Human multidrug resistance ABCB and ABCG transporters: participation in a chemoimmunity defense system, *Physiol Rev* 86:1179-1236, 2006.)

P-glycoprotein is expressed in various cells, but the highest concentrations are located in intestinal epithelial cells; renal proximal tubular cells; canalicular membranes of hepatocytes; the capillary endothelium of the brain, choroid plexus, testes, and placenta; placental trophoblasts; adrenocortical cells; and stem cells.[30] Other ABC transporters important in pharmacokinetics include the multidrug resistance-associated protein (MRP) family. Collectively, the MRP transporters are also widespread and involved in the vectorial (one-way) movement of drugs and other xenobiotics. In contrast to P-glycoprotein, the MRP transporters pump amphiphilic molecules with at least one negative charge. These substrates include bile salts, nucleotide analogues, and conjugates of glutathione, glucuronic acid, and sulfate.

The known SLC transporters encompass 48 families encoded in 400 genes. Because the SLC transporters do not directly use ATP as an energy source for transport, they are more accurately referred to as *secondary active transporters*. The Na^+ pump (or Na^+/K^+-ATPase), which uses about one fourth of the body's ATP production, is the principal driving force for secondary active transport. By maintaining a large electrochemical gradient for Na^+ across the plasma membrane, movements of molecules that are energetically coupled to Na^+ (or another ion with a strong electrochemical potential difference across the membrane) can occur against their own concentration gradients. Secondary active transporters that move the coupled substances in the same direction as the linked ion are termed *cotransporters* or *symporters*. In contrast, antiporters or exchangers move the coupled substances in the opposite direction. Many SLC transporters (including the GLUT family described previously) allow the transmembrane movement of specific chemicals down their own electrochemical gradients and support facilitated diffusion. In contrast to the ABC transporters, SLC transporters can facilitate the bidirectional movement of substrates based on their existing concentrations across the cell membrane.

Organic anion transporters (OATs) and organic anion–transporting polypeptides (OATPs) are important families of SLC transporters involved in pharmacokinetics.[35] As a group, they promote the cellular uptake of acidic drugs into the liver, kidney, intestine, lung, and brain, and their excretion via the bile and urine. An analogous family of organic cation transporters (OCTs) provides similar handling of positively charged drugs.

Endocytosis and Exocytosis

The processes of endocytosis and exocytosis are together the most complex methods of drug transfer across a biologic membrane. The term *endocytosis* refers to a series of events in which a substance is engulfed and internalized by the cell. (Phagocytosis, or "cell eating," is a variant of endocytosis associated more with the removal of particulate matter by macrophages than with drug transport.)

Endocytosis usually begins with the binding of a compound, usually a macromolecule, to be absorbed by its receptor on the membrane surface. Two good examples are the attachment of low-density lipoprotein (LDL) and insulin to their respective receptors. With time, the bound agent-receptor complex is concentrated in an indentation of the membrane called a coated pit. (This migration also occurs spontaneously with the LDL receptor.) Clathrin, a cytoplasmic protein that attaches to the internal surface of the plasma membrane, serves to capture the receptors within the pit while excluding other surface proteins.[49] Internal rearrangement of its structure deepens the pit, forming a coated bud. A second protein, termed *dynamin*, is believed to congregate around the collar of the invaginated bud and initiate separation from the membrane. When released, the vesicle loses its clathrin coat and fuses with an organelle called the endosome. Some of the captured contents, such as LDL receptors, are recycled back to the plasma membrane by transport vesicles; the remainder undergo lysosomal processing and release into the cytoplasm.

An alternative method of endocytosis involves indentations on the plasma membrane termed *caveolae*. Caveolae contain large amounts of cholesterol covalently linked to caveolin-1, the primary structural protein of these structures. The internalization process also involves vesicle formation, but clathrin and endosomes do not participate in the internalization process.

The complementary process of exocytosis occurs when vesicles, such as those produced by the Golgi apparatus, fuse with the plasma membrane and discharge their contents outside the cell. Exocytosis is the primary method by which cellular products such as regulatory hormones are secreted by the cell. The term *transcytosis* is descriptive of a coupled form of endocytosis and exocytosis leading to the transfer of drug from one epithelial surface of a cell to another. In this scenario, the endosomal vesicle described previously avoids lyso-

somal capture, is transported across the cell, and fuses with the plasma membrane to release its contents extracellularly.

Cells generally are capable of endocytosis; however, exocytosis and transcytosis are most intensive in tissues adapted for the absorption, distribution, and export of important foodstuffs, regulatory hormones, and secretory products. Endocytosis/transcytosis is probably responsible for the absorption of antigenic proteins and certain toxins from the small intestine and for the transfer of large molecules between tissue compartments. It plays a minor role in the transport of most drugs.

ABSORPTION

Absorption refers to the transfer of a drug from its site of administration into the bloodstream. The particular route of administration selected greatly influences the rate and perhaps the extent of drug absorption.

Oral Ingestion

Oral ingestion was the first and is still the most commonly used method for the administration of therapeutic agents. The major advantages of the oral route lie in three areas: convenience, economics, and safety. Patient acceptance of oral medication is good because the technique itself is painless, and trained personnel are not required for its accomplishment. The convenience and low cost with respect to other modes of therapy are especially prominent for drugs that must be given several times daily on a long-term basis. The oral route is relatively safe because drug absorption is comparatively slow. Sudden high blood concentrations are not nearly as likely to be achieved by the ingestion of drugs as they are by parenteral injection. Allergic reactions are also less likely to occur, especially serious reactions. The oral route does have some drawbacks, however. Because self-administration is the rule, patient compliance is required for optimal therapy. Drug absorption is likely to be delayed (on a clinical average of 30 to 60 minutes) and may be incomplete. Metabolic inactivation or complex formation may also occur before the drug has a chance to reach the systemic circulation. These limitations to the oral route translate into an increased variability in patient response. Finally, the spectrum of adverse reactions caused by oral medication can extend from one end of the gastrointestinal tract to the other.

Drugs taken orally may be absorbed along the entire alimentary canal, but the relative degree of contact with the mucosa determines the amount of uptake in each segment. Variables affecting absorption include the duration of exposure, the concentration of the drug, and the surface area available for absorption. Under normal circumstances, the oral and esophageal mucosa are exposed too briefly to a drug during the process of swallowing for any absorption to occur. The colon normally plays no role in the uptake of orally administered compounds because, with the exception of some sustained-release preparations, little absorbable drug usually reaches it. By exclusion, the bulk of drug absorption must occur in the stomach and small intestine.

Influence of pH

As previously discussed, absorption is favored when the drug ingested is lipid soluble. For weak electrolytes, the pH of the surrounding medium affects the degree of ionization and drug absorption. Because the H^+ concentrations of the stomach and small intestine diverge widely, the two structures seem to be qualitatively dissimilar in their respective patterns of drug absorption. Figure 2-6 illustrates this difference and its effect on the previously commonly used analgesic combination of aspirin plus codeine. Aspirin is an organic acid with a pK_a (negative log of the dissociation constant) of 3.49. In gastric juice (pH 1 to 3), aspirin remains largely nonionized, and its passage across the stomach mucosa and into the bloodstream is favored. The plasma has a pH of 7.4, however. On entering this environment, the aspirin becomes ionized to such an extent that return of the drug to the gastrointestinal tract is prevented by the low lipid solubility of the anionic species. When equilibrium is established, the concentration of nonionized aspirin molecules on both sides of the membrane is the same, but the total amount of drug (ionized plus neutral forms) is much greater on the plasma side. The relative concentration of drug in each compartment can be calculated with the Henderson-Hasselbalch equation, as follows:

$$\text{Log}\frac{\text{base}(A^-)}{\text{acid}(HA)} = \text{pH} - \text{pK}_a$$

This unequal distribution of drug molecules based on the pH gradient across the gastric membrane is an example of ion trapping. The biologic process that sustains this partitioning is the energy-consuming secretion of H^+ by the gastric parietal cells. Because few organic acids have a pK_a low enough to permit significant ionization at stomach pH, almost all acidic drugs should theoretically be effectively absorbed across the gastric mucosa.

For bases such as codeine (pK_a 7.9), the opposite applies. Codeine is almost completely ionized in the acidic environment of the stomach; absorption is negligible. At equilibrium, virtually all the drug remains within the stomach. Only very weak bases are nonionized at gastric pH and available for absorption. The ion trapping of basic compounds within the gastric lumen is sometimes useful in forensic medicine. Many drugs subject to abuse are organic bases (e.g., heroin, cocaine, and amphetamine). Even when injected

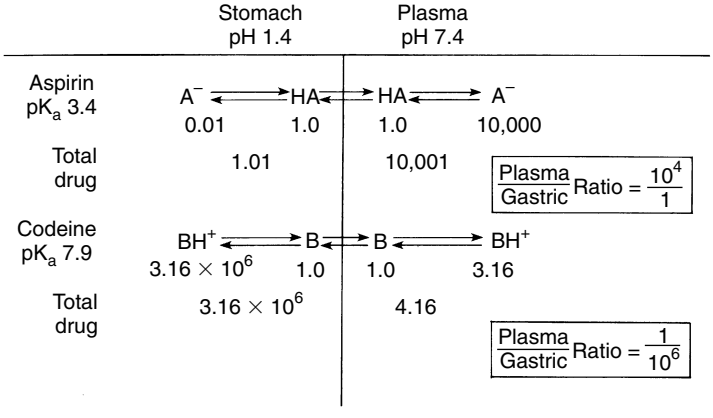

FIGURE **2-6** Gastric absorption of aspirin, a weak acid, and codeine, a weak base. The absorption of aspirin is promoted by ion trapping within the plasma; the low pH of stomach fluid favors gastric retention of codeine. (The 3.49 pK_a of aspirin is truncated to 3.4 for purposes of illustration.)

intravenously, they tend to accumulate in the stomach by crossing the gastric mucosa in the reverse direction. Questions of intravenous overdosage can often be answered from the analysis of stomach contents.

When the gastric fluid passes into the small intestine, it is quickly neutralized by pancreatic, biliary, and intestinal secretions. The pH of the proximal one fourth of the intestine varies from 3 to 6, but it reaches neutrality in more distal segments. Under these more alkaline conditions, aspirin converts to the anionic form, whereas a significant fraction of the codeine molecules give up their positive charge. Although basic drugs are favored for absorption over acids in the small intestine, ion trapping is not as extensive because the pH differential across the intestinal mucosa is small. Differences in intestinal absorption based on pH are more concerned with the rate of uptake than with its extent. As one might expect, neutralization of gastric contents by the administration of antacids or ingestion of food temporarily removes the qualitative disparity in electrolyte absorption normally observed between the stomach and the small intestine.

Mucosal surface area

A second major difference between absorption in the stomach and absorption in the small intestine relates to the intraluminal surface areas involved in drug uptake. Aside from certain mucosal irregularities (rugae), the stomach lining approximates that of a smooth pouch with a thick mucous layer. The mucosa of the small intestine is uniquely adapted for absorption, however. Contributions by the folds of Kerckring, villi, and microvilli combine to increase the effective surface area 600-fold. Assuming a small intestine 280 cm in length and 4 cm in diameter, approximately 200 m^2 are available for drug absorption. The surface/volume ratio in the small intestine is so great that drugs ionized even to the extent of 99% may still be effectively absorbed. Many studies have shown that acidic drugs with a pK_a greater than 3.0 and basic compounds with a pK_a less than 8.0 readily pass from the intestinal fluid into the plasma.[19] Although pH considerations favor the gastric absorption of aspirin, as much as 90% of the drug when given in tablet form is actually absorbed from the small intestine in vivo. Experimentally, nonelectrolytes such as ethanol are also absorbed from the intestine many times faster than from the stomach.

Gastric emptying

Because almost any substance that can penetrate the gastrointestinal epithelium is best absorbed in the small intestine, the rate of gastric emptying can significantly affect drug absorption, particularly for organic bases that are not absorbed at all from the stomach. Gastric emptying is accomplished by contraction of the antrum of the stomach. A cyclical pattern of activity occurs in fasting patients where periods of quiescence (about 1 hour each) are followed by contractions that increase in intensity over a 40-minute period before terminating in a short burst of intense contractions that migrate from the stomach to the distal ileum. Ingesting a tablet or small volume of liquid may result in gastric retention of the drug for 1 hour or longer. After eating a meal, sustained antral and pyloric contractions help break up the ingested food and permit the extrusion of liquid into the duodenum while retaining particles more than 1 mm in diameter within the stomach. A mixed meal of solids and liquids usually begins to enter the duodenum in about 30 minutes and requires about 4 hours to leave the stomach completely. A glass of water ingested on an empty stomach is moved into the small intestine in exponential fashion, with half of the water expelled from the stomach in 15 minutes, and essentially all of the liquid removed by 1 hour.

A major variable in delaying gastric emptying is the presence of fat. Unless drug-induced irritation of the gastric mucosa must be avoided, most oral medications should be taken in the absence of food but with a full glass of water. This procedure speeds drug entry into the small intestine and provides maximum access to the gastrointestinal mucosa. Occasionally, the presence of a fatty meal promotes the absorption of a drug that has a high lipid but low water solubility. The antifungal agent griseofulvin, the protease inhibitor saquinavir, and the fat-soluble vitamins are examples of substances that are better absorbed in the presence of lipids. In these instances, the delay in gastric emptying produced by the high fat content of the chyme is compensated for by a more complete absorption.

Additional situations in which food enhances drug uptake have been reviewed.[33] Nevertheless, because gastric emptying is often a limiting factor in the rate of drug absorption, many unrelated drugs exhibit latency periods (the lag phase between oral ingestion and onset of drug effect) of a similar magnitude.

Influence of dosage form

Although the times required for gastric emptying and for diffusion across the mucosal barrier undoubtedly contribute to the delayed onset of action of drugs taken orally, situations exist in which these events are not rate limiting. Most drugs intended for oral use are marketed in the form of capsules or solid tablets. In contrast to solutions, these preparations must first dissolve in the gastrointestinal fluid before absorption can occur. If dissolution is very slow, it can become the controlling factor in drug absorption.

The first step in the dissolution process is the disintegration of the tablet (or the capsule and its granules) to yield the primary drug particles. Various excipients are usually included in solid drug preparations to promote disintegration and particle dispersion. If disintegration is impaired, drug absorption is depressed accordingly. The dissolution of drug particles occurs by a diffusion-limited mechanism. The diffusion layer of solvent surrounding each particle becomes saturated very quickly with drug molecules escaping from the solid. Because saturation of the diffusion layer occurs far more rapidly than does diffusion from it into the bulk solution, the entire process proceeds no faster than the rate of drug diffusion. Several methods can be used, however, to accelerate the dissolution rate. Because the total surface area of the particles determines the area available for diffusion, reducing the mean particle size through the process of micronization promotes solubilization. A decrease in particle size of 85% with a compensating increase in particle number doubles the rate of dissolution.[27] Another useful approach is to manufacture drugs in the form of water-soluble salts. The concentration of drug in the dissolution layer is enhanced (often by many times), and the rate of diffusion is increased.

The dissolution process may be considered rate limiting whenever a drug solution produces a systemic effect faster than a solid formulation of the same agent does. Sometimes discrepancies in absorption between dosage forms are of such magnitude that clinical differences are noted. With aspirin, the concentration of drug in the plasma 30 minutes after administration can be twice as high for a solution as for a solid tablet.[27] Although it is unclear whether this difference results solely from drug dissolution or from other factors, such as the more rapid gastric emptying typical of liquids, dissolution is probably at least partially responsible.

The influence of dosage form on drug absorption is often taken advantage of by drug manufacturers. Some drugs (e.g., erythromycin) are unstable at a low pH, and others (e.g., ammonium chloride) are irritating to the gastric mucosa. To avoid release of these drugs within the stomach, they are often prepared in the form of enteric-coated tablets. An enteric coat consists of a film of shellac or some polymeric substitute. The covering is insoluble under acidic conditions, but does break down to permit tablet disintegration in the more alkaline

environment of the small intestine. Although these preparations are often beneficial, their usefulness nevertheless is negatively affected by an increased variability in patient response. Because drug absorption cannot begin until the tablet passes into the duodenum, the time required for gastric transit becomes an important variable. The passage of a single insoluble tablet from the stomach into the intestine is a random event that can take several minutes to more than 6 hours.[15]

Sustained-release preparations represent another method of capitalizing on the influence of formulation on drug absorption. These products are usually designed to release a steady amount of drug within the gastrointestinal tract for 12 to 24 hours. Some preparations also provide an initial loading dose that is readily available for absorption. Sustained release may be accomplished by using a porous matrix, with the drug located in the interior spaces and on the external surface. An alternative is to make spheres of drug that dissolve at different rates because of various coatings. An intriguing form of sustained-release tablet is the "elementary osmotic pump," in which the drug is enclosed in a semipermeable membrane that lets water in, but restricts drug egress. Constant release through a small hole in the membrane is achieved by the osmotic pressure that builds up within the tablet as the drug is slowly dissolved. Advantages claimed for these drug products include greater patient compliance and smaller fluctuations in blood concentration between dosages. Studies with some preparations have documented a greater variability in performance, however, than is normally encountered with conventional dosage forms. Because sustained-release products contain several conventional doses of medication, a danger exists that a too-rapid release of drug from these preparations might cause unexpected toxic concentrations. Conversely, inordinately slow or incomplete release could lead to inadequate drug therapy. Uncertainty over the effects of these formulations is recognized by the U.S. Food and Drug Administration (FDA), which regards them as new drugs and requires that efficacy and safety be shown before they can be marketed.

The sensitivity of gastrointestinal absorption to variations in drug formulation is best exemplified by the concern over bioavailability. In many instances, chemically identical drugs have proved in the past to be biologically nonequivalent. In one study of tetracycline hydrochloride, nine preparations of different manufacture were compared with an aqueous solution of the same drug.[29] Although seven brands produced blood concentrations ranging from 70% to 100% of the reference solution, two products exhibited relative bioavailabilities of only 20% to 30%. Differences in bioavailability are most likely to be clinically important with drugs that are poorly absorbed, have low margins of safety, and are inactivated by capacity-limited processes. Since 1977, federal law has required that bioequivalence testing be performed on all new drugs, and the FDA has mandated such testing of existing products for which a problem of nonequivalence is known to exist. Bioavailability considerations related to drug selection are considered further in Chapter 55.

Active transport

Most drugs intended for oral use are absorbed by passive diffusion. Active transport systems do exist, however, for specific dietary constituents that sometimes increase the absorption of certain drugs. The absorption of levodopa and baclofen from the intestine is enhanced because they are amino acid analogues and actively transported into intestinal cells by the large neutral amino acid transporter (LNAT, an SLC transporter). Valacyclovir is likewise much better absorbed than is its congener acyclovir because it is a substrate for PepT-1, another SLC transporter.

Active transport mechanisms can also inhibit drug absorption.[30] P-glycoprotein is highly expressed along the luminal surface of intestinal epithelial cells, where it exports xenobiotics that would otherwise be absorbed. This function is in concert with the "chemoimmunity defensive" role P-glycoprotein plays in protecting cells from exposure to potentially toxic compounds.[48] Although P-glycoprotein may delay the absorption of many drugs and prevent altogether the uptake of pharmaceuticals of low absorptive potential, it is probably of minor significance regarding the extent of absorption of most drugs intended for oral use, whose concentrations in the chyme are sufficient to overwhelm the capacity of P-glycoprotein to export them.[47] Figure 2-7 depicts the active transport of drugs into and out of intestinal cells and at other important sites.

Drug inactivation

A shortcoming of oral ingestion is the inactivation of drugs before they reach the systemic circulation. The destruction of some agents (e.g., epinephrine and insulin) is sufficiently great to preclude their administration by this route. With other drugs (e.g., penicillin G), losses may be smaller, but still large enough to make oral administration inefficient. Gastric acid is one of the principal causes of drug breakdown within the gastrointestinal tract, but degradation also results from enzymatic activity. Vasopressin, insulin, calcitonin, and other polypeptides are subject to hydrolysis by pancreatic and intestinal peptidases. Intestinal cells also contain intracellular

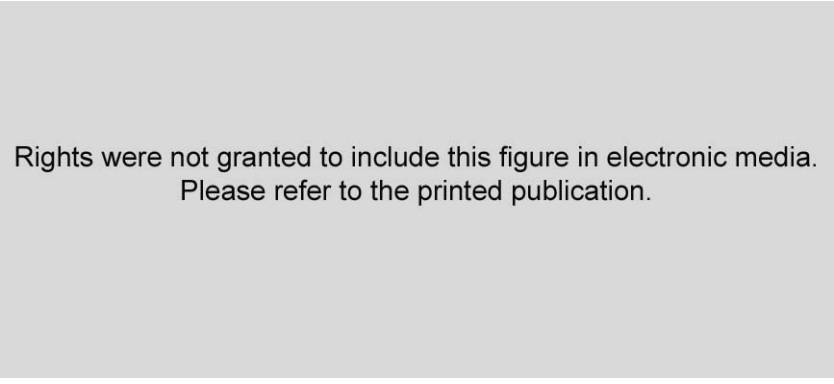

FIGURE **2-7** Transepithelial or transendothelial transport of drugs across the liver (absorption), brain capillaries (distribution), and liver and kidneys (elimination). *ABC*, ATP-binding cassette transporter; *SLC*, solute carrier transporter. (Adapted from Giacomini KM, Sugiyama Y: Membrane transporters and drug response. In Brunton LL, Lazo JS, Parker KL, editors: *Goodman & Gilman's the pharmacological basis of therapeutics*, ed 11, New York, 2006, McGraw-Hill.)

enzymes for metabolizing drugs. Of particular importance are the presence of monoamine oxidase for the inactivation of biogenic amines and the presence of CYP3A4/5 enzymes (described later) for the oxidation of numerous compounds. Enteric bacterial enzymes may also destroy certain ingested agents, such as chlorpromazine. Finally, intestinal contents can alter the effectiveness of many orally administered drugs. Binding to constituents of chyme, chelation with divalent cations, or formation of insoluble salts may decrease the amount of drug available for absorption.

A special fate exists for substances that are successfully absorbed from the gastrointestinal tract. The venous drainage of the stomach, small intestine, and colon is routed by the hepatic portal system to the liver. A first pass of high drug concentration through this enzyme-laden organ can significantly reduce the quantity of agent reaching the systemic circulation. Lidocaine is metabolized so rapidly in the liver that virtually all of an oral dose is destroyed during its first pass. Although less pronounced, disparities in opioid analgesic and antibiotic efficacies observed between the oral route and other modes of administration are of clinical importance to the practice of dentistry.

Other enteral routes

The oral and rectal mucosae are occasionally used as sites of drug absorption. Sublingual administration, in which a tablet or troche is allowed to dissolve completely in the oral cavity, takes advantage of the permeability of the oral epithelium and is the preferred route for a few potent lipophilic drugs, such as nitroglycerin and oxytocin. The oral and intestinal mucosal layers do not differ qualitatively as absorbing surfaces, and comparable absorption has been shown for many agents.[6] One reason for selecting the sublingual route is to avoid drug destruction. Because gastric acid and intestinal and hepatic enzymes are bypassed, sublingual absorption can be more efficient overall for certain drugs than is intestinal uptake. The onset of drug effect may also be quicker than with oral ingestion.

Rectal administration may be used when other enteral routes are precluded, as in an unconscious or nauseated patient. Although a significant fraction of absorbed drug enters the circulation without having to pass through the liver, uptake is often unpredictable. Several drugs irritating to the gastric mucosa (e.g., xanthines) may be given rectally; for others, rectal sensitivity prohibits administration by this route.

Inhalation

The alveolar membrane is an important route of entry for some drugs and many noxious substances. Although the alveolar lining is highly permeable, it is accessible only to agents that are in a gaseous state or are inhaled in sufficiently fine powders or droplets to reach the deepest endings of the respiratory tree. Gaseous agents include the therapeutic gases, carbon monoxide, the inhalation anesthetics, and numerous volatile organic solvents. The second category of alveolar membrane penetrants is collectively known as *aerosols*. This term refers to liquid or solid particles small enough (usually ≤10 μm in diameter) to remain suspended in air for prolonged periods. Particles of this sort include bacteria, viruses, smoke, pollens, sprays, and dusts. Any such finely divided material, when inhaled, reaches some portion of the respiratory tree and is affected by the processes of sedimentation and inertial precipitation. Most aerosols contain a mixture of particle sizes. Relatively large particles (≥5 μm) impact on the terminal bronchioles and larger branches of the respiratory tree and are removed from the lungs by a cilia-driven blanket of mucus flowing continuously toward the pharynx. Smaller particles, which do reach the alveolar sacs, can be absorbed through the lining cells into the bloodstream, taken up by the process of phagocytosis, or carried by an aqueous film covering the alveolar cells to the terminal bronchioles where they join the mucous blanket. Although two of these three possible fates involve particle uptake, the mechanism for removing solids is remarkably efficient. Only a minute portion of the inhaled dusts of a lifetime fails to be removed by ciliary transport.

Therapeutic use of aerosols is not widespread, but some emergency medications are prepared in this form. Because the onset of effect is extremely rapid after inhalation of an aerosol drug, this route can provide a means of quick self-medication for individuals in danger of acute allergic reactions to venoms or drugs. Epinephrine is one such emergency agent that is marketed as an aerosol. Many respiratory drugs are also prepared in aerosol form because they are highly effective by this route while minimizing systemic exposure. The rapidity and efficiency of alveolar membrane absorption can occasionally pose problems for therapy, however, as illustrated by the use of pressurized aerosols containing isoproterenol. Although 97% of an isoproterenol spray is swallowed under normal conditions and inactivated by various enzymes, overmedication can produce toxic effects. Data gathered over a 7-year period in the United Kingdom suggested that the undisciplined use of these preparations increased mortality in asthmatic patients. Restriction of over-the-counter sales and warnings to physicians were accompanied by a decline in mortality.[21] Findings such as these reflect the hazards of aerosols when abused and provide a caveat for uncontrolled self-medication with any potentially dangerous drug. Concern over aerosols is also related to questions of toxicology, such as the absorption of heavy metal dusts by industrial workers.

Parenteral Injection

Drugs are frequently given by parenteral injection when oral ingestion is precluded by the patient's condition, when a rapid onset of effect is necessary, or when blood concentrations greater than those obtainable with the enteral route are required. The method of injection selected varies with the particular drug and therapeutic need of the patient.

Intravenous route

The administration of drugs by infusion or injection directly into the bloodstream is particularly useful when immediate effects or exact blood concentrations are desired. Because absorption is bypassed, intravenous injection circumvents the delays and variations in drug response characteristically associated with other modes of administration. Rapid dilution in the bloodstream and the relative insensitivity of the venous endothelium to drugs often permit the successful administration of compounds or solutions too irritating for other routes (e.g., alkylating anticancer drugs and hypertonic fluids). Also, through the technique of titration, the intravenous route provides an avenue for the controlled administration of drugs that have a very narrow margin of safety between therapeutic and toxic concentrations. The infusion of lidocaine to prevent ventricular arrhythmias and the incremental injection of antianxiety drugs during intravenous sedation are two examples in which titration is used to achieve a desired effect while avoiding adverse reactions. Although many intravenous agents do not require titration and may be given in standardized doses, they should still be injected slowly. If administered too quickly, a dose may move initially through the heart, lungs, and major arteries as a bolus of high drug concentration. Nonspecific but potentially disastrous cardiopulmonary side effects may result, even from the rapid injection of simple salt solutions. Most drugs should be administered over a period of 1 minute, which approximates the circulation time of blood through the body. This procedure avoids high, transient concentrations and permits discontinuance if any untoward effect is observed during the course of injection.

A major disadvantage of the intravenous route is that, once the drug is injected, very little can be done to remove it from the bloodstream. When an adverse response is noted with another route, further absorption usually can be delayed or perhaps even prevented. Toxic reactions to drugs given intravenously are often instantaneous and severe. Life-threatening anaphylactic events are also more likely because of the possibility of a massive antigen-antibody reaction. Other complications of intravenous injection include vasculitis and embolism (from drug irritation, particulate matter in the injected solution, or needle trauma), fever (from injection of pyrogens such as bacterial lipopolysaccharides), infection, and hematoma formation. Finally, the accidental intra-arterial injection of drugs (e.g., promethazine) intended for intravenous use has led to arteriospasm, gangrene, and loss of limbs.

Intramuscular route

The intramuscular route is often selected for drugs that cannot be given orally because of slow or erratic absorption, high percentage of drug inactivation, or lack of patient cooperation. The rate of absorption from an intramuscular site is governed by the same factors influencing gastrointestinal uptake, such as lipid/water partition coefficient, degree of ionization, and molecular size. Many drugs are absorbed at approximately the same rate, however, regardless of these factors. The only barrier separating a drug deposited intramuscularly from the bloodstream is the capillary endothelium, a multicellular membrane with large intercellular gaps. Many lipid-insoluble substances can enter the vascular compartment through these gaps, and even proteins are capable of being absorbed. In these circumstances, blood flow through the tissue is often the primary determinant of the rate of drug absorption. Muscles with high blood flows (e.g., deltoid) provide faster absorption rates than muscles with lesser flows (e.g., gluteus maximus). Generally, 5 to 30 minutes is required for the onset of drug effect, but this latency period can be controlled to some extent. Exercise markedly speeds absorption by stimulating local circulation. Conversely, uptake may be minimized by the application of ice packs or (in an emergency) tourniquets.

With the exception of a few drugs that are relatively insoluble at tissue pH (e.g., diazepam, phenytoin), absorption from an intramuscular injection is usually rapid and complete. Formulations have been developed, though, to provide for prolonged and steady drug release. These depot preparations consist of drugs manufactured as insoluble salts or dispensed in oil vehicles, or both, such as procaine penicillin suspended in peanut oil. Relatively large volumes of solution may be given by this route, but soreness at the injection site is frequent, and some drugs (e.g., doxycycline) are too irritating to be administered in this manner.

Subcutaneous route

Injection of drugs into the subcutaneous connective tissue is a widely used method of administration for agents that can be given in small volumes (≤2 mL) and are not locally damaging. Subcutaneous absorption is similar to that of resting muscle, and onset times are often comparable. As with the intramuscular route, absorption can be delayed by diminishing blood flow, either through the application of pressure or by surface cooling. Pharmacologic interruption of circulation with vasoconstrictors is also a common strategy, especially in local anesthesia. Because of the ease of subcutaneous implantation, compressed pellets of drugs, sometimes mixed with insoluble matrix material, can be inserted to provide nearly constant drug release for weeks or months. Testosterone and several progestational contraceptive agents (e.g., levonorgestrel) have been successfully administered by this approach. Slow absorption also can be achieved through the use of depot forms as described for intramuscular injections.

When subcutaneous administration is chosen for a systemic effect, the hastening of drug absorption is sometimes advantageous. Toward this end, warming the tissue promotes drug uptake by improving local circulation. Massage of the injection site, in addition to stimulating blood flow, helps spread the drug and provides an increased surface area for absorption. This latter effect can also be accomplished through the coadministration of hyaluronidase, an enzyme that breaks down the mucopolysaccharide matrix of connective tissue. The lateral spread of aqueous solutions is so enhanced that hyaluronidase is sometimes used to permit the injection of large fluid volumes in situations in which continuous intravenous infusion is difficult or impossible.

Other parenteral injection routes

Intra-arterial injections are occasionally performed when a localized effect on a particular organ or area of the body is desired. Injections of radiopaque dyes for diagnostic purposes and antineoplastic agents to control localized tumors are the most commonly encountered examples. Intrathecal administration is used when the direct access of drug to the central nervous system (CNS) is necessary. Indications for injection into the subarachnoid space include the production of spinal anesthesia with local anesthetics and the resolution of acute CNS infections with antibiotics. The intraperitoneal infusion of fluids is a useful substitute for hemodialysis in the treatment of drug poisoning. Although intraperitoneal injection is commonly used in animal experimentation, the risk of infection usually precludes such use in humans. Lastly, intraosseous (anterior tibial) injection of emergency drugs can be used when intravenous access cannot be obtained quickly.

All these specialized injection techniques are potentially dangerous to the patient. They should be performed only when expressly indicated and then only by qualified personnel.

Topical Application

Drugs are often applied to epithelial surfaces for local effects and less frequently for systemic absorption. Penetration of drugs across the epithelium is strongly influenced by the degree of keratinization.

Skin

The epidermis is a highly modified tissue that isolates the body from the external environment. The outer layer of skin (stratum corneum) is densely packed with the protein keratin. This layer is impervious to water and water-soluble drugs, and its relative thickness and paucity of lipids in contrast to other biologic membranes retards even the diffusion of strongly lipophilic agents. The impermeable nature of skin to water-soluble drugs often requires that agents (e.g., antibiotics, fungicides) intended for dermatologic conditions be administered by a systemic route despite the accessibility of the skin. For lipid-soluble drugs, however, the percutaneous route is often successful for local problems. Disruption of the keratinized layer markedly enhances drug absorption, especially of hydrophilic compounds. The underlying connective tissue (dermis) is quite permeable to many solutes, although it differs from most tissues in having an abundant supply of arteriovenous shunts, which may cause systemic absorption to be particularly sensitive to changes in temperature.

The general resistance of the intact skin to drugs does not invalidate the need for caution when dealing with potentially toxic chemicals. Sufficient documentation of epidermal absorption of foreign substances has established that certain compounds may readily penetrate the skin to cause systemic effects. These drugs include organic solvents, organophosphate and nicotine-based insecticides, and some nerve gases. Severe poisoning has also resulted from the excessive application of sunburn creams containing local anesthetics. Even

lipid-insoluble substances such as inorganic mercury can diffuse across skin if exposure is prolonged.

The benefits of improving and sufficiently controlling percutaneous absorption to make it a reliable route of drug administration have prompted several strategies. A "transdermal therapeutic system" has been developed to provide continuous systemic uptake of nitroglycerin, scopolamine, fentanyl, and nicotine for prophylaxis of angina pectoris, prophylaxis of motion sickness, management of chronic pain, and assistance with smoking cessation. The system is a complex patch that consists of an outer impermeable backing, a reservoir containing the drug in a suspended form, a semipermeable membrane, and an inner adhesive seal.

In the early 1960s, it was discovered that the industrial solvent dimethyl sulfoxide promotes the percutaneous absorption of water-soluble drugs. The potential of simplified therapy for arthritic and other patients that this drug carrier offered generated much enthusiasm. Subsequent reports of adverse reactions in animals caused interest to wane, however, until the late 1970s, when it was promoted as an effective agent for the symptomatic relief of a wide variety of musculoskeletal and collagen disorders. Although widely available as an herbal remedy, dimethyl sulfoxide is currently approved by the FDA only for the treatment of interstitial cystitis.

Another approach to improving drug penetration through the epidermis is the use of occlusive dressings. These dressings retain moisture and break down the horny layer through the process of maceration. A final technique, iontophoresis, is discussed subsequently.

Mucous membranes

The topical application of drugs to mucous membranes offers several potential advantages for local therapy. The tissues can often be visualized by the clinician, permitting accurate drug placement. The use of this route generally minimizes systemic effects while providing an optimal concentration of drug in the area being treated. In contrast to the case with skin, drugs have little trouble permeating mucous membranes to affect localized conditions. Systemic absorption of lipophilic drugs from mucous membranes readily occurs. Before this fact was widely appreciated, the topical application of tetracaine to the pharyngeal and tracheal mucosae was a leading cause of local anesthetic overdosage. In dentistry, the use of corticosteroids to ameliorate inflammatory conditions has also led to systemic responses, such as the suppression of adrenocortical function by triamcinolone. Although these effects are generally mild and transient, they can create problems for patients with hypertension, diabetes mellitus, or peptic ulcer. Local therapies can also affect systemic health by serving as antigenic stimulants and, in the case of antibiotics, by disturbing the normal microbial ecology and promoting the emergence of resistant microorganisms.

Drugs are sometimes applied mucosally for their systemic effects. In addition to the previously discussed sublingual and rectal routes of administration, the nasal mucosa offers a suitable avenue for the uptake of certain agents. Desmopressin, used in the treatment of diabetes insipidus, and butorphanol, a potent analgesic, are examples of drugs that can be given intranasally.

Iontophoresis

Iontophoresis is the electric transport of positively or negatively charged drugs across surface tissues. The technique involves passing a direct electric current of appropriate polarity through the drug solution and patient. Permeation of mucous membranes, skin, and hard tissues is possible with this approach, yet the total dose delivered is small, and systemic toxicity is unlikely. In dental therapeutics, iontophoretic application of drugs has been used in several situations. Loose deciduous teeth have been extracted successfully after the iontophoretic administration of lidocaine with epinephrine for soft tissue anesthesia.[13] For the treatment of herpes orolabialis, galvanic current increases the tissue concentration of idoxuridine up to three times that obtainable with topical application alone. Probably the most common use of iontophoresis in dentistry is the promotion of F^- uptake into exposed hypersensitive dentin. A 1% solution of sodium fluoride administered in this manner produced better results than did a 33% paste.[36]

DISTRIBUTION

Distribution refers to the movement of drugs throughout the body. The rate, sequence, and extent of distribution depend on many factors: the physicochemical properties of the drug, cardiac output and regional blood flow, anatomic characteristics of membranes, transmembrane electric and pH gradients, binding to plasma proteins and tissue reservoirs, and carrier-mediated transport. For all but the very few drugs that act intravascularly, the capillary membrane constitutes the first tissue barrier to be crossed in the journey of a drug from the bloodstream to its site of action.

Capillary Penetration

After a drug gains access to the systemic circulation, it becomes diluted by the plasma volume of the entire vascular compartment. For a compound administered intravenously, this process requires only several minutes for completion; for drugs given by other routes, intravascular distribution occurs concurrently with absorption. The transfer of drugs out of the bloodstream is governed by the same factors that control its entrance. Lipophilic drugs diffuse across the capillary membrane extremely rapidly. The transfer is so expeditious that equilibrium with interstitial fluid is practically instantaneous. Under these conditions, the rate of drug uptake is determined by the blood flow through the tissue under consideration. Well-perfused organs are saturated with drug long before many other tissues have had a chance to reach even a fraction of the equilibrium concentration. Water-soluble drugs diffuse through gaps located between adjacent endothelial cells. With these agents, transcapillary movement is slower than for drugs that have high lipid/water partition coefficients and is inversely proportional to molecular weight. As molecular size increases beyond 20 kDa to 30 kDa, aqueous paracellular diffusion ceases to be quantitatively important. Current evidence suggests that caveolae-based transcellular movement takes over as the primary transport method for large drugs. Convection may also be important in vascular beds with large gaps between endothelial cells, and assumes special prominence when inflammatory signals cause paracellular pathways to widen.[34]

Entry of Drugs into Cells

As previously discussed, the cell membrane acts as a semipermeable barrier, admitting some drugs into the cell, while excluding others. Nonpolar, lipid-soluble compounds distribute evenly across plasma membranes, but distribution of weak electrolytes at equilibrium is more complex. The intracellular pH is approximately 7.0, differing slightly from the 7.4 pH of extracellular fluid. Acids with a pK_a less than 8.0 tend to remain outside the cell, whereas basic drugs with a pK_a greater than 6.0 tend to accumulate within. Because the concentration differential across the cell membrane based on a pH gradient of 0.4 can equal 2.5:1, the acid-base status of a patient can significantly affect the dose response of weak electrolytes acting intracellularly. (The influence of pH on the distribution of local anesthetics across nerve membranes is described in Chapter 16.) Ions, unless very small in size (molecular weights of ≤60 Da) or transported by membrane-bound carriers, penetrate cell membranes with difficulty if at

all. Charged drugs that do gain access to the cell by passive diffusion are distributed at equilibrium according to their electrochemical gradient across the membrane.

Restricted Distribution

In some tissues or organs, anatomic relationships and membrane transporters sequester interstitial or transcellular fluids from the general extracellular space and restrict intracellular access to drugs. The most important examples for therapeutics include the CNS and the fetal circulation.

Central nervous system

Entry of drugs into the CNS is unusually dependent on lipid solubility. Most drugs with high lipid/water partition coefficients are taken up very quickly, as exemplified by the immediate onset of general anesthesia after the intravenous injection of thiopental. The rapid distribution of lipophilic drugs into the brain and spinal cord arises from the fact that the CNS receives approximately 15% of the cardiac output yet composes only 2% of total body weight. Despite this favorable blood supply, drugs that are sparingly lipid soluble are largely excluded from the extracellular space of the brain. In contrast to the capillaries of most tissues, the endothelial cells of the CNS are joined together by tight junctions that limit the entry of water-soluble drugs to those agents with an effective molecular radius of 8 Å or less. Relatively large molecules (e.g., inulin, with a molecular weight of 5000 Da) that normally pass without difficulty into the interstitial space are completely barred, and most other drugs dependent on paracellular pathways for penetration and weighing more than 100 Da to 200 Da are slowed considerably. A relative absence of endocytosis/transcytosis is also notable in CNS capillaries.

A second impediment to the transfer of ions and other water-soluble substances is the cellular sheath that surrounds the capillaries of the brain. This investing layer is composed of processes extending from connective tissue astrocytes. Although the area of capillary surface coverage is incomplete, it nevertheless is sufficient to retard the diffusion of all but highly lipid-soluble compounds.

A third factor limiting access of drugs to the CNS is an extensive collection of membrane transporters that efficiently export drugs gaining entry into the endothelial cells (see Figure 2-7). Exporters such as P-glycoprotein constitute the only effective means of excluding toxic hydrophobic substances from the brain. Together, the modified capillary endothelium, astrocytic sheath, and export carrier system constitute the blood-brain barrier.

Drugs may also gain access to the CNS by way of the choroid plexuses. Each choroid plexus is composed of a network of small blood vessels and capillaries projecting into a ventricular space and covered by a layer of epithelial cells specifically adapted for the secretion of cerebrospinal fluid. Diffusion of drugs across the choroid plexus epithelium and into the cerebrospinal fluid is largely restricted to highly lipid-soluble drugs, indicating the functionally analogous existence of a barrier between blood and cerebrospinal fluid. The choroid plexus and cerebrospinal fluid are actually more closely involved with the removal of drugs from the CNS than with their entry. Secreted into the third, fourth, and lateral ventricles, the cerebrospinal fluid moves by bulk flow through the ventriculocisternal system to bathe the surfaces of the brain and spinal cord before exiting through the arachnoid villi. Drugs present in the extracellular fluid of the CNS are free to diffuse into the cerebrospinal fluid. Because the total quantity of cerebrospinal fluid (150 mL) approximates the volume of the interstitial space, and because it has a moderately fast turnover rate (10% per hour), the removal of drugs by bulk flow through the arachnoid villi can prevent an agent in the brain from ever reaching equilibrium with the blood. The presence of several active transporters in the lining cells of the choroid plexus also promotes the removal of many drugs from the cerebrospinal fluid back into the systemic circulation.

The selective distribution of compounds into the CNS has several important therapeutic ramifications. Some alkaloids intended for peripheral nervous system effects may cause central disturbances on entry into the brain. Conversion of such drugs (e.g., scopolamine) to positively charged quaternary ammonium derivatives (e.g., methscopolamine) prevents CNS influences yet allows essential peripheral nervous system activity. Conversely, drugs used for their central effects may benefit by molecular modifications that enhance their entry into the brain. Lower total doses can be given and peripheral effects minimized.

Sometimes the blood-brain barrier is a hindrance to therapy. Penicillin G, a water-soluble organic acid with a pK_a of 2.6, diffuses slowly into the CNS and is subject to active removal by the choroid plexus. For patients with bacterial encephalitis, this lack of drug penetration can complicate treatment. (Fortunately, capillary permeability in the brain often increases during meningeal inflammation.) A clever approach to circumventing the blood-brain barrier is embodied in the treatment of parkinsonism. This condition is associated with a deficiency of dopamine within selected portions of the brain. Replacement therapy with dopamine is ineffective, however, because the drug is excluded by the blood-brain barrier. To avoid this problem, levodopa, the amino acid precursor of dopamine, is used instead. Levodopa readily enters the brain, where it is subsequently decarboxylated to the active drug.

A more drastic and potentially dangerous method of breaking through the blood-brain barrier is to disrupt it temporarily by infusing hypertonic solution into the carotid artery. An osmotically induced shrinkage of cerebrovascular endothelial cells causes the tight junctions to pull apart and permits the uptake of water-soluble drugs.[42] Other strategies include attaching the drug to a carrier substance, or vector, that is transported into the brain. Such vectors may consist of naturally transported molecules or involve monoclonal antibodies targeted for these molecules.[50] Some peptide vectors have been identified that promote transcytosis. Coupling of drugs such as penicillin and doxorubicin greatly improves their uptake across the blood-brain barrier. A final approach to improving CNS uptake of medications is to inhibit competitively active export. Inhibition of P-glycoprotein transport has been shown to increase CNS concentrations of the anticancer drug paclitaxel by up to 10-fold.[23]

Placental transfer

Obstetric delivery of conscious infants from anesthetized mothers was previously misconstrued as evidence for a unique placental barrier excluding even lipid-soluble drugs from the fetus. It is now understood that such observations largely result from the finite rate of drug transfer from the maternal circulation to fetal tissues. Fetal blood vessels projecting into sinuses filled with maternal blood are covered by a single syncytium of cells called *trophoblasts*. The movement of drugs across the placenta is limited by the trophoblastic membrane, which is qualitatively similar to plasma membranes elsewhere. Although trophoblasts are known to secrete amino acids and other vital nutrients actively into the fetal circulation, the entry of most drugs depends on passive diffusion across the lipoid barrier. For highly lipophilic drugs such as thiopental, distribution is retarded only by the rate of maternal blood flow through the placenta and by peculiarities in the fetal circulation that limit tissue perfusion. Even so, it has been calculated that 40 minutes are required for fetal tissues to attain 90% equilibration with a constant maternal arterial concentration.[41] Limited by a sluggish transmembrane diffusion, the transfer of water-soluble compounds is so inefficient that virtually no drug from a single administration may gain access to

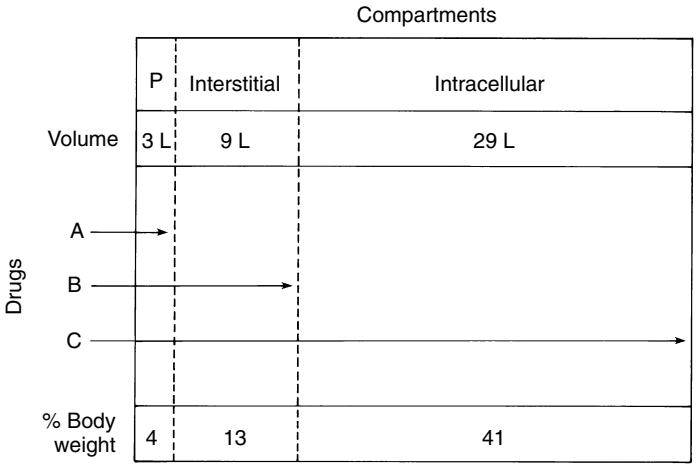

FIGURE **2-8** Body water compartments. The membrane barriers that separate plasma from interstitial fluid and interstitial fluid from intracellular water are indicated by *dashed lines*. The upper set of figures are the respective volumes for a 70-kg man; the lower set are percentages of total body weight. Of the drugs shown, *A* is restricted to the plasma, *B* is distributed within the extracellular compartment (plasma + interstitial fluid), and C is disseminated throughout the total body water.

the fetus. As in the CNS, P-glycoprotein located in the trophoblastic plasma membrane facing the maternal blood tends to prevent potentially dangerous substances from entering the fetal circulation. Nevertheless, even sparingly lipid-soluble agents eventually accumulate in the fetus if administered to the mother in multiple doses.

Concern over the placental transfer of drugs arises from the possibility of inducing toxic manifestations in the newborn and developmental defects in the embryo and fetus. These topics are discussed further in Chapter 3.

Volume of Distribution

Drugs are not distributed equally throughout the body. Although lipophilic substances tend to penetrate all tissue compartments (provided that they have a modicum of water solubility and are not actively ejected), hydrophilic compounds are often disseminated more restrictively. The volume of distribution (V_d) is a useful indicator of how drugs are dispersed among the various body compartments. In its simplest form, the V_d is calculated from the equation $V_d = Q/C$, where Q is the quantity of drug administered, and C is the plasma concentration of the drug at equilibrium. The V_d is the amount of water by which a particular dose would have to be diluted to produce a given plasma concentration, assuming that no drug has been lost through incomplete absorption or by metabolism or excretion.

Evans blue dye is typical of the few drugs that are distributed only within the vascular space. Several minutes after an intravenous injection, Evans blue becomes thoroughly mixed within the blood, and a V_d of 3 L is obtained. This value represents the total plasma volume of a 70-kg man of average build. Most compounds pass readily from the vascular tree into the interstitial compartment, however. At equilibrium, these drugs are distributed in an extracellular volume of 12 L, which includes the vascular and interstitial fluids. Ionic drugs (e.g., aminoglycosides) are generally contained in this V_d. Molecules that can freely penetrate all membranes are diluted by the water of the entire body, approximately 41 L. Figure 2-8 depicts the major body fluid volumes, and Table 2-1 provides a list of agents with representative V_d values.

It is apparent from Table 2-1 that the V_d of many compounds does not correspond to any definable anatomic fluid compartment. Accepting that the measurements were made correctly, and that problems in drug absorption and elimination were successfully avoided, several explanations remain for these results. The V_d equation provides only an apparent distribution, partly because it assumes that drugs are evenly dispersed. To illustrate this point, Na^+ is present in all body fluids (with an actual V_d of 41 L), but the apparent (calculated) V_d for Na^+ is only 18 L. This discrepancy arises because Na^+ is actively but incompletely extruded from intracellular water. Dissimilarities between true and calculated V_d values based on unequal compartment concentrations arise whenever ions are distributed across electrically polarized membranes, weak electrolytes are present in fluids of different pH, or drugs are actively transported into or out of a water space.

TABLE **2-1**

Volumes of Distribution of Various Agents

AGENT	V_d (L)	CORRESPONDING FLUID COMPARTMENT
Evans blue	3	Plasma water
Iodine 131—albumin	3	
Inulin	11	
Mannitol	12	Extracellular water
Amoxicillin	15	
Na^+	18	
Enalapril	40	
Urea	41	Total body water
Lidocaine	77	
Tetracycline	100	
Atropine	120	
Meperidine	300	
Chlorpromazine	1500	
Propofol	4000	
Chloroquine	13,000	

The enormous V_d values recorded for drugs such as propofol and chloroquine generally result from tissue binding. The sequestration of compounds within cells or certain tissues necessarily reduces the concentration of drug in the plasma, leading to an abnormally high calculation of V_d. (No drug can have a true V_d >41 L in the typical adult.) Plasma protein binding can also affect V_d determinations. Because the total drug in plasma is usually measured, binding artificially inflates the drug concentration and depresses V_d. If free drug is measured, significant binding by plasma proteins has the same effect as binding at extravascular sites.

Drug Binding and Storage

The sojourn of drugs in the body is considerably influenced by binding to proteins and other tissue components. Reducing the concentration of free solute causes a decrease in the rate of passage across membrane barriers and may alter drug dis-

TABLE **2-2**

Distribution of Drugs into Saliva

				SALIVA/PLASMA RATIO†	
DRUG	**L***	**PROTEIN BINDING (%)**	**pK_a**	**RESTING**	**STIMULATION**
Quinidine	3000	89	8.8 (b)	3.1	1.3
Sulfamerazine	0.4	88	7.1 (a)	0.69	0.55
Diazepam	820	99	3.3 (b)	1.0	1.0
Ethanol	0.5	0	—	1.0	1.0

tribution at equilibrium, as reflected in V_d determinations. Drug sequestration can also affect the processes of absorption, metabolism, and elimination.

Plasma protein binding

Numerous drugs become associated with plasma proteins, especially albumin. The predominant protein in plasma, albumin contains roughly 200 ionized functional groups per molecule and has the capacity to bind many different substances concurrently. A second plasma protein, α_1-acid glycoprotein (also known as orosomucoid), is a major "acceptor" of basic, or cationic, agents. Transcortin (which is specific for corticosteroids and a few other agents), other globulins, and various lipoproteins play more limited roles in drug binding.

The reversible attachment of drugs to plasma proteins is reminiscent of drug-receptor combinations in that the reaction obeys the law of mass action, as follows:

$$\text{Drug} + \text{Protein} \rightleftharpoons \text{Drug-protein complex}$$

This binding is capacity limited because the number of binding sites is finite. At concentrations less than the binding dissociation constant, the fraction bound is a fixed value; at concentrations greater than the dissociation constant, the fraction of drug bound varies inversely with the drug concentration. Clinically, the percentage of bound drug usually does not change over the dosage ranges used clinically, and assigning most drugs a fixed value is permissible (e.g., 99% for diazepam; Table 2-2). Drugs differ tremendously in their affinity for plasma proteins; the percentage of binding of individual agents ranges from 0% to 100%.

The binding of agents within the vascular compartment reduces the concentration gradient of free drug across the capillary membrane and slows egress from the plasma into the extravascular space. As free molecules leave the circulation, a portion of the bound drug dissociates according to the law of mass action and becomes available for further transport. The rate but not the extent of distribution is generally altered by plasma protein binding. There are exceptions. The attachment of Evans blue is so tight that the compound is retained virtually in toto within the bloodstream. For a drug that is 95% bound in plasma, a little more than half of the total dose would remain intravascular, assuming that the agent is not sequestered elsewhere. Drugs that are extensively but reversibly bound to plasma proteins generally bind to tissue elements as well, however, decreasing the fraction of drug in the plasma to less than one third the total even in the most extreme cases. Contributing to extravascular binding is the fact that approximately 60% of the body's total albumin is extravascular, with about 4% of the total albumin content exchanging between the two compartments every hour.

The reversibility of binding causes the plasma proteins to act as a drug reservoir. Agents must occasionally be administered in large loading doses to saturate binding sites as a prelude to achieving therapeutic concentrations at the site of action. When accommodated, reservoirs of bound drug can provide certain benefits. Fluctuations in drug concentration resulting from intermittent dosage schedules may be kept to a minimum. As the dose is absorbed, a portion becomes bound, only to be released later as metabolism and excretion reduce free drug titers. Also, drug binding often prolongs the duration of action, which may permit administrations to be spaced more conveniently than would otherwise be possible.

Glomerular filtration and passive hepatic uptake involve only free drug; significant binding may depress the metabolism and excretion of drugs. When compounds are actively or otherwise rapidly taken up by organs of elimination, however, the instantaneous reversibility of binding can lead to a faster-than-normal elimination rate. Penicillin G is secreted into the urine so efficiently that blood flowing through the kidney is almost completely cleared of the antibiotic in a single pass. Because albumin binding presents the kidney with more total drug per unit time, secretion is quicker than would be the case if the drug were more evenly distributed throughout the body.

Two potential clinical concerns related to plasma protein binding involve patient variability in binding efficacy and the possibility for drug interaction. Differences in drug binding affect the concentration of free drug within the bloodstream and may lead to insufficient therapy on the one hand and overdosage on the other. The unusual susceptibility to diazepam exhibited by patients with hypoalbuminemia should be considered when the drug is used for intravenous sedation.[16] Inasmuch as the attachment of drugs to plasma proteins is generally less selective than are drug-receptor associations, competition between drugs for binding sites is relatively common. Such interactions may reach clinical significance, however, only when the drugs are highly bound, are administered in large doses, and have a narrow margin of safety or a small V_d.

Tissue binding

As previously mentioned, drugs capable of associating with plasma proteins are also likely to bind to tissue constituents. Such binding does not impede the movement of drugs out of the bloodstream, but it does slow the rate of elimination. By virtue of its aggregate size, muscle tissue is a significant reservoir for many drugs. Fat is also quantitatively important, especially for highly lipid-soluble compounds. Although uptake into fat is limited by a parsimonious blood supply, adipose tissue constitutes 10% to more than 50% of total body weight, and most of an administered dose of a lipophilic drug may

accumulate in fat over the course of several hours. Certain tissues display unusual affinities for particular drugs. The antimalarial agents chloroquine and quinacrine are heavily concentrated in the liver. Guanethidine and other quaternary ammonium compounds adhere to negatively charged residues in mucous secretions of the gastrointestinal tract.

The attachment of drugs to drug receptors warrants special comment. Important in the pharmacologic sense, the contribution of drug-receptor interactions to the total amount of binding is usually quite small. When distribution throughout the body and the various types of sequestration are considered, the percentage of drug administered that actually reaches its receptor to evoke a response is quantitatively negligible.

Storage

The association between drugs and tissue elements is sometimes so stable that discussing such binding in terms of storage is appropriate. When drugs are stored, they are not readily available for release and generally do not prolong the duration of action. Some of the most common examples of storage involve mineralized tissues and fat. Bone-seeking ions such as F^- and lead, and Ca^{++} chelators such as the tetracyclines, may be deposited with bone salts during mineralization or become associated with existing hydroxyapatite crystals. Essentially in an insoluble state, these substances are difficult or impossible to remove completely. Bone and tooth mineralization may benefit from appropriate concentrations of F^-, but most drug-induced alterations are detrimental. In the case of radioactive metals (e.g., strontium 90), storage in bone can lead to the development of leukemia, osteogenic sarcoma, and other forms of neoplasia. Zoledronic acid is exceptional in that storage in bone does lead to an extended duration of action. Given once a year for the treatment of postmenopausal osteoporosis, zoledronic acid is taken up by new bone formed during remodeling and is sequestered. Later, as osteoclasts restart bone turnover in the same area, zoledronic acid is released to inhibit further activity.

Several general anesthetics (e.g., sevoflurane) and some lipophilic insecticides (e.g., chlorophenothane, otherwise known as DDT) are commonly sequestered in fat. Although not usually dangerous when stored, the slow release of these substances has been linked to various health problems.[31,41] Plasma proteins are generally not associated with drug storage, yet the now-obsolete radiocontrast medium 3-hydroxy-2,4,6-triiodo-α-ethylhydrocinnamic acid exhibited a binding half-life ($t_{1/2}$; in this case, the time required for half of the bound drug to dissociate from albumin) of approximately 2.5 years.

Redistribution

Strongly lipophilic drugs, especially when administered intravenously in bolus form, characteristically go through several phases of distribution: an initial transfer into vessel-rich organs (brain, heart, kidneys, liver, and lungs) followed by progressive redistribution to less highly vascularized tissues (muscle, skin, and eventually fat). When the target organ of a drug happens to have a high blood flow per unit mass, redistribution can result in the abrupt termination of drug effect. Thiopental has been extensively studied in this regard (Figure 2-9).[32] The onset of anesthesia with thiopental is almost instantaneous; however, consciousness is lost only temporarily, and the patient normally awakens in approximately 15 minutes. The quick onset and brief duration of thiopental reflect the rapidity by which the agent equilibrates between the blood and the CNS. Soon after a peak brain titer is reached (in 30 to 90 seconds), the concentration begins to decrease as thiopental continues to be absorbed by the relatively large mass of muscle. Consciousness returns at about the same time muscle reaches equilibrium with the blood. Thereafter, the brain and muscle concentrations parallel the plasma decay curve as the drug slowly passes into adipose tissue. With a metabolic $t_{1/2}$ of approximately 10 hours, thiopental would be a relatively long-acting drug if not for redistribution. When repetitive injections saturate the fat reservoir, thiopental assumes the characteristics of a long-duration anesthetic.

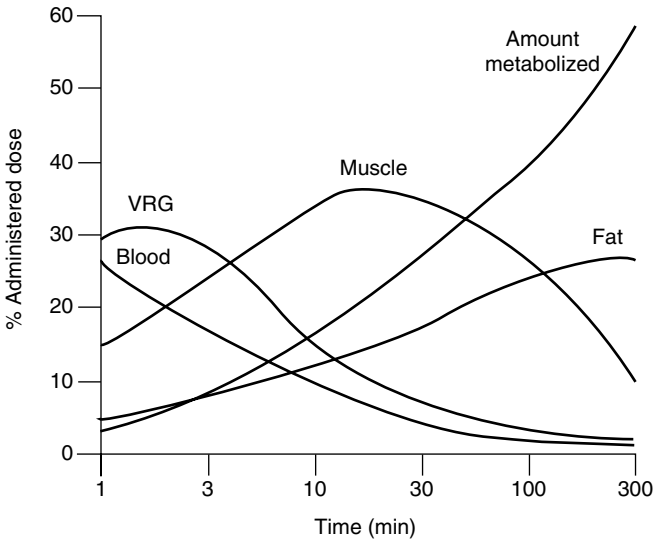

FIGURE **2-9** Redistribution of thiopental. *VRG,* Vessel-rich group tissues, including the brain, heart, lungs, kidneys, and liver. (Redrawn from Saidman LJ: Uptake, distribution and elimination of barbiturates. In Eger E II, editor: *Anesthetic uptake and action*, Baltimore, 1974, Williams & Wilkins.)

Saliva

The transfer of drugs into saliva can be thought of as a form of redistribution because the drugs regain access to the systemic circulation after the saliva is swallowed. Although not involved in drug elimination, the entry of agents into the saliva is of pharmacologic interest in two other respects. First, drugs gaining access to the oral environment from the systemic circulation can affect microorganisms or tissue surfaces within the mouth. Although these influences are usually undesirable, a drug developed for a local effect, such as caries prevention, could conceivably be administered systemically to achieve a sustained therapeutic concentration in the saliva, while obviating the necessity of intraoral application. The second pharmacologic interest in saliva stems from the fact that salivary drug determinations can provide a noninvasive measure of the free plasma concentration of drugs. Because the free drug concentration in plasma is normally the primary determinant of patient response, the benefit of salivary drug quantitation to therapeutics is potentially great. Clinical studies have documented a complex relationship between plasma and salivary drug titers that must be fully understood before salivary monitoring can be successfully used.[4,46]

Drugs may enter the oral fluids from several sources: (1) passive diffusion across the alveolar and ductal cells of salivary glands, (2) active transport into saliva, (3) passive diffusion across the oral epithelium, and (4) bulk flow of fluid from the gingival crevice. Of these avenues, the first is the most important, and the fourth is the least important (except for drugs that cannot gain entry by either of the other routes). As shown in Table 2-2, the salivary concentration of a drug is influenced by many factors.[11] Agents that are relatively lipid soluble (e.g., diazepam) or very small in size (e.g., ethanol) normally encounter little difficulty in equilibrating with saliva. Because only the unbound portion of a drug is involved in distribution across membranes, and the salivary compartment is quite

small with respect to the total intravascular space, protein binding does not affect the saliva/plasma ratio of the free drug (e.g., diazepam and acetaminophen). Regarding weak electrolytes, the disparity in pH between the plasma and the more acidic saliva results in the concentration of bases with a pK_a greater than 5.5 in saliva (e.g., quinidine) and an opposite effect on acids with a pK_a less than 8.5 (e.g., sulfamerazine). Finally, the rate of salivary flow can alter intraoral concentrations in at least two ways. Increased salivary production may outpace the diffusion rate of drugs with moderate to low lipid solubility (e.g., acetaminophen), reducing the saliva/plasma ratio. Additionally, the pH of stimulated saliva tends to approach 7.4, eliminating the unequal distribution of drugs based on pH (e.g., quinidine). With some weak acids, these two influences on drug concentration may tend to cancel each other out (e.g., sulfamerazine).

Active transport is a wild card with respect to predicting drug entry into saliva based on physicochemical characteristics. Digoxin is actively secreted into saliva by P-glycoprotein, effectively doubling the expected saliva/plasma ratio of 1/1 for a neutral drug with good lipid solubility. Coadministration of P-glycoprotein inhibitors significantly reduces the saliva/plasma ratio, as do polymorphisms that alter P-glycoprotein activity.[5]

METABOLISM

Metabolism is a major pathway for the termination of pharmacologic effects of drugs, and is often a prerequisite for the excretion of lipid-soluble chemicals. From an evolutionary standpoint, mechanisms for the biotransformation of lipophilic substances to compounds with reduced lipid/water partition coefficients seem necessary for terrestrial vertebrate life. The constraint imposed on land animals to eliminate waste products in limited volumes of water precludes the excretion of drugs with high lipid solubility. In humans, the kidney represents the major pathway for drug excretion. All drugs that exist free in the plasma are present in the glomerular filtrate. Polar compounds tend to remain within the renal tubule during the resorptive phase of urine formation, whereas lipophilic chemicals diffuse back into the systemic circulation. Because the urinary concentration of a lipid-soluble nonelectrolyte should theoretically equal the free plasma titer, the rate of renal excretion (given a normal urinary output of 1 L/day to 1.5 L/day) is small for a drug having a reasonably large V_d. Creatures in an aquatic habitat have little difficulty in eliminating lipophilic chemicals, however. Substances with a high lipid/water partition coefficient readily diffuse across the gill membrane and are lost to the surrounding water. The highly developed enzyme systems for metabolizing drugs in terrestrial species are often absent in marine and freshwater organisms.

Historically, the term *detoxification* was used in reference to drug metabolism. Although many compounds are rendered pharmacologically inert by metabolic attack, this is not always the case. Numerous drugs yield metabolites with full or partial activity, and some provide derivatives with novel or highly toxic drug effects. An increasing number of agents require chemical activation to be of therapeutic benefit (e.g., cyclophosphamide, mercaptopurine, methyldopa, and sulindac). The best generalization that can be drawn concerning drug metabolism is that agents are eventually converted to polar, relatively lipid-insoluble compounds that are susceptible to renal or biliary excretion or both.

Drug metabolism can be categorized according to the types of reactions involved and where they occur. Nonsynthetic reactions include the various transformations of molecular structure: oxidation, reduction, and hydrolysis. These events are also called phase I reactions because they often represent the initial stage of biotransformation. A common outcome of phase I reactions is the addition or uncovering of one or more functional groups: —COOH, —NH_2, —O, —OH, or —SH. Synthetic, or phase II, reactions consist of the conjugation of drugs or their metabolites with functional groups provided by endogenous cofactors. Drugs may be metabolized by virtually any organ of the body, but quantitatively the most important enzyme systems for the biotransformation of exogenous substances are located in the liver.

Hepatic Microsomal Metabolism

Each hepatocyte contains an extensive network of smooth endoplasmic reticulum that catalyzes the metabolism of various endogenous chemicals (e.g., bilirubin, thyroxine, and steroids). Studies of fragmented reticular elements isolated along with other membrane structures in the form of microsomes have shown that numerous drugs are also chemically altered by enzymes located within this subcellular organelle. The greatest number of reactions involve oxidation; however, reduction, hydrolysis, and conjugation with glucuronic acid also occur.

Oxidation

The oxidation of drugs results in compounds that tend to be more polar, relatively more hydrophilic, and less likely to penetrate cells and bind to tissue elements. Microsomal oxidations are catalyzed by a set of mixed-function oxidases, so named because one atom of an oxygen dimer is incorporated into the drug, while the other is converted to water through the addition of two hydrogen atoms. Of particular significance to microsomal oxidation is the component that actually binds the drug during metabolism, cytochrome P450 (CYP). This hemoprotein—actually a group of closely related isoenzymes—was designated P450 because of its absorption peak at 450 Å when combined in the reduced state with carbon monoxide. Approximately 18 distinct CYP families, encoded in 57 genes, have been identified in humans[37]; the major enzymes involved in drug metabolism are shown in Figure 2-10.[10]

In aggregate, the CYP superfamily constitutes up to 20% of the total protein content of liver microsomes. It acts as the terminal acceptor of electrons in a transport chain that also includes the reduced coenzyme nicotinamide adenine dinucleotide phosphate (NADPH) and the flavoprotein NADPH-cytochrome P450 oxidoreductase (Figure 2-11). A unique ability of the CYP enzymes is their collective capacity to react with a diverse array of chemicals. The only identified requirement for microsomal oxidation is that the drug sufficiently penetrate the cell membranes to reach the hemoprotein. Table 2-3 lists the major CYP enzymes in humans along with some drugs that are metabolized by them, and drugs that can inhibit or induce their activities.

The general pathway for oxidation of drugs by the hepatic microsomal enzyme system is depicted in Figure 2-12. The drug initially attaches to an oxidized (Fe^{+++}) CYP enzyme. This complex accepts an electron from the flavoprotein-catalyzed oxidation of NADPH. A ternary structure is produced next by the inclusion of molecular oxygen; the addition of a second electron and subsequently two protons causes the complex to break down, yielding the CYP enzyme, a water molecule, and the oxidized drug.

Some microsomal oxidations are carried out by a second superfamily of enzymes: the flavine monooxygenases (FMOs). The substrates for these enzymes contain nucleophilic atoms (nitrogen, sulfur, phosphorus, and selenium); they include such common drugs as nicotine and cimetidine. The products of oxidation are similar to those produced by the CYP enzymes except that reactive intermediates are rarely produced by FMOs. Because many drugs may be substrates for both enzyme superfamilies, the exact contribution made by each catalytic pathway is generally unknown for these agents.

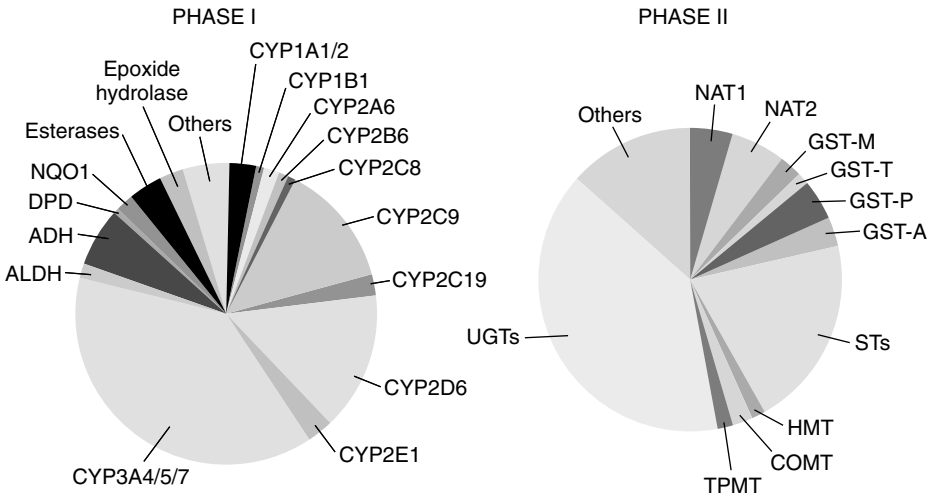

FIGURE **2-10** Major enzymes involved in drug metabolism. The percentage of phase I and phase II metabolism of drugs contributed by each enzyme is represented by the relative size of each section of the corresponding chart. *ADH*, Alcohol dehydrogenase; *ALDH*, aldehyde dehydrogenase; *CYP*, cytochrome P450; *DPD*, dihydropyrimidine dehydrogenase; *NQO1*, NAD(P)H:quinone oxidoreductase (or DT diaphorase); *COMT*, catechol-O-methyl transferase; *GST*, glutathione-S-transferase; *HMT*, histamine methyltransferase; *NAT*, N-acetyltransferase; *STs*, sulfotransferases; *TPMT*, thiopurine methyltransferase; *UGTs*, uridine diphosphate glucuronosyltransferases. (Adapted from Evans WE, Relling MV: Pharmacogenomics: translating functional genomics into rational therapeutics, *Science* 286:487-491, 1999.)

FIGURE **2-11** Location of cytochrome P450 *(CYP)* in the endoplasmic reticulum *(ER)*. The figure shows increasingly microscopic levels of detail, sequentially expanding the areas within each black box. CYPs are mostly embedded in the cytoplasmic surface of the ER membrane. A second enzyme, NADPH-cytochrome P450 oxidoreductase, transfers electrons to CYP, where it can, in the presence of molecular oxygen, oxidize xenobiotic substrates, many of which are hydrophobic and dissolved in the ER. A single oxidoreductase species transfers electrons to all CYP isoforms in the ER. Each CYP contains an iron-protoporphyrin ring that binds and activates the oxygen. Substitutions on the ring are methyl *(M)*, propionyl *(P)*, and vinyl *(V)* groups. (From Gonzalez FJ, Tukey RH: Drug metabolism. In Brunton LL, Lazo JS, Parker KL, editors: *Goodman & Gilman's the pharmacological basis of therapeutics*, ed 11, New York, 2006, McGraw-Hill.)

TABLE **2-3**

Major Cytochrome P450 Enzymes and Representative Substrates, Inhibitors, and Inducers

CYP	SUBSTRATES	INHIBITORS	INDUCERS
1A1/2	Acetaminophen, amitriptyline, caffeine, clozapine, estradiol, haloperidol, imipramine, mexiletine, naproxen, ondansetron, propranolol, ropivacaine, tamoxifen, theophylline, *R*-warfarin, zileuton	Amiodarone, cimetidine, ciprofloxacin, clarithromycin, erythromycin, grapefruit juice, insulin, ticlopidine	Benzo[*a*]pyrene, broccoli, chargrilled meat, modafinil, nafcillin, omeprazole, rifampin
2A6	Acetaminophen, halothane, nicotine, nitrosamines, valproic acid	Azole antifungals, pilocarpine, tranylcypromine	Barbiturates, dexamethasone, rifampin
2B6	Bupropion, cyclophosphamide, ifosfamide, methadone	Amlodipine, methimazole, thiotepa, tretinoin	Barbiturates, dihydropyridines, ifosfamide, lovastatin, rifampin
2C8/9	Amitriptyline, celecoxib, fluoxetine, fluvastatin, losartan, nonsteroidal anti-inflammatory drugs, oral hypoglycemics, phenobarbital, phenytoin, sulfaphenazole, *S*-warfarin, tamoxifen	Amiodarone, azole antifungals, fluvastatin, lovastatin, metronidazole, paroxetine, ritonavir, sertraline, trimethoprim, zafirlukast	Barbiturates, dihydropyridines, ifosfamide, rifampin
2C18/19	Amitriptyline, citalopram, diazepam, indomethacin, naproxen, phenobarbital, phenytoin, primidone, progesterone, propranolol, proton pump inhibitors	Chloramphenicol, cimetidine, fluoxetine, fluvoxamine, ketoconazole, modafinil, omeprazole, paroxetine, ticlopidine, topiramate	Aspirin, barbiturates, carbamazepine, norethindrone, rifampin
2D6	Amphetamine, β-adrenergic blockers, chlorpheniramine, clomipramine, clozapine, codeine, dextromethorphan, encainide, flecainide, fluoxetine, haloperidol, hydrocodone, metoclopramide, mexiletine, ondansetron, oxycodone, paroxetine, propoxyphene, risperidone, selegiline, thioridazine, tramadol, tricyclic antidepressants, venlafaxine	Amiodarone, antipsychotics, celecoxib, cimetidine, cocaine, fluoxetine, methadone, metoclopramide, paroxetine, quinidine, ritonavir, sertraline, terbinafine, ticlopidine, venlafaxine	Dexamethasone, rifampin
2E1	Acetaminophen, ethanol, sildenafil, theophylline, volatile inhalation anesthetics	Disulfiram, propofol, tricyclic antidepressants	Colchicine, ethanol, isoniazid, tretinoin
3A4/5/7	Acetaminophen, alfentanil, alprazolam, amiodarone, atorvastatin, buspirone, chlorpheniramine, cocaine, cortisol, cyclosporine, dapsone, diazepam, dihydroergotamine, dihydropyridines, diltiazem, dronabinol, ethinyl estradiol, fentanyl, indinavir, lidocaine, lovastatin, macrolides, methadone, miconazole, midazolam, mifepristone, modafinil, ondansetron, paclitaxel, progesterone, quinidine, ritonavir, saquinavir, sildenafil, spironolactone, sufentanil, sulfamethoxazole, tacrolimus, tamoxifen, testosterone, trazodone, triazolam, verapamil, zaleplon, zolpidem	Amiodarone, atazanavir, chloramphenicol, cimetidine, ciprofloxacin, clarithromycin, dihydroergotamine, diltiazem, doxycycline, erythromycin, felodipine, fluoxetine, fluvoxamine, glucocorticoids, grapefruit juice, HIV antivirals, itraconazole, ketoconazole, nefazodone, sildenafil, verapamil	Barbiturates, carbamazepine, glucocorticoids, ifosfamide, modafinil, nevirapine, phenytoin, rifampin, St. John's wort, troleandomycin

HIV, Human immunodeficiency virus.

The oxidation of a drug may lead to several different derivatives. Oxygen may be incorporated in the form of an alcohol, aldehyde, epoxide, ketone, or carboxylic acid in such structures as aliphatic residues, aromatic rings, amino groups, and sulfur moieties. Oxygen may also replace a sulfur atom (desulfuration) or an amino group (deamination), or it may not appear in the metabolite at all but become attached to a hydrocarbon unit released during the dealkylation of nitrogen, oxygen, or sulfur. The various types of microsomal oxidations are reviewed along with other phase I reactions in Table 2-4.

Reduction

The microsomal reduction of drugs is limited to molecules with nitro or carbonyl groups or azo linkages. Similar reactions may also be mediated by nonmicrosomal enzymes of the body, but most reductions of this variety seem to result primarily from the action of enteric bacteria. When reduction occurs at one site in a molecule, oxidation usually takes place elsewhere, and the final product is more polar despite the initial addition of hydrogen atoms.

Hydrolysis

The hydrolysis of ester or amide compounds resulting in the production of two smaller entities, each with a polar end, occasionally depends on microsomal enzymes. The hydrolysis of the ester meperidine and the cleavage of amide local anesthetics and their oxidized metabolites are two important examples of microsomal hydrolysis. Epoxide hydrolase, responsible for the biotransformation of highly reactive and toxic intermediates formed during microsomal oxidation reactions, yields inactive dihydrodiol products.

Dehalogenation

Various compounds, such as chlorophenothane and some volatile general anesthetics (e.g., halothane and sevoflurane), are

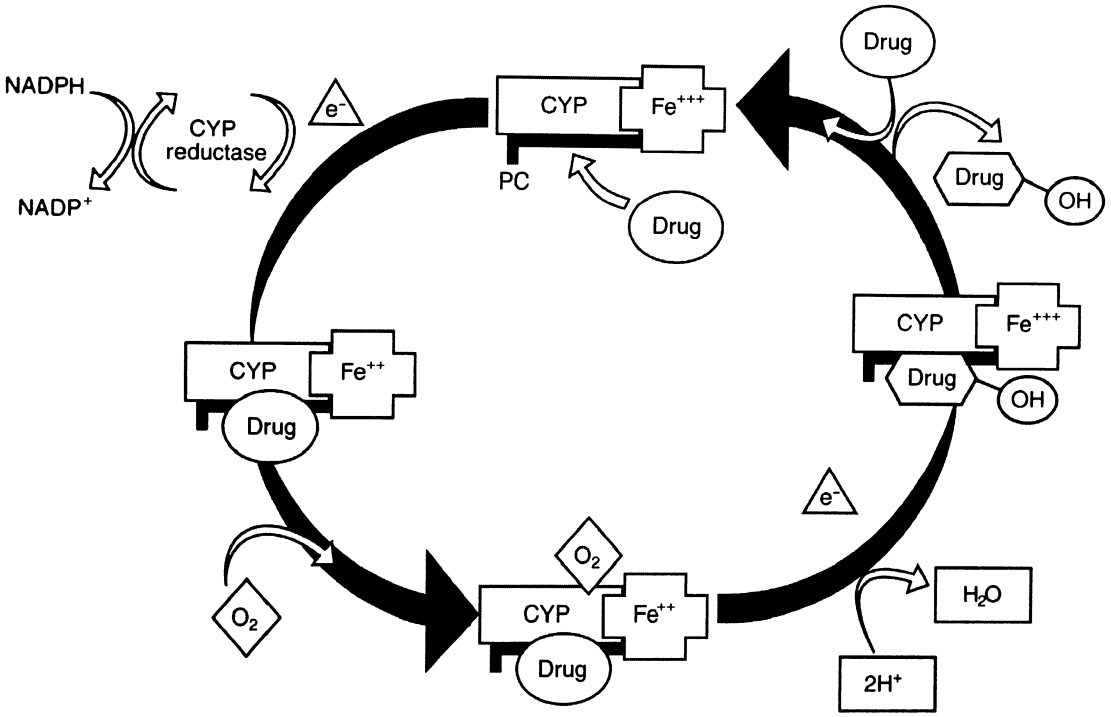

FIGURE **2-12** Microsomal oxidation. Free drug enters the cycle (*upper right*) and is complexed in the presence of phosphatidylcholine (*PC*) to CYP with its heme in the oxidized (Fe^{+++}) state. The Fe^{+++} is reduced (Fe^{++}) by an electron (e^-) generated in the oxidation of NADPH to $NADP^+$ by the enzyme NADPH–cytochrome P450 oxidoreductase (CYP reductase, *upper left*). The reduced complex absorbs molecular oxygen (O_2, *lower middle*). Addition of a second e^- and two protons ($2H^+$, *lower right*) results in the generation of one molecule of water (H_2O), oxidation of the drug (hydroxylation in this case), and oxidation of Fe^{++} to Fe^{+++}. The cycle is complete with release of the oxidized drug. (Adapted from Markey SP: Pathways of drug metabolism. In Atkinson AJ Jr, Abernethy DR, Daniels CE et al, editors: *Principles of clinical pharmacology*, ed 2, Amsterdam, 2007, Elsevier.)

dehalogenated by microsomal enzymes. The reactions are complex, may involve both oxidative and reductive steps, and may result in the formation of potentially toxic metabolites.[31]

Glucuronide conjugation

The combination of compounds with glucuronic acid is the only phase II reaction catalyzed by microsomal enzymes (in this case, by a group of glucuronosyltransferases). Originally derived from glucose, glucuronic acid is transferred from its donor, uridine diphosphate, to an appropriate reactive center on the drug molecule (Table 2-5). The glucuronide conjugate produced is excreted, often with the help of active secretion, into the bile or urine (see Figure 2-7). In contrast to many phase I reactions, conjugation with glucuronic acid almost invariably results in a total loss of pharmacologic activity. An important exception to this rule is morphine-6-glucuronide, which is 100 times more potent than morphine as an analgesic when injected into the CNS.[40] Some glucuronides excreted in the bile are subject to hydrolysis by bacterial and intestinal β-glucuronidase enzymes. If it has sufficient lipid solubility, the released drug may be absorbed again. Glucuronidation is a quantitatively significant metabolic pathway for many drugs and their metabolites; for agents such as morphine, it represents the primary mode of metabolism.

Nonmicrosomal Metabolism

The pattern of drug metabolism mediated by nonmicrosomal enzymes is considerably different from that of the microsomal system. Although important, the liver is not always predominant in nonmicrosomal biotransformations. The various major types of nonsynthetic reactions already described take place, but their relative frequencies of occurrence are dissimilar. Generally, drugs must resemble natural substrates to be metabolized by most nonmicrosomal enzymes; the spectacular lack of specificity displayed in microsomal oxidation has no counterpart here. Although cytosolic enzymes are most commonly involved, enzymes associated with the nucleus, mitochondria, and plasma membrane also play limited roles. Plasma esterase is an important example of an extracellular enzyme involved in drug metabolism.

Oxidation

Nonmicrosomal enzymes are responsible for the oxidation of numerous compounds. Selected alcohols and aldehydes are oxidized by dehydrogenases present in the cytosol of the liver. Other oxidation reactions include the oxidative deamination of drugs such as tyramine and phenylephrine by mitochondrial enzymes found in the liver, kidneys, and other organs, and the hydroxylation of the purine derivatives theophylline and allopurinol by xanthine oxidase.

Reduction

Nonmicrosomal enzymes promote the hydrogenation of double bonds and, through a reversal of the normal dehydrogenase pathway, the removal of oxygen atoms. The reduction of chloral hydrate to trichloroethanol by alcohol dehydrogenase is an often cited example of this latter type of reaction.

Hydrolysis

Most hydrolytic reactions of foreign substances depend on nonmicrosomal esterase and amidase enzymes. Nonspecific esterases are found throughout the body, but the two most

important sites, by virtue of their hydrolytic capacity and availability to drugs, are the liver and plasma. Ester local anesthetics such as procaine and benzocaine are hydrolyzed by these enzymes. Except for blood and other tissue peptidases responsible for the breakdown of pharmacologically active polypeptides, most amidase activities reside in the liver.

Conjugation reactions

A number of synthetic reactions are catalyzed by nonmicrosomal transferase enzymes. As with the microsomal synthesis of glucuronides, the body usually supplies an acidic moiety (e.g., sulfate, acetate, cysteine, glycine, glutamine, or riboside phosphate) attached to a particular cofactor or carrier molecule. The addition of methyl groups to phenols, mercaptans, and amines may lead to less polar compounds, but even here subsequent oxidation or conjugation reactions decrease lipid solubility. With amines, methylation may increase polarity, as in the formation of a quaternary ammonium cation. The quantitative contributions of the various phase II reactions are illustrated in Figure 2-10.

Conjugation with glutathione is unusual because it is directed against highly reactive metabolites, such as epoxides and quinones, and may occur with or without enzymatic support. Although a quantitatively minor pathway, glutathione conjugation is often of major importance in preventing metabolism-induced drug toxicity.

Phase II reactions can be expected whenever a drug carries one or more of the reactive centers listed in Table 2-5. Such conjugations generally result in the termination of drug effect, restriction in the apparent V_d, and acceleration of drug excretion through active secretory processes.

Nonhepatic Metabolism

Although focusing on the liver when considering biotransformation is appropriate generally, other organs contain drug-metabolizing enzymes (including members of the CYP family) and contribute to the microsomal and nonmicrosomal metabolism of drugs. This ability is occasionally taken advantage of by preparing prodrugs that become metabolically activated in target tissues. The aforementioned use of levodopa to circumvent the blood-brain barrier is an example of this approach; administration of acyclovir, an antiviral prodrug that is converted to the active nucleotide form in diseased cells (see Chapter 40), is another. By virtue of location and blood supply, certain organs play special roles in drug metabolism. As previously discussed in the context of bioavailability,

Other reactions (various)	Purines Pyrimidines Epoxides and other reactive metabolites	 **Naphthalene epoxide**

the intestine, working alone or in concert with the liver, can metabolize some drugs so completely that the oral route cannot be used for their administration. CYP3A4 is the principal enzyme involved. The kidney is well suited for drug metabolism because it has a well-developed microsomal enzyme system and receives a bountiful blood supply. Glucuronidation is an especially prominent activity.

In recent years, the role of the lung in drug disposition has been an active area of investigation. By means of the pulmonary circulation, virtually all the blood is exposed to lung tissue with each circulation. Studies have shown that the lung is a primary site for metabolism of endogenous blood-borne compounds such as bradykinin, angiotensin I, prostaglandins, and biogenic amines.[45] Its role in the biotransformation of purely exogenous compounds was discounted previously because the liver has such a high content of drug-metabolizing enzymes. This reasoning failed to account for the important influence of blood flow or drug delivery on the metabolism of some drugs. Although the activity of arylhydrocarbon hydroxylase in the liver is more than 1000 times that of the lung, the pulmonary metabolism of benzo[*a*]pyrene by this enzyme in vivo may approach or even exceed the hepatic rate.[45]

Factors Affecting Drug Metabolism

The rate of drug biotransformation depends on numerous variables, including access to the site of metabolism, the concentration and phenotype of the enzyme present, and the effect of certain agents on enzymatic activity. Because most drugs are metabolized in the liver, attention is centered on factors influencing hepatic drug biotransformation.

Entry into the liver

As stated previously, plasma protein binding can significantly reduce the rate of uptake and metabolism of drugs by the liver. Inverse correlations between the rate of biotransformation and the degree of protein binding have been reported for sulfonamides, warfarin, and phenytoin, among others.[15] A

similar relationship exists for drugs bound to extravascular reservoirs. For some compounds, however, plasma protein binding does not hinder metabolism and may even enhance it. Lidocaine and propranolol are so effectively absorbed by hepatic tissues that, even with significant binding, the clearance of these drugs from the body is primarily limited by hepatic blood flow. Because protein binding retains extra drug within the vascular compartment, more is presented to the liver per unit of time for metabolism.

Certain disease states and drug interactions can affect the accessibility of liver enzymes to pharmacologic agents. Uremia, by reducing the binding capacity of albumin, promotes the biotransformation of some highly bound drugs. Because inflammation and stress increase the plasma concentration of α_1-acid glycoprotein, the opposite effect may occur with some basic drugs.[55] Hepatic damage can affect drug delivery to the liver in several ways. It may lead to reduced plasma protein concentrations and altered drug binding. Decreased metabolism of bilirubin and other substrates may also alter distribution of a drug and its availability for hepatic uptake. Finally, cirrhosis, cardiac insufficiency, and other conditions that reduce hepatic blood flow may significantly retard the metabolism of lidocaine and similar agents whose biotransformation is normally limited by the rate of drug delivery to the liver.

As illustrated in Figure 2-7, hepatic transporters can significantly influence the uptake of drugs by the liver. SLC transporters, including several OATs, OATPs, and OCTs, facilitate the uptake of a wide variety of xenobiotics from the hepatocyte's sinusoidal surface into the cytoplasm. Although a handful of ABC transporters, including P-glycoprotein and several MRPs, actively export numerous compounds out of hepatocytes, most of this activity is aimed at exporting drugs and their metabolites through the canalicular membrane and into the bile. (It is unclear what role ABC transporters play in pumping drugs or their metabolites directly back into the blood.) Pravastatin and related statin cholesterol-lowering drugs provide excellent examples of the critical importance of active transport to hepatic uptake. Pravastatin is a hydrophilic drug that nevertheless is taken up efficiently into the liver by OATP transporters.[35] This sequestration of pravastatin reduces the drug's systemic bioavailability to 17%, while focusing the drug's effect within the liver. This action is beneficial in two respects: (1) it augments the ability of pravastatin to depress hepatic synthesis of cholesterol; (2) it minimizes the toxic effects of pravastatin on skeletal muscle and other tissues.

Enzyme inhibition

Drug-metabolizing enzymes are subject to competitive and noncompetitive antagonism. Because so many drugs are acted on by the CYP system, competitive inhibition of microsomal oxidation is easily shown in the laboratory. Drug interactions of this type are usually not clinically important. In many instances, the rate of biotransformation is limited not by the CYP electron transport chain but by the movement of drugs into the smooth endoplasmic reticulum. Some compounds exhibit saturation kinetics, however, and are restricted in metabolism by the rate of binding to specific CYP enzymes. Competition involving these agents (e.g., phenytoin and dicumarol competing for CYP2C9) is of practical significance.

Various metabolic poisons—carbon monoxide, cyanide, heavy metals—noncompetitively inhibit microsomal biotransformation. These actions are of experimental interest only, however, because effects on respiration and other vital processes take precedence in vivo. A much more specific inhibition of microsomal oxidation is achieved with proadifen, which avidly binds to the heme iron of CYP. This compound blocks the metabolism of numerous agents dependent on CYP enzymes; it can also inhibit glucuronidation. The effect on most drugs is a prolongation of action, but compounds requiring microsomal activation may have a loss of potency. The plethora of substances affected by proadifen prohibits its use in humans; however, similar compounds have applications as potentiators of insecticides that are inactivated by microsomal biotransformation. Clinically useful drugs that inhibit the metabolism of numerous other agents by inactivating various CYP enzymes include the macrolide antibiotics (other than azithromycin), chloramphenicol, certain imidazole derivatives (cimetidine and the azole antifungals), and amiodarone (see Table 2-3). These drugs—or their metabolites—react covalently or otherwise strongly with specific sites on the CYP molecule. Gingko biloba and grapefruit juice are herbal and dietary constituents that powerfully inhibit certain classes of CYP enzymes.

Several drugs are used specifically as inhibitors of selected nonmicrosomal enzymes. When the enzyme affected happens to be responsible for the inactivation of other therapeutic agents, drug interactions are likely to develop. Examples of such enzymes are monoamine oxidase, pseudocholinesterase, and xanthine oxidase. The inhibition of aldehyde dehydrogenase by disulfiram is exceptional because that drug's primary indication is to interrupt the metabolism of another foreign compound, ethanol (see Chapter 43).

Enzyme induction

Microsomal CYP drug-metabolizing enzymes are inducible; under an appropriate chemical stimulus, catalytic activity increases. Many chemicals, including therapeutic agents, "social" drugs, and environmental toxins, are capable of stimulating their own biotransformation and the biotransformation of closely related compounds. In addition, some chemicals can augment the breakdown of a host of diverse substances. Phenobarbital illustrates this latter type of induction. On reaching the interior of the hepatocyte, phenobarbital activates a nuclear transcription factor termed the *constitutive androstane receptor*, which then migrates into the nucleus to activate genes with the appropriate response elements.[14] Several hours thereafter, an elevation in hepatic protein synthesis becomes apparent. Reductions in the metabolic half-lives of affected drugs are paralleled by increases in microsomal weight and in the concentrations of NADPH-cytochrome P450 oxidoreductase and several CYP enzymes (most importantly, CYP2B6, CYP2C8/9, CYP2C18/19, and CYP3A4/5). The liver eventually hypertrophies, and hepatic blood flow and bile secretion are likewise enhanced. Rifampin, another broad-spectrum inducer, binds to a closely related transcription factor termed the *pregnane X receptor* to initiate a similar response.

By way of contrast, benzo[*a*]pyrene exemplifies agents with a more restrictive form of induction. Although benzo[*a*]-pyrene requires new enzyme formation for its stimulation of metabolism (inhibitors of protein synthesis block its action), structural changes in the smooth endoplasmic reticulum are not prominent and may be undetectable. Enzyme induction in this case principally involves the CYP1 gene family (CYP1A1/2 and CYP1B1). The transcription factor for benzo[*a*]pyrene and many other aromatic hydrocarbons and heterocyclics is the aryl hydrocarbon receptor.

Regardless of the pattern of induction, the rate of metabolism of affected compounds may be enhanced experimentally by seven times the baseline. Stimulation is usually less pronounced clinically; nevertheless, enzyme induction has many important therapeutic ramifications. It is a major cause of drug interactions. A classic example of this form of drug interaction is the stimulation by phenobarbital of the metabolism of the anticoagulant dicumarol, which causes standard doses of the anticoagulant to be ineffective.[9] Induction of microsomal enzymes leading to a loss of pharmacologic responsiveness is referred to as *pharmacokinetic tolerance*. Finally, enzyme induction may affect the function of endogenous chemicals metabolized microsomally. Acceleration of vitamin D oxida-

tion to yield inactive products is the leading cause of rickets and osteomalacia in epileptic patients receiving medications such as phenytoin and phenobarbital.[18]

It would seem an obvious outcome that enzyme induction should decrease drug toxicity in concert with any reduction in drug potency. This is not always the case, however. Of strong concern in the field of toxicology is the potential danger posed by highly reactive intermediary substances produced during microsomal oxidation of drugs such as acetaminophen, halothane, and benzo[*a*]pyrene.[39] These substances are normally synthesized in such limited quantities that succeeding reactions, including hydrolysis and glutathione conjugation, inactivate them before cellular injury can ensue. Selective microsomal enzyme induction may sufficiently increase their synthesis that subsequent protective reactions become overwhelmed. In agreement with this thesis is a report in which cigarette smokers who exhibited high inducibility of arylhydrocarbon hydroxylase activity, which converts benzo[*a*]-pyrene and related polycyclic hydrocarbons into epoxide intermediates, were estimated to have a 36-fold increased risk of developing bronchogenic carcinoma than individuals having low inducibility.[22]

Transporter inhibition and induction

Interactions that result in decreased or increased active transport of drugs to and from their sites of metabolism show many similarities to those described earlier for drug-metabolizing enzymes. P-glycoprotein is the most conspicuous example. Biologically, P-glycoprotein and CYP3A4 seem to act in a coordinated fashion to protect cells from toxic compounds. Both proteins share considerable overlap in substrate specificity. Most of the inhibitors for CYP3A4 listed in Table 2-3 also block P-glycoprotein transport, and drugs that activate the pregnane X receptor (e.g., rifampin) induce the formation of both proteins. Although P-glycoprotein exports drugs in the intestine back into the luminal space, it exposes the drugs to CYP3A4 metabolism during the process. In the liver, the principal action of P-glycoprotein is to convey drugs and their metabolites into the bile. This action ensures that the compounds either are excreted via the feces or are subjected again to intestinal and hepatic biotransformation.

The SLC transporters responsible for the active and facilitated uptake of drugs by the liver are subject to inhibition by various agents. With regard to the previously mentioned pravastatin, the antidiabetic drug repaglinide can completely block pravastatin uptake by OATPB1 in vitro.[3] Potential consequences of this inhibition include loss of therapeutic effect within the liver and increased systemic toxicity elsewhere. A case report of acute myopathy in a women taking pravastatin and colchicine underscores the potential for this interaction.[2] In contrast to P-glycoprotein, little is known about induction of SLC transporters other than complex patterns of induction and inhibition have been reported for drugs that activate transcription factors such as the pregnane X receptor.

Genetic factors

Individuals vary in their ability to metabolize drugs. Although differences can result from the environmental induction of microsomal enzymes (as seen in chemical factory workers and cigarette smokers), studies comparing identical and fraternal twins have conclusively established the preeminent influence of heredity on the rate of biotransformation.[54] For some drugs, the range in metabolic $t_{1/2}$ may exceed an order of magnitude, but usually this figure is restricted to a value of two or three. The ability to metabolize a particular type of compound at an abnormal rate does not usually signify anything concerning the biotransformation of unrelated substances. Normal individuals exhibiting the lowest microsomal metabolism rates are the most likely to undergo profound enzyme induction after phenobarbital treatment, however.[54]

Genetic influences on metabolism are most easily characterized when single genes are involved. A good example of this principle is provided by the plasma enzyme pseudocholinesterase. Approximately one individual in 3000 is homozygous for an atypical gene whose enzyme product metabolizes esters very slowly. A conventional dose of the muscle relaxant succinylcholine produces prolonged apnea in these patients. Individuals with a combination of typical and atypical genes (heterozygotes) still have enough normal enzyme to hydrolyze the drug fast enough to avoid unusual clinical manifestations. Since the discovery of the atypical gene for pseudocholinesterase, other novel genotypes have been described, including one that is "silent" (its product has no enzymatic activity whatsoever) and one that yields an enzyme so effective in catalysis that patients with it exhibit a remarkable innate resistance to the paralyzing effect of succinylcholine. The pharmacogenetics of drug metabolism are explored more fully in Chapter 4.

Information is accumulating that genetic differences in transporter expression may alter drug metabolism. In the case of pravastatin, several studies have documented polymorphisms that result in markedly increased pravastatin concentrations in a small percentage of patients exposed to the drug.[25]

Age

Neonates, especially premature infants, often lack certain functional drug-metabolizing systems. The relative inability to conjugate bilirubin with glucuronic acid and the resultant development of hyperbilirubinemia is a commonly observed example of this deficiency in biotransformation. The failure to account for marked quantitative differences in neonatal metabolism is highlighted by the "gray syndrome" and infant death associated with chloramphenicol. In contrast to newborns, children are often more adept at metabolizing drugs on a weight basis than are young adults.[52] Thereafter, biotransformation capacity seems to diminish with age; elderly individuals may often exhibit retarded rates of drug metabolism.

Pathology

Significant destruction of the hepatic parenchyma with loss of drug-metabolizing enzymes can directly depress the biotransformation of many agents. The clinical effect may be quite small, however, because of the liver's reserve metabolic capacity and enzyme induction in the unaffected tissue. (See Chapter 3 for further discussion of hepatic dysfunction and patient response.)

A more subtle effect of pathology is exemplified by the influence of infection on hepatic metabolism.[43] Viral illnesses have been linked to depression of CYP activity and inhibition of the microsomal oxidation of theophylline and a few other drugs. Interferons produced in response to these diseases or to vaccines prepared from disrupted virions may cause the inhibition. Several nonviral infections, such as malaria, leprosy, and various forms of pneumonia, have also been associated with impaired drug biotransformation.

Finally, endocrine derangements may alter drug metabolism. Hypothyroidism may slow biotransformation of certain drugs; hyperthyroidism tends to have the opposite effect. In animals, derangements of the pituitary gland, adrenal cortex, and gonads have been shown to affect drug metabolism; whether similar effects occur in humans is unknown.

EXCRETION

Foreign substances, including therapeutic medications, are prevented from building up in the body by the combined action of metabolism and excretion. Drugs and their metabolites may be eliminated by numerous routes, including urine,

bile, sweat, saliva and other gastrointestinal secretions, pulmonary exhalation, tears, and breast milk. Quantitative considerations make the kidney the major organ of drug excretion.

Renal Excretion

Three processes—glomerular filtration, tubular reabsorption, and active transport—control the urinary elimination of drugs. Although all drugs are subject to filtration, the percentage filtered varies inversely according to the degree of plasma protein binding and to the V_d. When filtered, agents tend to be resorbed in relation to their lipid/water partition coefficients. These considerations favor the renal excretion of highly polar compounds, but the exact rate of elimination also depends on whether active transport into (or, rarely, out of) the tubular fluid occurs.

Glomerular filtration

Each day, the kidneys filter approximately 180 L of plasma. Arterial blood entering Bowman's capsule is routed through a tuft of capillaries collectively described as the glomerulus. These capillaries are uniquely modified for filtration, having large numbers of pores with an effective diameter to 80 Å penetrating through the endothelium. Because these pores are sufficiently large to allow passage of all but the cellular elements of blood, the actual filtration barrier is provided by the thick basement membrane. Large amounts of negatively charged glycosaminoglycans help to repel albumin and other plasma proteins from entering the nephron. Approximately one fifth of the plasma entering the glomerular apparatus is actually filtered; the remainder exits by way of efferent arterioles to supply other portions of the nephron. Generally, molecules smaller than albumin (molecular weight 69 kDa) appear in the tubular fluid. Because plasma proteins are almost completely retained within the bloodstream, bound drugs are not subject to filtration.

Tubular reabsorption

Only about 1.5 L of urine is excreted every 24 hours (<1% of the daily filtered load); the kidney must have an efficient reabsorption system. Were this not the case, a person would lose valuable fluid and nutrients and quickly die. Approximately 80% of the glomerular filtrate is reclaimed by the proximal convoluted tubule. A high-capacity pump actively transports Na^+ back into the bloodstream, with anions (principally Cl^-) and water following passively. This process continues throughout the nephron and is aided by specific transport systems, such as in the ascending loop of Henle, where cotransport of Na^+, K^+, and Cl^- occurs. In addition, the reabsorption of Na^+ is aided by its exchange with H^+ and, in the distal convoluted tubule, K^+. The resultant concentration of the tubular fluid creates a chemical gradient for the diffusion of drugs back into the systemic circulation. Agents with a favorable lipid/water partition coefficient readily traverse the tubular epithelium and escape from the urine.

A major factor influencing the reabsorption of weak electrolytes from renal tubular fluid is the pH. Depending on the rate of H^+ secretion, the urinary pH may vary from 4.5 to 8.0. Weak acids such as aspirin and phenobarbital are reabsorbed more effectively under acidic conditions; the reverse is true for weak bases such as amphetamine and ephedrine. Occasionally, the influence of pH on drug excretion is used to clinical advantage. A common strategy in the face of aspirin toxicity is to promote salicylate elimination through alkalization of the urine by the systemic administration of sodium bicarbonate. For the sulfonamides (also weak acids), alkalization of the urine may reduce the plasma $t_{1/2}$ by 50% and prevent the development of crystalluria by increasing aqueous solubility.[15] Attempts to enhance renal excretion are of little value for agents whose inactivation depends largely on biotransformation.

Active secretion

Numerous organic anions and cations are actively secreted by cells of the proximal convoluted tubule (see Figure 2-7). The anionic transport system, responsible for the secretion of amphiphilic anions and conjugated metabolites (e.g., glucuronides, sulfates), relies primarily on two basolateral transporters—OAT1 and OAT3—to take up anions (and some neutral and even cationic drugs). These antiporters exchange intracellular α-ketoglutarate for the interstitial anions. Transfer of the now intracellular organic anions into the urine principally involves the Na^+/phosphate transporter-1 (NPT-1) and two ABC transporters (MRP2 and MRP4). Because each transport carrier is nonselective, competition for binding sites is sometimes observed. Probenecid, an acidic anion, has been used to block the active secretion of another acid, penicillin G. The inhibition of penicillin secretion by NPT-1 was beneficial at a time when the drug was in short supply and is still used when it is necessary to maintain a high concentration of the antibiotic for prolonged periods.

Vectorial transport of organic cations also involves SLC transporters (OCT1, OCT2, OCT3) on the basolateral side of the tubular epithelium and a mix of transporters on the luminal side. Because of a favorable electrochemical gradient for cations, energy is not required for facilitated transport of extracellular cations. When inside, the compounds are pumped into the urine by one or more transporters, including P-glycoprotein, OCT3, OCTN1, and OCTN3.

Specific transport systems of the kidney, found principally in the distal convoluted tubule, also exist to reabsorb specific agents actively. The most important active reuptake of organic ions by this mechanism involves uric acid. Because probenecid can compete with urate ions as readily as it can with penicillin, probenecid has an application in gout as a promoter of uric acid excretion.

Active secretion of substances into the urine is not adversely affected by plasma protein binding. The transport is often so effective that drug dissociation occurs instantly, making available more drug for secretion, until all the drug has been cleared from the local blood supply. Binding to extravascular tissues does reduce the rate of renal elimination, however, regardless of the mechanisms involved.

Clearance

The amount of drug removed by the kidney per unit of time is often evaluated as a function of the plasma water "cleared" of drug. Mathematically, the volume of plasma cleared per minute (CL) can be written as $CL = U \times V/P$, where U is the urinary concentration of drug, V is the volume of urine produced per minute, and P is the plasma concentration. The clearance and V_d are related by the simple formula $CL = k_e \times V_d$, where k_e is the elimination rate constant. Agents that are filtered but not resorbed or secreted, such as inulin, yield a clearance of 130 mL/min (assuming no plasma protein binding), and serve as a measure of the glomerular filtration rate. With a V_d of 12 L, this clearance rate translates into a plasma $t_{1/2}$ for inulin of 64 minutes. Compounds actively secreted into the urine and not reabsorbed, such as penicillin G and *p*-aminohippurate, may approach a clearance of 650 mL/min, which is the rate of total plasma flow through the kidneys. Assuming a V_d of 12 L, such a drug would have a plasma $t_{1/2}$ of approximately 13 minutes. By way of contrast, drugs that are highly bound and subject to passive reabsorption may exhibit clearance rates approaching 0.

Biliary Excretion

Numerous cationic, anionic, and steroid-like molecules are selectively removed from the blood for excretion into the bile and eventually the feces. Generally, these substances have molecular weights exceeding 500 Da. The transport

process is an active one in which the dissolved substance is transferred from the plasma to the hepatocytes and then to the bile, as described previously for drugs that are metabolized. The bile is also a route of excretion for metabolized drugs, especially drugs that have undergone phase II reactions such as glucuronidation.

Biliary excretion is responsible for all but a small portion of the fecal elimination of drugs. The remainder results from direct transmucosal passage into the gastrointestinal tract from the bloodstream or represents compounds dissolved in one or more gastrointestinal tract secretions. The feces may also contain a variable amount of unabsorbed drug. Reabsorption of molecules excreted through the bile can occur, such as with the laxative phenolphthalein. Such enterohepatic recycling can prolong the duration of action and may continue *ad infinitum* until the system is interrupted (e.g., by metabolism, curtailment of bile flow, or ingestion of a drug chelator).

Other Routes of Excretion

Pulmonary excretion is a primary route for the elimination of gases and some volatile compounds. Except for the inhalation anesthetics, however, excretion of chemicals into the respiratory tree may be of more aesthetic concern than pharmacokinetic interest. Halitosis produced by odoriferous agents (e.g., paraldehyde) may impair clinical suitability.

Elimination of drugs by breast milk is important, not because of any quantitative significance, but because it represents a potential danger to the nursing infant. Drugs of particular concern include lithium, various anticancer agents, and isoniazid.[7] The primary variable influencing the passage of drugs into milk is lipid solubility.

Other minor routes of excretion include sweat; tears; saliva; and gastric, pancreatic, and intestinal secretions. In all cases, excretion is limited by the lipid/water partition coefficient. For saliva and related gastrointestinal fluids, drugs are deposited into the gastrointestinal tract after secretion and are available for reabsorption into the systemic circulation.

TIME COURSE OF DRUG ACTION

The close correspondence between the plasma concentration of an agent and its magnitude of effect has already been emphasized. Because drug administration usually encompasses the linear midrange of the log dose-response curve, the relationship between plasma titer and patient reaction is often straightforward. A temporal description of drug concentration on the basis of pharmacokinetic principles is useful in illustrating how absorption, distribution, metabolism, and excretion influence drug effects in concert and provides guidance for adjusting dosage schedules to achieve therapeutic results with a minimum of drug toxicity.

Kinetics of Absorption and Elimination

Most biologic events involving the fate of drugs can be described in simple kinetic terms: zero order, first order, or capacity limited (a combination of the two).

Zero-order kinetics

Zero-order kinetics define processes that occur at a constant rate per unit of time. Mathematically, this can be written as $dC/dt = k_0$, where dC/dt is the rate of change in concentration, and k_0 is a constant in units of amount per time. A good example of zero-order input of drugs is the continuous intravenous infusion in which the quantity of compound entering the bloodstream each minute is held constant (e.g., 5 mg/min). Another example of zero-order absorption is provided by the intramuscular or subcutaneous injection of a depot form of drug. Poor aqueous solubility of the preparation permits a constant rate of drug release for hours to days. With oral administration, essentially zero-order absorption is realized whenever the rate-limiting factor is the dissolution of the primary drug particles. Finally, topical therapy often results in zero-order uptake. As long as the agent is in great excess, a relatively fixed quantity of drug permeates the skin per unit of time.

First-order kinetics

First-order kinetics relate to events that occur at a constant fractional rate per unit of time (e.g., 5%/min). Here $dC/dt = k_1C$, with k_1 representing the fractional rate constant in units of $time^{-1}$ and C representing the drug concentration. The absorption, distribution, and elimination of compounds commonly exhibit this type of kinetics because they generally rely on processes that are first-order in character: passive diffusion, blood flow, or drug transport or metabolism operating well below saturation. Because the fraction of drug affected per unit of time is independent of concentration, referring to the reaction rate by its $t_{1/2}$, the period required for the process to reach 50% of completion, is often useful. The $t_{1/2}$ is related to the fractional rate constant by the formula $t_{1/2} = 0.693/k_1$. The greater the rate constant, the shorter the $t_{1/2}$ and the faster the reaction. It is easily shown that first-order processes are essentially complete (94%) after four half-lives. Figure 2-13 provides an example of the first-order elimination of a drug with a $t_{1/2}$ of 2 hours, and Table 2-6 lists the elimination half-lives of some commonly used categories of drugs in dentistry.

Capacity-limited reactions

Capacity-limited reactions involve enzymes responsible for the metabolism of drugs and transporters concerned with moving drugs across membranes. This kind of process initially displays zero-order kinetics when the endogenous factor (enzyme or transporter) is saturated with drug; it gradually takes on the features of a first-order reaction as the drug concentration decreases. As already stated, doses used clinically are usually less than the doses required for saturation. Some exceptions exist, however, in which saturation kinetics are evident. Alcohol, even in moderately intoxicating doses, is metabolized at a constant rate of approximately 8 g/hr. Only when the concentration decreases to far less than that producing any observable effect does alcohol dehydrogenation assume a first-order rate.

Another important instance of capacity-limited biotransformation involves aspirin. Aspirin is quickly deacetylated to salicylate, the anion responsible for much of the drug's pharmacologic activity. The salicylate is eliminated through several metabolic pathways and by renal excretion, yielding an overall elimination $t_{1/2}$ of approximately 3 hours. Some of the inactivation routes are easily saturated, however, so that when an overdose is ingested the toxicity problem is compounded by a relative loss in elimination efficiency. Elimination half-lives can be calculated for drugs displaying capacity-limited kinetics, but the values obtained vary continuously according to the drug concentration (see Table 2-6). Salicylate has a plasma $t_{1/2}$ of 20 hours when a very high concentration is present in the bloodstream. As the salicylate titer decreases into the therapeutic range, the elimination $t_{1/2}$ decreases to a constant of 3 hours.

Single-Compartment Model

In its entirety, the body's disposition of an administered drug involves such a complex temporal interplay of biochemical and physiologic processes, each with its own unique set of kinetic parameters, that a full quantitative description of the time course of drug action may be impossible to achieve. For practical purposes, however, the sojourn of many agents can be described by a simple model system (Figure 2-14) in which

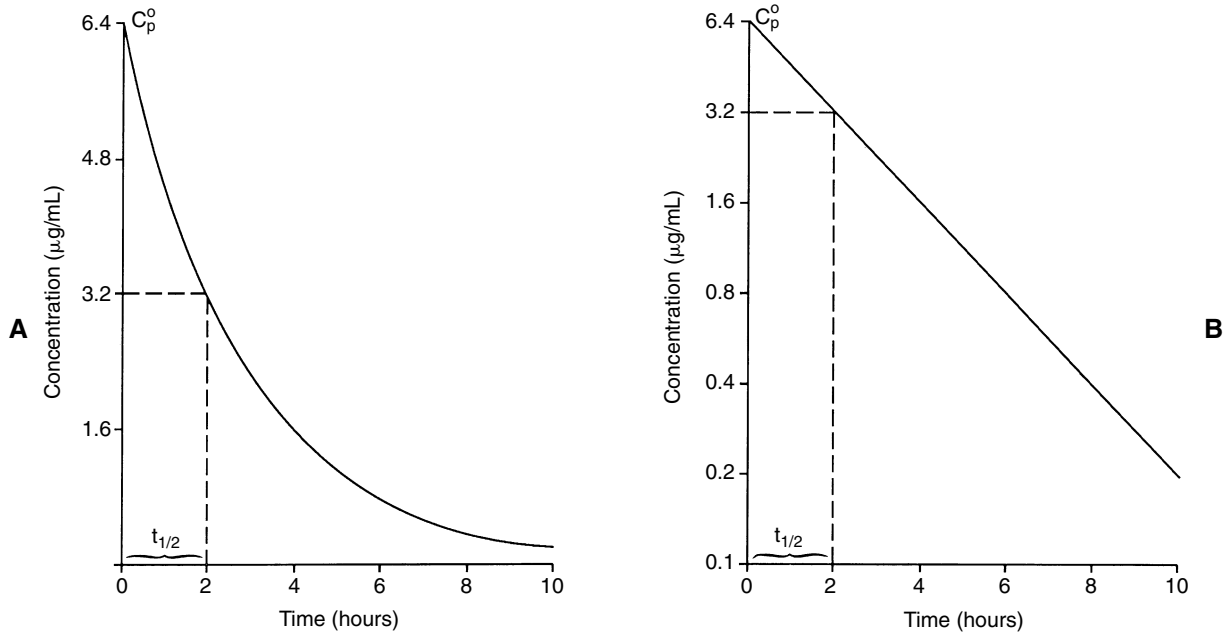

FIGURE **2-13** First-order elimination of a drug given as an intravenous bolus. In this example of a plasma concentration-time curve, it is assumed that the body behaves as a single compartment and that the distribution of the drug is essentially instantaneous. **A,** The plasma concentration is plotted on an arithmetic scale. **B,** A logarithmic scale is used to yield a straight line. The elimination half-life ($t_{1/2}$) is determined by the time interval required (2 hours in this case) for the plasma concentration to decrease by 50%. C_p^o indicates the interpolated concentration of drug immediately after drug injection.

TABLE **2-6**

Approximate Half-Lives of Common Drugs

DRUG	ELIMINATION HALF-LIFE (hr)
Antibiotics	
Amoxicillin	1.7
Clindamycin	3
Erythromycin	1.5
Penicillin G	0.5
Tetracycline	10
Analgesics	
Acetaminophen	3
Aspirin (as salicylate)	3-20*
Codeine	3†
Meperidine	3
Morphine	2†
Local Anesthetics	
Articaine	0.4
Bupivacaine	2.4
Lidocaine	1.8†
Procaine	0.01
Sedative Agents	
Alcohol	1.4-20*
Diazepam	45†
Pentobarbital	30
Triazolam	3

*Capacity-limited metabolism.
†Converted to active metabolite.

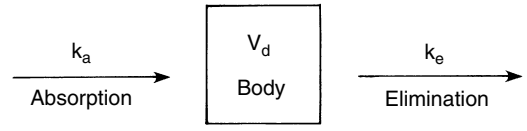

FIGURE **2-14** Single-compartment model of drug kinetics. Absorption into and elimination from the body are each assigned a single first-order rate constant. Distribution, assumed to be rapid regarding absorption and elimination, is not considered.

the body is depicted as a single compartment whose size corresponds to the V_d and whose elimination is based on first-order kinetics. In this model, which assumes rapid distribution with respect to absorption and elimination, the relationships among elimination $t_{1/2}$, total body clearance (CL, or the volume of blood "cleared" of the drug per unit of time by the combined processes of metabolism and excretion), and V_d are straightforward, as follows:

$$t_{1/2} = 0.693 \times V_d / CL$$

The unknowns of this equation are best determined by injecting the drug intravenously (eliminating the absorption variable) and measuring the plasma concentration at regular intervals sufficient to construct a plasma concentration-time curve, as shown in Figure 2-13. Given an initial dose of 500 mg (Q) and an initial plasma concentration of 6.4 μg/mL (C_p^o), determined by extrapolating the plasma concentration curve back to the moment of injection, V_d equals Q/C_p^o, or approximately 78 L. With a $t_{1/2}$ of 2 hours, clearance approximates 27 L/hr or 450 mL/min.

The elimination $t_{1/2}$ is a dependent variable based on two independent attributes: the V_d and drug clearance. If a drug exhibits an increased $t_{1/2}$ in a patient, this could mean that tissue binding of the drug is greater than normal just as easily as it could indicate a reduction in the rate of metabolism or excretion of the agent. Similarly, a significant reduction in V_d, which can occur in some diseases, could have the curious result of reducing the $t_{1/2}$ of a drug even in the face of impaired clearance.

Plasma concentration—single doses

Therapeutic agents are often administered in dental practice as single doses. Whether the drug is lidocaine injected for regional anesthesia, atropine to control salivation, or midazolam to provide preoperative sedation, the plasma concentration increases to a peak during the absorptive phase and subsequently decreases, eventually to zero, as the drug is eliminated from the bloodstream. By using the single-compartment model, it is possible to construct theoretic plasma concentration curves and observe how modifications of dosage, absorption, or elimination can alter drug concentrations and, presumably, drug effects. As shown in Figure 2-15, the plasma concentration is at all times directly proportional to the dose. This relationship does not exist for agents that are capacity limited in absorption, binding, metabolism, or excretion.

As long as absorption is several times faster than elimination, changes in the rate of drug uptake have little effect other than to alter the peak concentration. The duration of action is hardly influenced at all. A different pattern emerges, however, in instances in which the rate of absorption approximates that of elimination (not shown in Figure 2-15), either because a timed-release formulation is used to slow absorption or because the drug is quickly metabolized or excreted. As exemplified by penicillin G ($t_{1/2}$ of 30 minutes), the slow absorption achieved by oral ingestion relative to its swift excretion results in a peak concentration that is much reduced and considerably delayed compared with intravenous injection. On the positive side, oral administration can result in a duration of effect that is significantly prolonged.

Variations in the elimination rate markedly affect the postabsorptive phase of drug action. As shown in Figure 2-15, a threefold decrease in elimination can be more effective than a similar increase in the dose in extending the duration of effect. Because the peak titer is generally not nearly as sensitive to changes in elimination as it is to alterations in dosage, retarding elimination may be the better approach to lengthening the duration of effect of compounds with a low or moderate margin of safety. For penicillin G, retarding elimination can be accomplished by inhibiting urinary excretion through the coadministration of probenecid. Penicillin G is exceptional, however, in that the antibiotic has such a low toxicity that its rapid elimination can be offset safely by simply multiplying the dose several times.

Plasma concentration—repeated doses

Whenever a drug is administered more than once every four elimination half-lives, accumulation of the compound occurs within the body. Figure 2-16 shows the result of continued use of a drug given either by intravenous infusion (a zero-order process) or by repetitive administration (first-order absorption of each dose, but zero-order in aggregate). Regardless of the administration format, a plateau concentration is reached in approximately four elimination half-lives. The periodic fluctuations obtained with intermittent administration are a function of the absorption rate and the dosage interval. Approaching 50% of the peak concentration when absorption is very rapid and the dosage period equals the elimination $t_{1/2}$, such variations can be minimized by increasing the frequency of administration or retarding the rate of absorption.

The average steady-state concentration relative to the peak value obtainable after an initial dose can be determined by multiplying the number of doses administered per elimination $t_{1/2}$ by 1.44. The steady-state concentration of a drug given once every $t_{1/2}$ equals 144% of the initial peak concentration. For diazepam ingested three times per day, the average equilibrium concentration approximates (assuming a $t_{1/2}$ of 2 days) 1.44×6, or 8.6 times the peak concentration after a single dose. At least 8 days (four half-lives) are required to reach this final drug titer.

The gradual approach to steady-state concentrations associated with slowly eliminated drugs can either benefit or hinder therapy. On the positive side, a long $t_{1/2}$ permits the clinician to administer the drug at convenient intervals, perhaps once a day, without having to be concerned with wide swings in plasma concentration. If patient monitoring reveals an unusual buildup of drug because of impaired metabolism or excretion or some other cause, time is available to adjust the dose before toxic effects ensue. On the debit side, the attainment of a therapeutic effect is delayed by the time required for drug accumulation to proceed. If an immediate pharmacologic effect is needed, a loading dose of the drug must be administered. A loading dose is a large, initial quantity of drug substituted for the normal amount to produce quickly a concentration approximating the steady state. For an agent given once each $t_{1/2}$, the loading dose equals twice the maintenance dose; for drugs given more frequently, the loading dose is larger. Dividing a loading dose into several

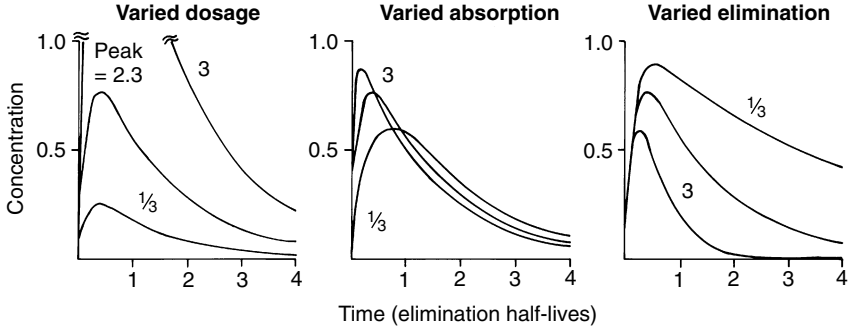

FIGURE **2-15** Time course of plasma concentration after single doses of drug. The various curves illustrate the influence of threefold increases *(3)* or decreases *(⅓)* of dosage, absorption, and elimination on drug titers. The standard curve reproduced in all three graphs represents an agent whose first-order absorption rate is 10 times faster than elimination. A concentration of 1.0 is the value that would result if the drug were absorbed instantaneously, as with an intravenous injection.

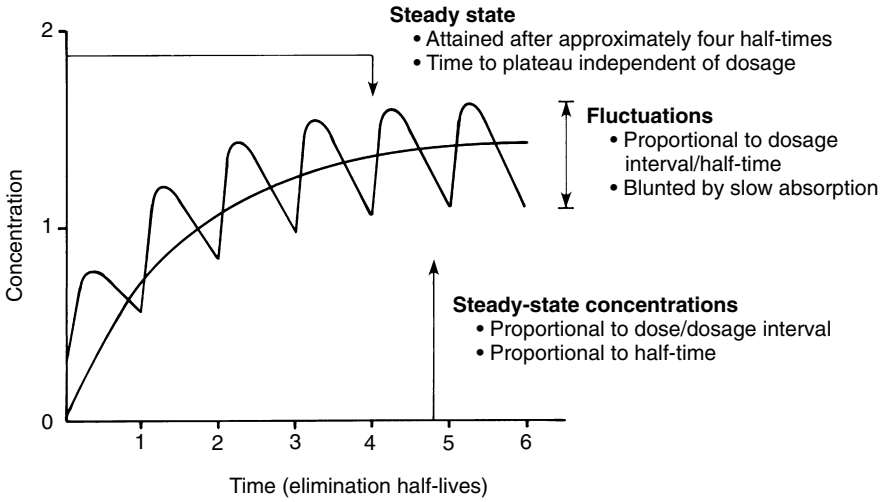

FIGURE **2-16** Time course of plasma concentration involving drug accumulation. The *serrated line* reflects the pattern of accumulation observed during the repeated administration of a drug at intervals equal to its elimination half-life, when drug absorption is 10 times as rapid as elimination. As the relative rate of absorption increases, the concentration maximums approach twice the minimums during the steady state. The *smooth line* depicts drug accumulation during the administration of an equivalent dosage by continuous intravenous infusion. (Adapted from Benet LZ, Kroetz DL, Sheiner LB: Pharmacokinetics: the dynamics of drug absorption, distribution, and elimination. In Hardman JG, Limbird LE, Gilman AG, editors: *Goodman & Gilman's the pharmacological basis of therapeutics*, ed 9, New York, 1996, McGraw-Hill.)

smaller fractions is often wise. The sacrifice of some speed in attaining a therapeutic concentration is usually more than compensated for by the ability to evaluate patient responses during the early phase of therapy. The fact that elimination rates, which help regulate steady-state concentrations, can vary greatly among individuals should dictate caution whenever cumulative drug effects are sought.

Multiple-Compartment Models

For many drugs, the simple single-compartment model does not adequately describe the early time course of plasma concentration. Large discrepancies are particularly likely to be observed when a relatively lipophilic drug is given intravenously, as in the use of CNS depressants for conscious sedation. In that situation, the assumption that the body acts as a single compartment does not hold, and one or more additional drug reservoirs must be postulated.

Figure 2-17 depicts a two-compartment model in which the drug is administered into a small central compartment. The agent may leave the central compartment either by distribution to a larger peripheral compartment or by processes of elimination. With time, a quasi–steady state is established between the central and peripheral reservoirs in which net redistribution back into the central compartment occurs as the drug is metabolized or excreted. In the example provided, which is analogous to the scenario in Figure 2-13, the initial high concentration (C_p^o) after a 500 mg dose reflects the smaller V_d of the central compartment (V_c = 9.8 L). The central compartment consists of organs (including the brain, heart, lungs, and kidneys) that receive a large blood supply. A terminal $t_{1/2}$ is determined from the log-linear portion of the curve, but in this case the term reflects distribution and elimination functions. Other parameters, such as the total V_d, are likewise more complex in derivation and interpretation than their counterparts in the single-compartment model.[15] This complexity is compounded as the number of compartments in the model is increased. Nevertheless, multicompartment models are useful in understanding how the duration of a drug's effect after a single injection may be largely independent of the clearance rate or elimination $t_{1/2}$. In Figure 2-17, if the threshold concentration for a sedative effect of the drug was 10 μg/mL, a patient would recover from the sedation within 30 minutes, even if metabolism and excretion were completely blocked, simply by distribution into less well-perfused tissues.

Context-Sensitive Half-Lives

The numerous variables of the multicompartment model make it impossible to predict intuitively the influence of individual pharmacokinetic parameters such as half-lives, V_d values, and clearance rates on the plasma-concentration profile of a highly lipid-soluble drug given repeatedly or continuously for a period of time. This situation poses a problem when intravenous agents are administered by continuous infusion for anesthesia or sedation. A partial solution involves the use of computer modeling to estimate context-sensitive half-lives.[20] The context-sensitive $t_{1/2}$ is the time required for the plasma concentration of a drug to decrease by 50% when consideration is given to how long the drug has been infused. As illustrated in Figure 2-18, fentanyl shows a significant increase in this parameter as the duration of infusion exceeds 2 hours. This phenomenon is the result of saturation of redistribution sites. Conversely, propofol, with its enormous capacity for redistribution, experiences only a slow increase over time. Such information is useful clinically in selecting the appropriate agent for use and in estimating the changing duration of drug effect. Similar context-sensitive curves can be generated for recovery to different percentages (e.g., 25%) of the plasma concentration, depending on what value best predicts recovery of function. Further advances in computer modeling will undoubtedly help address other limitations of the multicompartment model, such as the oscillations in arterial plasma concentrations that occur with bolus injection of drug and errors associated with the fact that some drugs are metabolized in more than a single compartment.[12]

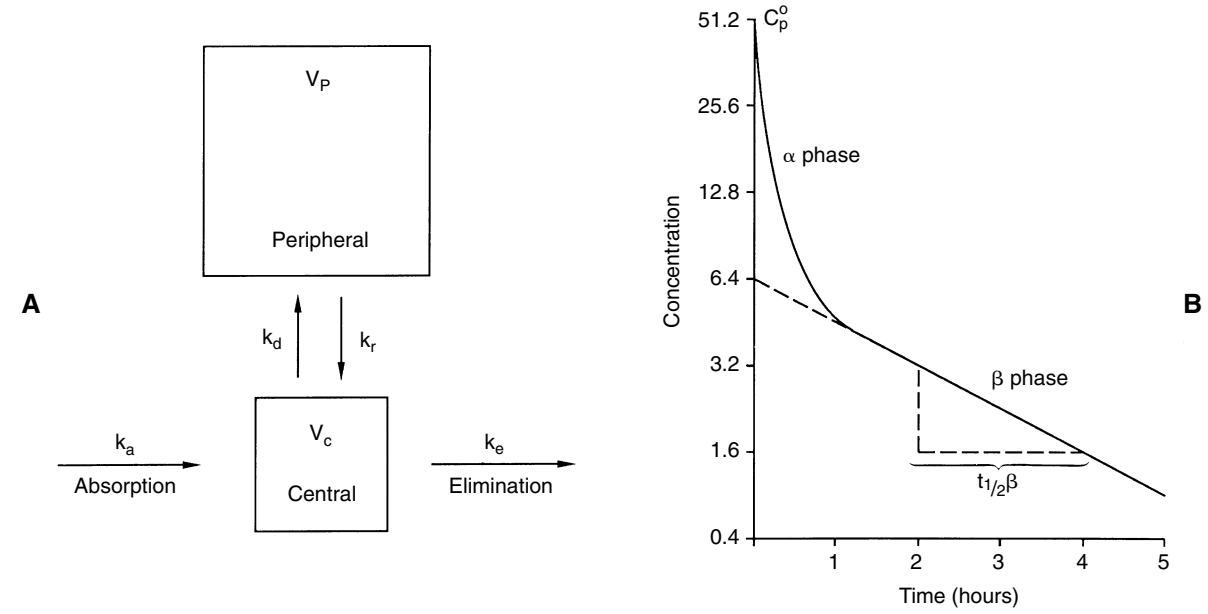

FIGURE **2-17** Two-compartment model of drug kinetics. **A,** In this model, drugs are absorbed into and eliminated from a central compartment that is linked by distribution processes (having rate constants of k_d and k_r) to a second, peripheral compartment. The central compartment includes the blood, from which drug determinations are taken. **B,** The plasma concentration-time curve consists of two phases: an early distribution or *α phase,* during which the concentration decreases largely as a result of distribution out of the central compartment, and a late elimination or *β phase,* during which metabolism and excretion predominate. The terminal half-life ($t_{½}\beta$) is calculated from the log-linear portion of the elimination curve.

(Data from Van Dyke C, Jatlow P, Ungerer J, et al: Oral cocaine: plasma concentrations and central effects, *Science* 200:211-213, 1978.)

PHARMACOKINETIC-PHARMACODYNAMIC MODELING

Two basic assumptions underlying pharmacokinetic studies are that the plasma concentration of a drug is predictive of the concentration around the site of drug action and the magnitude of drug effect depends on this concentration. Although these assumptions generally hold, important exceptions to them do exist. As previously stated, drugs that bind covalently to their receptors produce effects that far outlast the drugs' passage in the bloodstream. Drugs that rely on transcription and protein synthesis are delayed in effect because of the time required for these processes to occur. Additional discrepancies between plasma concentration and drug effect arise because of delays in reaching the site of action and temporal changes that occur in receptor responsiveness. Pharmacokinetic-pharmacodynamic modeling seeks to account for these discrepancies.

Lorazepam provides a good example of a drug whose effects are temporally delayed (Figure 2-19). Lorazepam, a benzodiazepine used for relief of anxiety, must gain access to the CNS to stimulate its receptor and produce its characteristic CNS effects. The drug's modest lipid solubility ensures, however, that the peak plasma concentration after oral administration occurs before the drug has had any significant effect in the brain.[17]

Cocaine produces the opposite relationship in that maximal drug effects after oral administration precede the peak plasma concentration (Figure 2-20).[53] In this case, receptors that mediate the pharmacologic effect of cocaine undergo desensitization. Desensitization often involves a change in receptor sensitivity, either by phosphorylation of a regulatory subunit of the receptor or uncoupling of the receptor from its intracellular response system. Longer lasting losses of drug responsiveness may include downregulation of receptors, in which the number of receptors decreases on continuous exposure to the drug. See Figure 1-12 for an example of desensitization and downregulation.

CHAPTER 3

Pharmacotherapeutics: The Clinical Use of Drugs

JOHN A. YAGIELA AND FRANK J. DOWD

The primary goal of drug treatment is to achieve a desired pharmacologic effect without causing adverse reactions. Because no therapeutic regimen is without risk, the clinician must weigh the benefits expected from a drug against the dangers inherent in its use. If drugs are to be properly selected and administered, numerous factors should be considered that complicate the attainment of therapeutic responses and the avoidance of unwanted effects.

As stated in Chapter 1, drugs are often selective in the effects they produce because they activate or inhibit specific drug receptors. Even the most selective agents generally evoke a spectrum of reactions, however, rather than a single pharmacologic outcome. Atropine in therapeutic concentrations specifically prevents the stimulation of muscarinic receptors by acetylcholine. Because these receptors are vital to the normal function of the entire parasympathetic nervous system, their blockade can result in a wide range of autonomic responses. Although specific in action, atropine is nonselective in effect. In addition, specificity of receptor binding is usually a matter of dose; in concentrations greater than therapeutic, atropine blocks the nonmuscarinic effects of acetylcholine and may inhibit the actions of other chemicals, such as histamine and 5-hydroxytryptamine. Finally, nonspecific effects unrelated to receptor blockade may be observed. Large concentrations of atropine have local anesthetic activity and directly affect the central nervous system (CNS) and peripheral vasculature.

In addition to the fact that single agents can produce multiple effects, pharmacotherapeutics is complicated by variations in patient responsiveness. A therapeutic dose of drug for one person may be ineffective for a second person and toxic to a third person. Even highly inbred laboratory species display measurable biologic variations in drug sensitivity. Figure 3-1 is a quantal dose-effect graph illustrating the percentage of subjects responding to an agent as a logarithmic function of the dose. The graph is constructed by counting the number of animals or patients exhibiting a specified effect at various doses. With low amounts of drug, very few individuals react; as the dose is increased, however, more are affected until a dose is reached at which the response is universal. Although similar in appearance, this *quantal* dose-effect relationship must not be confused with the *graded* dose-response curve described in Chapter 1 (see Figure 1-6). The quantal dose-response curve is sigmoidal because of the log-normal distribution of drug sensitivities found in most populations (see Figure 3-1). The median effective dose (ED_{50}) is the amount of drug required to produce a particular effect in 50% of treated individuals. Although potency is represented in quantal and graded relationships by the position of the curve on the abscissa, intrinsic activity or efficacy is apparent only in graded responses. Biologic variation, which is inversely correlated with the slope of the quantal dose-effect curve, cannot be estimated from a single graded dose-response graph.[53]

Patients who are unusually sensitive to a drug are said to be *hyperreactive*. Terms more or less synonymous with hyperreactivity include *hypersusceptibility* and *drug intolerance*. The term *hypersensitivity* is also used occasionally, but this usage can be misleading because hypersensitivity commonly indicates drug allergy. Individuals unexpectedly resistant to conventional doses of drug are referred to as being *hyporeactive*. Tolerance, tachyphylaxis, and several additional types of hyporeactivity are discussed later. Many variables influence the responsiveness of individuals to drugs. Some of these are readily apparent and under the control of the clinician; others are often hidden from view and not amenable to modification. Because it is impossible to predict how a given patient will respond to a particular agent, appropriate monitoring of drug effects is usually necessary to achieve optimal therapy.

FACTORS INFLUENCING DRUG EFFECTS

Differences between patients in reaction to a therapeutic agent may arise from disparities in drug concentration obtained with a standardized dose (*pharmacokinetic differences*), from variations in individual responsiveness to a given drug concentration (*pharmacodynamic differences*), or from secondary factors such as the failure of patients to take their medication as prescribed (*noncompliance*). Figure 3-2 shows the lack of correlation that can develop clinically between the prescribed dose of a drug—in this case the anticonvulsant phenytoin—and the resultant plasma concentration and pharmacologic response. Even with the daily dose corrected for body weight, this study revealed that the steady-state concentration of phenytoin differed 20-fold or more.[27] A small percentage of patients experienced nystagmus, an early indication of drug toxicity, at plasma concentrations barely sufficient to control convulsions in other patients. It is apparent that, given a therapeutic concentration range of 10 μg/mL to 20 μg/mL (the plasma concentration of phenytoin supposed to provide seizure protection with minimal adverse effects), most patients were prescribed or took on their own either insufficient medication or an overdose. Although pharmacokinetic dissimilarities account for many differences in patient responsiveness, the fact that phenytoin has a "therapeutic range," rather than a single effective concentration, indicates that there also exists some variation in pharmacodynamic sensitivity to the anticonvulsant.

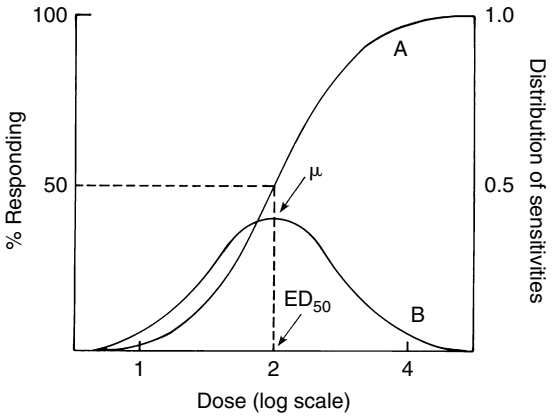

FIGURE **3-1** Quantal dose-response curves (log scale). Curve *A* represents the cumulative distribution, and curve *B* represents the frequency distribution of patient responses in a normal population. As shown, the mean *(μ)* and median (50% responding) sensitivities fall on the same dose (median effective dose, ED_{50}). (Adapted from Goldstein A, Aronow L, Kalman SM: *Principles of drug action: the basis of pharmacology,* ed 2, New York, 1974, John Wiley & Sons.)

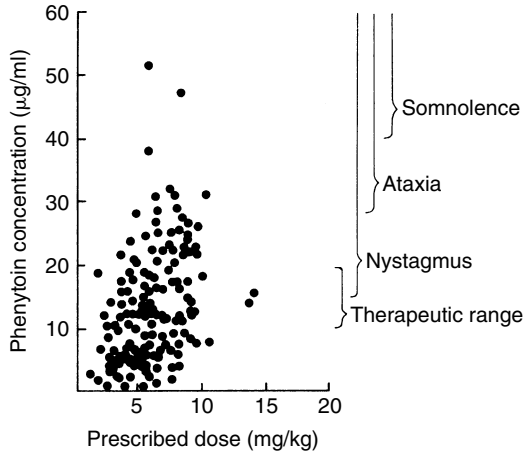

FIGURE **3-2** Plasma phenytoin concentration as a function of the prescribed dose. Each *black circle* represents a single patient (n = 294). *Closed bracket* indicates the accepted therapeutic concentration range for phenytoin in plasma; *open-ended brackets* denote concentrations at which the various toxic manifestations listed may occur. (Data from Lund L: Effects of phenytoin in patients with epilepsy in relation to its concentration in plasma. In Davies DS, Prichard BNC, editors: *Biological effects of drugs in relation to their plasma concentrations,* Baltimore, 1973, University Park Press; and Kutt H, Winters W, Kokenge R, et al: Diphenylhydantoin metabolism, blood levels, and toxicity, *Arch Neurol* 11:642-648, 1964.)

Patient Factors

Many factors that can influence drug effects clinically are highly variable in individual patients. Although attributes such as size, age, and genetic makeup are not amenable to modification, they must be taken into account whenever drug therapy is planned.

Body weight and composition

Adults may differ three times or more in weight. Because the volume of distribution of a drug is a function of body mass, extremes in patient size may result in significant differences in plasma concentration when drugs are administered in the form of a "standard adult dose." Body composition is also an important variable. Two equally heavy patients, one obese and the other muscular, may react quite differently to certain agents. Because adipose tissue contributes very little to body water, the obese person will be more susceptible to a drug distributed essentially within one or more body fluid compartments. The same person may show unusual resistance to a highly lipophilic agent such as thiopental, especially when it is given in repeated doses.

Age

Pediatric patients generally cannot be given adult dosages of drugs. The primary reason is their smaller body size, and various formulas (discussed in Chapter 55) have been devised to calculate pediatric fractions of the adult dose. For the following reasons, however, children must not be thought of as merely miniature adults. First, even with the size differential taken into account, neonates display an unusual hyperreactivity to drugs. Immature hepatic and renal systems during the first weeks of life tend to promote drug accumulation, and the relative inefficiency of drug binding by albumin (sometimes because of competition for binding sites by bilirubin) may also lead to abnormal concentrations of drug in the vicinity of receptors. In addition, distribution of compounds into the CNS may be enhanced by an incomplete maturation of the blood-brain barrier. Second, in contrast to neonates, children and infants older than 6 months often require large milligram-per-kilogram body weight doses of drugs during therapy. This relative hyporeactivity is mostly attributable to an enhancement in the rate of elimination.[14] Dosage adjustment on the basis of surface area (see Figure 55-6) rather than body weight is empirically a useful strategy in correcting for age-related differences in elimination.

Pharmacodynamic differences also exist in pediatric patients. Incomplete maturation renders children especially vulnerable to the toxic effects of certain agents. Benzocaine is especially likely to cause methemoglobinemia in infants younger than 6 months, tetracyclines pose the risk of tooth discoloration until age 8 years, and sex steroids and other hormones administered before puberty may impair normal growth and development. In part because of the young child's high metabolic rate, atropine intoxication may readily cause hyperthermia, and salicylate overdosage may quickly lead to acid-base and electrolyte disturbances. The association of Reye's syndrome with aspirin and excitement reactions with antihistamines give added proof that children respond differently than adults to certain drugs.

There is no method of pediatric dosage calculation suitable for all drugs and therapeutic situations. In older children, adjustments based on age, weight, or (preferably) surface area may be satisfactory, but no general guide is possible for very young children. Dosages for neonates, infants, and young children should be based on clinical trials; studies of this nature were rarely performed before 1998, when the U.S. Food and Drug Administration (FDA) first mandated that information pertaining to safety and effectiveness of new drugs include data for demographic subgroups, such as children, who would benefit from their use. Pediatric dosage schedules for older drugs are often unavailable.

Geriatric patients are frequently hyperreactive to drugs. Although increased sensitivity may result from organic pathologic conditions or from drug interactions (both more likely to occur in elderly patients), age-related functional changes in drug disposition and cellular responsiveness are also involved. Because patients older than 65 years are much more likely to experience adverse drug reactions than young adults, at least in part because elderly patients consume many more medi-

cines, careful selection of drug and dosage schedules is necessary, especially with drugs of low safety. Geriatric pharmacology is becoming increasingly important to the dentist as the general population ages and a higher proportion of elderly individuals retain their teeth (thanks to improved oral hygiene and professional care); this subject is covered in its entirety in Chapter 53.

Sex, pregnancy, and lactation

The sex of a patient is sometimes important with respect to drug effects. As with children, information is lacking for many drugs because of the historic exclusion of female subjects from most drug studies. Dosage adjustments may be necessary for some drugs simply because women tend to be smaller than men and to have a higher percentage of body fat. Hepatic disposition of drugs seems not to be influenced by sex when variables such as age, size, body composition, and drug use are taken into account. Side effects such as hirsutism are less tolerable in women, and gynecomastia is more disconcerting in men.

Women seem to be more susceptible to drug-induced blood dyscrasias, and women taking systemic contraceptives may be more prone to some drug interactions. Drug-induced torsades de pointes is a potentially life-threatening arrhythmia with a significant sex bias. Women may be more likely to develop torsades because the QT interval of the electrocardiogram (see Chapter 24) is longer in women after puberty. The antiarrhythmic sotalol, one of the approximately 50 drugs that prolong the QT interval, is associated with a three times higher incidence of torsades in women.[7] Because the preapproval clinical trials of sotalol enrolled only men, the relatively common side effect of QT prolongation was not recognized before the drug was released for general use.

Pregnancy is a major concern in pharmacotherapeutics. Alterations in liver function are common, and the hepatic toxicity of tetracycline and certain other compounds is markedly accentuated by pregnancy. The metabolism of numerous drugs is increased because of the ability of the high estrogen and progesterone concentrations to stimulate the pregnane X receptor (see Chapter 2) and cause enzyme induction. Renal excretion is likewise increased because of the elevated cardiac output and glomerular filtration. When present, pregnancy toxemia may increase drug effects by reducing the binding capacity of albumin, which is already reduced in a healthy pregnancy.

Of primary importance are the actions of drugs on the fetus. Spontaneous abortion, teratogenesis, mental retardation, drug dependence, and cancer have resulted from drug administration during pregnancy. Because few, if any, agents have been proved to be totally safe for the fetus, it is best to avoid all medications when possible. Drug administration should also be conservative in women of childbearing age because pregnancy is often undiagnosed during the first trimester, the most critical period of fetal development. Many drugs (e.g., methadone) are excreted in the milk. Because some of these agents may cause unwanted effects in the nursing infant, it is advisable to review carefully drug exposure during lactation as well. Nursing is contraindicated in women taking anticancer drugs, immunosuppressants, radioactive chemicals, ergot alkaloids, drugs of abuse, lithium salts, gold, iodine, and various antibiotics. Toxicologic concerns related to pregnancy are discussed in more detail later in this chapter.

Environmental factors

Factors such as ambient temperature, sunlight, and altitude are capable of influencing responses to certain drugs. Children given atropine on a warm day are especially susceptible to drug-induced hyperthermia, toxic skin reactions to sulfonamides increase with exposure to sunlight, and nitrous oxide loses efficacy in mountainous regions. Probably the most important environmental factor influencing drug effects is diet. The timing of meals and the types of food eaten can markedly affect drug absorption. The gastrointestinal absorption of most tetracyclines is impaired when taken with milk or other dairy products.

Numerous chemicals that are ingested, inhaled, or absorbed through the skin can influence the body's disposition of, or response to, various drugs. Patients receiving monoamine oxidase inhibitors risk severe hypertension and death if they eat foods containing tyramine (e.g., certain cheeses, beers, and wines). The therapeutic effects of levodopa in parkinsonism may be prevented by pyridoxine (vitamin B_6), present in foods and multivitamin supplements. Grapefruit juice contains substances that inhibit the CYP3A enzymes responsible for metabolizing a host of drugs (see Chapter 2). Finally, the use of insulin must be carefully matched to the patient's dietary intake to avoid complications associated with hypoglycemia and hyperglycemia.

The indigenous microflora represents a special kind of environmental variable. Several drugs given orally are metabolized by bacterial enzymes to such an extent that absorption may be significantly impaired. The dose of coumarin anticoagulants is partially governed by the amount of vitamin K produced by enteric bacteria. During antibiotic therapy, the type and number of microorganisms surviving play a large role in determining whether superinfection develops in patients.

Physiologic variables

Numerous physiologic factors can modify clinical responses to drugs. Fluctuations in gastric, plasma, and urinary pH may alter the pharmacokinetics of weak electrolytes. Salt and water balance, exercise, sleep, body temperature, blood pressure, and many other factors also influence patient reactions. The effects of blocking agents are particularly sensitive to variations in physiologic or biochemical events. Isoproterenol, an adrenergic agonist, increases heart rate regardless of autonomic nervous system tone, but atropine, an acetylcholine antagonist, increases heart rate only in the face of tonic vagal activity.

Many physiologic functions reveal a daily periodicity of intensity. These circadian rhythms often result in daily fluctuations of drug responsiveness. In dentistry, the duration of local anesthesia after nerve blockade varies by a factor of two during the course of a day, with the greatest effect occurring in the afternoon in patients with normal sleep patterns.[40]

Pathologic factors

Diseases may influence pharmacotherapeutics by modifying drug disposition or tissue responsiveness. Pathologic states most commonly associated with altered patient reactivity involve the organs of absorption, distribution, metabolism, and excretion. Achlorhydria, diarrhea, malabsorption syndromes, and other disturbances of the gastrointestinal tract may depress the absorption of ingested agents.

The distribution of drugs is sensitive to pathologic changes in the blood and circulatory system and to perturbations in anatomic and functional barriers to diffusion. Disturbances in the concentration of plasma proteins (e.g., hypoalbuminemia) or in their function (as in uremia) may lead to drug toxicity or to a loss of therapeutic benefit. Congestive heart failure and arteriosclerosis may so diminish tissue perfusion that drug elimination is significantly retarded. Meningeal inflammation permits entry into the CNS of many drugs (e.g., penicillins) normally excluded by the blood-brain barrier.

Hepatic dysfunction, whether caused by specific hepatic disease, infection, or other conditions, can markedly retard the metabolism and biliary excretion of drugs. Reduced trans-

port capabilities can inhibit the uptake of drugs into the liver and export of metabolites from it.[52] Standard liver function tests are of little prognostic value regarding drug biotransformation. Some patients with demonstrable cirrhosis or hepatitis may show little metabolic deficit, whereas others may exhibit marked hyperreactivity to standard doses of drugs. Within the same individual, the metabolism of some drugs may be impaired but not others. Because the liver is responsible for the synthesis of plasma proteins such as albumin and pseudocholinesterase, and for the breakdown of compounds such as bilirubin that compete for drug binding sites in plasma and various tissues, hepatitis may significantly alter (up or down) a drug's volume of distribution and elimination half-life independently of its specific effects on hepatic drug metabolism. For drugs with high hepatic clearance, metabolism is decreased by cirrhosis-induced reductions in total liver blood flow. The uncertainties of drug metabolism introduced by hepatic disease require that substances inactivated in the liver be used cautiously in affected patients and that drug effects be monitored carefully to avoid serious adverse reactions.

Renal disease is a common modifier of drug effects. The plasma half-lives of agents eliminated in the urine are often greatly prolonged by renal failure. Even for compounds completely inactivated in the liver, inadequate excretion of metabolites may increase the incidence of untoward reactions. A good measure of renal status is provided by the endogenous creatinine clearance. A 50% decrease in creatinine clearance should theoretically indicate a twofold increase in the elimination half-life of a drug that is removed from the blood solely by glomerular filtration. For a drug partially eliminated in the urine, the increase in plasma half-life should be correspondingly less. The customary approach to avoiding excessive drug accumulation in patients with renal disease is to lengthen the dosage interval in accordance with the degree of impaired elimination. Table 3-1 lists for several drugs (including some commonly used in dentistry) the approximate dosage intervals indicated for patients with moderate or severe renal failure.[44] Although it is possible for active secretory and resorptive processes to be relatively less or more affected by renal disease than is glomerular filtration, the renal elimination of most drugs simply parallels the creatinine clearance.

An insidious form of interaction between pathologic factors and drug effects occurs with agents potentially toxic to their primary organs of elimination. Acetaminophen accumulation permitted by liver disease may result in hepatic necrosis and further impairment of drug metabolism.[10] A similar vicious cycle involving the kidney has been observed with various drugs.

Exaggeration of the systemic effects of epinephrine and reduction in the analgesic potency of morphine in uncontrolled hyperthyroidism are two examples of drug effects modified by disease states through nonpharmacokinetic means.

TABLE **3-1**

Dosage Adjustments in Renal Failure

		DOSE INTERVAL IN HOURS (AND PERCENTAGE OF NORMAL DOSE) ACCORDING TO DEGREE OF RENAL FAILURE*		
DRUG	**ROUTE OF ELIMINATION**	**NORMAL FUNCTION**	**MODERATE IMPAIRMENT**	**SEVERE IMPAIRMENT**
Antibiotics				
Cefoxitin	Mainly renal	6	8-12	24
Erythromycin	Hepatic	6	6	12
Penicillin G	Mainly renal	4-6	4-6 (50%)	8 (33%-50%)

Data from St. Peter WL, Halstenson CE: Pharmacologic approach in patients with renal failure. In Chernow B, editor: *The pharmacologic approach to the critically ill patient,* ed 3, Baltimore, 1994, Williams & Wilkins.

*The degree of renal failure as defined by creatinine clearance: normal function to minimal impairment, >50 mL/min; moderate impairment, 10-50 mL/min; severe impairment, <10 mL/min.

†Drugs that may accentuate renal damage.

‡Accumulation of active metabolite limits dosing.

CNS, Central nervous system.

Although pathologic factors may influence drug-receptor interactions directly, as in myasthenia gravis (in which receptor reactivity to acetylcholine is reduced), most alterations of patient response occur indirectly through the augmentation of overt disease or the unmasking of latent physiologic deficits. Agents that promote hyperuricemia may cause an acute exacerbation of gout, and propranolol may induce heart failure in patients with a severely compromised myocardium.

Genetic influences

Genetic variables contribute greatly to the differences in drug responsiveness illustrated in Figure 3-1. Although the importance of heredity is underscored by the evolution of pharmacogenetics into a recognized field of study, the elucidation of multigenetic factors that lead to log-normal distributions in drug reactivity has proved difficult (see Chapter 4). Previously, the only variations in drug effects that had been unequivocally linked to genetic differences were variations that exhibit simple inheritance patterns and yield bimodal or otherwise discontinuous distribution curves and variations that can be associated with certain groups of people on the basis of blood type, race, or ethnic background. Now, studies of gene expression and polymorphisms are helping to uncover an increasingly broad array of genetically determined differences in drug responsiveness. Genetic factors are responsible for idiosyncratic reactions and determine, in part, the relative likelihood of a patient having other adverse responses to an administered agent. Genetic influences can alter drug effects quantitatively; they may also result in the appearance of novel pharmacologic outcomes. Genetic influences affecting drug metabolism and drug receptors are discussed in Chapter 4.

Drug Factors

In addition to individual variations in patient reactivity, certain drug factors, namely the formulation and dosage regimen of an agent and the development of tolerance, can markedly influence the success of drug therapy.

Variables in drug administration

Of all factors influencing pharmacologic responses clinically, only those involved with drug selection and administration are totally under the control of the clinician. Some of these variables—dose, drug formulation, route of administration, and drug accumulation—are discussed in detail in previous chapters. Two additional factors are the time of administration and the duration of therapy. Many disturbing side effects are minimized if an agent can be given shortly before sleep, including the autonomic effects of the belladonna alkaloids, the vestibular component of nausea associated with opioid analgesics, and the sedative properties of the antihistamines. Conversely, agents producing mild CNS stimulation are better tolerated in the daytime. The scheduling of doses with or between meals to limit gastrointestinal upset or to enhance absorption is discussed in Chapter 2.

The duration of therapy has several important ramifications. Treatment must be sufficiently long to be effective. This is particularly true with antimicrobial agents, in which an inadequate duration of coverage can lead to reinfection. Because adverse drug reactions are more likely to occur during extended courses of therapy, treatment should never be unduly prolonged. It is generally inappropriate to continue a patient on medication after the condition requiring therapy has subsided. The duration of administration should be monitored especially carefully when drugs capable of producing physical or psychological dependence are being used.

Drug tolerance and sensitization

In pharmacology, *tolerance* to a drug refers to a state of decreased responsiveness that develops on repeated or continuous exposure to the agent or one of its congeners. Two major categories of tolerance are recognized: pharmacokinetic or drug-disposition tolerance, in which the effective concentration of the drug is diminished, and pharmacodynamic or cellular tolerance, in which the reaction to a given concentration of the drug is reduced.

Most documented cases of drug-disposition tolerance involve agents that stimulate their own metabolism through the induction of microsomal enzymes. It has also become apparent that induction of active transporters can reduce plasma concentrations by increasing hepatic uptake (and metabolism) and biliary excretion of drugs and possibly by decreasing gastrointestinal absorption and enhancing renal secretion. Immune tolerance may also occur in which circulating antibodies produced in response to an antigenic substance (e.g., bovine insulin) combine with the agent, decreasing its effective concentration at the receptor site. When pharmacokinetic tolerance is encountered, clinical effectiveness can usually be restored through simple adjustment of the dose or administration interval.

Cellular tolerance is commonly observed with drugs that alter mood, perception, or thought; opioid analgesics, barbiturates, benzodiazepines, alcohol, amphetamines, caffeine, and cocaine are examples. Tolerance is usually acquired gradually, depending on the drug, its dose, and how often it is administered. In general, cellular tolerance does not develop equally to all effects of a drug. Sometimes this is beneficial, as when undesirable side effects of an agent are lost, but therapeutic activity is retained. Differences in tolerance can also promote adverse reactions. Alcoholics become tolerant to the effects they desire from ethanol yet remain normally susceptible to the lethal effect. Continual use of ethanol leads to a potentially dangerous reduction in the drug's margin of safety because the user is forced to approach toxic concentrations to achieve the desired level of inebriety. (The ability of alcoholics to walk a straight line while inebriated also involves a "learned tolerance," in which they develop coping skills to mask their inebriation.) A similar phenomenon occurs with other CNS depressants. Clinical management of pharmacodynamic tolerance can often be accomplished by increasing the dose; however, this approach is occasionally ineffective in restoring drug activity and may result in serious toxicity or drug dependence. Normal sensitivity in a tolerant person can be restored eventually through abstention from the drug.

Although the bases for most types of cellular tolerance are not well understood, it seems that adaptive changes to oppose drugs administered long-term that act on specific receptor systems are a common phenomenon. Receptor responsiveness is not static; in the case of agonist drugs, receptors may become diminished in activity and number through the respective processes of desensitization and downregulation, as described in Chapter 1. Response elements downstream from the primary receptor may be similarly affected. Other adaptive changes may include alterations in endogenous mediator synthesis, storage, release, and reuptake.

Specific mechanisms of tolerance have been established for certain drugs that evoke a rapidly developing form of tolerance termed *tachyphylaxis*. The sympathomimetic agent tyramine provides a classic example of tachyphylaxis. Administered intravenously to an animal whose vagal innervation of the heart has been interrupted, tyramine indirectly increases heart rate and blood pressure by causing the release of norepinephrine from adrenergic nerves. A subsequent dose given after the effects of the first dose have disappeared generates a smaller response, and, after a series of repetitions, the drug may lose essentially all activity. Acute tolerance to tyramine is produced by rapid depletion of the functional norepinephrine stores of the adrenergic nerve terminals. Two additional examples of

tachyphylaxis are associated with histamine. Because endogenous stores of histamine can be quickly depleted but take a long time to be replenished, drugs that cause histamine release (e.g., morphine and tubocurarine) generate tolerance in much the same manner as does tyramine. Tachyphylaxis may also occur to histamine itself. Repetition of increasing doses of intravenous histamine can produce in several hours a hyporeactivity of 100-fold less than normal. Other drugs capable of evoking acute tolerance include the benzodiazepines, nitrites, cholinergics, and anticholinergics.

A final form of tolerance involves drug-induced changes in cellular distribution. A classic example is the development of tolerance to anticancer chemotherapy by cells that overexpress the drug exporter P-glycoprotein, otherwise known as *multidrug resistant protein-1*. Similarly, the induction of P-glycoprotein by toxins may increase the ability of the blood-brain barrier to prevent their entry into brain cells.[30] This form of "distributional tolerance" exhibits aspects of pharmacokinetic and pharmacodynamic tolerance—pharmacokinetic in the sense that the distribution of the drug is altered and pharmacodynamic in that increasing the dose may be an unsuitable strategy to restoring drug effect (because of toxicity to cells not protected by P-glycoprotein).

Pharmacodynamic sensitization, in which the individual becomes increasingly responsive to drugs administered on a regular basis, has been documented for several CNS stimulants. Cocaine given in single daily doses to rats causes increased motor activity after 1 week of treatment. This effect, associated with increased release of dopamine in the brain, is a conditioned response because placebo substitution for cocaine after 1 week elicits a similar response.[19]

Factors Associated with the Therapeutic Regimen

Some factors influencing drug effects are related to the therapeutic context in which the agent is administered or prescribed. Attitudes toward the drug regimen or practitioner may determine whether an agent proves effective in a patient (or even if the drug is taken). Concurrent use of other medicines may alter drug effects directly through pharmacologic mechanisms or indirectly by promoting errors in drug administration.

Placebo effects

A placebo effect is any effect attributable to a medication or procedure that is not related to its pharmacodynamic or specific properties.[55] The term *placebo* is derived from the Latin verb *placere*, meaning "to please." In pharmacotherapeutics, a placebo may be either "pure," in which the preparation is pharmacologically inert (e.g., a lactose tablet), or "impure," in which the drug has pharmacologic activity, but is given for a condition or in a manner such that no benefit can be obtained from its specific properties. Two commonly held misconceptions are that placebos provide nothing more than a means of placating patients and that they may help in psychosomatic illness but are worthless when symptoms are organically based. Numerous studies have revealed, however, that placebo medication is effective in treating the subjective responses to various "real" medical conditions (e.g., the pain of cancer, angina pectoris, headache, and surgical wounds). The distinction between psychogenic and organic illness has become blurred by the realization that psychological disturbances often produce physiologic or pathologic manifestations and that organic diseases, or at least their signs and symptoms, can be influenced by the CNS through regulation of hormonal secretion and peripheral nervous system activity. Placebo effects are not merely subjective in nature; the administration of pharmacologically inert substances has led to measurable changes in gastric acid secretion, in heart rate and blood pressure, in the number of circulating leukocytes, and in the plasma concentrations of various compounds, including adrenal steroids, catecholamines, electrolytes, and glucose. Even so-called subjective responses to placebos may have a biochemical basis. It has been argued that placebo analgesia can be blocked by naloxone, a specific opioid antagonist,[24] and that the placebo effect may involve the dopaminergic reward system.[12] Nevertheless, "physical parameters" (e.g., blood pressure and bronchial muscle tone) are much more likely to be affected than are "biochemical parameters" (e.g., blood cholesterol or glucose concentrations).[42]

Placebo responses to drugs arise from expectations by the patient concerning their effects and from a wish to obtain benefit or relief. Expectations develop at the conscious and subconscious levels and are influenced by many factors. The patient must be aware that treatment is being rendered. The symbolic association of receiving medication in a therapeutic environment generates placebo reactions. The patient must also be anxious about the problem and desirous of being cured. Placebo effects are unlikely if there is patient indifference to the condition or to the therapeutic regimen. Past experience is another important variable. Previous drug exposure informs a patient of what to expect from a drug; repeated administrations evoking prompt, noticeable effects may produce conditioned reflexes. Because suggestion is involved, placebo effects are subject to modification by the practitioner's attitudes (toward the patient, toward the patient's illness, and toward the drug or placebo) and how these feelings are communicated. In one study, a 45% reduction in placebo response occurred solely as a result of the administrators' negative bias toward the placebo medication.[3]

Several important similarities and differences between placebo and specific effects of drugs must be remembered if clinicians are to avoid being deceived by the preparations they use. Therapeutic responses to placebos and to active agents may resemble each other in magnitude and duration. The pain relief and cough suppression afforded by a placebo may parallel that of codeine. Toxicities can also overlap. Pure placebos are associated with many common side effects—nausea, drowsiness, sweating, xerostomia—and may occasionally be associated with life-threatening emergencies such as bronchial asthma, acute hypotension, and cardiac arrhythmia. In contrast to active agents, placebos have a relative lack of predictability. Although some drugs can be relied on to produce a given effect in essentially all patients, only approximately one third of patients receiving placebos usually react. Attempts to identify placebo responders on the basis of psychological profile or other characteristics have been unfruitful; it seems that anyone may respond to placebos in the appropriate situation. Finally, there are many classes of drugs, such as the general anesthetics and the antibiotics, whose effects placebos cannot duplicate.

More recently, the placebo effect has been more carefully scrutinized. Because most studies using placebo controls have not adequately distinguished between the effects they produce and the natural course of a symptom, disease, or healing process, the placebo effect may have been overemphasized.[18] The administration of a placebo involves the placebo intervention (e.g., the giving of a lactose tablet) and the remainder of the patient-doctor interaction.[17] Determining the relative contributions of each experience may be especially difficult.

Placebos are valid and often necessary inclusions in clinical trials, especially in studies such as analgesic drug trials, in which the placebo effect is well documented.[15] Studies involving other subjective outcomes also represent a strong argument for placebo use.[30] Placebo effects advantageous to therapy—in addition to beneficial pharmacologic effects—should also be sought whenever a drug is administered clinically.[33] Sometimes the effective communication of confidence and other positive attitudes by the practitioner can make the

difference between therapeutic success and failure. The clinical application of placebo drugs should be restricted, however, to conditions for which no other agent is superior. Even then, the evolution of informed consent into a basic patient right has, at best, complicated the clinical administration of placebo medication.[33] Despite the apparently widespread continuing use of placebos (mostly impure varieties) in medicine,[49] there seems to be no justification for the therapeutic use of placebo medication in routine dental practice.

Medication errors and patient noncompliance

Medication errors commonly result in suboptimal therapy and occasionally life-threatening responses. Poor pharmacotherapeutic decisions by the clinician may stem from a lack of knowledge about the patient, disease, or drug. In addition, drugs are often not used in the manner intended by the prescriber. Occasionally, the clinician may miswrite the prescription, or the pharmacist may supply the wrong drug or incorrectly transcribe the instructions to the patient. In the hospital setting, the nursing or house staff may administer the drug incorrectly, neglect to administer it, or administer it to the wrong patient. Most medication errors arise, however, from the failure of patients to take their preparations as directed. Drug defaulting is a major problem in therapeutics; most studies document a noncompliance rate of 25% to 60%.[46]

The reasons for noncompliance are varied. They include a lack of understanding of the drug, the purpose for which it was prescribed, or how it is to be administered; economic factors; negative feelings toward the drug or prescriber; development of adverse reactions; forgetfulness or carelessness; and resolution of the problem before the drug regimen is complete or, conversely, failure to notice any therapeutic benefit. Although infrequent omissions and minor mistakes in dosage or time of administration are often innocuous, complete failure to take the prescribed drug, premature discontinuance, or ingestion of excessive amounts can be disastrous. The possibility of noncompliance should be considered whenever a drug is seemingly without activity. Patients are notoriously inaccurate in reporting their own compliance, and physicians are not much better in estimating its occurrence. When effective therapy is essential, direct assay of the patient's blood, urine, saliva, or feces for the drug or its metabolites may be necessary to detect noncompliance.

As with the placebo responder, attempts have been made to characterize the potential drug defaulter on the basis of such factors as age, sex, education, race, and socioeconomic status. Although some correlations have been drawn (e.g., elderly patients are more apt to forget their medicine or to confuse one type of pill with another), many investigations have been either inconclusive or contradictory. The most important variables relate, not to the patient, but to the illness, the drug administered, the overall therapeutic regimen, and the doctor-patient relationship. Administration schedules are followed more faithfully by patients with life-threatening diseases than by patients with minor ailments. Even with serious illnesses such as essential hypertension, chronic infection, or hyperlipidemia, compliance is generally poor (approximately 50%) when the benefits of therapy are not superficially apparent.[35] Drugs that produce unwanted side effects are especially likely to be discontinued. Deviations in self-administration tend to increase progressively with drugs that are taken long-term. Also, the more complex the therapeutic regimen in terms of doses and drugs, the higher the incidence of drug defaulting. The quality of the doctor-patient relationship is important in several respects. Patients who trust and respect their dentist or physician are more likely to take their prescribed medications. Effective communication further promotes compliance and reduces the possibility of a patient unilaterally terminating the drug if adverse effects occur. Measures that the clinician may use to enhance patient compliance are discussed in Chapter 55.

Drug interactions

The effect of a drug may be increased, decreased, or otherwise altered by the concurrent administration of another compound. Because agents routinely used in dental practice have been implicated in drug interactions, the topic is of considerable interest to the clinician and is addressed separately in Appendix 1.

ADVERSE DRUG REACTIONS

According to the Institute of Medicine, at least 1.5 million preventable adverse drug events occur annually in the United States.[2] It has also been estimated that 5% to 17% of all patients hospitalized in the United States each year are admitted because of adverse reactions to drugs.[5,28] Estimates of the annual cost of managing these reactions range from $3 billion to $7 billion.[28] In addition, a survey of hospitalized patients between 1966-1996 revealed that 7% of hospitalized patients had a serious adverse drug reaction resulting in death, permanent disability, or prolonged care.[22]

The introduction of new, highly efficacious compounds into pharmacotherapy during the past few decades has led to a disturbing increase in the incidence of adverse reactions; drug toxicity is now considered a major cause of iatrogenic disease. Reductions in mortality rate associated with certain drugs (e.g., aspirin) show, however, that toxic responses to therapeutic agents can be minimized through concerted efforts by health professionals, the pharmaceutical industry, government, and lay public.

Classification of Adverse Drug Reactions

Drug toxicity may come in many forms: acute versus chronic, mild versus severe, predictable versus unpredictable, and local versus systemic. Therapeutic agents also differ widely in their tendency to elicit adverse reactions. Acetaminophen used to relieve headache rarely causes undesired responses, but many agents used in cancer chemotherapy invariably produce some degree of toxicity. Agents that are safe for some individuals may be life-threatening to others. Penicillin V, which normally has an exceptionally high margin of safety, can in small doses initiate fatal anaphylaxis in allergic patients. Adverse drug reactions can be classified according to their onset (acute, subacute, or delayed), degree (mild, moderate, or severe), or predictability (type A, predictable and dose related; type B, unpredictable and not necessarily dose related, such as idiosyncratic and immunologic reactions). Although no classification of adverse drug reactions is universally accepted, a taxonomy based on mechanism of toxicity is the most useful in promoting the recognition, management, and prevention of untoward responses to drugs.

Extension effects

Many drugs are used clinically in dosages that provide an intensity of effect that is submaximal. The reason for this conservatism is simple: increasing drug effects beyond a certain point may be dangerous. The anticoagulant warfarin is a typical example of a drug whose therapeutic action must be held in check to avoid serious toxicity. For the treatment of peripheral vascular thrombosis, warfarin is administered in doses that sufficiently increase the prothrombin time to yield an international normalized ratio (see Chapter 31) of 2 to 3. Warfarin could be given in larger amounts to inhibit clotting further, but the risk of spontaneous bleeding would be unacceptably high. Even with conventional therapy, hemorrhage—

TABLE **3-2**

Examples of Drug Toxicity as an Extension of the Therapeutic Effect

DRUG	MEDICAL INDICATION	THERAPEUTIC EFFECT	TOXIC EXTENSION OF THERAPEUTIC EFFECT
Furosemide	Edema	Diuresis	Hypovolemia
Heparin	Thromboembolic disorders	Inhibition of coagulation	Spontaneous bleeding
Insulin	Diabetes mellitus	Reduction of blood glucose concentration	Hypoglycemia
Modafinil	Narcolepsy	Wakefulness	Insomnia
Vecuronium	Abdominal surgery	Skeletal muscle relaxation	Prolonged respiratory paralysis
Zolpidem	Insomnia	Hypnosis	Unconsciousness

the toxic extension of warfarin's anticoagulant effect—occurs in 2% to 4% of the patients treated. Inadvertent overmedication is one cause of warfarin toxicity; however, many additional factors influencing drug effects may also be involved, such as diet; heredity; gastrointestinal ulceration; genetic differences in drug metabolism; renal, hepatic, or cardiac insufficiency; drug interactions; and variable patient compliance. "Normal dose" has little meaning regarding warfarin because a therapeutic dose to one patient may represent an overdose to another.

Adverse responses arising from an extension of the therapeutic effect are dose related and predictable. Theoretically, they are the only toxic reactions that can always be avoided without loss of therapeutic benefit by properly adjusting the dosage regimen. Table 3-2 provides additional examples of drugs that display this form of toxicity.

Side effects

Predictable, dose-dependent reactions unrelated to the goal of therapy are referred to as *side effects*. As illustrated in Table 3-3, drugs can produce a huge array of deleterious side effects. Although many such reactions are associated with only a single agent or class of drugs, others seem to be almost universal in occurrence. It is questionable, however, whether frequently noted side effects, such as nausea and drowsiness, are always drug related; similar symptoms are also commonly observed in patients after placebo administration and are reported by individuals receiving no medication whatsoever.

Side effects may be produced by the same drug-receptor interaction responsible for the therapeutic effect, differing only in the tissue or organ affected. In these instances, the categorization of drug responses as toxic or therapeutic may depend on the purpose of treatment. Xerostomia induced by atropine is a side effect during the management of gastrointestinal hypermotility, but is a desired effect when the drug is used to control excessive salivation. Side effects unrelated pharmacodynamically to the therapeutic action are also quite common, and they too may occasionally be useful. Table 3-4 lists some drugs whose side effects were found sufficiently noteworthy to provide new and unanticipated indications for therapeutic use.

Many side effects, particularly the more dangerous forms, develop only with drug overdose. Careful alteration of the administration regimen usually resolves these problems while maintaining effective treatment. Many other side effects occur at therapeutic or even subtherapeutic concentrations, and cannot be avoided by dosage adjustment without loss of drug benefit. Such reactions can be tolerated, however, if they are mild, brief in duration, reversible, and compatible with therapy. Occasionally, even disturbing side effects are accepted if the need for medication is great. Drugs used in the treatment of various cancers produce severe toxic effects that must be tolerated because no therapeutic alternative is available.

When two drugs share a common desired effect but cause different side effects, it is sometimes possible to limit toxic responses by using reduced doses of the agents in combination. Another pharmacologic approach to avoiding side effects is to add a secondary agent that is capable of blocking or otherwise compensating for the unwanted activity of the principal drug. These strategies presuppose that no additional toxicity will be generated by the combination over that produced by a single effective drug. The association of renal papillary necrosis with long-term abuse of analgesic mixtures that formerly contained aspirin, phenacetin, and caffeine is highly instructive regarding the noncritical acceptance of this assumption.[43] The most fruitful pharmacologic approach to eliminating undesired side effects is through the development of more selective drugs. Studies of structure-activity relationships have proved invaluable in removing side effects unrelated to therapeutic actions and in reducing side effects that are related.

Idiosyncratic reactions

An *idiosyncratic reaction* may be defined as a genetically determined abnormal response to a drug. Although dose dependent, such reactions are unpredictable in most instances because very few patients given an agent respond idiosyncratically and because the genetic trait responsible for an atypical reaction may be completely "silent" in the absence of drug challenge. When confronted with an unexpected response to a drug, it is a common, although erroneous, practice to describe the event as an idiosyncrasy. This habit may explain why the idiosyncratic reaction is jocularly defined as a reaction the "idiots can't explain." Most responses lying outside the normal range of drug reactivity are not truly idiosyncratic in nature but represent allergic manifestations or reflect extension or side effects in patients intolerant to the drug by virtue of factors such as age, weight, or existing disease. In dentistry, most "idiosyncratic" reactions to local anesthetics are the result of accidental intravascular injections or anxiety reactions to the process of injection.

An idiosyncratic reaction is often manifested as abnormal drug sensitivity in which the agent produces its characteristic effect at an unconventional dose. Drug effects may be unusually strong or weak in intensity or brief or prolonged in duration. In most such instances (e.g., involving succinylcholine, isoniazid, vitamin D, or phenytoin), altered drug metabolism is responsible for the abnormal responses; however, additional mechanisms have been identified, such as abnormal distribution (iron, thyroxine) and unusual receptor affinity (warfarin). In addition to perturbing characteristic drug responses, genetic singularities can produce novel drug effects that, regardless of dose, may never occur in normal individuals. One example of a novel drug effect is hemolytic anemia caused by the antimalarial drug primaquine. Red blood cells of sensitive individuals are deficient in glucose-6-phosphate dehydrogenase,

TABLE **3-3**

Side Effects of Drugs

DRUG	EFFECT
	Oral Cavity
Diphenhydramine	Xerostomia
Griseofulvin	Black hairy tongue
Phenytoin	Gingival hyperplasia
Tetracycline	Pigmentation, hypoplasia of the teeth
	Skin and Hair
Amoxicillin	Dermatitis
Cyclophosphamide	Alopecia
Methandrostenolone	Acne
Minoxidil	Hypertrichosis
	Bone and Joints
Ciprofloxacin	Arthralgia
Hydralazine	Arthralgia
Phenobarbital	Osteomalacia
Prednisolone	Osteoporosis
	Sensory Apparatus
Baclofen	Blurred vision
Digoxin	Yellow vision
Gentamicin	Ototoxicity
Thioridazine	Pigmentary retinopathy
	Blood
Cytarabine	Pancytopenia
Prilocaine	Methemoglobinemia
Valproic acid	Thrombocytopenia
Zidovudine	Granulocytopenia
	Metabolic Effects
Aspirin	Metabolic acidosis
Furosemide	Hyperglycemia
Nadolol	Hypoglycemia
Rifampin	Jaundice
	Neuromuscular System
Atorvastatin	Myalgia
Chlorpromazine	Tardive dyskinesia
Dantrolene	Weakness
Lidocaine	Convulsions
Theophylline	Tremors
	Central Nervous System
Clonidine	Drowsiness and lethargy
Dexamethasone	Mental depression
Diazepam	Confusion
Levodopa	Mania
	Cardiovascular System
Bupivacaine	Bradycardia
Phenelzine	Hypertensive crisis
Propofol	Hypotension
Propranolol	Cardiac failure
	Respiratory System
Isoflurane	Cough
Ketamine	Larygospasm
Meperidine	Respiratory depression
Propranolol	Bronchospasm
	Gastrointestinal Tract
Aspirin	Melena
Erythromycin	Diarrhea
Lithium	Nausea and vomiting
Morphine	Constipation
	Genitourinary System
Ergonovine	Abortion
Guanethidine	Impotence
Sulfadiazine	Crystalluria
Testosterone	Priapism

TABLE **3-4**

Useful Side Effects of Drugs

DRUG	ORIGINAL USE	SUBSEQUENT USE
Amantadine	Antiviral	Parkinsonism
Amphetamine	CNS stimulant	Attention-deficit/hyperactivity disorder
Chlorothiazide	Diuretic	Antihypertensive
Diphenhydramine	Antihistaminic	Sedative
Lidocaine	Local anesthetic	Antiarrhythmic
Methadone	Analgesic	Heroin substitute
Metronidazole	Antiparasitic	Antibacterial
Phenytoin	Anticonvulsant	Antiarrhythmic
Probenecid	Inhibition of penicillin excretion	Uricosuric
Quinidine	Antimalarial	Antiarrhythmic

CNS, Central nervous system.

an enzyme involved in the intermediary metabolism of glucose.[38] Lacking the ability to produce normal amounts of reducing equivalents, these erythrocytes are susceptible to oxidative destruction by primaquine and several dozen other compounds. The genetic basis of primaquine hemolysis is clear: the reaction occurs almost exclusively in men of certain racial and ethnic groups (e.g., African Americans, Sardinians, Sephardic Jews, Iranians, and Filipinos).

Various idiosyncrasies are known to be associated with drugs. Some examples are listed in Table 3-5. If an adverse response is suspected to have a genetic basis, it becomes important to determine whether the patient has a personal or familial history of atypical reactivity to the drug. Because idiosyncratic reactions are quite reproducible within any individual, a single episode of serious toxicity should preclude future use of the inciting compound. Examination of the patient's family is helpful in establishing the hereditary nature of the reaction and identifying other individuals at risk.

Drug allergy

Adverse responses of immunologic origin account for approximately 10% of all untoward reactions to drugs. Allergy can be distinguished from other forms of drug toxicity in several respects. First, prior exposure to the drug or a closely related compound is necessary to elicit the reaction. Second, the severity of response is seemingly dose independent. Third, the nature of the unfavorable effect is a function not of the offending drug but of the immune mechanism involved. Finally, the reaction is unpredictable; it usually occurs in a small portion of the population, sometimes in patients who had been previously treated on numerous occasions without mishap.

Drugs differ enormously in antigenic potential. Certain compounds (e.g., caffeine and epinephrine) never cause drug allergy; others (e.g., phenylethylhydantoin) have proved too allergenic for human use. With drugs commonly implicated clinically in allergic reactions (e.g., penicillins, sulfonamides, quinidine), the incidence of such responses is approximately 5%. Occasionally, another substance in a preparation besides the active drug (e.g., a preservative or coloring agent) causes the allergy.

Aside from agents of high molecular weight (insulin, dextran, polypeptides), drugs are usually not antigenic in the free state but must be covalently linked to endogenous carrier molecules such as albumin to generate immunologic responses. Because these therapeutic agents are often chemically inert, they generally require activation by metabolism

TABLE **3-5**

Idiosyncratic Reactions to Drugs

GENETIC ABNORMALITY	DRUGS AFFECTED	IDIOSYNCRATIC RESPONSE
NADH-methemoglobin reductase deficiency	Benzocaine, prilocaine	Methemoglobinemia
Glucose-6-phosphate dehydrogenase deficiency	Aspirin, primaquine, sulfonamides	Hemolytic anemia
Abnormal heme synthesis	Barbiturates, sulfonamides	Porphyria
Low plasma cholinesterase activity	Procaine and other ester local anesthetics	Local anesthetic toxicity
Altered muscle calcium homeostasis	Volatile inhalation anesthetics, succinylcholine	Malignant hyperthermia
Prolonged QT interval	Cisapride, some antipsychotics and antiarrhythmics	Torsades de pointes

NADH, Reduced nicotinamide adenine dinucleotide.

or by sunlight (photoallergy) before serving as haptens in the formation of antigen. Penicillins, which are responsible for most fulminating reactions, are exceptional in that they spontaneously convert to highly reactive derivatives in addition to undergoing in vivo metabolism to a small degree.

Four types of drug allergy have been differentiated on the basis of the immune reactions that cause them and the loci of their actions.[36] Type I reactions, otherwise known as reaginic or anaphylactic responses, include the immediate forms of drug allergy, in which disturbances appear within minutes or hours of taking the drug. The underlying immune reactions are initiated by the attachment of antigen to IgE antibodies bound to the surface of mast cells and basophils. Subsequent cellular degranulation and release of histamine, leukotrienes, cytokines, and other mediators are responsible for the undesired effects. Major signs and symptoms of type I allergy involve the gastrointestinal tract (cramps and diarrhea), skin and mucous membranes (erythema, urticaria, angioneurotic edema), lungs (bronchoconstriction), and blood vessels (vasodilation, increased permeability). In its most severe form, anaphylaxis can cause death by airway obstruction or by cardiovascular collapse within a few minutes after drug exposure. Parenteral injection of the drug is more likely than oral or topical use to produce life-threatening reactions. Nevertheless, patients have died from topical application of less than 1 μg of penicillin. It is believed that patients with allergic diathesis (noted by a history of hay fever or bronchial asthma) are more prone to develop serious type I reactions. The immediate anaphylactic response is the only type of drug allergy that the dentist may be forced to treat without the benefit of medical backup. Epinephrine is the drug of choice to reverse the manifestations of a severe response; antihistamines and adrenal corticosteroids are useful as adjunctive medications (see Chapter 54).

Type II, or cytotoxic, reactions are caused by circulating antibodies (IgG and IgM). When a plasma membrane constituent serves as the hapten carrier, or when a complete antigen is adsorbed on the membrane surface, the binding of immunoglobulin is followed by complement fixation and lysis of the cell. Many forms of drug-induced hemolytic anemia, leukopenia, and thrombocytopenia are the result of this form of immunologic destruction. Type II responses are usually delayed and manifest from several hours to days after drug administration.

Type III, or immune-complex, reactions occur when soluble antigen-antibody complexes form in intravascular or interstitial spaces. Eventual deposition of the complexes on the walls of small blood vessels is followed by activation of complement and migration of neutrophils into the area. These cells degranulate in attempts to remove the complexes, releasing lysosomal enzymes that cause local tissue damage and promote thrombosis of affected vessels. Type III reactions can induce many unpleasant sequelae, some of which can be quite serious (e.g., neuropathy, glomerulonephritis, serum sickness). Reactions indistinguishable from disease states such as lupus erythematosus and erythema multiforme are also observed. Finally, soluble antigen-antibody complexes can attach to cell membranes and cause cytotoxicity indistinguishable from type II reactions.

Type IV reactions are synonymous with cell-mediated immunity. Sensitized T lymphocytes exposed to the drug hapten or its conjugate release lymphokines that attract additional cells (lymphocytes, macrophage, cytotoxic T cells) to the antigenic site. Lysozymes and other substances (including toxic lymphokines) elaborated by the recruited cells produce local tissue necrosis. Type IV reactions are usually delayed because of the time required for effector cells to concentrate in the area involved. For dentists, an important cellular immune reaction was the contact dermatitis acquired from repeated exposure of the hands to ester local anesthetics such as procaine. Before the availability of amide anesthetic drugs, allergy to procaine markedly complicated clinical practice. Allergy to ester-based local anesthetics presents a problem for some patients today because of various substances that may cross-react to elicit an eczematoid rash; two examples are methylparaben, a pharmaceutical preservative in widespread use, and *p*-phenylenediamine, a component of hair dyes.[1]

Although drug allergies cannot always be prevented, their frequency of occurrence can be minimized by observing the following precautions:

1. *Take an adequate medical history*. If a patient has a presumptive history of drug allergy, it is important to discover the identity of the inciting preparation and to determine whether the reaction is consistent with an immunologic cause.
2. *Avoid the offending drug and likely cross-reactors*. A patient truly allergic to a drug should not receive the agent or congener again unless need for the particular medication is great.
3. *Avoid inappropriate drug administration*. In one study, a review of 30 fatalities to penicillin revealed that the antibiotic was not even indicated in more than 50% of the cases examined.[41]
4. *Promote oral use and limit topical exposure*. With the penicillins, the oral and topical routes are the least (oral) and most (topical) allergenic avenues of drug administration.
5. *Request allergy testing when appropriate*. Although such methods are generally unreliable and can be dangerous, skin tests for penicillin allergy have proved predictive.[48] Success has also been claimed regarding local anesthetics.[1] Allergy testing may be necessary when suitable alternatives to the drug in question are unavailable.

Adherence to these recommendations will reduce the incidence of allergic reactions to drugs. For example, the more prudent use of penicillin in recent years may have led to a

decline in the drug's mortality rate, previously estimated in the United States to be 500 individuals per year.[34]

Pseudoallergic and secondary reactions

Pseudoallergic reactions are adverse drug responses caused by mediators of allergy that are released through antibody-independent processes. In the case of macromolecules, the alternate pathway of complement fixation may lead to various cytotoxic and immune-complex reactions. Much more common are anaphylactoid reactions that mimic one or more aspects of anaphylaxis. Some opioid analgesics, neuromuscular blocking drugs, and intravenous anesthetic agents can cause the release of histamine from mast cells. Aspirin, ibuprofen, and related inhibitors of prostaglandin synthesis can result in the overproduction of bronchospastic leukotrienes. As with true allergies, these reactions are unpredictable; however, they seem to be dose dependent, do not require prior sensitization, and may occur on initial exposure to the drug.

Secondary reactions are indirect (and often unpredictable) consequences of a drug's primary pharmacologic action. Antibiotics provide the best examples. One possible outcome of antibiotic administration is the development of superinfection, a secondary microbial disease made possible by the antibiotic-induced suppression of the normal microflora (see Chapters 38 and 39). Alternatively, the rapid lysis of susceptible bacteria may result in the Jarisch-Herxheimer phenomenon, a serum sickness–like syndrome caused by the release of microbial antigens, endotoxins, or both.

Carcinogenesis

One aspect of drug toxicity that has had a strong impact on public awareness is carcinogenesis. Although most attention has been focused on environmental pollutants, including chemicals that pose an occupational hazard, the association of leukemia with various anticancer agents and uterine neoplasia with diethylstilbestrol underscores the tumorigenic potential of certain therapeutic drugs. The most pervasive cancer-producing substances in our society are derived from a "social" drug—the cigarette.

Virtually any agent capable of altering the structure of DNA is a potential carcinogen. Agents known to be carcinogenic include radioactive substances, alkylating agents, nitrosamines, and various aromatic amines and polycyclic aromatic hydrocarbons. With the exception of radioactive materials, most drugs capable of initiating neoplastic change must become chemically activated. This process occurs spontaneously with some alkylating substances, but it usually depends on metabolic biotransformation. Cytochrome P450 enzymes are commonly involved, yielding highly reactive electrophilic intermediates. These activated molecules can interact with DNA at specific sites. Alkylating drugs can form covalent linkages with the 7-nitrogen atom of guanine. If replication occurs before the damage can be repaired, a transversion may occur in which the alkylated guanine-cytosine pair is replaced by a thymine-adenine. Such transversions are not randomly distributed throughout the genome, but are clustered at specific loci.[13] Neoplastic transformation occurs when mutations develop in genes regulating cellular growth.

Compelling evidence has accumulated since 1980 implicating two groups of genes in chemical carcinogenesis: oncogenes and tumor suppressor genes.[45] Oncogenes are derived from normal genes, or proto-oncogenes, whose function is to promote growth and development. Several mechanisms for neoplastic transformation of proto-oncogenes have been discovered, including point mutation, which would seem to be the most likely candidate for chemical carcinogenesis. The *ras* group of proto-oncogenes is frequently transformed in human cancer. Each *ras* gene codes for a protein that helps convey stimulatory signals from membrane-bound tyrosine kinase receptors to the nucleus. Ras proteins are activated by binding guanosine triphosphate (GTP) and inactivated by autohydrolysis of the bound GTP to guanosine diphosphate. The *ras* oncogene products differ from the natural protein by a single amino acid substitution at one of several key points that are apparently involved in nucleotide binding and protein regulation.[37] The net result is a protein that loses its ability to split GTP and remains activated at all times. Other oncogenes have been identified that code for various tyrosine kinases, serine/threonine-specific protein kinases, and gene regulatory proteins.

Tumor suppressor genes code for proteins that normally inhibit cell growth. An important example involved in most human cancers is the *p53* gene. Its protein derivative, p53, is a nuclear regulatory protein that activates transcription of a gene whose protein product prevents the cell from replicating. When the *p53* gene is rendered inactive or mutated, this important inhibitory pathway is lost, and the affected cell may begin to multiply.[50] Spontaneous errors in replication may also accumulate because rapid cellular division leaves insufficient time for DNA repair.

Cancer is normally a multistage phenomenon involving multiple genetic mutations.[11] In the case of oral squamous cell carcinoma, a series of deletions involving multiple tumor suppressor genes and overexpression of the proto-oncogenes cyclin D1 and epidermal growth factor receptor are common steps leading to carcinogenesis.[8] Collectively, these changes are responsible for the initiation of neoplastic transformation and the subsequent promotion of cellular growth.

Certain compounds cause tumors only after prior treatment with another agent. The first chemical seems to initiate the neoplastic transformation, and the second promotes tumor growth. The latter are called *promoters* or *nongenotoxic carcinogens*. It is hypothesized in these instances that the promoter removes the control of growth that distinguishes normal from cancerous cells. Examples of promoters in experimental models include phorbol esters, saccharin, chlorophenothane, and phenobarbital. Regardless of initiating or promoting factors, immunosuppressive drugs may foster cancer development generally by interfering with immunologic surveillance mechanisms responsible for the elimination of transformed neoplastic cells.

Carcinogens are often detected by screening for mutagenicity by the Ames test. Major difficulties are encountered, however, in assessing the carcinogenicity of agents intended for human use. First, the latency period between the initiation and clinical appearance of neoplasia may span years to decades. Second, although the incidence of tumor induction is dose dependent, it is not established whether a dose or duration of exposure below which tumors will not be produced can be found for any drug. Third, because an administered agent usually requires metabolism for activation, interspecies differences in biotransformation severely limit the use of animal testing in such instances. Without a foolproof method of screening drugs, continued appraisal of cancer rates regarding drug intake is a necessary, if not ideal, approach to identifying carcinogenic compounds. In view of the prolonged latency of cancer development and the flood of agents introduced into pharmacology in recent decades, it would be surprising not to witness the discovery of new carcinogens among therapeutic agents now in use.

Special Problems

Hazards of medication pertaining to abuse, poisoning, and effects on the unborn child warrant special comment because the individuals affected are generally not exposed to the agent for therapeutic purposes. In these situations, the prevention and management of adverse reactions can be complicated by matters such as the intent of the person taking the drug, an inability to identify the offending agent, and the unique susceptibility of the embryo to drug toxicity.

Drug abuse

Typified by persistent and excessive self-administration, drug abuse refers to the inappropriate and deviant use of any drug. Drug abuse presents a special problem in toxicology because, in addition to the hazards of taking pharmacologically active agents without proper medical supervision (e.g., drug toxicity, infection from inadequate antisepsis), adverse consequences may arise from the acts involved in procuring and using such compounds. Compulsive behavior is especially strong with drugs that act on the CNS, and, with the exception of substances to which little stigma is attached—caffeinated beverages and tobacco products—the attendant social, economic, and legal costs of the abuse of these agents can be enormous. Even in the case of tobacco products, restrictions are increasingly being placed on their use that can have legal ramifications if violated. Abstinence from drugs producing physical dependence results in the appearance of withdrawal symptoms characteristic of the substance involved and the intensity of previous use. A thorough discussion of drug abuse involving centrally acting agents is presented in Chapter 51.

Drug poisoning

As revealed by data from the American Association of Poison Control Centers, more than 2.4 million poisonings were reported in 2007.[6] Of the more than 1000 poisoning deaths in the same report, over half were believed to be the result of suicide. Drug poisoning accounts for a significant percentage of reported episodes and is a major concern for health professionals and laypersons alike. Drugs most commonly implicated in fatal poisonings are analgesics, antidepressants, alcohol, CNS stimulants, and cardiovascular agents.

Children younger than 5 years account for most poisonings and for approximately 2% of deaths from poisoning. Despite these statistics, fatal poisonings of small children have decreased by more than 70% since the early 1960s. Aspirin, historically the leading cause of drug toxicity in small children, provides a noteworthy example of how unintentional poisoning can be controlled. Recognizing the special hazard of flavored baby aspirin, the pharmaceutical industry voluntarily limited the number of aspirin tablets per bottle to a (normally) sublethal total of 36. Safety packaging, which became mandatory after the passage of the Poison-Prevention Packaging Act of 1970, reduced the incidence of fatal ingestion further. Finally, increased public awareness concerning the danger of aspirin overdose, engendered in part by the proliferation of poison control centers throughout the United States, led to safer storage of aspirin in the home. Further decrements in the aspirin mortality rate have occurred, aided partly by the increased reliance on liquid acetaminophen and ibuprofen preparations for analgesia and antipyresis. As one might predict, however, acetaminophen and ibuprofen poisonings, previously quite rare, are now more common. The principles of toxicology and the prevention and management of drug poisoning are discussed in Chapter 52.

Drugs and pregnancy

The hazard to the unborn child of administering drugs during pregnancy has received considerable attention in the lay and professional literature. Over the years, certain compounds have been implicated in the development of congenital abnormalities. These teratogens disturb organogenesis in the developing embryo so that defects in one or more structures are produced. If the defects are incompatible with life, fetal death and either resorption or spontaneous abortion ensues; if they are less severe, the result is a malformed child.

Very little is known about the teratogenic potential of most drugs in humans, but the thalidomide disaster of 1960-1962 proved that an ordinary drug, extremely safe in adults, could induce extensive malformation prenatally. Thalidomide is a sedative-hypnotic that was released for clinical use in Europe and elsewhere in the late 1950s. The drug quickly gained wide acceptance and was commonly used by women to relieve the nausea of "morning sickness." Shortly after its introduction, an epidemic occurred of infants born with phocomelia, or "seal limb" malformation of the arms and legs. Retrospective studies determined that phocomelia was caused by thalidomide when the agent was taken 24 to 29 days after conception.[23] Other defects were also produced by thalidomide (e.g., absence of external ears, cranial nerve dysfunction, anorectal stenosis), depending on the time of administration. Removed from the worldwide market for many years, thalidomide has made a comeback in therapy. It is currently approved for treating certain forms of leprosy; it is also used clinically to manage various sequelae of human immunodeficiency virus (HIV) infection, to treat multiple myeloma and aphthous ulcers, and as an immune modulator in disorders such as Crohn's disease. Strict prescribing controls are in place to prevent its use in pregnant women.

Laboratory experiments in animals and investigations of accidental teratogenesis in humans have found that drug-induced malformation is governed by the sequential pattern of embryonic and fetal development. From fertilization to approximately 20 days, an embryo either survives or succumbs to a chemical insult. No malformations occur, however, because the cells remain undifferentiated during this period. Beginning at day 21 (when the somites appear) and continuing until the end of the first trimester (when differentiation and organogenesis are well established), teratogenic malformations are possible. The defects produced vary with the toxic action of the agent and with the time of administration. Certain malformations, such as cleft palate, may be produced by various substances; some teratogens, such as antifolate drugs, can evoke a wide spectrum of structural defects.[51] Selective toxicity of drugs to the fetus does not end after 3 months' gestation. Although gross malformation may not occur, normal development may be retarded or otherwise affected throughout pregnancy. Immaturities in physiology and biochemistry may promote adverse reactions in the fetus at doses safe to the mother. The administration of drugs at the time of delivery is commonly associated with exaggerated effects in the neonate.

Table 3-6 lists several agents known to elicit toxic effects during pregnancy and indicates when their administration is most dangerous to the embryo or fetus. In an attempt to classify drugs on the basis of their toxic potential during pregnancy, the FDA instituted a pregnancy category rating, which is summarized in Table 3-7. Many older drugs have not yet been rated; of the drugs that have been classified, most fall into categories indicating a lack of definitive information regarding safety in humans.

Despite uncertainties concerning most drugs and the unborn child, pharmacologic agents have been used extensively by pregnant women. The major drug categories include iron supplements, analgesics, vitamins, sedative-hypnotics, diuretics, antiemetics, antimicrobials, cold remedies, hormones, "tranquilizers," bronchodilators, and appetite suppressants. Drugs vary widely in their relative risk during pregnancy.[4] Although women and health care professionals are now more aware of the risks posed by drugs, the admonition to restrict usage of therapeutic agents, especially during the first trimester, bears reiteration. For dentistry, there are no clear data regarding the use of local anesthetics in the first trimester. In light of the possibility that local anesthetics may pose a small risk to the unborn child, prudence dictates that only urgent or emergent treatment be rendered during this critical period of fetal development. Benzodiazepine sedatives, which are known to be human teratogens, must be avoided throughout the pregnancy. Regular dental care need not be postponed, however, during the second trimester as long as reasonable attention and care are given to avoiding undue physical and emotional stress in the patient and drugs that pose a known risk to the fetus.[31]

TABLE **3-6**

Toxic Effects of Drugs During Pregnancy

		MOST SUSCEPTIBLE PERIOD*			
DRUG	**TOXIC EFFECT TO FETUS**	**FIRST TRIMESTER**	**SECOND TRIMESTER**	**THIRD TRIMESTER**	**TERM**
Anticancer drugs	Cleft palate, extremity defects, severe stunting, death	✓			
Chloramphenicol	Gray syndrome, death				✓
Cortisone	Cleft palate	✓			
Coumarin anticoagulants	Hemorrhage, death				
Diazepam	Cleft palate, respiratory depression	✓			✓
Local anesthetics	Bradycardia, respiratory depression				✓
Lysergic acid diethylamide	Chromosomal damage, stunted growth	✓			
Opioid analgesics	Respiratory depression, neonatal death				✓
Potassium iodide	Goiter, mental retardation				
Quinine	Deafness, thrombocytopenia			✓	✓
Sex steroids	Masculinization, vaginal carcinoma (delayed)				
Streptomycin	Eighth cranial nerve damage, micromelia, multiple skeletal abnormalities				
Tetracyclines	Inhibition of bone growth, tooth discoloration, micromelia, syndactyly				
Thalidomide	Phocomelia, multiple defects	✓			
Thiazide diuretics	Thrombocytopenia, neonatal death			✓	✓

*Coumarins and other drugs with no indication mark are approximately evenly toxic throughout pregnancy.

TABLE **3-7**

U.S. Food and Drug Administration Pregnancy Risk Categories

CATEGORY	**DEFINITION**	**EXAMPLE DRUGS**
A	Adequate and well-controlled studies have failed to show a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters)	Levothyroxine, magnesium sulfate (injectable), sodium fluoride*
B	*Either* (1) adequate and well-controlled studies have failed to show a risk to the fetus in the first trimester of pregnancy, and there is no evidence of risk in later trimesters, but animal reproduction studies have shown an adverse effect on the fetus; *or* (2) human studies are lacking, but animal studies have failed to show a risk to the fetus	Acetaminophen,* amoxicillin and clavulanate, cefaclor, erythromycin, lidocaine, naproxen, penicillin V*
C	No adequate and well-controlled studies have been performed in pregnant women, but animal reproduction studies are lacking or have shown an adverse effect on the fetus. Potential benefit may warrant use of the drug in pregnant women despite potential risk	Atropine, bupivacaine, butorphanol, codeine, diflunisal, epinephrine, hydrocortisone (topical), mepivacaine, morphine, thiopental
D	Positive evidence exists of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans. Potential benefit may warrant use of the drug in pregnant women despite potential risk	Aspirin,* hydrocortisone (systemic),* lorazepam, midazolam, pentobarbital, valproic acid
X	Studies in animals or humans have shown fetal abnormalities, or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, or both, and the potential risk of the drug in pregnant women clearly outweighs the potential benefit	Ergotamine, estradiol, isotretinoin, temazepam, triazolam, warfarin

DEVELOPMENT OF NEW DRUGS

Advances in pharmacotherapy ultimately depend on the discovery, evaluation, and marketing of new drugs. The past several decades have witnessed an unprecedented proliferation of medicinal agents, and major revisions in how drugs intended for human use are evaluated have contributed to the manufacture of safer and more effective compounds. As a prescriber of drugs, however, the practitioner should be aware of the attendant problems and costs of developing therapeutic agents and of the unavoidable limitations in assessing drug safety before widespread use. Only with this knowledge can the clinician arrive at a balanced attitude toward new drugs and claims made for them.

Sources of New Drugs

For several centuries, considerable effort in pharmacology was devoted to the purification of active constituents from natural plant and animal products previously used for medicinal purposes. With the exception of various herbal medicines, these traditional sources of drugs are, for the most part, depleted.

Many new therapeutic agents are discovered by empiric screening. In screening tests, thousands of compounds from natural materials or synthetic chemistry are examined for a particular pharmacologic activity. Microplate, microarray, and other types of high-throughput technology have made screening an important method of finding new drugs capable of producing a defined drug effect. With the exception of penicillin, all the antibiotic groups have been isolated by the screening of soils and other materials for antimicrobial activity. In recent years, advances in synthetic chemistry and molecular biology have led to a proliferation of screening tests in which cells engineered to express receptors of interest and easily measured biologic responses to receptor activation are exposed to large collections of chemicals and examined for activity.

One productive technique of finding new drugs is to alter the molecular structure of an existing agent. Structure-activity relationship studies are intimately involved in this approach. When derivatives are produced, they are frequently little more than "me too" drugs—agents that, although similar in activity to the parent compound, offer no therapeutic advantage but are marketed anyway for economic reasons. Less often, a drug is synthesized that differs substantially from its predecessor in pharmacokinetic properties. Penicillin V, which is nearly identical in antimicrobial activity to its precursor, penicillin G, is nevertheless preferred for oral use because its absorption is two to five times better. Pharmacokinetic differences are especially prominent among the benzodiazepine congeners, with elimination half-lives ranging from several hours to several days. The least common but usually most desirable outcome of molecular modification is the synthesis of a derivative that differs qualitatively from the parent drug in pharmacodynamic effect. Such discoveries are generally the result of attempts to enhance one aspect of an agent's spectrum of activity over all others. The observations that sulfonamides used in chemotherapy of bacterial infections could decrease blood glucose concentrations and promote urine flow under appropriate conditions eventually led to the manufacture of several new classes of drugs: carbonic anhydrase inhibitors, thiazide diuretics, and sulfonylurea hypoglycemic agents.

Increasingly, discoveries of new drugs are evolving from advances in understanding of basic physiology, biochemistry, and the human genome. Nowhere is this "rational drug discovery" approach more apparent than in the synthesis of antimetabolites for antiviral and cancer chemotherapy and the development of drugs to modify immune reactions. The extraction of some natural effectors (e.g., insulin, calcitonin, and adrenocorticotropin) and the synthesis of others (e.g., adrenal and sex steroids, epinephrine, vitamin D derivatives, and prostaglandins) have provided a host of therapeutic agents. Recombinant DNA technology, by which bacteria or even transformed mammalian cells can be altered genetically to synthesize foreign proteins, is fulfilling its promise for the large-scale production of human-derived agents (e.g., interferons, insulin, calcitonin, growth hormone, hematopoietic growth factors, and monoclonal antibodies) that were previously obtainable only in small amounts. This source of drugs is likely to continue to grow, and it is expected that hitherto unknown agents will become available for pharmacotherapy as studies of the human genome progress.

A burgeoning source of new pharmaceutical products comes from the development of novel delivery systems for existing drugs. The use of prodrugs to provide for improved gastrointestinal absorption (e.g., enalapril), regional distribution (e.g., levodopa, when given with carbidopa), or greater safety (e.g., acyclovir) is a well-established strategy. More complex approaches, such as various lipid formulations of drugs, may provide a safer parenteral delivery of drugs such as amphotericin B, a highly toxic antifungal agent. Conjugated monoclonal antibodies, whose production is outlined in Chapter 41, are now being used in cancer patients as vehicles for cytotoxic substances (e.g., diphtheria toxin) and various anticancer drugs and radioactive isotopes.[21] The antibody attaches to tumor-associated surface antigens and positions the active ligand so that it can provide the tumoricidal effect. Similar drug-carrying monoclonal antibodies directed against discrete cellular elements of the immune system have found use in preventing transplant rejection and in the treatment of autoimmune diseases.[39] Attaching drugs, often covalently, to polymeric carriers is proving effective in localizing and prolonging drug effects, either because the controlled release of free drug from the immobilized matrix permits only local effects, or because the drug is active in the bound state. In either case, the distribution of drug action is determined by the properties of the carrier. There are many potential applications for such systems; in dentistry, the controlled release of antibiotics is useful in treating certain forms of periodontitis.[20]

The last major source of new drugs is serendipity. Probably the greatest single breakthrough in pharmacotherapeutics in the twentieth century was the isolation of penicillin, made possible by the chance but astute observation of Fleming that bacteria in a culture dish were lysed by a mold contaminant of the genus *Penicillium*. Other classes of agents that originated by accident include the antiarrhythmic drugs (quinine) and the oral anticoagulants (dicumarol). Table 3-4 lists several drugs for which new therapeutic applications were fortuitously discovered after marketing.

Evaluation of New Drugs

Before a drug can be released for general use, it must pass a rigorous evaluation program established by the FDA (Figure 3-3). This program, although subject to some modification depending on the drug's intended use, invariably includes a series of animal and human investigations to ensure the product's safety and efficacy. (See Chapter 55 for a review of drug regulations pertaining to the FDA and the development of new drugs.)

Preclinical testing

The first step in evaluating a newly discovered compound is to ascertain its pharmacologic activity in animals. Initially, a few rats may be given several different doses of the chemical and observed for any disturbances that may occur in physiology or behavior. If the drug is being developed for a given purpose (e.g., to reduce blood pressure), it would be tested for that particular effect as well. Agents that seem to have a

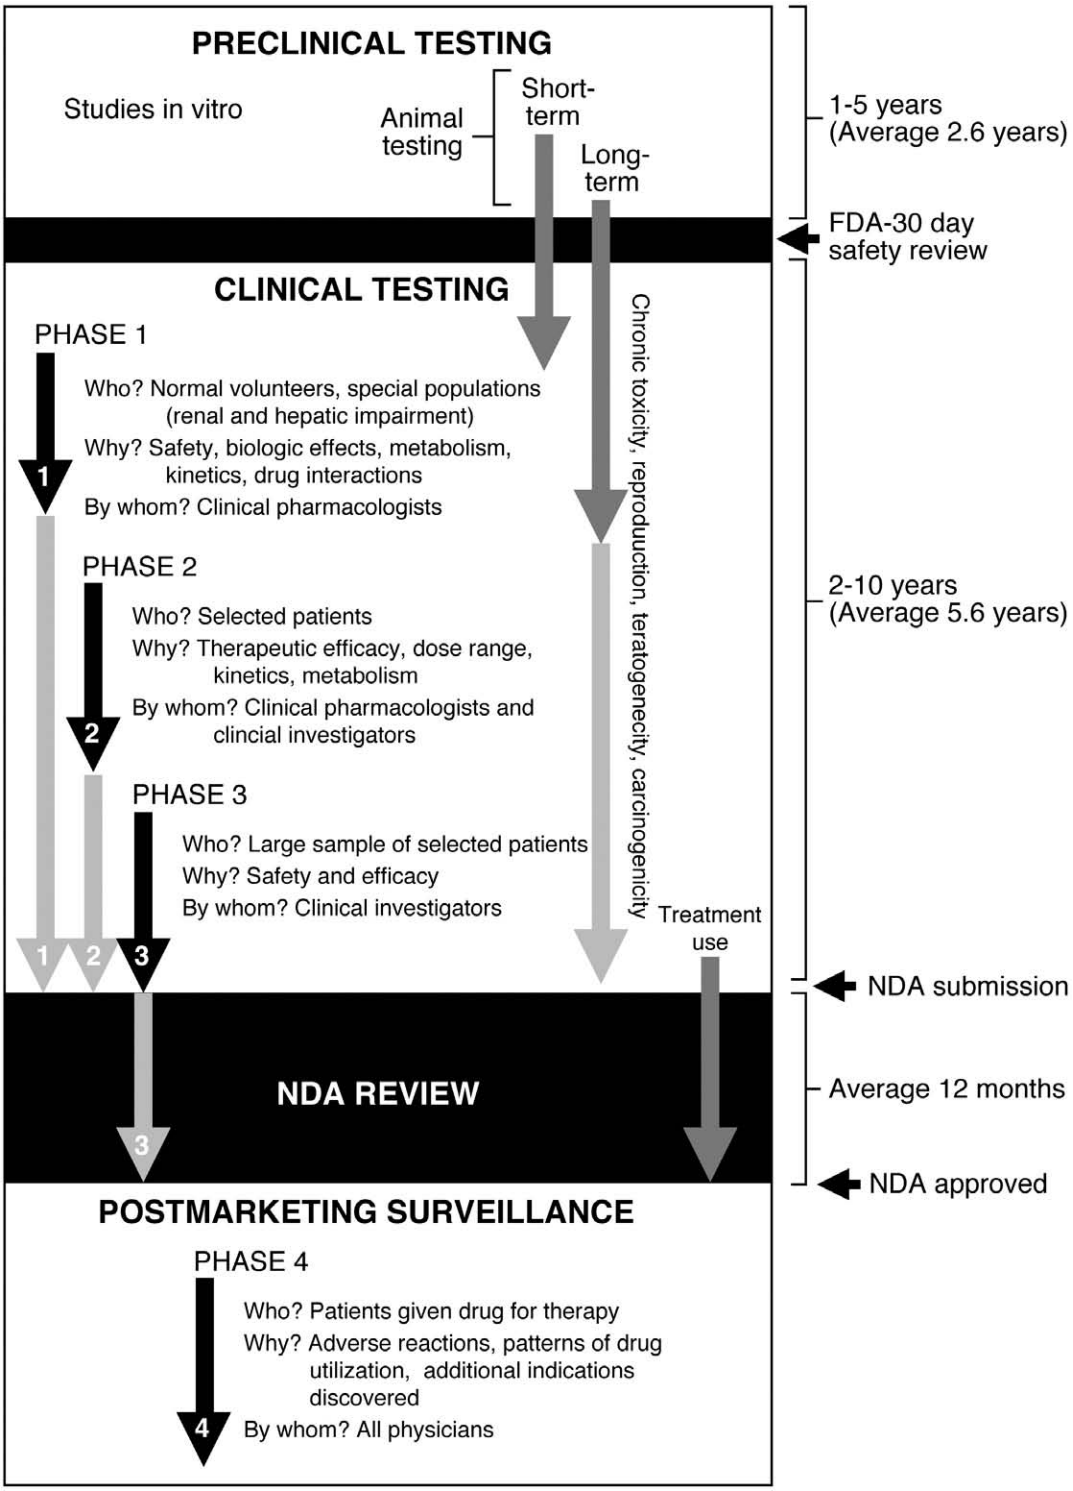

FIGURE **3-3** Overview of drug development. (Adapted from Oats JA: The science of drug therapy. In Brunton LL, Lazo JS, Parker KL, editors: *Goodman and Gilman's the pharmacological basis of therapeutics,* ed 11, New York, 2006, McGraw-Hill.)

useful action are enrolled in more extensive examinations. Graded dose-response curves are constructed to determine the potency and intrinsic activity of the compound (see Chapter 1). When a specific therapeutic effect is identified, quantal dose-effect relationships are drawn to estimate the compound's relative safety. As shown in Figure 3-4, quantal dose-effect curves can be prepared for desired and toxic responses.

When working with laboratory animals, one of the most convenient toxic effects to monitor is lethality. Death is universal, all drugs are capable of producing it, and it represents a definite end point that can be quickly and unequivocally recognized. The dose causing death in 50% of the test animals in a given period is designated as the median lethal dose (LD_{50}). The ratio of this dose to the median effective dose (LD_{50}/ED_{50}) defines the therapeutic index, a crude but

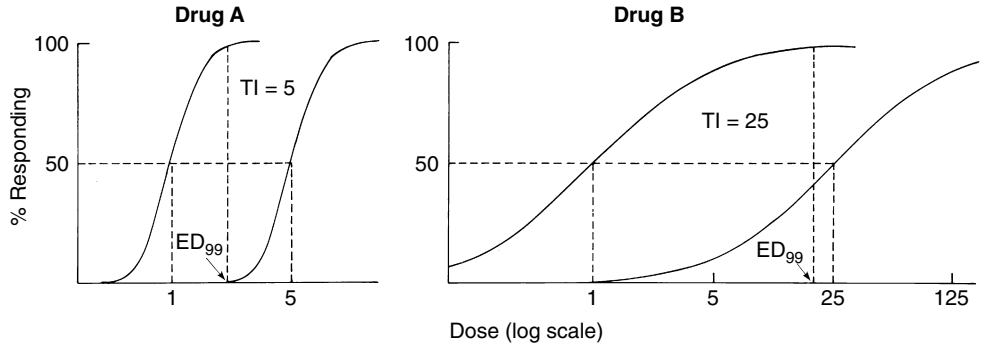

FIGURE **3-4** Quantal dose-response relationships (log scale) of two drugs, *A* and *B*. For each drug, the curve on the left reflects therapeutic responses, and the curve on the right represents toxic reactions. ED_{99}, Dose effective in 99% of the population; *TI*, therapeutic index.

TABLE **3-8**

Comparison of Potency, Irritancy, and Lethality of Local Anesthetics

		LOCAL IRRITANCY†		LETHALITY‡	
DRUG	**ANESTHESIA* TAC (mmol/L)**	**TIC (mmol/L)**	**RELATIVE SAFETY**	**LD_{50} (μmol/L)**	**RELATIVE SAFETY**
Procaine	8.8	176	1	220	1
Tetracaine	0.69	12	0.9	27	1.6
Propoxycaine	0.81	75	4.6	22	1.1
Lidocaine	2.69	62	1.2	85	1.3
Cocaine	1.16	79	3.4	62	2.1

LD_{50}, Median lethal dose; *TAC*, threshold anesthetic concentration; *TIC*, threshold irritant concentration.

useful measure of drug safety. Other things being equal, a drug with a large therapeutic index is safer than an agent with a smaller value. When many congeners are being tested concurrently, those with the most favorable therapeutic indexes are given preference in further investigations and are considered the most promising candidates for clinical application. The LD_{50}/ED_{50} ratio is not fully predictive of relative safety. Drugs produce many toxic effects besides death that can prevent their use in humans. An agent that has a large therapeutic index regarding one adverse reaction may fare poorly in regard to another type of toxicity.

Table 3-8 compares a group of local anesthetics in their propensity to elicit two separate toxic effects—death and local tissue irritation—as a function of the anesthetic concentration.[26] Each test was performed in a different species: lethality in mice, irritability in rabbits, and anesthesia in guinea pigs. With procaine used as a standard, propoxycaine was 4.6 times safer regarding tissue irritation, but essentially equivalent in relation to lethality. From these data, cocaine would seem to be the safest local anesthetic for human administration; however, cocaine has some additional liabilities—CNS stimulation and abuse potential—not shared by the other agents that severely restrict its medical usefulness.

A second limitation of the therapeutic index is that biologic variability is not taken into account. In Figure 3-4, drug B has a larger therapeutic index than drug A, but is nevertheless clinically inferior. The goal of pharmacotherapy is to achieve a desired effect in virtually all patients without producing toxicity in any. Because the slopes of the quantal dose-effect curves of drug A are steep (indicating little variation in responsiveness to the drug), a dose effective in 99% of the population (ED_{99}) can be administered with little risk to the recipients. Although drug B exhibits a therapeutic index five times greater than drug A, the biologic variability to it is so great that an ED_{99} would produce toxicity in a significant fraction of the population. Estimates of relative safety that take biologic variation into account include the *certain safety factor*, which is the LD_{01}/ED_{99} ratio (with LD_{01} being the lethal dose in 1% of the population), and the *standard safety margin*, which is the percent increase over the ED_{99} needed to reach the LD_{01}, calculated as follows:

$$\frac{LD_{01} - ED_{99}}{ED_{99}} \times 100$$

The disadvantage of these measures compared with the therapeutic index is the larger number of animals required for their determination.

To evaluate drug safety in animals thoroughly, acute, subacute, and chronic toxicity testing must be carried out in several different species and by several different routes of administration. Special studies are performed to detect carcinogenic and teratogenic activity, and adjuvants (e.g., Freund's) are used to test new products for their propensity to cause contact dermatitis. In addition to toxicity evaluations, pharmacokinetic investigations are done to determine the rate and extent of drug absorption, pattern of distribution, plasma half-life, and routes of elimination. Correlation of pharmaco-

logic effect with plasma titer has some predictive value for the therapeutic concentration in humans, and can indicate if the parent drug or a metabolite is the active moiety. Some more protracted and costly investigations may be run concurrently with human studies to save time and expense (if the drug proves unsuitable during initial clinical trials).

Regardless of the number, size, or sophistication of animal tests used, studies in humans are necessary to establish the clinical worth of any drug. Primarily because of unpredictable differences in biotransformation, pharmacokinetic studies in animals cannot be relied on to determine the correct dose or the duration of action of a drug in humans. Of even greater importance is the inability of preclinical studies to detect many forms of drug toxicity that occur in humans. Most revealing in this regard was a retrospective compilation of adverse reactions to six unrelated drugs, each used in humans, rats, and dogs.[25] Considering only toxic signs that are observable in animals and humans, 43% of the various kinds of human toxicity caused by the drugs were not found in either of the test species. When subjective responses (e.g., depression and giddiness) and other effects not detectable in animals (e.g., urticaria, nausea, headache) are taken into account, it becomes apparent that at least half of the untoward responses frequently caused by drugs cannot be ascertained preclinically. The need for human experimentation in drug development is unassailable.

Clinical trials

If an agent seems sufficiently promising on the basis of its preclinical evaluation to warrant testing in humans, the drug sponsor (generally a large pharmaceutical company) must first submit an application to the FDA in the form of a *Notice of Claimed Investigational Exemption for a New Drug* (IND application) detailing, among other things, (1) the identity of the drug and how it is prepared; (2) all results of preclinical investigations to date; (3) the intended use of the agent, dosage form, and route of administration; and (4) the procedures to be followed in assessing the drug's safety and effectiveness in humans. On FDA approval of the IND application, the first phase of clinical evaluation can begin.

Phase I trials represent an intensive study of the drug in a few, usually healthy, volunteers. The safe or tolerable human dose is arrived at by cautiously administering increasing increments of the drug to subjects until the desired response is obtained or a toxic side effect intervenes. Pharmacokinetic data from single and repeated administrations are collected to determine the bioavailability of the compound, its time course of action, and how it is eliminated from the body. Careful attention is given to any adverse effects that may occur. As with subsequent clinical studies, informed consent must be obtained from all subjects involved in phase I trials. Regulations by the FDA involving human experimentation conform to the principles incorporated in the Nuremberg Code and Declaration of Helsinki of the World Medical Association.[16]

The second phase of clinical evaluation involves administration of the drug to a few targeted patients. Phase II trials are the first real attempt to establish therapeutic efficacy, and many drugs are withdrawn from further investigation at this point. The exact studies made during phase II are determined in large measure by the drug. The major goals of investigation are constant, however: to establish efficacy and safety in patients and to arrive at the therapeutic dose. These first two phases are conducted exclusively by professionals trained and experienced in clinical pharmacology.

The decision to proceed to phase III trials commits the drug sponsor to a large-scale, controlled study of the drug. In phase III, the agent must be proved to be relatively safe and effective in a clinical setting. Such proof may require the combined efforts of more than 100 practitioners administering the drug to several thousand patients. It is most important that these trials be designed and organized to provide a scientifically sound appraisal of the drug's therapeutic value. There must be a clearly defined end point of treatment so that drug effectiveness can be accurately determined. Proper controls (i.e., placebos when appropriate, active drugs when available) must be run concurrently to provide the necessary comparisons of drugs, and sufficient numbers of subjects must be used in the study to make such comparisons meaningful. The assignment of subjects to control and test categories must be unbiased. This unbiased assignment generally requires either a randomly assigned allotment of patients, in which each volunteer has an equal chance of being in any treatment group, or a crossover design, in which every subject receives each treatment in a balanced order. Bias in reporting drug effects also must be avoided; this can often be accomplished only by performing the trial under "blind" conditions. In a single-blind study, patients are not informed of which drug they receive; in a double-blind investigation, the identity of the medication is concealed from all individuals directly engaged in the study. Finally, appropriate statistical methods must be used to verify any conclusions reached about the drug.

Drug approval and continued surveillance

At the conclusion of phase III, a considerable body of information will have been gathered about the drug. These data are submitted to the FDA in the form of a *New Drug Application* (NDA). If accepted as "complete," the drug is approved for marketing as a prescription drug or as an over-the-counter item, depending on the need for professional supervision to ensure user safety. More often than not, the NDA is labeled "incomplete," however, and the sponsor is advised of additional evaluations that must be performed for it to be accepted. Even with approval of the agent, the sponsor must continue to submit reports to the FDA at regular intervals describing the quantity of drug distributed and detailing any unusual responses to the preparation, such as allergic reactions, idiosyncratic responses, or unanticipated drug interactions. This review constitutes phase IV of the clinical investigation.

Continued surveillance of the drug after general release is often the only method available for identifying uncommon or delayed toxic effects. Chloramphenicol was extensively used for 2 years before it was discovered to be capable of inducing severe blood dyscrasias (in approximately 0.002% of treated patients),[29] and it was in use for 17 years before it was recognized to be capable of causing visual impairment.[9] It seems an ever-repeating cycle that a new drug is initially hailed as being essentially nontoxic, only to have enthusiasm dampened several years later by the realization that adverse effects are an integral part of the agent's pharmacologic profile.

Impact of FDA regulations on the development of new drugs

Regulations by the FDA governing the development and marketing of therapeutic agents exist largely as a result of public concern over the toxic liabilities of drugs. Had similar regulations been in force in Europe before 1959, the thalidomide disaster affecting approximately 10,000 children probably could have been averted. There are, however, several disadvantages to the present evaluation system used in the United States. It may take an average of 15 years for a new chemical entity (an agent unrelated to other drugs) to negotiate successfully the obstacle course of preclinical and clinical testing. The development expenses, including those associated with unfruitful compounds, may exceed $1 billion.

The delay in introducing new drugs into pharmacotherapeutics after 1962 opened up a "drug lag" between the United States and other countries.[54] In response to this problem (and more specifically in response to pressure from acquired immu-

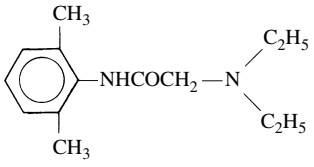
nodeficiency syndrome advocates), the FDA established new regulations that allowed patients to receive investigational drugs targeted against serious or life-threatening disease outside clinical trials when no satisfactory alternative therapy was available. In the most extreme example, several promising drugs against HIV were made available to patients immediately after completion of phase I trials. Other strategies were instituted within the FDA to speed the review process. The FDA Modernization Act of 1997 incorporated these and other additional changes to streamline drug development.

The uncertainty and expense of bringing new drugs to market in recent years have had a striking influence on the pharmaceutical industry. Only the largest drug manufacturers have the resources to meet FDA guidelines for new drugs. Because pharmaceutical companies are profit-oriented enterprises, the enormous cost of developing a drug is incurred only if a reasonable return on the investment can be anticipated. Without some additional incentive, the development of drugs for rare diseases has been priced out of consideration. It is also to be expected that agents under patent protection will be highly priced and heavily promoted.

Two laws pertaining to drug development have been enacted in an effort to stimulate therapies for "orphan" diseases and to reduce the cost of pharmaceuticals. The Orphan Drug Act of 1983 provided tax incentives and other considerations to companies for the development of drugs for rare disorders (affecting <200,000 people in the United States) and for more common diseases in which there is no reasonable expectation for recovery of development costs. Future advances in genetics and genomics are likely to increase the need for orphan drugs, which are likely to be "tailor-made" to fit the genetic traits of individual patients. The Drug Price Competition and Patent Term Restoration Act of 1984 extended the period of patent protection for drugs whose introduction is delayed by the FDA approval process, and it abbreviated the requirements for NDA approval of generic versions of drugs approved after 1962 that are pharmaceutically identical and have equivalent bioavailability.

Drug Nomenclature

During the course of development and marketing, a drug acquires various names or designations (Figure 3-5). The first identification of a drug is the formal chemical name. Although descriptive of the molecular structure of the compound, the chemical name is usually too unwieldy for practical purposes. A newly synthesized drug is often given a simple code name by the parent pharmaceutical firm to denote the agent during the various stages of drug evaluation. If the drug manufacturer intends to request approval by the FDA for distributing the agent, a nonproprietary name, or United States Adopted Name, is assigned to the drug by the United States Adopted Name Council (USANC), an organization jointly sponsored by the United States Pharmacopeial Convention, the American Medical Association, and the American Pharmacists Association. The nonproprietary name is commonly referred to as the "generic" name, but by definition, the generic designation should be reserved to indicate a family of compounds (e.g., penicillins), rather than a single entity (e.g., ampicillin). If the drug is eventually admitted to the *United States Pharmacopeia (USP)*, its nonproprietary name becomes the official name. The USANC works in cooperation with the World Health Organization to standardize nonproprietary names; drugs introduced before harmonization efforts began may have different nonproprietary names.



Chemical name (IUPAC):	2-(diethylamino) N-(2,6-dimethylphenyl acetamide)
Code name (Astra):	LL 30
Nonproprietary name (USANC):	Lidocaine
Official name (USP):	Lidocaine
Nonproprietary name (BAN)	Lignocaine
Trade names (selected):	Xylocaine, Dilocaine, Lignospan, Nervocaine, Octocaine

FIGURE **3-5** Full nomenclature of a local anesthetic. *BAN*, British Adopted Name; *IUPAC*, International Union of Pure and Applied Chemistry; *USANC*, United States Adopted Name Council; *USP*, United States Pharmacopeia.

Much confusion over drug nomenclature arises because a single drug may be marketed under many different trade names. A trade, or proprietary, name is given to a drug by the manufacturer when the agent is approved for general release. In contrast to the nonproprietary name, which is publicly owned, a trade name receives copyright protection and is the sole property of the drug company. Occasionally, a manufacturer may distribute the agent under several different trade names to promote separate uses of the drug. In addition, the manufacturer may arrange with other pharmaceutical firms to sell the drug, each using its own trade name. A profusion of trade names may develop when the drug patent expires, and all companies are permitted by law to produce the agent. Assignment of trade names to drug combination products contributes yet another voice to the babel of drug names.

Confusion has arisen when the manufacturer of a popular drug uses an extension of the drug's trade name to market additional, sometimes unrelated, products. Chlor-Trimeton is a well-known brand name for the antihistamine chlorpheniramine.[32] The marketing of the adrenergic vasoconstrictor pseudoephedrine in the 1990s as Chlor-Trimeton Non-Drowsy raised the potential for ineffective therapy in allergic patients and hypertension and angina pectoris in patients with cardiovascular disease. Today, chlorpheniramine is marketed by the manufacturer with the label Chlor-Trimeton Allergy; the combination of chlorpheniramine and pseudoephedrine is not sold with the Chlor-Trimeton name.

Throughout this book, nonproprietary names are emphasized in discussions of the various drugs. This practice reduces confusion and equips the reader to use other sources of drug information to the best advantage. The benefits and debits of using nonproprietary designations in prescription writing are discussed in Chapter 55.

SOURCES OF DRUG INFORMATION

The continued development of new drugs and the acquisition of new information about existing agents make pharmacology a discipline requiring continual study. Various resources are available to aid the clinician in keeping abreast of advances in pharmacotherapeutics.

Official Compendia

The *USP* and the *National Formulary (NF)* were designated as official compendia of drugs in the United States by the Pure Food and Drug Act of 1906. First published in 1820, the *USP* is revised every 5 years, with interim supplementation as needed, by the United States Pharmacopeial Convention, Inc. Members of the Council on Scientific Affairs of the American Dental Association serve in an advisory capacity during the revision process. Before 1975, only single-entity drugs (prepa-

rations with a single active ingredient) of proven therapeutic value were considered for inclusion in the *USP*. The *NF,* first released in 1888, was a publication of the American Pharmaceutical Association. In addition to single-entity agents of therapeutic value, the *NF* admitted combination products when their use provided a therapeutic advantage to the patient. After publication of the fourteenth edition in 1975, the *NF* was consolidated with the *USP* under the management of the *USP* organization. With this consolidation, the *USP* was expanded to include "all drugs having proven efficiency as therapeutic agents," including selected combination products, whereas the *NF* was restricted to describing pharmaceutical ingredients used in the formulation of marketed products.[47] The *USP-NF* is not a good source of information about the clinical use of drugs. It provides an invaluable service to the practitioner, however, by defining criteria for the manufacture of pharmaceutical preparations. It ensures that when a prescription is written for an official drug, the medication supplied to the patient meets certain standards of strength, purity, and chemical and physical properties.

The *American Hospital Formulary Service Drug Information (AFHS DI)* is currently the only compendium recognized by the federal government for determination of medically accepted but not FDA-approved indications of drugs. Published by the American Society of Health-System Pharmacists, a nonprofit organization, the *AFHS DI* is independent of the FDA and the pharmaceutical industry and relies on peer review by more than 500 physicians, pharmacologists, and other health care professionals to ensure information is accurate and evidence based. The *AFHS DI* contains information on more than 100,000 drug products and includes extensive off-label use information. Updates are available online.

Many other nations have their own official compendia. In addition, the *International Pharmacopoeia* is issued by the World Health Organization. Although not official in the sense of the *USP,* the *International Pharmacopoeia* is instrumental in promoting the standardization and unification of the various national compendia.

Unofficial Compendia

The *Physicians' Desk Reference (PDR)* is perhaps the most widely distributed source of prescribing information available to health professionals. The *PDR* is published annually (with interim revisions as necessary) by Thompson Healthcare in cooperation with more than 200 pharmaceutical manufacturing and distributing concerns. More than 2400 drugs are listed by proprietary name in an alphabetical arrangement according to drug distributor. (The cost of including a drug deters many companies from listing all their products.) Although the *PDR* is well indexed, its organization makes the comparison of similar agents difficult. The product information, which is largely derived from phase III trials and must legally conform to FDA regulations, contains concise summaries of the uses, dosage forms and schedules, contraindications, and adverse effects of the drugs listed. Nevertheless, the lack of critical appraisals of, or relative comparisons between, the various preparations included in the *PDR* limits its use as a reliable guide for the rational selection of drugs in therapy. The *PDR for Nonprescription Drugs, Dietary Supplements, and Herbs*, and the *PDR Guide to Drug Interactions, Side Effects, and Indications* are specialized sources of information offered by Thompson Healthcare. These books are also available on compact disc (CD) format, and an electronic site called PDR.net provides World Wide Web access to these resources for health care personnel (including dentists) free of charge.

A suitable alternative to the *PDR* is *Facts and Comparisons*. Published independently of the pharmaceutical industry, *Facts and Comparisons* contains monographs in a format designed to facilitate comparisons between drugs. *Facts and Comparisons* is available in a hardcover edition, a loose-leaf version, on CD-ROM, and online. The publisher of *Facts and Comparisons* has also combined efforts with Unbound Medicine and Skyscape to produce a product called *A2z Drugs* for handheld devices.

Mosby's Drug Reference for Health Professions is a concise compilation of monographs for more than 950 "generic" drugs (including 4500 proprietary name products). Because drug entries in *Mosby's Drug Reference* are not paid for by pharmaceutical companies, the book contains information specifically for health care providers and not necessarily to be in compliance with FDA-approved drug information.

In 1975, the *USP* organization decided to assist and benefit health care practitioners directly in the use of drugs. Publication of the *USP Dispensing Information (USP DI)* was a major outcome of that decision. The *USP DI* comprised three separate volumes. Volume I, *Drug Information for the Health Care Professional,* contained useful clinical information for numerous drugs. Volume II, *Advice for the Patient, Drug Information in Lay Language,* included information for the patient regarding the proper use of specific medications, precautions to consider, and adverse effects that may occur. Drug monographs from this volume could be reproduced and distributed without authorization to patients receiving the medications. Volume III, *Approved Drug Products and Legal Requirements,* contained information on the therapeutic equivalence of drugs and various regulatory issues. For a decade, the *USP DI* was published by Thompson Micromedex, but in 2007, publication of *USP DI* ceased in favor of its "successor" *DrugPoints,* a prescription online source of drug information.

Books on Pharmacology and Therapeutics

Textbooks of general pharmacology usually present basic principles of drug action and pharmacologic profiles of the various classes of therapeutic agents. Descriptions of relationships between pathophysiologic characteristics and drug effects contained in textbooks significantly contribute to the understanding of pharmacotherapeutics. Although textbooks can provide the best overview of pharmacology, for clarity of presentation and because of limitations of space, detailed coverage of individual agents in each drug category is generally restricted to a few prototypical compounds. Epinephrine may be discussed in depth, whereas other sympathomimetic amines commonly used by practitioners (e.g., levonordefrin as a vasoconstrictor in local anesthetic solutions) or patients (e.g., pseudoephedrine as a vasoconstrictor in cold remedies) may not be discussed as extensively. Textbooks are also limited in that they cannot include information on the most recent advances in pharmacotherapeutics, such as the introduction of new drugs.

The *Handbook of Nonprescription Drugs,* published by the American Pharmacists Association, is one of the few sources of information concerning over-the-counter drugs. The handbook presents critical evaluations of the various preparations available to the public. Of special interest to dentists are the chapters on headache and muscle and joint pain, herbal remedies, and oral pain and discomfort.

Periodicals

Numerous journals and reviews are devoted to pharmacology and therapeutics. The *Journal of Pharmacology and Experimental Therapeutics* and *Molecular Pharmacology* offer in-depth treatment of all areas of pharmacology. These journals are primarily concerned with the experimental aspects of pharmacodynamics. *Clinical Pharmacology and Therapeutics* has articles dealing with drug effects in humans. Journals that review pharmacologic information of direct clinical relevance include *Drugs* and the *Annual Review of Pharmacology and Toxicology*. Although not restricted in scope to drugs, the *New*

England Journal of Medicine is noteworthy for its excellent coverage of pharmacotherapeutics. Specialty journals of significance to dentistry include *Anesthesiology, Anesthesia and Analgesia*, and *Pain*.

The *Medical Letter on Drugs and Therapeutics* provides a unique service to practitioners in the United States. Published biweekly, the *Medical Letter* offers current, concise, and critical reviews of new drugs and pharmaceutical preparations. Expert opinion is also provided regarding the therapeutic and toxic effects of established drugs. In this respect, the periodic updates on drug interactions and on clinical selection of antimicrobial agents are especially helpful.

Dental Sources of Information

The *American Dental Association Guide to Dental Therapeutics* is published by the American Dental Association in association with Thompson Healthcare. This resource has information on drugs listed in tabular form, with more extensive coverage of drugs pertaining predominantly to dentistry. It uses the Thompson *PDR* database for much of its information. In addition, chapter authors provide specific details pertinent to clinical dental practice.

Mosby's Dental Drug Reference and *Drug Information Handbook for Dentistry* are reference handbooks useful for the quick identification of drugs and their dental implications. Both sources are published annually; the latter is now available online and for downloading to computers and handheld electronic devices.

Although there is currently no dental periodical solely concerned with pharmacology, numerous journals feature articles dealing with drugs in dental practice. *Anesthesia Progress* is the official journal of the American Dental Society of Anesthesiology. It publishes articles on drugs useful in pain and anxiety control, and prints abstracts from other periodicals of related articles of interest. The *Journal of the American Dental Association* is also a good source of information about dental pharmacotherapeutics. In addition to publishing original contributions and review articles, the *Journal of the American Dental Association* provides evaluations from the Council on Scientific Affairs on issues pertaining to drugs and dentistry. The *Journal of Dental Research*, which features *Critical Reviews in Oral Biology and Medicine*, occasionally publishes articles and reviews relating to drug therapy in dentistry. Specialty journals, such as the *Journal of Oral and Maxillofacial Surgery* and the *Journal of Periodontology*, also publish articles on dental pharmacotherapeutics.

Electronic Media

Computerization of sources of drug information is rapidly progressing. Most of the sources of information described previously, or the databases from which they are derived, are now available on CD. These formats permit the use of Boolean descriptors and hypertext links to facilitate searches within a single source or among several sources at the same time. Digital book systems, incorporating one or more sources of information in a palm-sized reader, facilitate immediate access to drug information in all clinical settings. ePocrates Rx (www.epocrates.com) is a free resource on drugs that includes concise information ranging from pharmacodynamics to cost of drugs. It is available online and for download to Palm, Windows Mobile, iPhone, and BlackBerry devices.

The Internet is increasingly becoming a vital source of drug information. Numerous sites on the World Wide Web provide information regarding specific issues pertaining to dental therapeutics. Some of these are free; others charge a monthly or connect fee. Many of the book titles listed previously are also available online. Some other sources are as follows. PubMed (www.ncbi.nlm.nih.gov/PubMed) is the National Library of Medicine's interface to MEDLINE and other information sources. It provides access, for a fee, to numerous scientific journals. Free access to numerous journal articles may be obtained through PubMed Central (www.pubmedcentral.gov). Micromedex (www.micromedex.com) is a reference that provides useful drug information for health care professionals. Lexi-Comp ONLINE (www.lexi.com) has a useful drug identification and vocal pronunciation guide for drugs and information on pharmacokinetics, adverse effects, and drug interactions. eMedicine (www.emedicine.medscape.com) is an extensive online resource that presents a discussion of disorders and treatment options.

RxList (www.rxlist.com) is a handy and valuable online resource concentrating on the clinical aspects of drugs. xPharm (www.xpharm.com) is a comprehensive online resource in pharmacology. xPharm is extensively linked internally and externally, offering significant search capabilities. Principles of pharmacology and drug and receptor characteristics are covered in depth. This resource also has extensive discussions of disorders for which the drugs are used. It is available for institutional subscriptions.

CHAPTER 4

Pharmacogenetics and Pharmacogenomics

DAVID W. HEIN AND DENIS M. GRANT

Individual patient differences in drug responsiveness are well recognized by health care professionals. Understanding the basis for these differences is of major clinical and economic importance because of the high frequency of therapeutic failure and adverse reactions to drugs. Patients may receive inadequate or suboptimal benefit, suffer adverse effects from drug treatment, or both. This chapter highlights pharmacogenetic and pharmacogenomic principles and provides illustrative examples where these principles can be applied to optimize therapeutic benefit and minimize adverse effects.

Pharmacogenetics is the branch of pharmacology that seeks to understand the genetic basis for differences in drug responsiveness among humans. The ability to select the safest and most effective drug and dose for a patient based on the patient's pharmacogenetic profile should simplify the process of adjusting the therapeutic regimen to achieve the desired clinical response. Pharmacogenetics is defined by the U.S. Food and Drug Administration (FDA) as the investigation of the role of variations in DNA sequence on drug response. The term *pharmacogenomics*—sometimes used interchangeably with *pharmacogenomics*—is defined by the FDA as the investigation of variations in DNA and RNA characteristics as related to drug response. Pharmacogenomics may also refer to the application of genomic information toward the discovery and development of drugs with new and more specific targets.

FDA labeling regulations now stipulate "if evidence is available to support the safety and effectiveness of the drug only in selected subgroups of the larger population with a disease, the labeling shall describe the evidence and identify specific tests needed for selection and monitoring of patients who need the drug." So far, the FDA has recommended changes in the labeling for 6-mercaptopurine, irinotecan, and tamoxifen to include pharmacogenetic information on treatment outcome. It has also been estimated more recently that 25% of all outpatients receive at least one prescribed medication that contains pharmacogenetic information in the drug label.[18] This information is not generally helpful at present because testing for most pharmacogenetic variants is not yet routine in clinical practice and most general practitioners would be incapable of using such information even if it were currently freely available. The broader field of "personalized medicine" also includes more rational targeting of drugs, such as restricting the use of trastuzumab to treat tumors based on their tumor phenotype (i.e., only those tumors that overexpress human epidermal growth factor receptor 2, the ligand for trastuzumab). This approach to therapy is sometimes included under the umbrella of pharmacogenetic testing.

Pharmacogenetics and pharmacogenomics are areas of intense interest and development within the biotechnology and pharmaceutical industries.[49] Many pharmaceutical companies are beginning to genotype patients in premarket clinical trials to exclude individuals who are predicted to experience adverse effects or therapeutic failure. This concept is illustrated in Figure 4-1. A consortium that includes major pharmaceutical companies is assembling a high-density map of the single nucleotide polymorphisms (SNPs) that exist throughout the human genome to facilitate the construction of pharmacogenetic profiles that predict drug responsiveness. SNPs occur, on average, about once every 1000 bases in the 3 billion–base human genome. A website (http://www.ncbi.nlm.nih.gov/SNP) sponsored by the National Center for Biotechnology Information maintains an updated listing of these SNPs.

This chapter presents basic principles and mechanisms that account for pharmacogenetic differences in drug therapy and toxicity. The pharmacogenetic examples included are of historical or clinical interest (or both); they are not intended to be exhaustive because, with the sequencing of the human genome, tabular listings of pharmacogenetic traits of clinical interest fall rapidly out of date. For more comprehensive and contemporary information, readers are directed to monographs,[30,59] chapters,[22,23] and general reviews[11,13,15,25,45,61] on pharmacogenetics and pharmacogenomics, and to the regularly updated Pharmacogenomics Knowledge Base (http://www.pharmgkb.org), which forms part of the National Institutes of Health–funded Pharmacogenetics Research Network.[21]

The genome determines the structure, configuration, tissue distribution, subcellular compartmentalization, and concentration of endogenous proteins. In most cases, for a drug to produce a therapeutic or toxic response, it must interact with one or more proteins, which are subject to genetic variation in humans. Genetic differences in plasma proteins may affect the affinity and the extent of drug binding. Genetic differences in the enzymes that metabolize a drug may confer differences in the concentrations of the parent compound, its active metabolites, and toxic derivatives. Genetic differences in cell membrane proteins or drug transporter proteins may influence drug absorption, distribution, and excretion. Finally, patients may have cell surface or intracellular drug receptors mediating therapeutic or adverse effects that are genetically more or less abundant or sensitive than is the norm.

The influence of genetic differences on drug response and toxicity has been highlighted in the popular press:

> *Every year, more than 100,000 people die in the U.S. because they carry "misspelled" genes that make medications either ineffective or deadly. Now doctors can test for the genes before prescribing … Imagine, a lawyer asking: "Doctor, did you know this drug would kill your patient? Did you know there is a test that would have predicted that? And why did you not give your patient the test?"*[4]

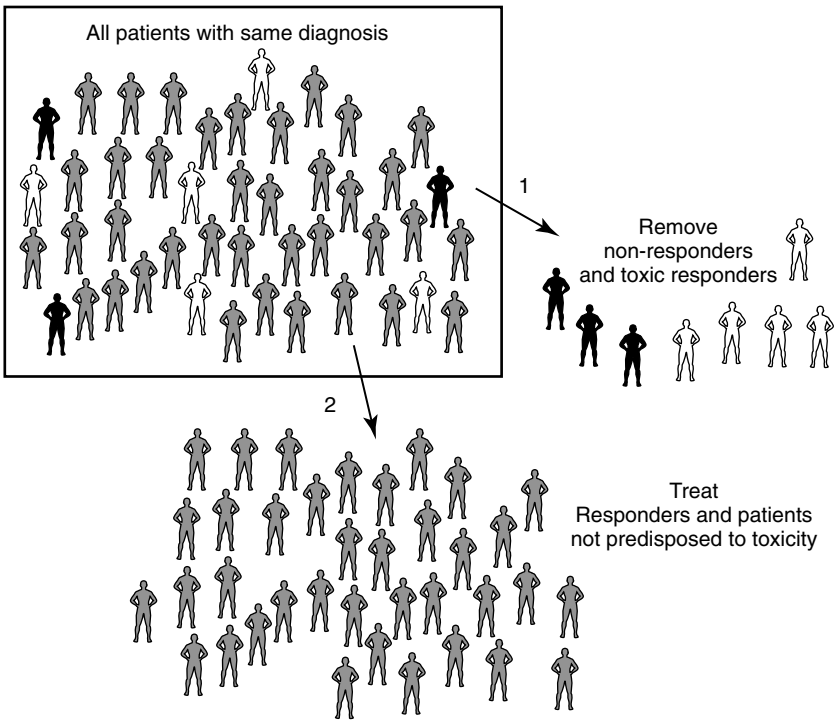

FIGURE **4-1** Diagram illustrating the strategy of selecting patients for drug therapy based on response to the drug. *Shaded figures,* responders who lack a genetic predisposition for toxicity; *white figures,* inadequate responders; *black figures,* patients predisposed to toxicity because of a genetic trait.

Such statements widely read by the lay public (and their lawyers) underscore the need for dental professionals to understand the role of pharmacogenetic factors in drug responsiveness. Patient malpractice claims have already alleged negligence in the use of pharmacogenetic information.[50]

PHARMACOKINETICS AND PHARMACODYNAMICS

Proteins affect drug concentration (*pharmacokinetics*) and response (*pharmacodynamics*). Historically, genetic variation most often has been identified in pharmacokinetics, particularly in drug metabolizing enzymes.[6] Genetic variation in the pharmacokinetic profile often necessitates a change in the dosage regimen of a drug, but not in its selection. Pharmacogenetic differences in drug target responsiveness[28] are less well understood, but potentially will also have a significant impact on patient outcomes in the future. In these instances, certain drugs would be contraindicated for patients with particular genotypes. Just as drug prescribers are currently responsible for avoiding adverse "drug-drug" interactions, as described in Appendix 1, they increasingly will be held accountable for avoiding untoward "gene-drug" interactions in clinical practice. Genetic differences in pharmacokinetics and pharmacodynamics are anticipated for many, if not most, drugs, yielding important consequences for drug responsiveness, especially for agents with a narrow therapeutic index. Figure 4-2 illustrates the separate and combined influences of genetic polymorphisms in pharmacokinetics and pharmacodynamics.[14]

There are many gene-drug interactions with importance to dentistry. Codeine, one of the mostly commonly prescribed opioid analgesics for pain relief, is a prodrug and depends on its activation to morphine by CYP2D6, a drug-metabolizing enzyme that is known to exhibit a common genetic polymorphism in humans.[48] As a result, codeine is an ineffective analgesic in a significant genetic subset (10%, depending on ethnic group) of the population. Genetic polymorphisms in opioid receptors or in second messenger systems mediating opioid receptor actions have also been observed. If a patient inherits a deficiency in CYP2D6 or the μ-opioid response system, it is unlikely that standard doses of codeine will be of therapeutic benefit. Increasing the dose of codeine to compensate for the genetic deficiency will most likely result not in analgesia but rather in an adverse reaction mediated by overstimulation of an alternative receptor that is responsive to codeine.

PHENOTYPE AND GENOTYPE

An individual's *genotype* is a genetic trait defined by the DNA sequences (i.e., alleles) inherited from the mother and the father. An individual can inherit two copies of the same allele (homozygous genotype) or a different allele from each of the parents (heterozygous genotype). The *phenotype* is a biologic or measurable expression of the genetic trait that depends on the level of penetrance of the gene, the accuracy and selectivity of the method used to measure it, and the influence of environmental factors in the expression of the trait. Historically, one of the most easily measured phenotypes was plasma drug concentration, which is probably why most of the initially identified pharmacogenetic traits were pharmacokinetic phenotypes. Determination of drug concentration is invasive, however, requiring administration of a drug or surrogate chemical and collection of blood samples over time. The drug concentration also depends to varying degrees on patient age, general health, nutritional status, and other factors such as exposure to enzyme inducers and inhibitors. Determination of a patient's genotype is much less invasive because it does not require administration of a test drug or collection of blood samples over time. Instead, the genotype is determined from a small sample of DNA obtained easily from a buccal swab, hair follicle, or other ready source, and is not affected by age, general health, nutritional status,

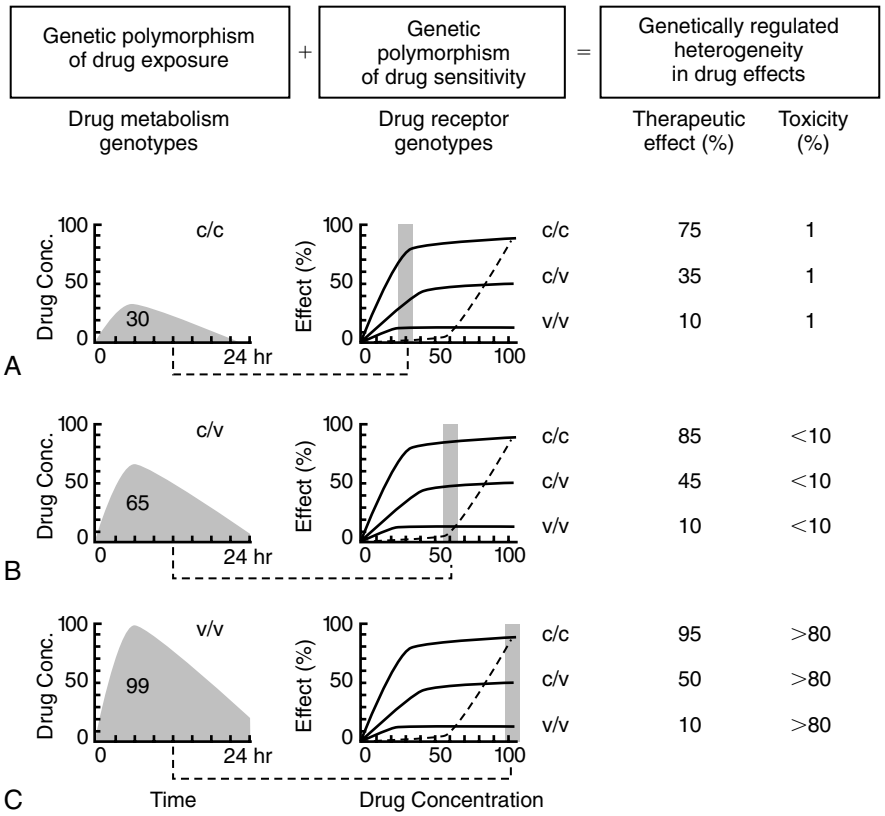

FIGURE **4-2** The potential consequences of administering the same dose of drug to individuals with genetic polymorphisms in both pharmacokinetics (drug-metabolizing enzymes) and pharmacodynamics (drug receptors). Active drug concentrations in the systemic circulation are determined by the individuals' drug metabolism genotype, with (**A**) homozygous common *(c/c)* genotype converting 70% of a dose to the inactive metabolite, leaving 30% to exert an effect on the target receptor. **B,** For the patient with heterozygous *(c/v)* drug metabolism genotype, 35% is inactivated, whereas (**C**) the patient with homozygous mutant *(v/v)* drug metabolism inactivates only 1% of the drug dose, yielding the three drug concentration time curves. The drug response is further influenced by drug receptor genotypes. Patients with a c/c receptor genotype exhibit a greater therapeutic effect (*solid lines*) at any given drug concentration in comparison to those with a c/v receptor genotype, whereas those with v/v receptor genotypes are relatively refractory to drug effects at any plasma drug concentration. The combination of genetic polymorphisms in drug metabolism and receptor yields nine different theoretical patterns of drug effect. The therapeutic ratio (efficacy versus toxicity) ranges from very favorable in a patient with c/c genotypes for drug metabolism and drug receptor to very unfavorable in the patient with v/v genotypes. (It is assumed here that the toxic dose-response curve, shown in *dotted lines*, is not influenced by these polymorphisms.) (Redrawn from Evans WE, Relling MV: Pharmacogenomics: translating functional genomics into rational therapeutics, *Science* 286:487-491, 1999.)

or other factors. For these same reasons, the prediction of drug response from a genetic test may not always be accurate or reproducible because of the influence of such nongenetic factors on drug response.

Many methods to determine the genotype have been developed in the past two decades, including restriction fragment length polymorphism analysis, allele-specific amplification, and DNA sequencing. Most methods rely on DNA amplification techniques based on the polymerase chain reaction that yield millions of copies of the specific target gene. New high-throughput methods promise to make the simultaneous determination of multiple genotypes readily available to health care professionals.[52] Understanding the important and complex relationships between genotypes and phenotypes has fostered much research in functional genomics and proteomics.

MONOGENIC VERSUS POLYGENIC PHENOTYPES

A discussion of genetic polymorphisms in enzymes and receptors would be incomplete without consideration of the differences inherent between monogenic and polygenic phenotypes. *Monogenic* phenotypes derive from genetic variations in a single gene. Monogenic variation often separates populations into discontinuous (bimodal or trimodal) distributions of the phenotype. If the least commonly occurring phenotype arising from the monogenic variation has a frequency of greater than 1% in a population, it is termed a *polymorphism*. Different drugs or dosing regimens may be appropriate for specific phenotypes. *Polygenic* traits, in contrast, are phenotypes that derive from some combination of variations in multiple genes. In this case, clearly distinct or discontinuous phenotypes are not observed in a studied population. Instead, there is a uni-

modal, continuous, normal (Gaussian) distribution of the phenotype. A unimodal distribution of drug response is observed for most drugs metabolized by multiple enzymes, transported by multiple proteins, or acting through multiple receptors or second messenger systems. This unimodal distribution does not mean an absence of genetic variation in one or all of these proteins, but rather that multiple genes contribute to the overall drug response phenotype. Because each of the genes is potentially subject to genetic variation, the utility of genetic information in predicting therapeutic and toxic responses is considerably more complicated. Until recently, polygenic phenotypes were too complex to consider in optimizing drug therapy.

ETHNIC DIFFERENCES IN PHARMACOGENETICS

The frequency of specific alleles, genotypes, and phenotypes for drug metabolizing enzymes varies widely with ethnic origin.[29] A similar variance is expected for drug receptors. Clinical trials are best conducted either with ethnically diverse study populations to capture differences among ethnic groups with ethnically defined subgroups to define effects in these groups precisely. Some genotyping methods were designed originally to identify only alleles prevalent in whites. With the documented ethnic heterogeneity within the human population, however, genotyping tests need to identify all relevant alleles of a particular gene regardless of ethnic frequency.

PHARMACOGENETICS OF DRUG METABOLISM

As indicated earlier, most of the pharmacogenetic traits identified to date occur in genes encoding drug metabolizing enzymes. It is anticipated that genetic polymorphisms may be identified in all drug metabolizing enzymes. Many of these genetic polymorphisms are already known to be important in therapeutics,[63] and examples of historical and clinical interest are highlighted next.

Acetylation Polymorphisms

N-acetylation is an important phase II conjugation reaction for many drugs that possess an aromatic amine (e.g., procainamide, dapsone, many sulfonamides) or hydrazine (e.g., isoniazid, hydralazine) moiety. The acetylation polymorphism was originally discovered by studying the development of peripheral neuropathy in patients administered isoniazid.[59] N-acetylation of aromatic amine-containing and hydrazine-containing drugs may be catalyzed by either or both of two different N-acetyltransferase isozymes, NAT1 and NAT2.[24] Genetic polymorphisms have been identified in both enzymes, but genetic polymorphisms in NAT2 are more common and important for the metabolism of many drugs in common use.[59,60] Human populations can be distinguished as rapid and slow acetylator phenotypes by measuring the production of N-acetylated metabolites after administration of drugs such as isoniazid, dapsone, or caffeine. Eleven identified SNPs in the NAT2 gene affect protein expression or stability or both.[17] Acetylator genotypes derived from more than 25 different NAT2 alleles have been identified in humans. A listing of these alleles is regularly updated at http://N-acetyltransferasenomenclature.louisville.edu.

As is the case for most drug metabolizing enzyme polymorphisms, the frequencies of these SNPs, genotypes, and acetylator phenotypes vary markedly with ethnic origin. The frequency of slow acetylator phenotypes is about 10% in Asian populations, about 50% in many white and African populations, and greater than 85% in Egyptians. Slow acetylator phenotypes exhibit higher plasma concentrations of parent drug and higher incidences of complications such as peripheral neuropathy from isoniazid and systemic lupus erythematosus from procainamide or hydralazine. In contrast, rapid acetylator phenotypes exhibit greater myelosuppression after treatment with amonafide.[27] Genetic polymorphisms in NAT2 are associated with altered cancer predisposition after environmental and occupational exposure to aromatic and heterocyclic amine carcinogens.[24]

Oxidation Polymorphisms

The cytochrome P450 (CYP) system, as described in Chapter 2, is a family of microsomal enzymes with selective but frequently overlapping substrate specificities. CYP-mediated oxidation is the predominant pathway for phase I metabolism (activation and deactivation) and is responsible for the metabolism of a very large diversity of therapeutic drugs and environmental carcinogens. Genetic polymorphisms in many of the CYP enzymes have been identified in humans.[7] A continuously updated listing of these polymorphisms and alleles is available at http://www.imm.ki.se/cypalleles. Variant alleles possess gene deletions, gene conversions with related pseudogenes, or SNPs yielding frameshift, missense, nonsense, or alternative splice sites. The phenotypic consequences of variant alleles and genotypes include absent, diminished, qualitatively altered, and enhanced CYP enzymatic activities. Three drug oxidation polymorphisms that have received the most clinical attention involve CYP2D6, CYP2C9, and CYP2C19. The different CYPs are products of separate genes. Genetic deficiency in one CYP does not infer genetic deficiencies in the others.

The oxidation polymorphism in CYP2D6 was originally discovered by the toxic responses observed in some patients after administration of debrisoquine and sparteine.[59] Humans with this genetic defect differ in their capacity to oxidize not only debrisoquine and sparteine but up to 25% of all drugs.[26] Poor metabolizer CYP2D6 phenotypes result from defective splicing causing inactive enzyme, gene deletion resulting in absence of protein, and missense SNPs yielding enzyme with reduced stability or reduced substrate affinity. An ultrarapid phenotype resulting from gene duplication has also been identified. Poor metabolizer phenotypes experience higher concentrations of parent drug after administration and consequently experience greater adverse effects. When CYP2D6 is required for prodrug activation to a more efficacious metabolite (e.g., codeine to morphine), poor metabolizers often experience therapeutic failure.[54] The opposite effects can occur in the ultrarapid metabolizer phenotype. Severe abdominal pain attributable to morphine has been observed in an ultrarapid metabolizer treated with codeine.[5]

Similarly, tamoxifen is biotransformed to the potent antiestrogen endoxifen by CYP2D6.[55] Genetic variation and inhibitors of CYP2D6 markedly reduce endoxifen plasma concentrations in tamoxifen-treated breast cancer patients. Patients with decreased metabolism have significantly shorter times to cancer recurrence and worse relapse-free survival rates relative to patients with extensive metabolism.[51] The poor metabolizer phenotype is an independent predictor of breast cancer outcome in postmenopausal women receiving tamoxifen for early breast cancer. Because genetically determined impaired tamoxifen metabolism results in worse treatment outcomes, genotyping for CYP2D6 alleles can identify patients who would obtain little benefit from adjuvant tamoxifen therapy.

CYP2C9 catalyzes the oxidation of the vitamin K antagonist warfarin and many other drugs, including phenytoin, tolbutamide, and losartan.[46] More than 2 million patients in the United States receive warfarin treatment to prevent blood clots, heart attack, and stroke. Warfarin is a difficult

drug to use because the optimal dose varies widely and depends on many factors, including genetic polymorphisms in CYP2C9, CYP4F2 (which oxidizes vitamin K), and vitamin K epoxide reductase (VKORC1, the target of warfarin inhibition); patient age; diet; and concurrent drug therapy. Allelic variants of CYP2C9 encode enzymes with reduced or altered affinities. Individuals homozygous for certain variant CYP2C9 alleles may exhibit a 90% reduction in S-warfarin clearance, resulting in bleeding complications during warfarin therapy. The FDA has recommended labeling changes to advise patients and health care providers regarding the effects of CYP2C9 genetic polymorphism on initial dose and response to warfarin therapy, although the routine clinical use of CYP2C9 or VKORC1 genetic testing has not yet been recommended.[16]

CYP2C19 catalyzes the oxidation of drugs including mephenytoin and omeprazole.[10] Individuals with genetic deficiencies may experience increased sedation and ataxia with the anticonvulsant mephenytoin and enhanced therapeutic efficacy with omeprazole used for the treatment of peptic ulcer.[19]

Plasma Cholinesterase Polymorphisms

Plasma cholinesterase catalyzes the hydrolysis of choline esters. Succinylcholine is an important neuromuscular blocking agent frequently used to produce muscular relaxation for endotracheal intubation and brief operative procedures. As described in Chapter 2, individuals with genetic deficiency in plasma cholinesterase experience prolonged apnea when treated with succinylcholine, which is potentially fatal unless appropriate respiratory support is provided. The primary atypical form of plasma cholinesterase possesses a SNP that changes an amino acid (aspartic acid to glycine) in the anionic site of the esterase, reducing its affinity for succinylcholine.[32]

Thiopurine S-Methyltransferase Polymorphism

Thiopurine S-methyltransferase (TPMT) catalyzes the deactivating S-methylation of the anticancer and anti-inflammatory drugs 6-mercaptopurine, 6-thioguanine, and azathioprine. The gene encoding this enzyme exhibits genetic variation in human populations such that the frequency of the homozygous deficient phenotype is approximately 0.3% and that of heterozygotes is about 10% in whites and African Americans. More than 10 variant alleles have been identified that encode enzymes with reduced stability or catalytic activity or both.[11,12] Treatment of acute lymphoblastic leukemia often requires long-term treatment with 6-mercaptopurine. Individuals with the homozygous deficient phenotype frequently develop severe hematopoietic toxicity when treated with standard doses of 6-mercaptopurine, requiring substantial reductions in dose. Individuals with heterozygous genotypes experience milder degrees of toxicity.[31] Long-term outcome studies suggest that relapse-free survival is longer in patients whose chemotherapy dosing schedules were set according to prior testing for TPMT function.[36] 6-Mercaptopurine package inserts now provide detailed information and advice regarding pharmacogenetic TPMT deficiencies.

Dihydropyrimidine Dehydrogenase Polymorphism

5-Fluorouracil is used extensively in the chemotherapy of solid tumors. Dihydropyrimidine dehydrogenase catalyzes the rate-limiting step in the deactivation of 5-fluorouracil. Patients with genetic deficiency of this enzyme have a 90% lower clearance of 5-fluorouracil and may experience severe toxicity from modest doses.[40] The toxicity depends on the route of administration, but involves rapidly dividing tissues such as bone marrow and the mucosal lining of the gastrointestinal tract. Life-threatening neurotoxicity also has been observed.

Uridine Diphosphate Glucuronosyltransferase Polymorphism

Uridine diphosphate glucuronosyltransferase (UGT) catalyzes the glucuronidation of bilirubin and various drugs and xenobiotics. The UGT1A family of enzymes is represented in the genome by a series of four invariant exons. The transcribed product is then spliced to the product of any one of nine exons representing different substrate-binding domains. The family members are designated UGT1A1, UGT1A2, and so forth. UGT1A1 is the enzyme primarily responsible for bilirubin glucuronidation. UGT enzyme levels are regulated primarily through transcriptional control, and genetic variation in promoter structure influences transcription rate.[58] A series of TA repeats (thymine, adenine) in the proximal promoter vary in number from five to eight in different populations. The lower the number of repeats, the more efficient is the transcriptional activity of the gene. The UGT1A1*28 allele has seven TA repeats and is associated with Gilbert's syndrome.[57] The frequency of the homozygous UGT1A1*28 genotype varies with ethnic origin but is about 10% in white and African populations and 5% in Asian populations.

Irinotecan is a topoisomerase I inhibitor that is effective against several cancers, particularly colon cancer. It is a prodrug that is converted to an active metabolite, SN-38. This active metabolite is inactivated by glucuronidation catalyzed by UGT1A1. Individuals with genetic polymorphism in UGT1A1 have been shown to experience increased toxicity (myelosuppression and diarrhea) with the use of irinotecan alone and in combination with other anticancer drugs. The FDA-required package insert for irinotecan states: "individuals who are homozygous for the UGT1A1*28 allele are at increased risk for neutropenia after initiation of CAMPTOSAR [irinotecan] treatment." The FDA has also approved a pharmacogenetic test to identify these individuals, although the clinical utility of the test is debated.[8]

Drug Transporter Polymorphisms

Numerous families of specific small-molecule transport proteins are now known to mediate the movement of endogenous and exogenous substances across cellular membranes, influencing their tissue distribution and concentration (as described in Chapter 2). Genetic variants of many of these proteins have been identified, with consequences for drug pharmacokinetics and response.[39] Genetic variants of the multidrug resistance transporter P-glycoprotein, the product of the *MDR1* gene, have been associated with altered transport, efficacy, and toxicity of digoxin, tacrolimus, and irinotecan,[37] whereas variants in the organic anion transporter families OATP and OAT may alter the cellular uptake of a broad array of charged substances.[38]

PHARMACOGENETIC POLYMORPHISMS IN DRUG TARGETS

Because therapeutic response is often more difficult to quantify than plasma drug concentration, genetic polymorphisms in drug targets have been less extensively characterized. There is little doubt, however, that genetic polymorphisms exist in most, if not all, proteins, including drug receptors. Several genetic polymorphisms reported in recent years are provided here as examples. Many more clinically relevant genetic polymorphisms in drug receptors are expected to be discovered in the near future.

Malignant Hyperthermia

Malignant hyperthermia (MH) is perhaps the first pharmacogenetic trait identified resulting from genetic polymorphism in a drug target (receptor).[56] As described in Chapter 18, MH

is triggered in susceptible individuals by the administration of inhalation anesthetics such as halothane and the depolarizing muscle relaxant succinylcholine.[35] The syndrome manifests with tachycardia, hypercarbia, hypoxia, muscular rigidity, arrhythmias, and, eventually, high fever. The molecular basis of the phenotype, at least in some individuals, is a variant of the ryanodine receptor 1, an intracellular Ca^{++}-release channel that bridges the gap between the sarcoplasmic reticulum and the t-tubular system in skeletal muscle. Administration of a volatile anesthetic to predisposed individuals disturbs Ca^{++} regulation and enhances Ca^{++} release in the sarcoplasmic reticulum, which in turn stimulates muscle contraction, ATP hydrolysis, carbon dioxide production, and lactate buildup. These responses result in the symptomatic heat generation that gives MH its name. If appropriate therapy is not initiated immediately, the patient may die within minutes from ventricular fibrillation, within hours from pulmonary edema or coagulopathy, or within days from neurologic damage or renal failure. An acute attack of MH is treated by administration of the muscle relaxant dantrolene.

β-Adrenergic Receptor Polymorphisms

β-Adrenergic receptors mediate crucial sympathetic responses in the cardiovascular, pulmonary, metabolic, and central nervous systems. β_2-Adrenergic agonists such as albuterol are potent bronchodilators widely used in the treatment of asthma. Other β-adrenergic agonists are administered to increase cardiac output in the emergency management of cardiogenic shock and decompensated congestive heart failure. Antagonists of β-adrenergic receptors are used to treat several disorders, including hypertension and chronic heart failure.

Genetic polymorphisms in β_1 and β_2 receptors have been identified in human populations.[33] β_2-Adrenergic receptor genotype variation has been shown to affect therapeutic response to β_2-selective agonists such as albuterol.[34] Polymorphisms in β receptors potentially influence drug treatment of cardiovascular diseases in two ways. The primary effect is alteration of agonist or antagonist efficacy because of a variant β_1 or β_2 receptor. The influence on drug efficacy also may be secondary, however, to an effect of the polymorphism on cardiovascular function. One β_2 receptor variant is associated with lower systemic vascular resistance and a greater vasodilatory response. Individuals with this β_2 receptor variant might be more sensitive to a vasodilator (e.g., captopril) acting via another mechanism, secondary to the altered systemic vascular tone.

Dopamine and Other Receptor Polymorphisms

Genetic polymorphisms in dopamine receptors have been associated with drug abuse liability and the reinforcing effects of alcohol, cocaine, and nicotine. Genetically variant dopamine receptors are also associated with an increased incidence of tardive dyskinesias after long-term treatment of schizophrenia with dopamine receptor antagonists.[23] Schizophrenia is itself a complex set of diseases that is not adequately managed in many patients. Typical and atypical antipsychotic drugs have been found to be effective in some but not all patients with schizophrenia. Genetic polymorphisms in antipsychotic medication receptor targets (dopaminergic, adrenergic, serotonergic, or histaminergic receptor subtypes) have been associated with different clinical responses.[2] Combinations of drug target polymorphisms and drug metabolism variants may eventually form the basis for targeting genetic subgroups of patients with schizophrenia for effective treatment with specific antipsychotic drugs.[3,9]

Miscellaneous Drug Targets

Many additional genetic polymorphisms in drug targets have been reported, and many more are expected. A genetic polymorphism in the cholesterol transport protein apolipoprotein E is associated with a loss of efficacy of acetylcholinesterase inhibitors such as tacrine in the treatment of Alzheimer's disease.[43] Genetic polymorphisms in cholesteryl ester transfer proteins have been found to alter the benefits of HMG-CoA reductase inhibitors such as pravastatin in the treatment of coronary atherosclerosis.[44]

IMPLICATIONS FOR DENTISTRY

The sequencing of the human genome—coupled with advances in DNA array technology, high-throughput genotyping, and bioinformatics—will soon enable rapid elucidation of complex genetic factors necessary for better optimization of drug therapy. Pharmacogenomics is expected to result increasingly in the development of drugs that are targeted to specific, genetically identifiable subgroups of patients.[49] Some drugs previously abandoned for clinical use because they proved toxic in some patients will likely return to clinical use, albeit with restrictions for specific genetic subgroups. Health care providers, including dentists, will be accountable for prescribing drugs appropriately to genetic subgroups. Automated genotyping systems and easily accessible genetic data will provide crucial information necessary for optimal drug therapy in the individual patient.

The determination and accessibility of human pharmacogenetic information carry potential ethical and legal concerns.[42,53] One proposed solution is to use "abbreviated pharmacogenetic chips" that assess anonymous genetic information specific to each drug, rather than a "comprehensive genetic profile" determined for each patient.[62] Alternatively, patient-specific pharmacogenetic information may be part of the patient's "electronic record" accessible at secure websites.[1] Although significant challenges exist to the development of means by which pharmacogenetic information is accessed and fully used,[20,41,47] genetically enabled "personalized medicine" is likely to become more and more the standard of patient care.[64] The "one size fits all" mode of drug therapy that fails to consider pharmacogenetic information will increasingly be considered substandard clinical care.

PART II

Pharmacology of Specific Drug Groups

CHAPTER 5

Introduction to Autonomic Nervous System Drugs

PETER W. ABEL AND MICHAEL T. PIASCIK

The autonomic nervous system (ANS) and the endocrine system are the major regulatory systems for controlling homeostatic functions. These two systems collectively regulate and coordinate the cardiovascular, respiratory, gastrointestinal, renal, reproductive, metabolic, and immunologic systems. Drugs that alter the activity of either the ANS or the endocrine system often exhibit multiple actions and side effects. This chapter introduces the pharmacology of the ANS; the endocrine system and drugs are reviewed in Chapters 34 through 37. An understanding of the pharmacology of agents affecting the ANS rests on two basic foundations: a knowledge of the structural and functional organization of the ANS, and an understanding of where certain neurotransmitters are located and how these neurotransmitters affect cellular function.

AUTONOMIC NERVOUS SYSTEM

The ANS, also referred to as the visceral, vegetative, or involuntary nervous system, regulates the function of smooth muscle, the heart, and certain secretory glands. These structures possess intrinsic mechanisms that allow them to function in the absence of neuronal input, but the ANS contributes a regulatory and coordinating function. Most of our knowledge of the ANS is restricted to efferent functions; much less is known about the afferent limb. Sensory afferent fibers carry impulses that are received and organized centrally, often at an unconscious level. A person is unaware of impulses generated at the baroreceptors, although these impulses may trigger a generalized body response, such as a reflex decrease in blood pressure, which the person may sense. It has been estimated that approximately 80% of the vagus nerve consists of primary afferent fibers and that the effects of certain drugs (e.g., opioids) may be mediated in part by altering autonomic sensory inputs.[16,30] Nevertheless, most currently available ANS drugs influence efferent activity.

Anatomy

The structural organization of the efferent arm of the ANS differs from that of the somatic nervous system. Somatic efferent fibers originate from cell bodies located in the central nervous system (CNS) and innervate skeletal (striated) muscle without intervening synapses (Figure 5-1). In contrast, the ANS consists of a two-neuron system in which preganglionic nerves emanating from cell bodies in the cerebrospinal axis synapse with postganglionic nerves originating in autonomic ganglia outside the CNS. The ANS is divided into two parts on the basis of the anatomic characteristics of each division. The sympathetic division includes nerve pathways that originate in the thoracolumbar regions of the spinal cord, whereas the parasympathetic division includes nerve pathways from the craniosacral regions of the cerebrospinal axis.

Sympathetic nervous system

The organizational anatomy of the two divisions of the ANS is shown in greater detail in Figure 5-2. The sympathetic division originates from neurons with cell bodies located in the intermediolateral columns of the spinal cord, extending from the first thoracic to the third lumbar segments. The myelinated preganglionic fibers emerge with the ventral roots of the spinal nerves and synapse with second neurons in one of three possible types of ganglia: paravertebral (vertebral or lateral), prevertebral, or terminal. The paravertebral ganglia are composed of 22 pairs of ganglia lying on either side of the spinal cord and connected to each other by communicating nerve fibers. The superior cervical ganglia (the topmost pair) innervate structures in the head and neck, including the submandibular glands, whereas the superior, middle, and inferior cervical ganglia all innervate the heart. The prevertebral ganglia are located in the abdomen and pelvis and include the celiac, superior mesenteric, and inferior mesenteric, which innervate the stomach, the small intestine, and the colon. The few terminal ganglia lie near the organs they innervate, principally the urinary bladder and rectum.

A striking anatomic aspect of the sympathetic nervous system—and one that has great functional significance—is that a single preganglionic nerve may contact 20 or more postganglionic nerves. Impulses arising in one preganglionic neuron of the sympathetic nervous system may ultimately affect many postganglionic neurons, which explains the diffuse and widespread character of sympathetic nervous system responses. Stimulation of the sympathetic nervous system also activates nerves that innervate the adrenal medulla and cause it to release a mixture of the catecholamines epinephrine and norepinephrine. This release provides an additional basis for the widespread effects of the sympathetic nervous system.

Parasympathetic nervous system

The parasympathetic nervous system, or craniosacral division, has its origin in neurons with cell bodies located in the brainstem nuclei of four cranial nerves—the oculomotor (cranial nerve III), the facial (cranial nerve VII), the glossopharyngeal (cranial nerve IX), and the vagus (cranial nerve X)—and in the second, third, and fourth segments of the sacral spinal cord. The preganglionic nerves arising from the brainstem form part of the cranial nerves and travel with them to synapse with postganglionic neurons located in ganglia near or actually within the structures innervated. The midbrain outflow from the nucleus of the oculomotor nerve synapses in the ciliary

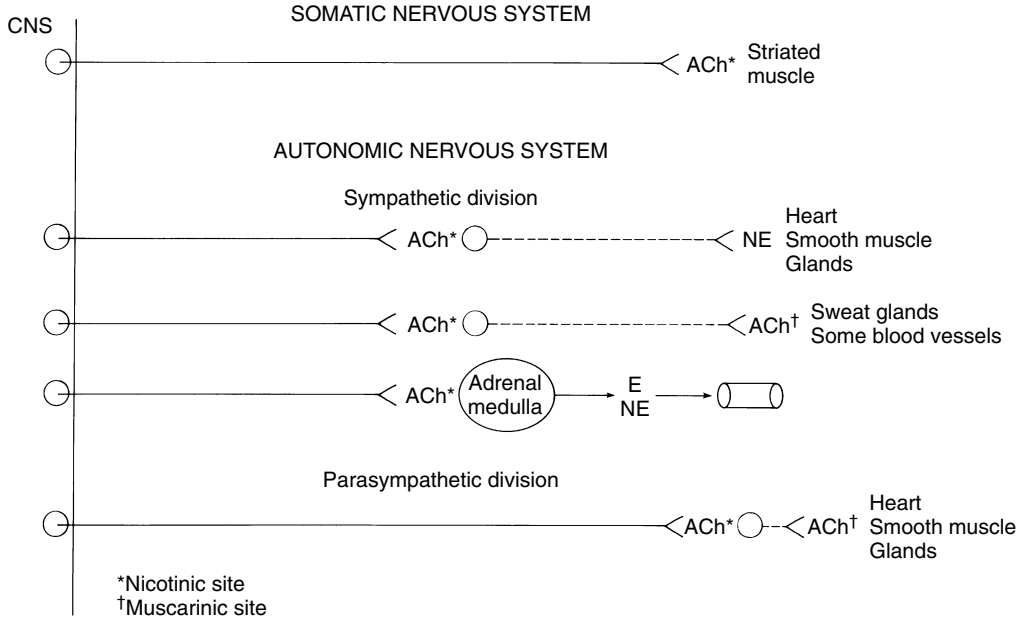

FIGURE **5-1** Functional organization of the somatic nervous system and the autonomic nervous system, with the structures innervated by the different nerves and the chemical mediators responsible for transmission at the various sites. *Solid lines* indicate somatic motor or preganglionic autonomic nerves; *dashed lines* indicate postganglionic autonomic nerves. *ACh*, Acetylcholine; *E*, epinephrine; *NE*, norepinephrine.

ganglion located in the orbit. The ganglion gives rise to nerves that supply the ciliary muscle and the sphincter muscle of the eye. Neurons of the facial nerve that synapse in the sublingual and submandibular ganglia form the chorda tympani and provide innervation to the sublingual and submandibular glands. Other neurons of the facial nerve synapse in the sphenopalatine ganglion; postganglionic nerves terminate in the lacrimal gland and in mucus-secreting glands of the nose, palate, and pharynx. Nerves originating in the glossopharyngeal nuclei synapse in the otic ganglion; its postganglionic neurons innervate the parotid gland. A major component of the cranial outflow is the vagus nerve, which originates from vagal nuclei in the medulla oblongata. Preganglionic nerves pass to ganglia located within the heart and the viscera of the thorax and abdomen. Postganglionic nerves, very short in length, arise from these ganglia to terminate in the aforementioned structures. Neurons originating from sacral segments form the pelvic nerves, which synapse in terminal ganglia lying near or within the uterus, bladder, rectum, and sex organs.

In contrast to the arrangement in the sympathetic nervous system, there is little overlap or divergence in the parasympathetic nervous system. With few exceptions (e.g., in Auerbach's plexus in the gastrointestinal tract, where 1 preganglionic nerve exists for every 8000 postganglionic nerves), there is a one-to-one relationship between preganglionic and postganglionic nerves, which makes possible discrete and limited responses in the parasympathetic nervous system. The parasympathetic nervous system is characterized by long preganglionic and very short postganglionic nerves and, with only a few exceptions, an absence of well-defined, anatomically distinct ganglia.

Functional Characteristics

Most organs are dually innervated by the sympathetic and parasympathetic nervous systems, such as most salivary glands and the heart, lungs (bronchial muscle), and abdominal and pelvic viscera, whereas other organs receive innervation from only one division. The sweat glands, adrenal medulla, piloerector muscles, and most blood vessels receive innervation from only the sympathetic nervous system. The parenchyma of the parotid, lacrimal, and nasopharyngeal glands are supplied only with parasympathetic nerves. Table 5-1 lists the organs to which nerve fibers of the parasympathetic and sympathetic nervous systems are distributed, the effects of stimulation of these nerves, and the autonomic receptors that are activated by neurotransmitters released from autonomic nerves.

To understand or predict the effects of autonomic drugs on a specific organ, it is necessary to know how each division of the ANS affects that organ, whether the organ is singly or dually innervated, and if dually, which of the two systems is dominant in the organ. In most circumstances, one or the other of the two divisions of the ANS will provide the dominant influence, but often neither division is totally dominant in many of the dually innervated organs. The fact that both divisions of the ANS modulate the intrinsic activity of the various tissues cannot be overemphasized.

The anatomic and functional characteristics of the two divisions of the ANS show that there are striking differences between the sympathetic and parasympathetic nervous systems. Cannon[11] was the first to recognize that the sympathetic nervous system is capable of producing the kind of widespread and massive response that would enable an organism confronted with a stressor (e.g., pain, asphyxia, or strong emotions) to mount an appropriate response ("fright, fight, or flight"). Controlled clinical trials in dental patients indicate that oral surgical procedures constitute physiologically significant stressors for stimulating the sympathetic nervous system, with noticeable increases in circulating norepinephrine concentrations observed in patients during surgery and with the development of postsurgical pain (Figure 5-3). The stress of oral surgery is mediated by the CNS because drugs that reduce anxiety (e.g., diazepam) also reduce the sympathetic response to surgical stress and postoperative pain.[15,19] The parasympathetic division is primarily concerned with the pro-

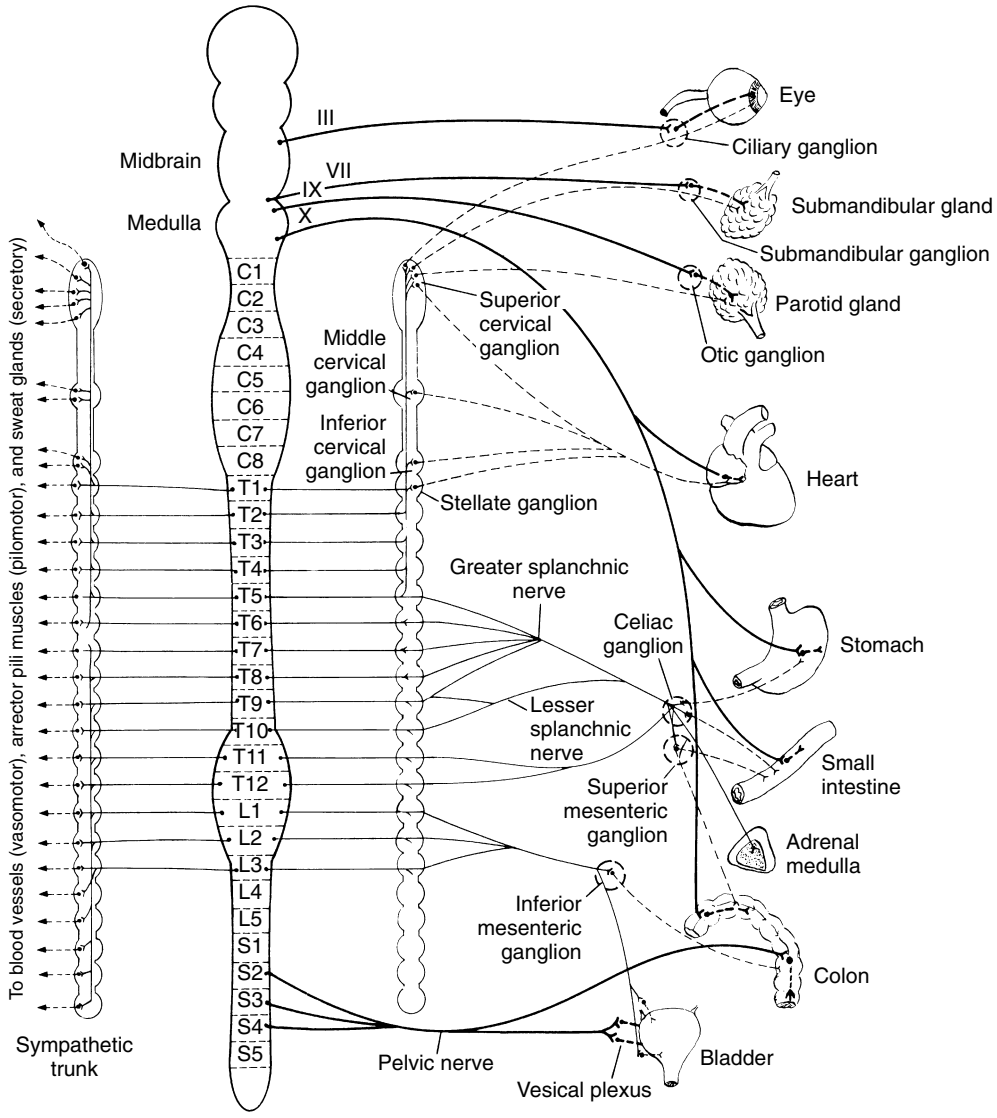

FIGURE **5-2** General arrangement of the autonomic nervous system showing one side of the bilateral outflow. On either side of the spinal cord (*C1* to *S5*) are pictured the two chains of the paravertebral sympathetic ganglia. Preganglionic nerves of the sympathetic nervous system are indicated by *light solid lines;* postganglionic nerves of the sympathetic nervous system are indicated by *light dashed lines.* Preganglionic nerves of the parasympathetic nervous system, originating from the brain and sacral spinal cord, are shown by *bold solid lines;* postganglionic nerves of the parasympathetic nervous system are shown by *bold dashed lines.* (Adapted from Copenhaver WM, editor: *Bailey's textbook of histology,* ed 15, Baltimore, 1964, Williams & Wilkins.)

tection, conservation, and restoration of bodily resources. These differences in function are subserved by some of the anatomic characteristics that have already been mentioned, including the involvement of the adrenal medulla and the high ratio of postganglionic to preganglionic nerves in the sympathetic, but not the parasympathetic, nervous system.

NEUROTRANSMITTERS

The concept that chemical mediators were responsible for transmission of information in the ANS emerged at the end of the nineteenth and the beginning of the twentieth century. Acetylcholine was identified as the primary neurotransmitter released from preganglionic nerves and from postganglionic nerves in the parasympathetic nervous system. Norepinephrine was found to be the neurotransmitter released from most postganglionic sympathetic nerves, whereas norepinephrine and epinephrine are released after sympathetic stimulation of the adrenal medulla. More recently, dopamine has also been found to be an important neurotransmitter at some sites in the ANS. Although acetylcholine, norepinephrine, epinephrine, and possibly dopamine have come to be recognized as the principal mediators of ANS activity, evidence exists that other molecules may also serve as chemical transmitters for specific neuronal circuits. Among these are histamine; 5-hydroxytryptamine (5-HT, serotonin); γ-aminobutyric acid (GABA); prostanoids; aspartate; adenosine triphosphate (ATP); glutamate; glycine; and various peptides, including neuropeptide Y, cholecystokinin, enkephalins, substance P,

TABLE **5-1**

Responses of Various Effectors to Stimulation by Autonomic Nerves

	SYMPATHETIC		
EFFECTOR	**RESPONSE**	**RECEPTOR**	**PARASYMPATHETIC RESPONSE***
Eye			
Radial muscle of the iris	Contraction (mydriasis)	α_1	—
Sphincter muscle of the iris	—		Contraction (miosis)
Ciliary muscle	Slight relaxation (far vision)	β_2	Contraction (near vision)
Heart[†]			
Sinoatrial node	Increase in rate	β_1, β_2	Decrease in rate
Atria	Increased contractility and conduction velocity	β_1, β_2	Decreased contractility, usually increased conduction velocity
Atrioventricular node	Increase in automaticity and conduction velocity	β_1, β_2	Decrease in conduction velocity
Ventricles	Increased contractility, conduction velocity, and automaticity	β_1, β_2	—
Blood vessels[‡]			
Coronary	Functional significance is doubtful	α_1, α_2, β_2	Same as sympathetic
Skin and mucosa	Constriction	α_1, α_2	Dilation, but of questionable significance
Skeletal muscle	Constriction; dilation	α, β_2[§]	—
Abdominal viscera	Constriction; dilation	α_1, β_2	—
Salivary glands	Constriction	α_1, α_2	Dilation
Erectile tissue	Constriction	α	Dilation
Lungs			
Bronchial smooth muscle	Relaxation	β_2	Contraction
Bronchial glands	Decreased secretion; increased secretion	α_1, β_2	Increased secretion
Gastrointestinal tract			
Smooth muscle	Decreased motility and tone	α_1, $\alpha_2\beta_1$, β_2	Increased motility and tone
Sphincters	Contraction	α_1	Relaxation
Secretion	Inhibition	α_2	Stimulation
Salivary glands	Protein-rich secretion[‖]	α_1, β_1, β_2	Profuse, watery secretion
Spleen capsule	Contraction; mild relaxation	α_1, β_2	—
Urinary bladder			
Detrusor	Relaxation	β_2	Contraction
Trigone and sphincter	Contraction	α_1	Relaxation
Ureter			
Motility and tone	Increased	α_1	Increased (?)
Uterus	Variable, depending on species, endocrine status	α_1, β_2	Variable
Skin			
Pilomotor muscles	Contraction	α_1	—
Sweat glands	Secretion[¶]		—
Liver	Glycogenolysis, gluconeogenesis	α_1, β_2	Glycogen synthesis
Adipose tissue	Lipolysis	α_2, β_1, β_3	—

*All parasympathetic responses are mediated by activation of muscarinic receptors.

[†]Norepinephrine released from sympathetic nerves to the heart activates only β_1 receptors; epinephrine released from the adrenal medulla stimulates β_1 and β_2 receptors. The predominant adrenergic receptor in the heart is β_1.

[‡]In most smooth muscles, including blood vessels, α_1 receptors contract (constrict), whereas β_2 receptors relax (dilate). Prejunctional α_2 receptors on sympathetic nerve terminals inhibit norepinephrine release, which relaxes blood vessels and causes vasodilation; postjunctional α_2 receptors cause vasoconstriction.

[§]Blood vessels in skeletal muscle are innervated by some sympathetic nerves that release acetylcholine, which acts on muscarinic receptors to cause vasodilation.

[‖]The human parotid glands do not receive sympathetic innervation.

[¶]The sweat glands receive sympathetic innervation, but with few exceptions (e.g., the sweat glands of the palms of the hands, which are activated by α_1 receptor stimulation), the transmitter is acetylcholine, and the receptors activated are muscarinic.

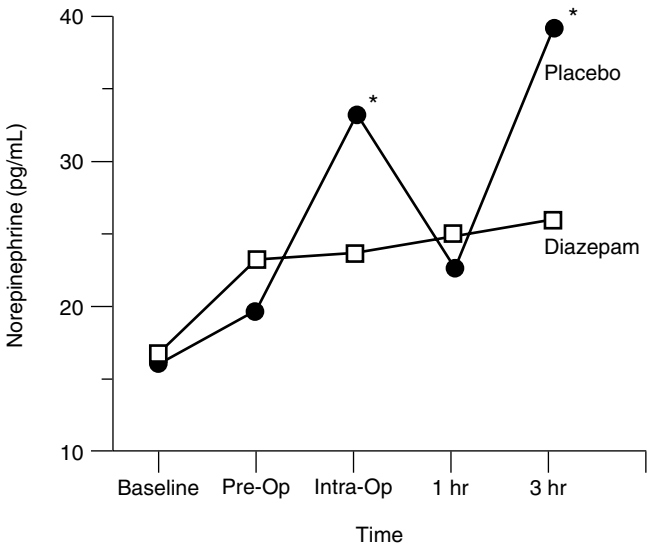

FIGURE **5-3** Response of the sympathetic nervous system to the stress of oral surgery, as indicated by the circulating concentration of norepinephrine. Plasma norepinephrine was measured 1 week before surgery (baseline) and on the day of surgery at the indicated time points. Patients were randomly injected intravenously with either placebo or diazepam (0.3 mg/kg), followed by intraoral injections of 2% lidocaine with 1:100,000 epinephrine before surgical removal of impacted third molars. Placebo-treated patients showed significant increases (*asterisks*) in norepinephrine at the intraoperative and 3-hour postoperative periods, whereas diazepam-treated patients did not. (Adapted from Hargreaves KM, Dionne RA, Mueller GP, et al: Naloxone, fentanyl, and diazepam modify plasma β-endorphin levels during surgery, *Clin Pharmacol Ther* 40:165-171, 1986.)

calcitonin gene–related peptide, and vasoactive intestinal peptide.

Location of Adrenergic and Cholinergic Junctions

Figure 5-1 shows the sites at which the neurotransmitters acetylcholine and norepinephrine and the hormone epinephrine act as chemical mediators. With the exception of effectors (smooth muscle, the heart, and secretory glands) that are innervated by postganglionic sympathetic nerves where the neurotransmitter is norepinephrine, all other sites are innervated by cholinergic nerves, including the ganglia of the ANS, the adrenal medulla, a few effectors of the sympathetic nervous system, and all the effectors of the parasympathetic nervous system. At cholinergic junctions, cholinergic nerves release acetylcholine, which acts on cholinergic receptors to produce an effect. These ubiquitous cholinergic receptors are composed of two structurally unrelated types, called *muscarinic* and *nicotinic*, which are located at specific sites in the ANS. Muscarinic receptors are located on effectors innervated by cholinergic nerves; this includes effectors at postganglionic parasympathetic junctions and a few postganglionic sympathetic junctions (most sweat glands and some blood vessels). Nicotinic receptors are found at different anatomic sites, including postganglionic nerve cell bodies at all autonomic ganglia, the adrenal medulla, and skeletal muscle. There are also different types of structurally related adrenergic receptors (α_1, α_2, β_1, β_2, β_3)[10,37] that are found at postganglionic sympathetic junctions where norepinephrine is released from postganglionic sympathetic nerves. These adrenergic receptors do not have a precise anatomic distribution, however; some effector organs have only a single adrenergic receptor, whereas other organs have two or more adrenergic receptor types. The fact that there are significant differences in autonomic receptor types is supported by the discovery of agonists that stimulate one receptor type but not others and of antagonists that block one receptor but not others. Research has revealed the existence of additional subtypes for adrenergic and cholinergic receptors, and it is anticipated that drugs highly selective for these additional receptor subtypes will be developed for future clinical use.

Mechanism of Neurotransmitter Release

The current understanding of exocytotic neurotransmitter release has arisen from the work of many different investigators. Although several mechanisms for neurotransmitter release may exist, as summarized in reviews on the subject,[26,36] one main model has been developed for the secretion of classic neurotransmitters, such as acetylcholine (Figure 5-4) and norepinephrine (Figure 5-5). It has been proposed that when an action potential reaches the axon terminal it depolarizes the membrane, leading to the opening of voltage-gated Ca^{++} channels.[31] This activation of Ca^{++} channels causes high, but transient, increases in intracellular Ca^{++} concentrations near the neurotransmitter storage vesicles. Intracellular Ca^{++} activates calmodulin, a small Ca^{++}-binding protein found in nearly all cells.[14] Calmodulin activates an enzyme called Ca^{++}/calmodulin-dependent protein kinase. This enzyme, found in extremely high concentrations in neurons (approximately 1% of total protein), catalyzes the phosphorylation of several proteins associated with the storage vesicle, including synapsin I. Synapsin I binds to actin present on the cytoskeleton and is thought to interact with other proteins (e.g., synaptobrevin, synaptophysin, and synaptoporin) to initiate docking and fusion of the storage vesicle with the cell membrane, followed by exocytotic neurotransmitter release. The neurotransmitter crosses the synaptic or junctional cleft and binds to its receptor on the nerve or effector cell membrane, which could be located on a ganglionic neuron, a skeletal muscle fiber, an autonomic effector, or a cell in the CNS.

ADRENERGIC NEUROTRANSMISSION

Catecholamine Synthesis

The catecholamines norepinephrine and epinephrine are the primary neurotransmitters and hormones released after stimulation of the sympathetic nervous system. The synthesis and storage of the catecholamines can be modified by a number of clinically useful drugs. The synthetic process, shown in Figure 5-6, involves numerous enzymes that are synthesized in the nerve cell body and carried by axoplasmic transport to the nerve endings. The enzyme tyrosine hydroxylase, which catalyzes the conversion of tyrosine to dihydroxyphenylalanine, is the rate-limiting enzyme in this process; any drug that inhibits the function of tyrosine hydroxylase reduces the rate at which norepinephrine is produced in the nerve terminal. The concentration of norepinephrine in the cytoplasm is one of the factors that regulates its own formation, principally by feedback inhibition on tyrosine hydroxylase activity.[27] The enzyme phenylethanolamine-N-methyltransferase, which catalyzes the conversion of norepinephrine to epinephrine, occurs almost exclusively in the chromaffin cells of the adrenal medulla and is missing in peripheral nerve terminals.[3] Norepinephrine is the final product in most adrenergic nerves, whereas mainly epinephrine (80%), with some norepinephrine (20%), is produced in adrenal chromaffin cells in human beings.

Catecholamine Release

Evidence suggests that 90% to 95% of intracellular norepinephrine is stored in small granulated vesicles, where it is protected from intracellular enzymatic destruction until it is

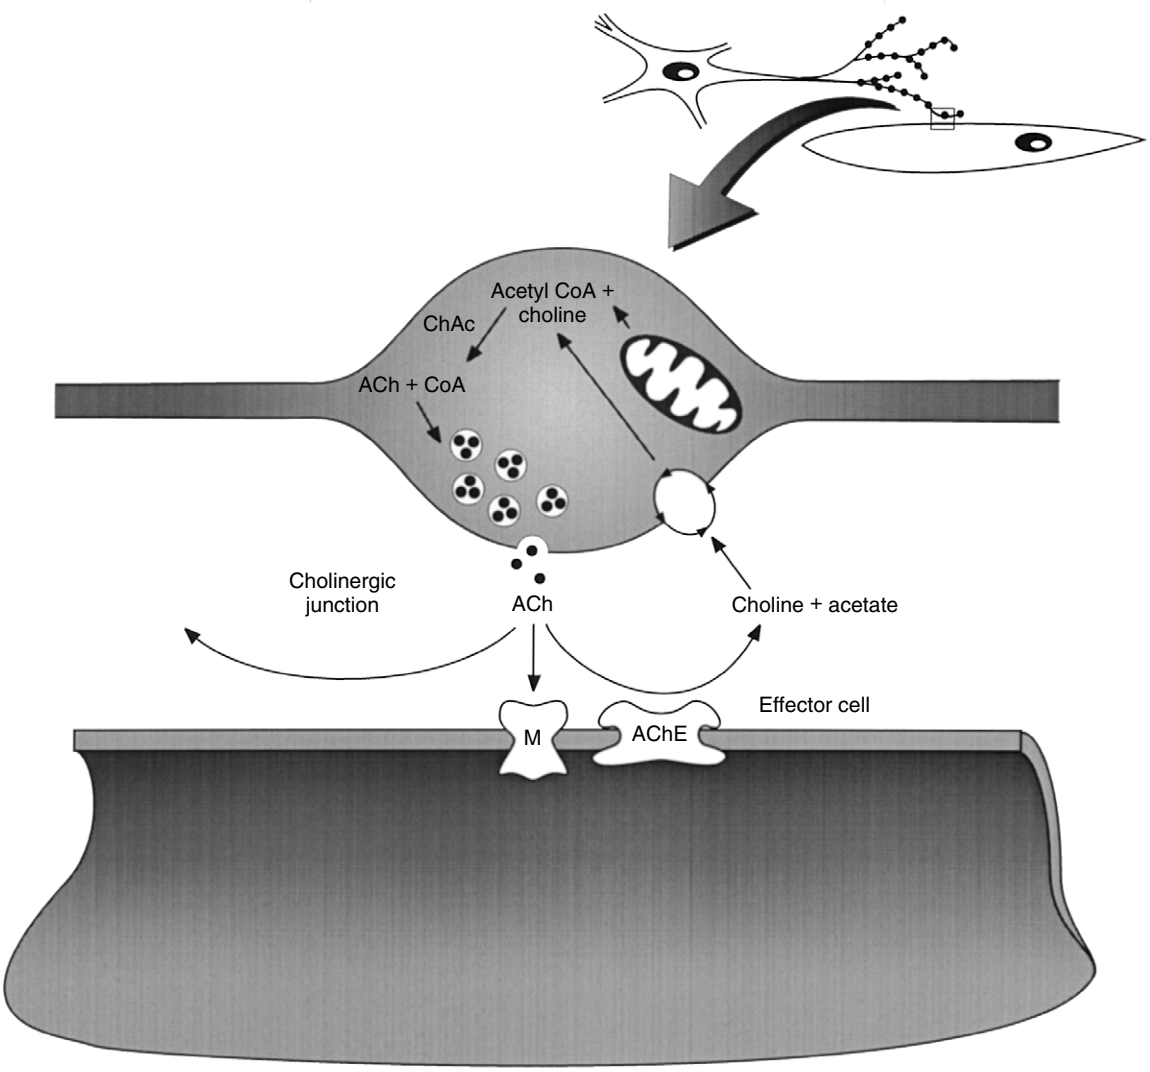

FIGURE **5-4** Cholinergic nerve terminal and its effector, in which are shown the intraneuronal synthesis of acetylcholine *(ACh)*, the vesicles containing ACh, the release of ACh into the junctional cleft, its removal by the action of acetylcholinesterase *(AChE)* and diffusion, and the subsequent reuptake of choline back into the nerve terminal. *CoA*, Coenzyme A; *ChAc*, choline acetyltransferase; *M*, muscarinic receptor. (Adapted from Hubbard JI: Mechanism of transmitter release from nerve terminals, *Ann N Y Acad Sci* 183:131-146, 1971.)

released by depolarization; the other 5% to 10% is found in the cytoplasm. Most norepinephrine is stored in vesicles complexed with the protein chromogranin, the enzyme dopamine β-hydroxylase, and ATP. There are two different norepinephrine pools inside the neuron: a mobile and a reserve pool. Membrane depolarization causes release of transmitter from the mobile pool. Newly synthesized norepinephrine would seem to constitute the mobile pool because it is preferentially released during depolarization.[40] The function of the small cytoplasmic pool and its relationship to vesicular norepinephrine are not well understood. A diagrammatic representation of the adrenergic nerve terminal is shown in Figure 5-5.

Autonomic neuroeffector junctions are less structurally organized than the classic neuromuscular junction. The autonomic axon resembles a string of beads as it passes among smooth muscle fibers in blood vessels, intestines, and other sites (see the top right of Figure 5-5). The beaded varicosities release neurotransmitter near directly innervated effector cells. As the nerve impulse passes down the axon, and depolarization successively involves each varicosity, extracellular Ca^{++} enters into the nerve terminals, and norepinephrine is released into the junctional cleft by the process of exocytosis, as previously described. The cleft distances in the sympathetic and parasympathetic nervous systems are quite variable, ranging from 15 nm to many hundred nanometers, depending on the specific neuroeffector junction.[6] After crossing the junctional cleft by passive diffusion, the transmitter binds to receptor sites on the effector organ and elicits an appropriate response.

Adrenergic Receptors

In 1948, Ahlquist[1] proposed the existence of two kinds of adrenergic receptors. He called these alpha (α) and beta (β). Two types of the β-adrenergic receptor, called β_1 and β_2, were identified, followed by two different α-adrenergic receptors: α_1, the predominant postjunctional membrane receptor, and α_2, located prejunctionally[33] and postjunctionally.[5] The presence or absence of these different adrenergic receptors, identified in part by experiments using synthetic drugs (ago-

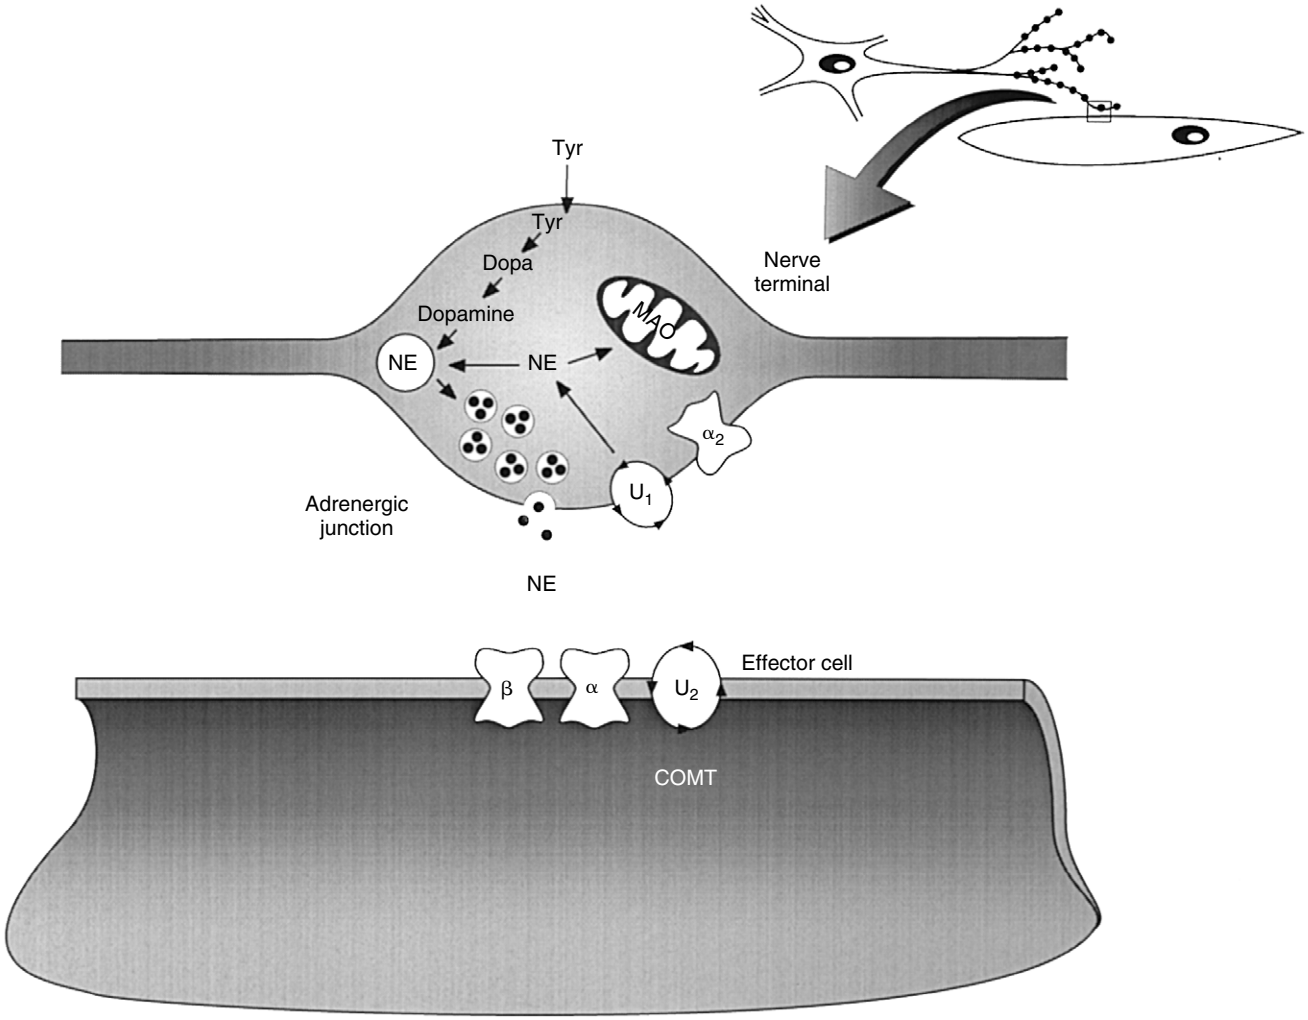

FIGURE **5-5** Adrenergic nerve terminal and its effector cell. Shown are the precursors of norepinephrine (*NE*), the sites of synthesis and storage of dopamine and NE, and the location of prejunctional and postjunctional adrenergic receptors *(α_2, α, β)*. It also shows the enzymatic (catechol-O-methyltransferase [*COMT*], monoamine oxidase [*MAO*]) and uptake-1 (U_1) and uptake-2 (U_2) mechanisms by which the action of NE is terminated. *Dopa*, Dihydroxyphenylalanine; *Tyr*, tyrosine.

nists and antagonists) highly selective for individual adrenergic receptor types, provides an explanation for the seemingly contradictory (or opposing) actions of the adrenergic transmitters (e.g., vasodilation in some vascular beds and vasoconstriction in others; see Table 5-1).

More recent molecular cloning and pharmacologic studies have shown the existence of multiple subtypes of adrenergic receptors. The α_1-adrenergic receptor family consists of three subtypes, classified as α_{1A}, α_{1B}, and α_{1D}.[28,42] Similar studies have shown the existence of multiple subtypes of the α_2 receptor (α_{2A}, α_{2B}, α_{2C}) and the β-adrenergic receptor (β_1, β_2, β_3).[10] Using molecular biologic techniques, it is now possible to define a protein structure for these receptors.[37] The human β_2 receptor is a protein of 413 amino acids, with seven transmembrane spanning domains (see Figure 1-3). This heptahelical structure is a general characteristic of many cell surface neurotransmitter receptors. Because many of these receptors seem to have substantial differences in tissue distribution and function, considerable research is being directed toward the development of drugs with selectivity at individual receptor subtypes.[4,28] These drugs may possess greater specificity of action compared with currently used adrenergic agonists or antagonists.

As can be seen in Table 5-1, some organs express only one type of adrenergic receptor, whereas others have several types. α_1-Adrenergic receptors mediate smooth muscle contraction and glandular secretion and are often excitatory. The function of α_2 receptors at postjunctional sites includes regulation of several metabolic functions (e.g., glycogenolysis, lipolysis, and water absorption)[4] and vascular smooth muscle contraction. Norepinephrine acts on prejunctional α_2 receptors to inhibit transmitter release. This negative feedback control is supported by the observation that antagonists for these receptors (e.g., phentolamine) cause an increase in the release of transmitter in response to nerve stimulation.[33] Centrally, α_2 receptors are known to be involved in the regulation of blood pressure. Although several important exceptions exist, β_1 receptors are often associated with excitatory cellular

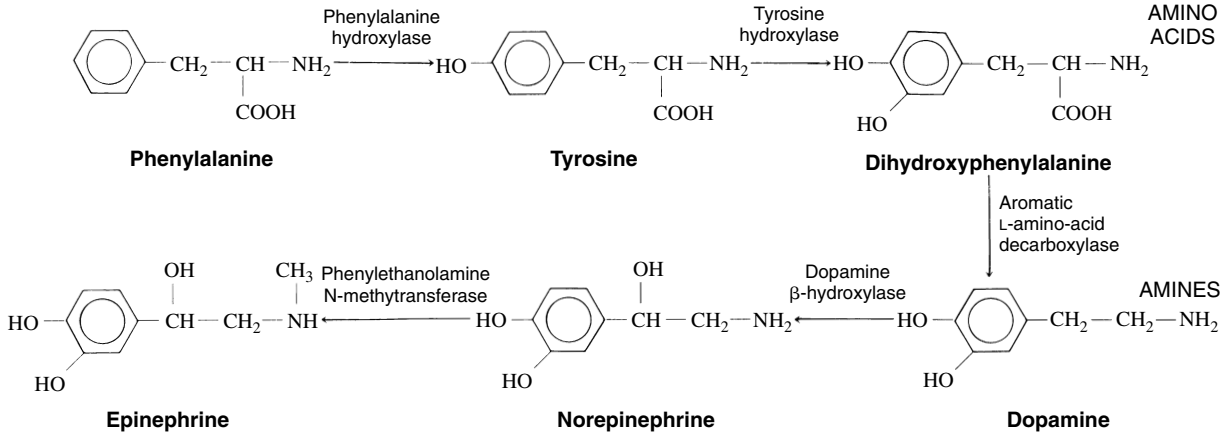

FIGURE **5-6** Biosynthesis of adrenergic transmitters. The amino acids in the top row can penetrate the blood-brain barrier, whereas the amines in the bottom row cannot. Conversion of dopamine into norepinephrine occurs in the storage vesicles of adrenergic nerves and the adrenal medulla, whereas conversion of norepinephrine to epinephrine occurs only in storage vesicles in the adrenal medulla and in some neurons of the central nervous system. The enzyme tyrosine hydroxylase is the rate-limiting regulatory enzyme in the synthesis of catecholamines and is a target for the enzyme inhibitor metyrosine.

responses, and β_2 receptors are associated with relaxation. β_3 Receptors primarily stimulate lipolysis in fat cells.

Catecholamine Fate

The fate of the released catecholamines and systems responsible for termination of their action are quite different from mechanisms of neurotransmitter termination at cholinergic junctions. At adrenergic junctions, enzymatic destruction of the transmitter normally plays a minor role. Uptake of the transmitter accounts for the greatest proportion of transmitter loss, with enzymatic breakdown and diffusion away from the junction responsible for only a small percentage of the total. As depicted in Figure 5-5, uptake can be neuronal (uptake-1) or extraneuronal (uptake-2).[21] Uptake-1, also called the *norepinephrine transporter,* requires energy and extracellular Na^+ and exhibits stereospecificity. Amphetamines, tyramine, and levonordefrin (α-methylnorepinephrine) are examples of drugs that are taken up by this transporter system. Inhibitors of neuronal uptake include cocaine and imipramine. Uptake-2, synonymous with the *extraneuronal transporter* or *organic cation transporter 3*, has a greater capacity but lower affinity than uptake-1. At high concentrations of norepinephrine, uptake-2 results in the rapid removal of the transmitter. Uptake-2 is sometimes described as the cocaine-insensitive uptake.

Within the nerve terminal, uptake of norepinephrine into the storage vesicles also takes place. It is an active process, requiring ATP and Mg^{++}; by this mechanism, norepinephrine and structurally related compounds (e.g., some vasoconstrictors added to local anesthetic solutions) ultimately enter the storage vesicles. The drug best known for its ability to inhibit this transfer of norepinephrine and related compounds from the neuronal cytoplasm into storage vesicles is reserpine.

In the cytoplasmic pool, the neurotransmitter is susceptible to the enzymatic action of a mitochondrial enzyme, monoamine oxidase (MAO), which is capable of deaminating the molecule. MAO is widely distributed throughout the body, especially in the liver, kidney, and brain, and is associated with the mitochondria of the adrenergic nerve terminals. It is the principal intraneuronal enzyme concerned with the breakdown of norepinephrine. Certain drugs are capable of inhibiting MAO, leading to an accumulation of the transmitter in the nerve terminal, an effect that has physiologic and therapeutic implications. A second enzyme concerned with the breakdown of norepinephrine is catechol-O-methyltransferase (COMT). It is widely distributed in many tissues and is the principal extraneuronal enzyme involved with the metabolic inactivation of norepinephrine.

CHOLINERGIC TRANSMISSION

Synthesis, Release, and Fate of Acetylcholine

The general concept of transmitter synthesis, storage, and removal also applies to acetylcholine at cholinergic junctions of the ANS. As shown in Figure 5-4, the conversion of choline to acetylcholine in the nerve terminal is accomplished by the enzyme choline acetyltransferase. The mitochondrial cofactor acetyl coenzyme A serves as the acetyl group donor for the reaction. The newly synthesized acetylcholine is stored in vesicles.[20] The vesicles are transported toward the presynaptic membrane and make contact with specialized docking proteins, and the contents of the vesicles are released by exocytosis,[20] as described previously. Acetylcholine crosses the junctional cleft and attaches reversibly to the postjunctional receptor, which exists in close proximity to a highly specific enzyme, acetylcholinesterase (AChE). Acetylcholine becomes bound to the enzyme at two primary sites (see Figure 8-6) and is hydrolyzed to choline and acetate at such a rapid rate that the nerve can respond to another stimulus milliseconds later. The choline produced by the action of AChE is returned to the nerve terminal by a carrier mechanism and is used again in the synthesis of acetylcholine.

Even in the total absence of AChE activity, the action of acetylcholine can be terminated quickly by pseudocholinesterase, a nonspecific plasma enzyme also known as butyrocholinesterase, which is found in many tissues, including blood. Clinically, a subpopulation of patients lacks plasma pseudocholinesterase activity and can have prolonged paralysis with muscle-relaxing agents such as succinylcholine, which is metabolized primarily by this enzyme (see Chapter 10). Acetylcholine is also removed from the junctional cleft by the simple process of diffusion.

Cholinergic Receptors

As with the adrenergic receptors, receptors for acetylcholine can be separated into two major categories: nicotinic and muscarinic. The anatomic distribution and functional signifi-

cance of these receptors have been described (see Table 5-1 and Figures 5-1 and 5-2). Nicotinic receptors outside the CNS are located on postganglionic nerves in autonomic ganglia, on chromaffin cells in the adrenal medulla, and on skeletal muscle in neuromuscular junctions. Nicotinic receptors on postganglionic neurons and in the adrenal medulla are classified as N_N (nerve) receptors; N_M (muscle) receptors are found on skeletal muscle in neuromuscular junctions. In contrast to adrenergic receptors and muscarinic receptors, nicotinic receptors are ion channel receptors composed of an allosteric protein containing four different subunit types—α, β, δ, and γ—gathered together in a transmembrane pentamer.[24] Each of the subunits has an intracellular and extracellular exposure, and together they surround a central channel. Recognition sites for acetylcholine and other agonists, cholinergic antagonists, and certain snake venom toxins are located primarily on the α subunits.

Muscarinic receptors of the ANS are located primarily on effector cells—smooth muscle, the heart, and secretory glands—that are innervated by postganglionic parasympathetic nerves. Molecular cloning studies have deduced the amino acid sequence of five subtypes of muscarinic receptors classified as M_1 to M_5.[12] As with adrenergic receptors, muscarinic receptors all have seven transmembrane-spanning domains and display the same general structure as the β_2-adrenergic receptor shown in Figure 1-3.

SIGNAL TRANSDUCTION AND SECOND MESSENGERS

The binding of an autonomic neurotransmitter to its receptor on the plasma membrane surface of a target cell initiates a signaling cascade that alters the physiologic activity of the cell. The exact response elicited depends not on the neurotransmitter per se, but on the type of receptor activated. There are two general classes of membrane-bound receptors that interact with autonomic drugs: ion channel–linked and G protein–linked receptors.

Ion Channel—Linked Receptors

Ion channel–linked receptors, otherwise known as ionotropic receptors, are ligand-gated ion channels that undergo binding-dependent conformational changes leading to an opening of the ion channel (see Chapter 1). The nicotinic receptor was first isolated and purified from the electric organ of the eel, *Electrophorus torpedo*, and by 1984 it had become the first receptor for which complete structural data had been obtained.[13] The nicotinic receptor is a ligand-gated ion channel that, when activated, leads to rapid membrane depolarization as a result of the net inward passage of positively charged ions through the channel. Ligand-gated ion channels may increase permeability of the membrane to all ions or selectively increase permeability only to certain ions. In the case of a ligand-gated Na^+ or Ca^{++} channel, opening produces an excitatory postsynaptic potential, and in the case of a ligand-gated K^+ or Cl^- channel, an inhibitory postsynaptic potential. An excitatory postsynaptic potential activates a neuron, whereas an inhibitory postsynaptic potential inhibits neuronal activity.

G protein–linked receptors

Adrenergic and muscarinic receptors belong to a large family of receptors characterized by their functional dependence on G proteins (shorthand for guanine nucleotide-binding proteins) to initiate cellular signaling. G proteins are heterotrimers, so named because they consist of three different proteins: the α subunit, which activates target proteins (enzymes, ion channels) and hydrolyzes guanosine triphosphate (GTP) to guanosine diphosphate (GDP), and the β and γ subunits, which attach the G protein to the cell membrane and have signaling properties distinctly different from the α subunit.[7,38] G proteins are signal transducers in that they convert the external signal of neurotransmitter binding into an alteration of cellular function. Molecular cloning studies suggest that there are many different types of G protein heterotrimers consisting of different varieties of α, β, and γ subunits.

As an immediate result of G protein actions, intracellular signaling molecules are generated that serve as "second messengers" for the neurotransmitters, which are the primary messengers. Figure 5-7 depicts two major second messenger pathways: the cyclic 3′,5′-adenosine monophosphate (cAMP) and the Ca^{++}/inositol phospholipid pathway. These two pathways mediate many of the actions of the G protein–coupled adrenergic and muscarinic receptors.[7,22,41]

G_s protein–dependent events

In the example illustrated in Figure 5-7, activation of the β_1-adrenergic receptor by norepinephrine leads to the receptor's association with a membrane-bound G protein heterotrimer called G_s ("s" implies a stimulatory effect). This binding activates G_s, causing the G_s α subunit to exchange its bound GDP for GTP and to dissociate from the adrenergic receptor and from the βγ subunit pair. The free $G_{\alpha s}$ complexed with GTP is capable of binding to and activating effector enzymes such as adenylyl cyclase, leading to the production of cAMP. cAMP activates protein kinase A, which phosphorylates numerous target proteins. This phosphorylation step alters the ongoing activity of the cell because many of these target proteins are either enzymes or ion channels. Protein kinase A can activate the enzyme glycogen phosphorylase, leading to increased glycogen breakdown and release of glucose. Some other responses linked to increased cAMP synthesis include relaxation of vascular smooth muscle, increased contractile force of the myocardium, and secretion of amylase and other proteins by salivary glands.[9,32,34] In addition to β receptors, many other receptors activate the cAMP pathway, including dopamine D_1 and D_5 receptors, 5-HT_4 receptors, histamine H_2 receptors, adenosine A_2 receptors, and certain peptide and prostanoid receptors.[38,39] These receptors are discussed in other chapters.

Hydrolysis of the bound GTP by $G_{\alpha s}$ leads to inactivation of the subunit. $G_{\alpha s}$, complexed with GDP, now reassociates with the β and γ subunits. The heterotrimer can be reactivated by an appropriate stimulus. Cholera toxin blocks the ability of $G_{\alpha s}$ to hydrolyze GTP. $G_{\alpha s}$ is permanently activated, contributing to the signs and symptoms of cholera. When formed, cAMP is subject to breakdown by a second enzyme, cAMP phosphodiesterase. Inhibition of this enzyme blocks the breakdown of cAMP and accentuates the adrenergic response. Caffeine and related methylxanthines are effective inhibitors of phosphodiesterase, at least in vitro.[2] A particular form of cAMP phosphodiesterase is the site of action for inamrinone and milrinone, agents used to treat congestive heart failure (see Chapter 25).

The G protein system serves to amplify greatly the biologic response to a drug or neurotransmitter. Because of the large degree of signal amplification, stimulation of only a small proportion of the total receptors may be required to elicit a maximal biologic response. It has been estimated that binding of only 1% of the insulin receptors can produce maximal rates of glycogenolysis in liver cells. Amplification of the biologic response by second messenger systems may contribute to the phenomenon of "spare receptors" described in Chapter 1, in which maximal responses are observed after activation of only a fraction of the available receptors.

G_i protein–dependent events

Different biologic responses can occur when receptors activate different G_α protein subunits. Stimulation of α_2-adrenergic receptors (see Figure 5-7) leads to the release of

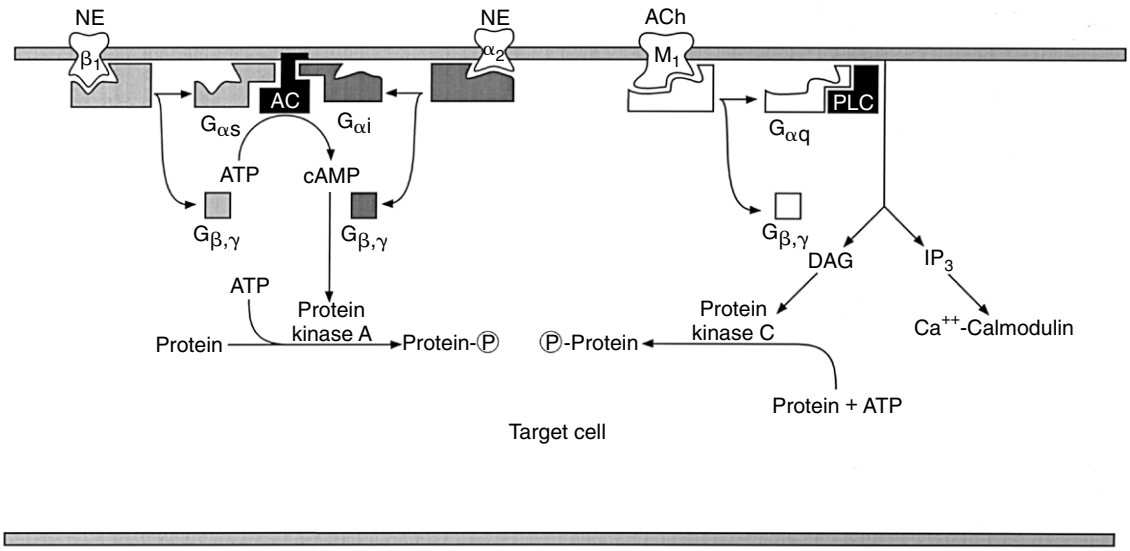

FIGURE **5-7** Sites of action of primary messengers, such as norepinephrine *(NE)* and acetylcholine *(ACh)*, and their role in regulating the formation of second messengers in target cells. The binding of the agonist to its receptor (in this example, β_1-adrenergic or α_2-adrenergic, or M_1-muscarinic) leads to release of the α subunit of the associated G protein *($G_{\alpha s}$, $G_{\alpha i}$,* or *$G_{\alpha q}$)*. $G_{\alpha s}$ activates adenylyl cyclase *(AC)*, leading to the production of cAMP. Elevated cAMP activates protein kinase A, which catalyzes the phosphorylation of numerous target proteins. $G_{\alpha i}$ inhibits AC, leading to a reduction in cAMP. Receptor activation of $G_{\alpha q}$ leads to stimulation of the enzyme phospholipase C *(PLC)*. PLC catalyzes the hydrolysis of phosphatidylinositol 4,5-bisphosphate in the cell membrane, yielding diacylglycerol *(DAG)* and inositol 1,4,5-trisphosphate *(IP_3)*. DAG activates protein kinase C, which catalyzes the phosphorylation of numerous target proteins. IP_3 increases intracellular Ca^{++} release from intracellular storage sites, resulting in activation of calmodulin and other Ca^{++}-dependent events.

$G_{\alpha i}$ ("i" for inhibitory). $G_{\alpha i}$ inhibits adenylyl cyclase and causes decreased cAMP concentrations.[23] Other receptors that act by reducing cAMP include adenosine A_1 receptors; dopamine D_2 receptors; 5-HT_1 receptors; $GABA_B$ receptors; M_2-muscarinic and M_4-muscarinic receptors; and several glutamate, opioid, and other peptide receptors.[39] In addition, certain toxins, such as pertussis toxin, inactivate $G_{\alpha i}$ so that it cannot inhibit adenylyl cyclase, which promotes an increase in cAMP and contributes to many of the signs and symptoms of whooping cough.

G_q protein–dependent events

$G_{\alpha q}$, a third G_α subunit important in ANS responses, activates the Ca^{++}/inositol phospholipid pathway. In the example in Figure 5-7, acetylcholine stimulation of the M_1-muscarinic receptor leads to release of $G_{\alpha q}$, from its associated β and γ subunits. $G_{\alpha q}$ activates the enzyme phospholipase C, which hydrolyzes phosphatidylinositol 4,5-bisphosphate (PIP_2), a minor phospholipid found on the cytoplasmic surface of the cell membrane. The hydrolysis of PIP_2 yields two biologically active products, diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). DAG stimulates the enzyme protein kinase C, which phosphorylates target proteins generally consisting of other enzymes or ion channels. In addition, DAG itself can be hydrolyzed to yield prostanoids, resulting in activation of additional cellular responses. IP_3 releases Ca^{++} from intracellular binding sites, leading to increased activation of protein kinase C and to other biologic responses, including activation of calmodulin-mediated events.

α_1 Receptors activate the second messenger system linked to $G_{\alpha q}$—Ca^{++}, DAG, and IP_3. Additional receptors that activate this second messenger system include histamine H_1 receptors; M_1-muscarinic and M_3-muscarinic receptors; leukotriene receptors; several 5-HT_2 receptors; and certain receptors for glutamate and various peptides, including angiotensin, bradykinin, cholecystokinin, and substance P.[38,39]

Additional second messenger systems

Other second messenger systems exist besides those mentioned, and the roles of cyclic 3′,5′-guanosine monophosphate, Ca^{++}, calmodulin, nitric oxide, prostanoids, peptides, and other mediators of cellular function are currently under extensive investigation.

DOPAMINERGIC TRANSMISSION

Dopamine receptors exist outside the CNS, in the kidney (where their activation leads to vasodilation), the mesenteric vascular bed, the coronary blood vessels, and other vascular and nonvascular smooth muscle. The discovery of dopamine receptors in the periphery has led to the application of dopamine to many clinical situations, such as the treatment of cardiogenic shock and renal failure, where it has the capacity to increase cardiac contractility (by stimulating β_1-adrenergic receptors) and renal blood flow without causing marked systemic vasodepressor effects.[17] The existence of dopaminergic nerves in the peripheral nervous system is less settled; one location where dopamine may be a neurotransmitter is the gastrointestinal tract. The possible role of dopamine in sympathetic ganglionic transmission is outlined in Chapter 10. Most of the evidence to date indicates that dopamine is synthesized, stored, released, and taken up in a manner identical to that of norepinephrine.[17] Molecular cloning studies indicate that there are five subtypes of dopamine receptors (D_1 to D_5), all of which resemble adrenergic receptors in overall structure and use G protein–mediated second messenger systems.[38]

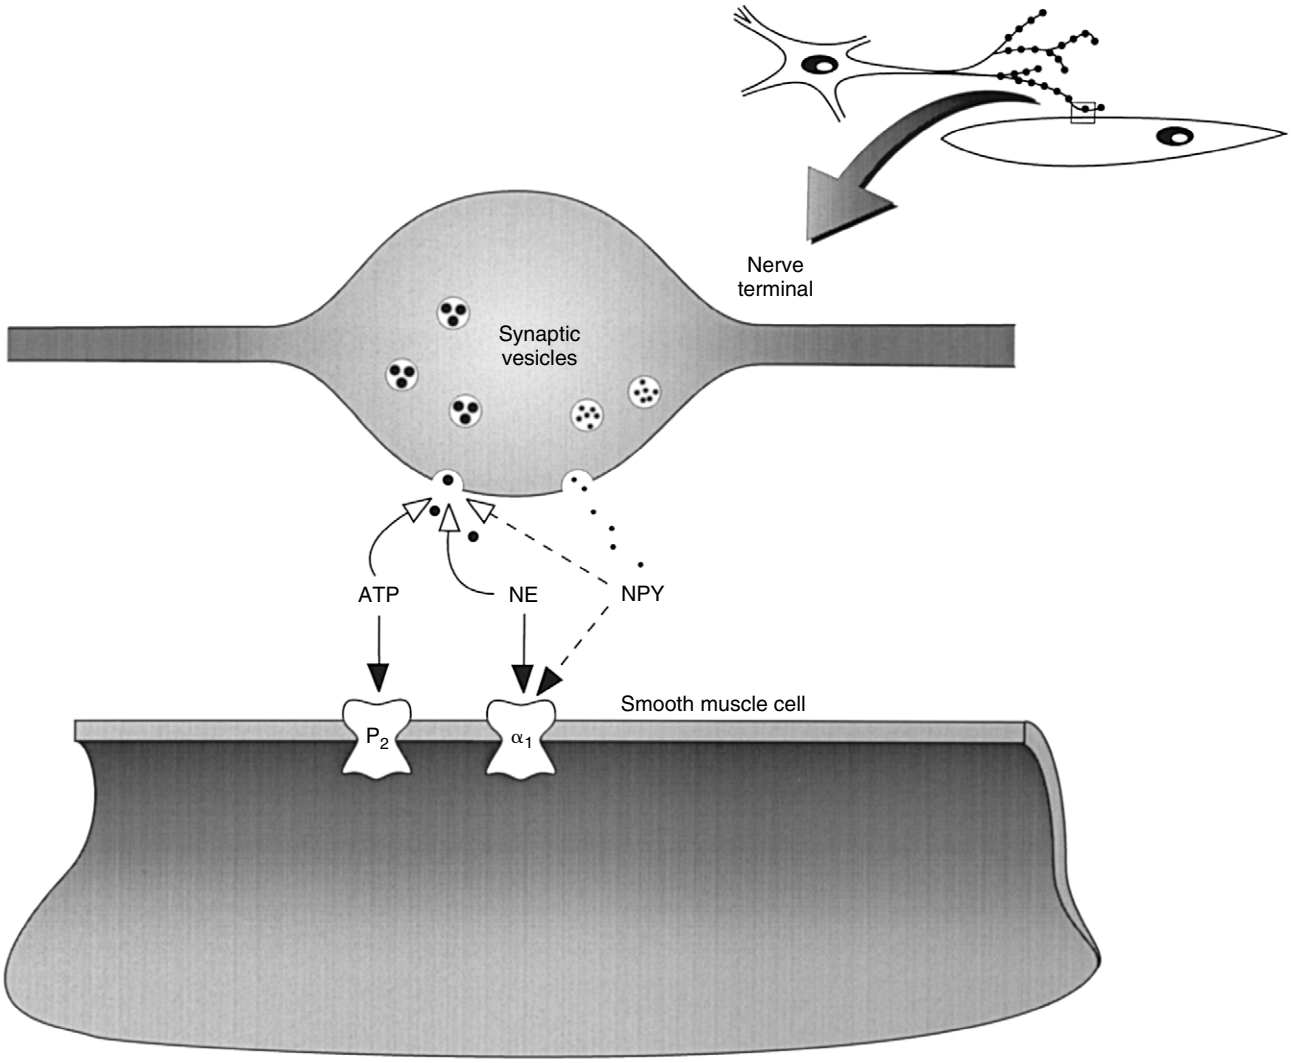

FIGURE **5-8** Co-release of neurotransmitters and neuromodulators. Norepinephrine *(NE)* and ATP, stored in the same storage vesicles, are released together from the sympathetic nerve varicosity to stimulate *(solid arrows)* their respective α_1 and P_2 receptors on smooth muscle. Neuropeptide Y *(NPY)*, stored in separate vesicles, is also released during sympathetic nerve stimulation. Here, NPY serves as a neuromodulator *(dashed arrows)*, increasing the activity of NE. All three agents inhibit further release *(open arrowheads)* through effects on prejunctional receptors (not shown).

PURINERGIC TRANSMISSION

Evidence has accumulated that there are noncholinergic, nonadrenergic nerves, designated as purinergic, that are found in the gastrointestinal tract of all vertebrates and in certain areas of the CNS; the vasculature; and the lungs, trachea, and bladder.[8] ATP is stored in vesicles in purinergic nerve endings and, when released, directly activates purinergic receptors of the P2 type, or it is broken down to adenosine, which activates P1 or adenosine receptors. There are four types of adenosine receptors (A_1, A_{2A}, A_{2B}, A_3), which are linked to either $G_{\alpha s}$ or $G_{\alpha i}$, and two major groups of P2 receptors ($P2X_{1\text{-}7}$ and $P2Y_{1,2,4,6,11\text{-}14}$), which are either ligand-gated ion channels (P2X) or G protein–linked receptors (P2Y).[8,29] The demonstration that adenosine and its nucleotides inhibit norepinephrine release from adrenergic nerves has led to the hypothesis that purines may act as neuromodulators, regulating the release of norepinephrine through a feedback mechanism.[35] ATP can also act as a neurotransmitter or as a cotransmitter with norepinephrine and acetylcholine (Figure 5-8).

PEPTIDE TRANSMISSION AND CO-RELEASE OF NEUROTRANSMITTERS

Certain neurons release more than one neurotransmitter, such as norepinephrine with ATP. Often, co-release is automatic because both substances are found in the same storage vesicle. Simultaneous release of transmitters may also occur when they are stored separately. In recent years, it has become increasingly clear that various peptides in particular are co-released with classic ANS transmitters through both of these mechanisms.

When co-release occurs, it is thought that the two substances may have slightly different functions, with one substance functioning as a neurotransmitter and the other

TABLE **5-2**

Mechanism of Action of Representative Drugs Affecting the Autonomic Nervous System

	SITE OF ACTION	
MECHANISM OF ACTION	**CHOLINERGIC JUNCTIONS**	**ADRENERGIC JUNCTIONS**
Interfere with synthesis of transmitter	Hemicholinium	Metyrosine
Causes formation of "false" transmitter	—	Methyldopa
Prevent release of transmitter	Botulinum toxin	Guanethidine
Prevent reuptake of transmitter	—	Imipramine, cocaine
Prevent incorporation of transmitter in storage vesicles	Vesamicol	Reserpine
Cause release of transmitter	Carbachol	Tyramine, amphetamine
Activate postjunctional receptor	Muscarinic: choline esters, cholinomimetic alkaloids; nicotinic: nicotine	α_1 Receptor: phenylephrine; α_2 receptor: clonidine; β_1 and β_2 receptors: isoproterenol; β_2 receptor: albuterol
Block access of transmitter to receptor	Muscarinic: atropine; nicotinic: tubocurarine, trimethaphan	α_1 and α_2 Receptors: phentolamine; α_1 receptor: prazosin; α_2 receptor: yohimbine; β_1 and β_2 receptors: propranolol; β_1 receptor: metoprolol
Inhibit enzymatic breakdown of transmitter	Acetylcholinesterase inhibitors (physostigmine, isoflurophate)	MAO inhibitors (tranylcypromine, selegiline); COMT inhibitors (entacapone, tolcapone)

COMT, Catechol-O-methyltransferase; *MAO,* monoamine oxidase.

functioning as a neuromodulator, or that they act cooperatively as transmitters to elicit some physiologic response. Cholinergic neurons in the cat submandibular gland contain and release vasoactive intestinal peptide, a transmitter that potentiates the salivary secretion induced by acetylcholine, possibly by enhancing the binding of acetylcholine to its receptor.[25] Similarly, neuropeptide Y enhances vasoconstriction by a direct action on the vasculature and by potentiating the effects of norepinephrine (see Figure 5-8).[18] The recognition of the existence of multiple peptide neurotransmitters affecting the ANS offers additional new targets for drug development.

CENTRAL CONTROL OF AUTONOMIC FUNCTION

Virtually all levels of the CNS contribute significantly to the regulation of the ANS; this includes the spinal cord and brainstem, where reflexes regulating blood pressure are integrated, and the higher centers in the hypothalamus, limbic system, and cerebral cortex, which integrate highly complex autonomic responses involved in behavior, reproduction, and emotional states. The finding that benzodiazepines reduce sympathetic responses to oral surgery (see Figure 5-3) emphasizes the role of the CNS in initiating and coordinating sympathetic responses to stress. The locations of centers in the CNS that directly regulate functions such as blood pressure, respiration, micturition, and sweating are known. The ANS modulates the activity of these centers by the hypothalamus, which plays a crucial role in the integration of responses to changes in temperature, emotional states, and patterns of sexual and reproductive activity, all of which involve integration of the endocrine, autonomic, and somatic nervous systems. The limbic system has been shown through stimulation experiments to cause changes in blood pressure, sexual activity, ragelike responses, and a host of other reactions characteristic of ANS stimulation. It is believed that the limbic system plays an important role in patterns of sexual activity and states of rage and fear, and that its effects may be superimposed on the effects exerted by the hypothalamus. The cerebellum and the cerebral cortex also make contributions to patterns of autonomic activity, but their importance is less than that of the hypothalamus (see Chapter 11).

SPECIFIC SITES AND MECHANISMS OF ACTION OF AUTONOMIC DRUGS

The foregoing discussion in this chapter has shown that neurotransmission in the ANS—and normal function of the two divisions of the ANS—depends on many integrated steps, including synthesis of transmitter, release of transmitter, combination of the transmitter with the receptor, and destruction by highly specific enzymes or reuptake and reuse of the transmitter in the nerve terminal. The explosion of knowledge about the function of the ANS at the neuronal and molecular levels has been accompanied by the discovery and development of drugs that interfere with one or several steps in the complex processes described in the earlier sections on cholinergic and adrenergic transmission.

Some of these drugs and their specific mechanisms and sites of action are listed in Table 5-2. Their pharmacology is described in the appropriate chapters of this book. With a working knowledge of the ANS and the role it plays in the normal function of various organs, it is possible to predict what effects a drug with a known mechanism of action would have. If a drug (e.g., reserpine) prevents norepinephrine from being transferred from the cytoplasm of the neuron into storage vesicles, it is reasonable to expect that the norepinephrine that has been taken up from the neuroeffector junction will remain in the cytoplasm. Here it will be subject to destruction by MAO, and in time (a relatively short time) the stores of norepinephrine will be reduced, leaving adrenergic nerve terminals throughout the body depleted of norepinephrine. It is now possible to predict that the depletion of norepinephrine throughout the sympathetic nervous system will place the animal under the unopposed control of the parasympathetic nervous system. The pupils are constricted, postural hypotension occurs, and gastrointestinal motility and secretion are increased. Knowledge of autonomic drug mechanism of action is important to understand the actions of and therapeutic uses of the various types of autonomic drugs.

CHAPTER 6

Adrenergic Agonists

YAPING TU, MICHAEL T. PIASCIK, AND PETER W. ABEL

The endogenous catecholamines norepinephrine, epinephrine, and dopamine compose an important class of neurotransmitters and hormones. By activating adrenergic receptors, these biochemicals mediate numerous functions in the periphery and in the central nervous system (CNS). These and other adrenergic agonists represent an important group of drugs with a broad spectrum of actions. Adrenergic agents are also referred to as *sympathomimetic drugs* because they mimic the effects caused by stimulation of the sympathetic nervous system. There are several therapeutic uses for these compounds: as vasoconstrictors in local anesthetic solutions and for hemostasis; as decongestants in ophthalmic and nasal preparations; as vasopressor agents to maintain blood pressure in some types of shock; and as bronchodilators for asthmatic attacks and for allergic reactions, including anaphylaxis. Centrally acting adrenergic agonists are used to treat essential hypertension, narcolepsy, and attention-deficit/hyperactivity disorder.

HISTORY

The first recorded study of an adrenergic agent resulted in the isolation in 1887 of ephedrine from the herb *ma huang*, which had been grown and used in China for centuries. At the same time, investigators were making extracts of all the organs of the body in an attempt to discover new hormones. Studies by Oliver and Schafer in the early 1890s showed a potent vasopressor substance in extracts of the adrenal gland. The active agent, epinephrine, was soon isolated by Abel, prepared commercially, and marketed in the United States under the trade name of Adrenalin(e). By 1905, it had been synthesized and was being incorporated with local anesthetics. In that year, an account was published of the results of mixing procaine with epinephrine to obtain dental anesthesia.[3] 1887 also witnessed the synthesis of amphetamine, which was first marketed in the 1930s and became widely abused by the mid 1950s. The addictive nature of amphetamine was soon realized and led to its designation in 1970 as a drug of high abuse potential. Concerns in more recent years regarding the potential adverse cardiovascular effects of various sympathomimetic drugs have prompted the U.S. Food and Drug Administration to regulate increasingly their use as appetite suppressants, nasal decongestants, and cold remedies. In 2004, ma huang was banned for sale as a dietary supplement.

CLASSIFICATION OF ADRENERGIC DRUGS AND RECEPTORS

Since the identification of norepinephrine as the neurotransmitter at adrenergic neuroeffector junctions, and of epinephrine and norepinephrine as the two adrenergic agents released by the adrenal medulla, numerous agonists with adrenergic activity have been developed. Direct-acting adrenergic agonists are agonists that directly bind to adrenergic receptors and activate the receptors to produce their effects. Indirect-acting agonists act by increasing the amount of norepinephrine available to stimulate adrenergic receptors. Although indirect-acting agonists may act through many different mechanisms, their most common action is to cause the release of the neurotransmitter norepinephrine from sympathetic nerve terminals. Mixed-acting adrenergic agonists have direct and indirect mechanisms of action. One common feature of all these drugs is that their effects are mediated through activation of adrenergic receptors.

Adrenergic receptors have been classified into three major types: α_1-adrenergic, α_2-adrenergic, and β-adrenergic receptors. In recent years, numerous receptor subtypes (α_{1A}, α_{1B}, α_{1D}; α_{2A}, α_{2B}, α_{2C}; β_1, β_2, β_3) have been discovered by molecular cloning and pharmacologic techniques.[4,20,36,43] Several dopamine receptors have also been identified (D_1, D_2, D_3, D_4, D_5).[15,45] These receptor subtypes are distinguished by differences in their amino acid sequences, as determined from gene-cloning experiments,[4,45] and by their affinity for subtype-selective drugs. Many adrenergic agonists activate more than one of the major adrenergic receptor types. In contrast, some agonists selectively activate α receptors, others activate β receptors, and some are selective for an individual adrenergic receptor subtype (e.g., β_1 or β_2). Similarly, as discussed in Chapter 7, there are antagonists for the various adrenergic receptors, some of which are receptor type or subtype selective, and some of which are nonselective. The development of receptor-selective agonists and antagonists remains an active area of research.[33,37,40,43]

Although most adrenergic agonists have prominent peripheral actions that form the basis for their therapeutic applications, some of these drugs have important actions in the CNS. Adrenergic drugs such as amphetamine and ephedrine are capable of causing stimulation of adrenergic receptors in the CNS. Several drugs have been developed, including the antihypertensive agent clonidine, that have their principal action on CNS α_2 receptors, whose stimulation results in a decrease in sympathetic outflow from the brain.

CHEMISTRY AND STRUCTURE-ACTIVITY RELATIONSHIPS

The chemical structures of the three endogenous adrenergic amines—dopamine, norepinephrine, and epinephrine—are illustrated in Figure 6-1. These compounds are synthesized sequentially in adrenergic nerve terminals and adrenal chromaffin cells (see Chapter 5). These three agents, all derived

†Different stereoisomers have opposing actions on β_1 receptors and β_2 receptors; thus β_1 selectivity is more apparent than real.
CNS, Central nervous system.

from tyrosine, are also referred to as *catecholamines* because they are catechol derivatives of phenylethylamine.

Table 6-1 lists some adrenergic agonists currently in use and illustrates certain major alterations in biologic activity that occur with structural modifications. The following conclusions about the relationship between structure and activity can be drawn:

1. Direct-acting agonists (agonists that bind to adrenergic receptors) generally require a hydroxyl group at positions 3 and 4 of the aromatic ring plus a hydroxyl group on the β-carbon atom of the side chain for maximal stimulation of α and β receptors. The two hydroxyl groups on the ring are believed to form hydrogen bonds with serine residues in the fifth membrane-spanning region of the receptor.[46]
2. Indirect-acting agonists (agonists that cause release of norepinephrine) have no β-hydroxyl group and either no or one hydroxyl group on the ring. Agents devoid of hydroxyl substitutions can penetrate the blood-brain barrier better and exert prominent CNS effects.
3. Mixed-acting agonists (agonists having both actions already described) generally have a β-hydroxyl group and a single ring hydroxyl group.

4. Dopamine, which lacks the β-carbon hydroxyl moiety present in other endogenous catecholamines, stimulates dopamine receptors in addition to α_1 and β_1 receptors. Low concentrations of systemically administered dopamine selectively stimulate D_1 receptors.
5. Slight modifications in chemical structure can confer significant differences in pharmacodynamics. Therapeutic agents can be designed to provide specific responses by selective action on receptor subtypes.[33] Other structural modifications yield differences in pharmacokinetics. Methyl substitution on the α carbon yields orally active compounds able to resist enzymatic destruction by monoamine oxidase (MAO) in the stomach and small intestine.
6. As the alkyl substitution on the nitrogen is increased in molecular weight, a shift in drug affinity toward the β_2-adrenergic receptor is observed. The affinity of norepinephrine, with no alkyl substitution, is much greater for α-adrenergic receptors than for β_2-adrenergic receptors; the affinity of epinephrine, with a methyl group, is similar for α-adrenergic and β_2-adrenergic receptors; and the affinity of isoproterenol, with an isopropyl group, is much greater for β_2 receptors than for α receptors. All three drugs have significant β_1-adrenergic receptor effects. Changes in the position of ring hydroxyl groups (to the 3 and 5 positions, or a single hydroxyl group in the 4 position) lead to compounds (e.g., terbutaline and ritodrine) with selective affinity for the β_2-adrenergic receptor.
7. Besides structural modifications, many of the compounds listed exist as optical isomers. Substitutions on either the α-carbon or β-carbon atom of the phenylethylamine nucleus produce stereoisomeric pairs. Levorotatory substitution on the β carbon enhances adrenergic receptor effects. Dextrorotatory substitution on the α carbon increases CNS stimulant activity (e.g., *d*-amphetamine).

The catecholamine nucleus is extremely sensitive to oxidation. This chemical reaction results in the formation of a quinone, adrenochrome, which accounts for inactivation and color changes that may occur in solutions of catecholamines, such as in dental anesthetic cartridges. A sulfite salt (e.g., sodium metabisulfite) is incorporated in such solutions as an antioxidant to prevent catecholamine degradation.

PHARMACOLOGIC EFFECTS

The pharmacology of the adrenergic agonists is complicated by the diversity of the drugs in this group. They differ in mode of action (direct, indirect, or mixed), receptor selectivity, and relative predominance of peripheral and CNS effects. Predicting the pharmacologic activity of any adrenergic agonist is possible by knowing whether it is direct acting or indirect acting, and what receptors it affects. The density of the receptor population in a particular organ or organ system also influences the effectiveness of adrenergic agonists. A smooth muscle with a high density of α-adrenergic receptors would be strongly contracted by a drug that is efficacious in activating α-adrenergic receptors, but another smooth muscle, expressing few or no α receptors, would be minimally or not at all affected by the same agonist. Table 6-2 summarizes the relative receptor preferences of several adrenergic drugs.

Of the many adrenergic agonists that have been isolated or synthesized and are used clinically, only a few are considered in detail here. The following discussion begins with agents that are endogenous transmitters or hormones, capable of interacting with α and β receptors, and then focuses successively on other direct-acting agonists that are more selective in receptor preference. This discussion concludes with indirect-acting and mixed-acting drugs that cause the release of norepinephrine as their primary mode of action. Where appropriate, additional drugs are mentioned in the sections on therapeutic applications and adverse effects.

Endogenous Catecholamines: Norepinephrine and Epinephrine

Vascular effects

The net effect of systemic administration of norepinephrine or epinephrine on the cardiovascular system depends on various factors, including the route and rate of administration, the dose given, and the presence or absence of interacting drugs. When injected locally, norepinephrine and epinephrine cause contraction of vascular smooth muscle and vasoconstriction in the surrounding tissues by stimulating α-adrenergic receptors. Systemic effects on the vasculature occurring after absorption of these catecholamines into the circulation depend on the plasma concentrations achieved and on the drugs' actions at α-adrenergic and β-adrenergic receptors. With plasma concentrations attained by an intravenous infusion of 0.2 μg/kg/min or more, the response to norepinephrine reflects stimulation of α receptors causing increased systolic and diastolic blood pressures, with a reflex bradycardia caused by activation of the baroreceptor reflex. The bradycardia occurs despite the direct stimulation of cardiac β_1 receptors by norepinephrine, which tends to increase heart rate.

Although the same infusion of epinephrine stimulates α-adrenergic and β_2-adrenergic receptors in the vasculature,

TABLE **6-2**

Receptor Selectivity of Adrenergic Receptor Agonists

Epinephrine (1)	Epinephrine	Epinephrine	Epinephrine
Levonordefrin (3)	Levonordefrin	Levonordefrin	
Norepinephrine (10)	Norepinephrine	Norepinephrine	
		Isoproterenol	Isoproterenol (0.05)
α_1-AR	**α_2-AR**	**β_1-AR**	**β_2-AR**
Phenylephrine (20)	Oxymetazoline	Dobutamine	Albuterol
Methoxamine	Tetrahydrozoline		Terbutaline
	Brimonidine		Bitolterol
	Clonidine		Salmeterol
	Guanabenz		Ritodrine

Note: Drugs listed in the same column as an adrenergic receptor (AR) activate that receptor. At low doses, the drugs below the receptors selectively activate a single receptor type. As the dose of these selective drugs is increased, they can also activate some of the other receptor types. Numbers in *parentheses* indicate the potency ratio of α to β_2 receptor—mediated effects, with epinephrine having equal potency at α-adrenergic and β_2-adrenergic receptors. Potency ratios are approximate only, and vary with the tissue and species studied.

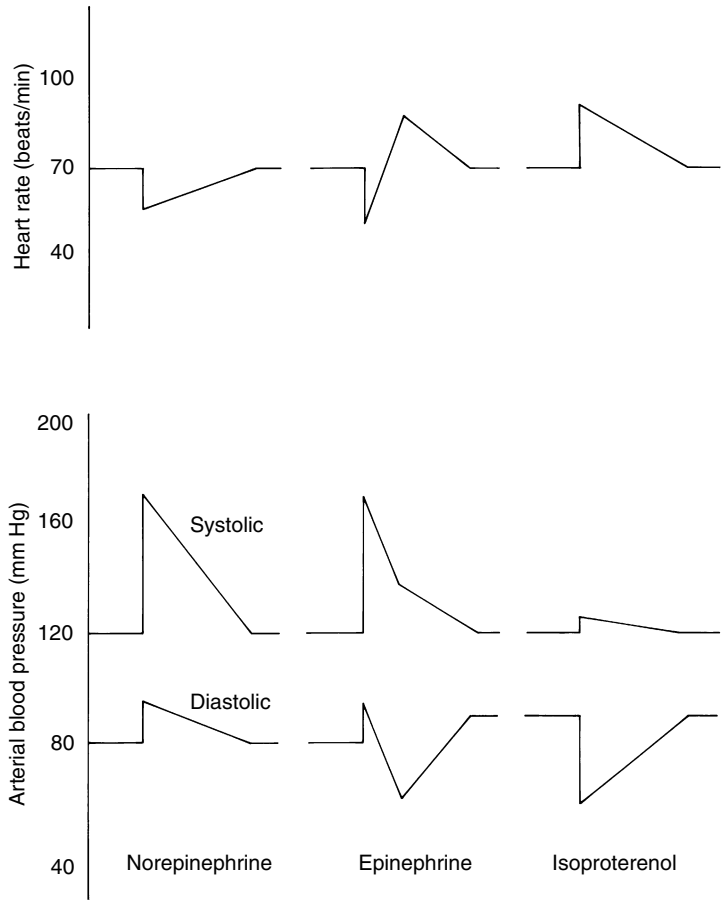

FIGURE **6-2** Schematic representation of the effects of three catecholamines on heart rate and arterial blood pressure in the dog. The drugs were administered intravenously by bolus injection at a dose of 1 μg/kg. Note the biphasic effect of epinephrine. Initially, the drug resembles norepinephrine by causing an increase in blood pressure and reduction in heart rate. As the concentration of epinephrine falls into the physiologic range, however, β-adrenergic receptor activation predominates. Diastolic pressure decreases, and direct cardiac effects are unmasked. The decreased heart rates seen with norepinephrine and at the beginning of the epinephrine response are produced indirectly by the baroreceptor reflex. The drug effects shown here last for approximately 5 minutes.

the more robust α receptor–mediated vasoconstrictor response masks the vasodilatory effect of β_2 receptor stimulation, and the net result is usually vasoconstriction, similar to that of norepinephrine. However, at low plasma concentrations, as achieved by an intravenous administration of 0.1 μg/kg/min or less, the effect of epinephrine on α-adrenergic receptors is less, allowing the β_2 receptor vasodilator response to become manifest. Under these conditions, mean arterial blood pressure may decrease, and the direct stimulant effect of epinephrine on the myocardium (tachycardia) is observed. This effect is not shared by norepinephrine because it does not stimulate β_2 receptors.

Figure 6-2 shows the typical cardiovascular responses to the intravenous bolus injection of these catecholamines. The qualitatively different effects of high versus low doses of epinephrine on blood pressure and heart rate described earlier are apparent as the initially high concentration of drug declines over the course of several minutes into the low dose range.

Cardiac effects

Norepinephrine and epinephrine stimulate β_1-adrenergic receptors located in cardiac muscle, pacemaker, and conducting tissues of the heart; β_2 receptors, also located in these tissues but in smaller numbers, contribute to the cardiac effects of epinephrine. Not only is the strength of contraction increased by β receptor stimulation (positive inotropic effect), but also the rate of force development and subsequent relaxation is accentuated, resulting in a shorter systolic interval. The spread of the excitatory action potential through the conductile tissues is also increased (positive dromotropic action). Pacemaker cells increase their firing rate (positive chronotropic effect), and automaticity is enhanced in normally quiescent muscle (latent pacemaker cells are activated).

All the effects described are effectively antagonized by β receptor blockade. Simulation of α_1-adrenergic receptors has been shown to enhance myocardial contraction and to prolong the refractory period, however, and has been implicated in certain ventricular arrhythmias occurring during general anesthesia.[41]

Stimulation of β-adrenergic receptors increases the work of the heart, which elevates cardiac oxygen consumption. Overall, cardiac efficiency (cardiac work done relative to oxygen consumption) is diminished. The delivery of oxygen to the heart by the coronary arteries is variably affected by the relative amounts of α and β receptor activation produced by each adrenergic agonist (see Table 6-2) and by metabolic regulators of local blood flow.

Effects on nonvascular smooth muscle

The effect of adrenergic agonists on smooth muscle in the organs of the thoracic and abdominal cavities is usually relaxation. The gastrointestinal tract shows decreased motility from activation of β_2-adrenergic receptors on smooth muscle, causing relaxation, and α_2-adrenergic receptors located on excitatory parasympathetic nerves that inhibit acetylcholine release. The sphincters are constricted through α_1 receptor stimulation. A similar situation exists for the urinary bladder. The sphincter and trigone muscles contract as a result of α_1 receptor stimulation, whereas the detrusor muscle is relaxed by β_2 receptor stimulation, causing urinary retention. The response of the uterus varies with the species, the stage of the

estrous cycle, and pregnancy. Generally, α_1-adrenergic receptor activation leads to contraction, whereas β_2 receptor activation leads to relaxation. In either case, these effects require doses of epinephrine or norepinephrine that result in significant cardiovascular stimulation and are too evanescent to be useful therapeutically.

Bronchodilation is another example of smooth muscle relaxation that is of major therapeutic importance. The β_2-adrenergic receptors of the bronchioles are stimulated by epinephrine. Although epinephrine is a drug of choice to counteract bronchospasm associated with hypotension, as in anaphylactic shock, β_2 receptor–selective drugs such as albuterol produce bronchodilation with less concomitant β_1 receptor stimulation of the heart and are preferred in asthmatic patients.

Epinephrine and norepinephrine stimulate α_1 receptors to cause the splenic capsule to contract, although in humans this does not seem to play an important role in increasing the hematocrit. The pilomotor muscles of the skin contract to cause piloerection, and the radial muscle of the iris contracts to cause mydriasis in response to norepinephrine and epinephrine activation of α_1 receptors.

Effects on salivary glands

Epinephrine and norepinephrine affect secretion by salivary glands through activation of adrenergic receptors on secretory cells and by stimulation of vascular adrenergic receptors that alter blood flow to the glands. Secretory cells of the major salivary glands contain α_1-adrenergic, β_1-adrenergic, and some β_2-adrenergic receptors. The principal adrenergic receptor linked to protein secretion is the β_1 receptor, although α_1 receptors also play a secretory role, and some evidence supports a role for β_2 receptors, at least in some species. The primary effect of α_1 receptor stimulation on secretory cells resembles qualitatively that of muscarinic receptor stimulation because water and electrolyte secretion is stimulated. Salivary glands also contain myoepithelial cells, in which α_1 receptor stimulation causes contraction around secretory acinar units, contributing to secretion. Stimulation of β receptors causes a more protein-rich (e.g., amylase) secretion. Overall, the predominant characteristic of epinephrine and norepinephrine stimulation of the salivary glands is a modest secretion with a high concentration of protein.

Metabolic responses

Metabolic responses to β_2-adrenergic and β_1-adrenergic receptor stimulation lead to a transitory increase in circulating blood glucose as a result of liver glycogenolysis and increased glucagon secretion.[1] An α_2 receptor–mediated inhibition of insulin secretion contributes to the hyperglycemia caused by epinephrine. Stimulation of β_1 and β_3 receptors is involved in the hydrolysis of triglycerides, causing an increase in triglyceride lipase activity and subsequently in the concentration of circulating free fatty acids. The specific receptors that mediate metabolic effects vary among species.

Central nervous system effects

Although the catecholamines are extensively involved in neurotransmission in the CNS, peripherally administered catecholamines gain little access to the CNS because hydroxyl groups on the aromatic ring deter passage across the blood-brain barrier. Intravenous injection of epinephrine produces a variety of apparently central effects, however, including feelings of anxiety, jitteriness, and apprehension. Most, if not all, of these effects are thought to be indirect, resulting from sensory input to the brain from the periphery. Centrally mediated reflex respiratory apnea is induced by drugs that cause an increase in blood pressure.

Dopamine

Although dopamine is primarily a CNS neurotransmitter, it also has effects in the periphery, where dopamine receptors have been identified in various tissues. Molecular cloning studies have revealed at least five subtypes of the dopamine receptor (D_1 to D_5). Although the D_1 receptor subtype is thought to cause peripheral vasodilation, other dopamine receptor subtypes may also contribute to the various peripheral effects of dopamine. Peripheral dopamine-containing neurons have been found in autonomic ganglia in the form of small, intensely fluorescent cells and in kidney glomeruli. Evidence suggests that dopamine neurons help regulate sympathetic nervous system transmission, promote gastrointestinal relaxation, and cause vasodilation in some vascular beds.

Cardiovascular effects

Dopamine interacts with various receptor types to influence vascular function, and is used therapeutically for maintaining renal function in cases of shock associated with compromised cardiac output. Although "low-dose" dopamine has now been used in this manner for more than 30 years, there is currently a growing body of evidence suggesting that this use for dopamine should be abandoned. Early data using indirect clearance measurements of blood flow suggested that dopamine stimulates vascular D_1 receptors to dilate selectively the renal, celiac, hepatic, and mesenteric vasculatures, and that increases in glomerular filtration rate and Na^+ excretion occur in conjunction with increased renal blood flow.[16] With moderate doses, dopamine was thought to act at myocardial β_1-adrenergic receptors to increase contractile force. Critics of low-dose dopamine have suggested that this increase in cardiac index, rather than dilation of the renal vasculature, is the primary reason for any observed increases in renal blood flow with low-dose dopamine,[44] and that the potential for harm outweighs the benefits.[30] At higher doses, dopamine also stimulates α_1-adrenergic receptors, which produces vasoconstriction. As with all catecholamines, excessive doses of dopamine can cause tachycardia and generate arrhythmias. In addition to stimulating α_1 and β_1 receptors directly, dopamine in moderate to high doses causes the release of norepinephrine from sympathetic nerve terminals.

Fenoldopam, a pharmacologic congener of dopamine, selectively activates D_1 receptors at therapeutic doses. It decreases mean blood pressure, increases renal blood flow, and causes diuresis and natriuresis. It is used intravenously for acute treatment of severe hypertension (see Chapter 28).

Other effects

Dopamine is involved with the sensory division of the autonomic nervous system. The high concentration of dopamine in the glomus cells of the carotid body and the effects of hypoxia on these cells suggest that dopamine is an inhibitory transmitter that modulates the frequency of discharge of the sensory fibers from that structure.[19] It is theorized that, by this mechanism, dopamine may affect cardiovascular and respiratory responses.

Dopamine itself does not penetrate the blood-brain barrier. Levodopa, which is converted into dopamine, does enter the CNS, however, and is used to treat Parkinson's disease (see Chapter 15). Approximately 95% of an oral dose of levodopa is normally decarboxylated in the periphery to dopamine,[8] leading to significant peripheral side effects attributable to dopamine. Dopamine can also produce nausea and vomiting as a result of excitation of the medullary chemoreceptor trigger zone, which lies outside the blood-brain barrier.

Another physiologic role for dopamine is modulation of the release of several anterior pituitary hormones. Dopamine acts as a prolactin release–inhibiting hormone by binding to D_2 receptors on the lactotrope cells of the anterior pituitary.

Although dopamine itself is limited therapeutically by its inability to penetrate the blood-brain barrier, bromocriptine and other dopamine receptor agonists that are sufficiently lipid soluble to enter the CNS have been used successfully in the treatment of female infertility and other health problems resulting from hyperprolactinemia. Bromocriptine has also proved effective in controlling excessive secretion of growth hormone associated with pituitary adenomas. This last therapeutic application is surprising because dopamine is a stimulant of growth hormone release in the normal pituitary.

α-Adrenergic Receptor Agonists

The group of drugs classified as α-adrenergic receptor agonists is growing increasingly diverse. These drugs stimulate α-adrenergic receptors, but have low affinity for β-adrenergic receptors. Phenylephrine and methoxamine differ from epinephrine and norepinephrine by being selective agonists at α_1-adrenergic receptors. Their primary pharmacologic effect is to cause contraction of vascular smooth muscle, resulting in an increase in systolic and diastolic blood pressures and reflex bradycardia. They are often administered either intranasally or systemically for temporary relief from nasal congestion. Because these drugs increase blood pressure, safety is always a concern. The α-adrenergic receptor agonist phenylpropanolamine was widely used in over-the-counter cold remedies until research studies showed that it increased the risk of hemorrhagic stroke in women,[25] which led the U.S. Food and Drug Administration (FDA) to mandate its removal from these medications. Other agonists with actions similar to phenylephrine and methoxamine include metaraminol, although it is a mixed-acting agonist (discussed later) because it releases catecholamines in addition to directly stimulating α_1-adrenergic receptors. Midodrine is a newer synthetic drug that selectively activates α_1-adrenergic receptors. It also causes vasoconstriction, and is used to treat postural hypotension caused by impaired autonomic nervous system function.

The α_2-adrenergic receptor agonists clonidine, guanabenz, guanfacine, and methyldopa (Figure 6-3) effectively enter into the CNS and stimulate α_2-adrenergic receptors in the brain. They are, in varying degrees, selective agonists at α_2 receptors. Methyldopa, an α-methyl derivative of dopa (dihydroxyphenylalanine, an important intermediate in the synthesis of norepinephrine), enters into the nerve terminal and is converted into the α_2 receptor–selective agonist α-methylnorepinephrine by the same synthetic process that converts dopa into norepinephrine. Although α-methylnorepinephrine is present in neuronal storage vesicles in peripheral sympathetic nerves, this metabolite of methyldopa is nearly equipotent to norepinephrine as a vasoconstrictor in humans. This agent has been developed as the drug levonordefrin, which is used as a vasoconstrictor in local anesthetic solutions. Clonidine was first used as a nasal decongestant, but it was soon found to decrease blood pressure. An imidazoline derivative, clonidine is a selective α_2-adrenergic receptor agonist with relatively weak peripheral effects. Guanabenz and guanfacine are guanidine derivatives that, similar to clonidine, also selectively activate α_2-adrenergic receptors.

These centrally acting agonists are thought to exert their antihypertensive effect by acting on α_2 receptors in the nucleus tractus solitarius of the brainstem, leading to a decrease in sympathetic outflow. This proposed mechanism of action is supported by experiments involving the stereotaxic administration of α_2 receptor agonists into the nucleus tractus solitarius followed by inhibition of drug effects by α receptor antagonists injected into the cerebrospinal fluid. Blocking the conversion of methyldopa to α-methylnorepinephrine prevents the antihypertensive action of this drug.

The administration of these centrally acting drugs in humans results in moderate decreases in mean arterial blood pressure. This effect usually occurs without increases in heart rate because a decrease in CNS sympathetic outflow tends to reduce venous return, heart rate, and cardiac output. Guanfacine decreases peripheral vascular resistance without affecting cardiac output.[18] Intravenous administration of these drugs may increase blood pressure acutely as a result of stimulation of peripheral vasoconstrictor α_2 receptors. This effect is not usually seen with oral administration.

Serendipity has played a role in the use of clonidine to treat the withdrawal symptoms of opioid addiction.[29] Clonidine, when given to addicts undergoing withdrawal, blocks the nausea, vomiting, sweating, diarrhea, and other symptoms of excessive autonomic discharge (see Chapter 51). Evidence indicates that either systemic or intracerebral injection of opioids inhibits neuronal activity in the locus ceruleus of the dorsolateral pons. When the opioids are withdrawn, certain neurons are thought to be disinhibited and to release excessive norepinephrine, which gives rise to the symptoms of withdrawal. Clonidine, by stimulating presynaptic α_2 receptors on these same neurons, causes inhibition of neurotransmitter release. The current clinical practice is to follow abrupt withdrawal of the opioid with oral administration of clonidine for 2 weeks or until opioid detoxification is complete. Similarly, patients with alcohol abuse problems, certain neurologic diseases, or some forms of psychotic illness show some improvement in their condition with clonidine. Other studies have found that clonidine has analgesic and sedative effects when given alone or in combination with opioids, and clonidine has been used as an adjunct in general anesthesia and for treating

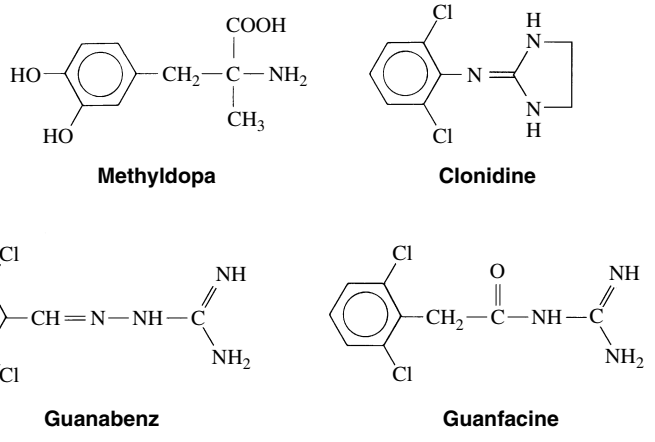

FIGURE **6-3** Structural formulas of some centrally acting α_2-adrenergic receptor agonists.

some patients with chronic pain. Dexmedetomidine is the first α_2 agonist specifically developed as a sedative for patients receiving intensive care (see Chapter 18).

Oxymetazoline is also an imidazoline derivative selective for α_{2A} receptors, causing contraction of smooth muscle in certain blood vessels. It is used as a nasal decongestant. Other imidazoline agonists available for the same therapeutic indication include tetrahydrozoline, xylometazoline, and naphazoline. Brimonidine and apraclonidine are newer α_2 receptor agonists that are used to decrease intraocular pressure in patients with glaucoma.

β-Adrenergic Receptor Agonists: Isoproterenol

Isoproterenol, a synthetic catecholamine, is a potent nonselective β-receptor agonist. It does not appreciably distinguish among the β_1, β_2, and β_3 receptor subtypes, but has very low affinity for α-adrenergic receptors, and has no significant effect resulting from α receptor stimulation.

Cardiac and vascular effects

The actions of isoproterenol on the cardiovascular system are based solely on the stimulation of β-adrenergic receptors (see Figure 6-2). It causes a marked decrease in diastolic blood pressure from β_2 receptor–mediated vasodilation, primarily caused by relaxation of blood vessels in skeletal muscle, with some additional vasodilation in the renal and mesenteric vascular beds. There is also an increase in systolic blood pressure largely resulting from the increase in cardiac output caused by β_1 receptor stimulation of contractility. Because of the effects on systolic (slight increase) and diastolic (decrease) pressures, the mean arterial blood pressure is usually decreased. Heart rate is increased by the stimulation of β_1 receptors in pacemaker cells. The drug's ability to increase excitability and conduction velocity in the heart may induce palpitation and arrhythmias. The powerful inotropic and chronotropic actions may increase myocardial oxygen demand sufficiently to cause ischemia.

Effects on bronchial smooth muscle

As an agonist of β_2-adrenergic receptors, isoproterenol relaxes bronchial smooth muscle in the lungs to relieve or prevent bronchoconstriction. Disadvantages of the use of isoproterenol for relief of bronchospastic disorders that limit its clinical use are its nonselectivity for β-adrenergic receptor subtypes (which can result in β_1 receptor–induced tachycardia, palpitation, and arrhythmias) and the development of tolerance and refractoriness with frequent use.[39] The introduction of selective β_2 receptor agonists has provided an important alternative class of drugs for bronchodilation. Although the β_2 receptor–selective drugs have weaker cardiac effects than isoproterenol, they still have the potential to cause cardiac acceleration and tachyarrhythmias.

Metabolic and other effects

Although the β receptor agonist activity of isoproterenol stimulates glycogenolysis and gluconeogenesis in the liver, it is not as effective as epinephrine in elevating plasma glucose. Isoproterenol stimulates the secretion of saliva that is rich in amylase and other proteins. The drug is also capable of causing CNS excitation at doses higher than are conventionally used clinically.

Dobutamine

A synthetic analogue of dopamine, dobutamine acts as an adrenergic receptor agonist with little or no effect on dopamine receptors.[34] The two stereoisomers of the racemic drug preparation have different effects on the various adrenergic receptor types, which together account for β_1 and α_1 receptor stimulation and α_1 receptor inhibition. The primary action of dobutamine is to increase myocardial contractility and cardiac output without significantly increasing the heart rate. The inotropic effect results primarily from direct β_1 receptor stimulation in the heart, with lesser contributions from β_2 receptor activation. Peripheral vascular resistance is usually changed very little. Because blood pressure effects of this drug are a function of the combination of α_1 and β_2 receptor activation and α_1 receptor blockade, however, some patients may show a greater pressor effect, whereas others may experience a moderate reduction in ventricular filling pressure and peripheral vascular resistance. Dobutamine is used for short-term treatment of acute myocardial insufficiency resulting from congestive heart failure, myocardial infarction, or cardiac surgery.[31]

Selective β_2-Adrenergic Receptor Agonists

Although isoproterenol and epinephrine are capable of relaxing bronchial smooth muscle, both drugs (especially isoproterenol) can also cause dangerous tachycardia and arrhythmias. These side effects limit the therapeutic use of these drugs and stimulated a search for selective agonists capable of stimulating β_2-adrenergic receptors in bronchial and uterine smooth muscle, while having less effect on the β_1 receptors of the heart. Even with the selective β_2 receptor agonists, effects on the heart are substantial, however, especially at higher doses. Metaproterenol, terbutaline, albuterol, levalbuterol, pirbuterol, and salmeterol are relatively selective β_2 receptor agonists that are effective in decreasing airway resistance without causing as much cardiac acceleration as isoproterenol. These drugs are usually inhaled; however, oral administration of metaproterenol, albuterol, and terbutaline may be useful under certain limited conditions. Systemic adverse effects are usually greater by the oral route. Ritodrine, another selective β_2-receptor agonist, was used as a uterine relaxant in the short-term management of preterm labor for several years, but was withdrawn from the market in 2001. The drug was initially given intravenously, followed in some cases by oral dosing. The use of β_2 agonists in the therapy of bronchospastic disorders is discussed in Chapter 32.

Mixed-Acting and Indirect-Acting Adrenergic Agonists

Numerous adrenergic agonist drugs produce some or all of their effects by causing the release of norepinephrine from adrenergic nerve terminals. They do so by being transported into the adrenergic nerve ending or adrenal chromaffin cells, where they are transported into the storage vesicles. These drugs displace catecholamines from their vesicular storage sites into a cytoplasmic pool in the nerve endings or chromaffin cells, from which norepinephrine or epinephrine is released. This cytoplasmic pool is distinct from that of the storage vesicles from which release occurs during nerve stimulation. These drugs have a pharmacologic profile similar to that of norepinephrine. Differences that do exist are associated with the relative ability of the various drugs to stimulate α or β receptors directly and with the ease by which these agents gain access to the CNS. In contrast to norepinephrine, these drugs are generally not subject to rapid inactivation and are usually effective by the oral route.

Ephedrine is an example of an orally active, mixed-acting drug. In addition to releasing norepinephrine, ephedrine is a direct α and β receptor agonist. It can cause bronchodilation, vasoconstriction, increased heart rate, and modest CNS stimulation. Amphetamine, a more lipophilic drug, is primarily a purely indirect-acting drug that easily enters the brain and stimulates the release of catecholamines in the CNS. Amphetamine is a potent CNS stimulant that causes numerous effects, including increased alertness, relief of fatigue, enhanced athletic performance, and euphoria. Although a person taking amphetamine may work more rapidly, there is a dispropor-

tionate increase in mistakes. The need for sleep can be delayed with amphetamine but not diminished. Drugs related to amphetamine include dextroamphetamine and methamphetamine. Compared with amphetamine, both tend to have more effects on the CNS relative to the periphery. The addition of a single hydroxyl group (4-OH) to yield hydroxyamphetamine produces a drug with less CNS activity.

Acute tolerance (tachyphylaxis) is a common outcome of repeated administration of indirect-acting adrenergic drugs. Multiple doses of either mixed-acting or indirect-acting adrenergic agonists may lead to a depletion of the neurotransmitter, resulting in a reduction or loss of activity in response to nerve stimulation. These drugs are also susceptible as a class to several drug interactions. Compounds such as the tricyclic antidepressants and some adrenergic neuron-blocking drugs interfere competitively with the uptake of indirect-acting agonists into adrenergic nerve terminals and block their subsequent release of norepinephrine. MAO inhibitors promote the accumulation of intraneuronal catecholamines, which are released by these agonists. The combination of an MAO inhibitor and an indirect-acting or mixed-acting sympathomimetic drug typically results in excessive release of catecholamines with serious consequences. Some indirect-acting compounds, such as tyramine, occur naturally in several foods and beverages, and pose a great risk to patients taking MAO inhibitors.

ABSORPTION, FATE, AND EXCRETION

As noted in the section on chemistry and structure-activity relationships, the route for administering adrenergic agonists is determined by the chemical structure. All catecholamines and certain other drugs, unless specifically modified at the α carbon of the side chain, are subject to enzymatic destruction in the gastrointestinal tract. Catecholamines are usually administered systemically by parenteral injection or intravenous infusion. Topical instillation and inhalation are the preferred routes of administration for ocular and respiratory applications, respectively.

The inactivation and metabolic disposal of catecholamines can involve many processes, as illustrated by the fate of endogenously released norepinephrine (Figure 6-4). After neuronal release, a large portion (80% in some cases) of the adrenergic neurotransmitter is returned to the nerve terminal by an active neuronal uptake process. What remains in the junctional cleft is subjected to O-methylation by catechol-O-methyltransferase (COMT) after uptake by postjunctional effector cells. Norepinephrine that diffuses out of the junction may be taken up by other cells and metabolized by COMT. When the transmitter is O-methylated to normetanephrine, it can no longer be transported into the adrenergic nerve terminal but is instead carried by the blood to the liver, where it is largely deaminated by hepatic MAO.[12] Some portion of the released neurotransmitter also diffuses away from the junctional cleft to enter the circulation intact.

Of the norepinephrine that is actively transported back into the neuron, a large part is actively returned to the storage vesicles from which it can be released again on neuronal stimulation. A smaller portion is deaminated by MAO located in the outer membrane of the mitochondria to form 3,4-dihydroxyphenylglycoaldehyde. Most of the aldehyde is converted to a glycol, the remainder to an acid. Both metabolites enter the circulation and are eventually O-methylated by COMT. The major metabolic products of norepinephrine resulting from the combined action of MAO and COMT (and several supportive reductases and dehydrogenases) are 3-methoxy-4-hydroxymandelic acid, also referred to as vanillylmandelic acid, and 3-methoxy-4-hydroxyphenylglycol.[10] About 90% of the total endogenous norepinephrine load excreted in the urine is in the form of vanillylmandelic acid and 3-methoxy-4-hydroxyphenylglycol, with the remainder consisting of other O-methylated compounds and lesser quantities of other derivatives and unmetabolized norepinephrine.[28] Several of these products are conjugated to the sulfate or glucuronide before being excreted by the kidney.

Exogenously administered catecholamines and endogenous dopamine and epinephrine are transported and metabolized in much the same manner as norepinephrine. Nevertheless, there are some differences. The metabolic inactivation of epinephrine and most injected catecholamines (including norepinephrine) largely depends on COMT because COMT is widely distributed throughout the body and the administration of exogenous catecholamines allows them to be distributed far beyond the adrenergic neuroeffector junctions. The relative shift toward COMT for the initial

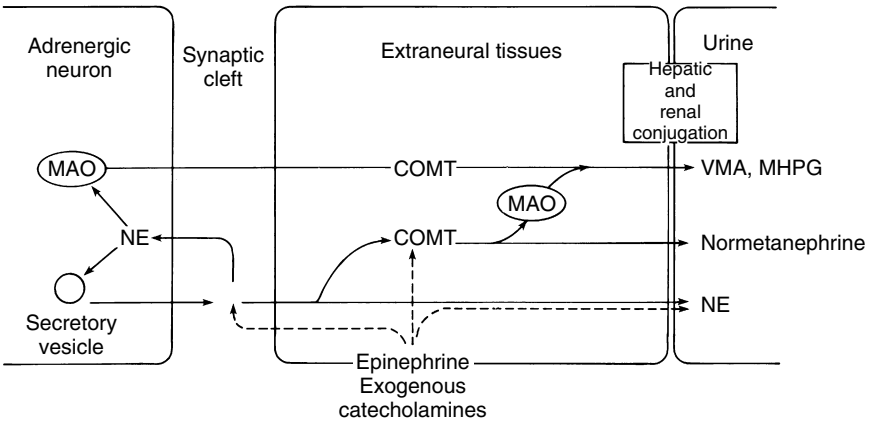

FIGURE **6-4** Biotransformation and excretion of catecholamines. After release, up to 80% of norepinephrine *(NE)* is taken up by a reuptake process into the nerve terminal, where most is recycled into storage vesicles, and some is metabolized by mitochondrial monoamine oxidase *(MAO)*. Extraneuronal tissues metabolize endogenously released catecholamines through catechol-O-methyl transferase *(COMT)* and MAO. Excreted substances include the metabolites 3-methoxy-4-hydroxymandelic acid *(VMA)* and 3-methoxy-4-hydroxyphenylglycol *(MHPG)*, and normetanephrine, small amounts of unmetabolized catecholamines, and related sulfate and glucuronide conjugates. Injected vasoconstrictors and some other adrenergic agonists are also biotransformed and excreted by some of these same pathways.

enzymatic attack ensures the recovery of high concentrations of O-methylated derivatives in the urine. In patients with a pheochromocytoma, the relatively large percentage of catecholamines produced by the adrenal medulla is converted in the adrenal gland to metanephrine and normetanephrine. These two metabolites are released into the plasma, and measuring them in the plasma is a sensitive test for pheochromocytoma.[10] As with norepinephrine and epinephrine, dopamine is a substrate for MAO and COMT. The metabolite formed by the combined action of these enzymes is homovanillic acid. In contrast to the other endogenous catecholamines, dopamine, when given by intravenous infusion, is significantly potentiated by MAO inhibitors.

A small percentage of epinephrine injected as a vasoconstrictor during local anesthesia ultimately resides in the patient's adrenergic nerve terminals and is released during sympathetic nerve stimulation.[14] Similarly, a small amount of administered dopamine may be converted to norepinephrine by β hydroxylation in the adrenergic nerve terminal.

Noncatecholamines are not subject to metabolism by COMT and typically have durations of action significantly longer than the catecholamines. The centrally acting α_2 receptor agonists used to treat hypertension are given orally and are eliminated largely as unchanged drug (e.g., clonidine), are extensively metabolized (e.g., guanabenz), or are partly metabolized and partly excreted as the parent compound (e.g., guanfacine, methyldopa). Several of the selective β_2 receptor agonists are excreted in the urine as conjugates of sulfate or glucuronic acid.

The indirect-acting adrenergic agonists, which act by displacing the neurotransmitter norepinephrine from the cytoplasmic pool, must first enter the neuron to evoke this release. While in the cytoplasm, these compounds may be subjected to deamination by MAO and other enzymes. A small amount of tyramine in the neuron is oxidized at the β carbon to form octopamine. Octopamine, which has only weak adrenergic activity, can be transported into the storage vesicles, where it may act as a false transmitter.[27] Other avenues for the metabolism of these noncatecholamines include *p*-hydroxylation, N-demethylation, deamination, conjugation in the liver and kidney, or a combination of all these. Amphetamine and ephedrine, which are resistant to the actions of MAO (also found in abundance in the gastrointestinal tract), can be administered orally.

GENERAL THERAPEUTIC USES

Clinical applications of the adrenergic agonists can be divided into eight major categories: local vasoconstriction, vasoconstriction in the treatment of hypotension and shock, bronchodilation, relaxation of uterine smooth muscle, ophthalmic uses, relief of allergic states (including anaphylaxis), CNS stimulation, and control of hypertension. The choice of a specific drug for each of these uses depends on the relative contribution of α-adrenergic or β-adrenergic receptors or dopamine receptors to the response in these tissues, and the drug's receptor subtype selectivity. Other factors that determine the choice of a drug include the therapeutic effect versus adverse effects profile and pharmacokinetic factors, such as the rate and routes of absorption, duration of action, and metabolic fate. Most commercially available adrenergic agonists are marketed as water-soluble salts. The following section examines all of these therapeutic uses, indicating in each case one or more preferred drugs.

Local Vasoconstriction

Various drops, sprays, aerosols, and oral dosage forms of several adrenergic agonists have proved useful in providing temporary symptomatic relief of nasal congestion associated with a variety of causes. These compounds are agonists at α receptors (α_1 or α_2 or both) and have minimal CNS stimulant effects. Common examples include phenylephrine, pseudoephedrine, and oxymetazoline.

An adverse effect associated with the local administration of nasal decongestants is rebound congestion, a chronic swelling of the nasal mucous membranes after the effect of the drugs wears off. This response is more likely with the longer acting α_2 receptor–selective nasal decongestants that have the imidazoline structure. Overdose, with systemic effects, is frequently manifested by signs of excessive adrenergic stimulation. Imidazoline derivatives, such as tetrahydrozoline and oxymetazoline, can paradoxically produce drowsiness, comatose sleep with hypotension, and bradycardia. These effects are thought to be caused by the entry of the drugs into the CNS, where they stimulate central α_2-adrenergic receptors. Children and infants are especially prone to these adverse effects.

Decongestants have also been used to constrict dilated conjunctival vessels and to relieve itching in hyperemic (bloodshot) eyes. Such agents include naphazoline and tetrahydrozoline. Sometimes these drugs are mixed with other agents used to treat disorders of the conjunctiva or corneal epithelium.

Adrenergic agonists are often used to produce hemostasis for surgery and to enhance local anesthesia. Whether applied topically or administered by injection with or without a local anesthetic, adrenergic agonists can significantly improve visibility in the operative field in certain situations. Because vasoconstriction is temporary, the use of these drugs is no substitute for the adequate surgical control of bleeding. Adrenergic agonists must often be used with special caution during general anesthesia because certain inhalation anesthetics (e.g., halothane) predispose the heart to the arrhythmogenic action of the adrenergic agonists.[13,23] Finally, the injection of vasoconstrictors into appendages supplied by end arteries is commonly listed as an absolute contraindication. Failure to heed this admonition has been reported to cause tissue necrosis and gangrene of the fingers, toes, ears, and penis. A more recent study found that epinephrine with lidocaine produced no adverse sequelae when administered for local anesthesia of the digits.[50] Employment of vasoconstrictors for surgical hemostasis and as adjuvants for local anesthetics is discussed later in the section on dental uses.

Treatment of Hypotension and Shock

Shock is a condition caused by inadequate tissue perfusion. It is usually associated with a decrease in arterial blood pressure and, if not treated, may quickly lead to multiorgan system failure. Shock has many causes, including hemorrhage; fluid losses from diarrhea or third-degree burns; internal fluid derangements from sepsis or anaphylaxis; disruption of autonomic tone as a result of drugs or spinal damage; and inadequate cardiac output because of myocardial infarction, arrhythmia, mechanical defects, or outflow obstruction. In most cases of hypotension, baroreceptor reflex–mediated sympathetic stimulation occurs, causing tachycardia, peripheral vasoconstriction, dyspnea, excessive sweating, and mental disturbances.

Treatment of shock includes specific therapies aimed at reversing the underlying problem and nonspecific measures to sustain an effective circulation. If hypotension is the result of blood or fluid loss (hypovolemic shock), the intravascular volume should be restored with blood or other intravenous fluids or both. Additional specific treatments include antibiotics for sepsis, surgery to correct reparable myocardial defects, and antidotes to reverse the effects of drug overdose. Lastly, adrenergic agonists may prove useful in restoring blood pres-

sure and in correcting the distribution of blood flow, especially to the vital organs, whenever shock develops under normovolemic conditions.

The pharmacologic management of shock has three general goals: (1) constriction of capacitance vessels to reduce venous pooling, (2) dilation of resistance vessels to increase perfusion of vital organs, and (3) improvement of myocardial contractility to increase cardiac output. Adrenergic agonists are used to treat various conditions associated with hypotension. α-Adrenergic receptor agonists (e.g., phenylephrine), which increase blood pressure by causing vasoconstriction, are most useful during episodes of inadequate sympathetic nervous system function that may result from spinal anesthesia or hypotensive drug overdose. Such drugs are less beneficial in other shock states associated with hypotension, however, because they may impair blood flow to the kidneys and mesenteric organs.

In cardiogenic shock, which is most often caused by acute myocardial infarction, the β_1-adrenergic receptor agonists should be useful, but the improvement in tissue perfusion and coronary blood flow is often accompanied by increased myocardial oxygen demand. A drug such as isoproterenol, which typically causes tachycardia, may worsen the myocardial ischemia and predispose an already damaged heart to arrhythmias. Dopamine has often been used for initial therapy of cardiogenic shock because it causes less generalized vasodilation than typical β receptor agonists, increases contractile force in the heart without increasing heart rate, and, through stimulation of dopamine receptors, may improve renal and mesenteric perfusion.[16,38] Newer studies have cast doubt, however, on the benefits of dopamine.[30,44] Dobutamine, similar to dopamine, can increase the force of myocardial contraction without producing changes in heart rate and is also used in patients with heart failure.

Bronchodilation

Acute and chronic obstructive pulmonary diseases are marked by increased inspiratory and expiratory resistance, and the adrenergic agonists have historically played an important role in the relief of these conditions. Epinephrine or isoproterenol, given by spray or aerosol, promptly relieves constricted bronchial passageways. The β_1 receptor stimulation by these drugs is associated with cardiac palpitation and arrhythmias, however, which severely limit their usefulness. Epinephrine also causes an undesired drying effect because of decreased secretions.

Currently, the adrenergic agents most useful in the treatment of bronchospastic disease are agonists with selectivity for β_2-adrenergic receptors because they produce marked bronchodilation with less effect on the heart than nonselective β receptor agonists. The selective β_2 receptor agonists used for bronchodilation include metaproterenol, terbutaline, albuterol, levalbuterol, pirbuterol, salmeterol, and formoterol. Salmeterol and formoterol have durations of action of about 24 hours.[42] This extended duration can be of significant benefit in treating patients with asthma.[39] The shorter acting drugs are used to reverse acute bronchoconstriction, whereas salmeterol and formoterol are used prophylactically to prevent bronchoconstriction. See Chapter 32 for a more complete discussion of the use of these agents in bronchial asthma.

Uterine Relaxation

Selective β_2-adrenergic receptor agonists have been administered to arrest premature labor by relaxing uterine smooth muscle. Drugs that control premature labor are often termed *tocolytics*. β_2 agonists are effective at relaxing the uterus for only a few days. Simultaneous stimulation of β receptors in the heart can cause palpitation and arrhythmias, which limits the usefulness of these drugs. The β_2 agonist ritodrine was used almost exclusively to cause uterine relaxation, but was withdrawn from the market in 2001 because of safety concerns. Terbutaline is currently the only β_2-adrenergic receptor agonist available in a form that could be injected as tocolytic therapy, but it is not FDA-approved for this purpose, and this use is discouraged by its manufacturer.

Ophthalmic Uses

The two major ocular indications for adrenergic agonists are for the production of mild mydriasis and the reduction of intraocular pressure. The former is mediated by stimulation of α_1-adrenergic receptors in the radial muscle of the eye. Although muscarinic receptor antagonists such as atropine produce a much stronger pupillary dilation, adrenergic agonists are useful because they cause mydriasis without paralyzing the ciliary muscle (cycloplegia). Even greater mydriasis can be obtained if a combination of a muscarinic receptor–blocking drug and an adrenergic agonist drug is used. Phenylephrine and hydroxyamphetamine are the principal adrenergic agonists used to produce mydriasis.

The mechanisms for the reduction in intraocular pressure by adrenergic agonist drugs are not well elucidated, but several of these drugs seem to reduce the production and enhance the outflow of aqueous humor and are useful in treating wide-angle glaucoma. These drugs include the nonselective adrenergic agents epinephrine and dipivefrin (a prodrug of epinephrine), and the α_2-adrenergic receptor–selective agonists apraclonidine and brimonidine. The treatment of glaucoma is discussed in Chapter 8.

Treatment of Allergic States

Adrenergic agonists, especially epinephrine, are especially useful in reversing the effects of histamine and other mediators associated with allergic reactions. In contrast to the antihistamines, adrenergic agonists are physiologic antagonists, producing responses opposite to the acute effects produced by histamine and associated autacoids. For acute allergic reactions such as urticaria, subcutaneous injection of 0.1 mL to 0.5 mL of 1:1000 epinephrine should be adequate. Fulminating disturbances such as anaphylactic shock require a faster absorption of epinephrine than provided by subcutaneous injection, especially if circulation is impaired. Intramuscular (intralingual) injection of 0.3 mL to 0.5 mL of 1:1000 epinephrine or, if the patient has previously been prepared for intravenous injections, slow intravenous administration of 1:10,000 epinephrine (0.1 mg in 5 minutes) is recommended. With this latter route of administration, there is a considerable risk of precipitating serious cardiac arrhythmias and ventricular fibrillation. Because of the rapid metabolism of epinephrine, reinjection at intervals of 5 to 15 minutes may be required. Subcutaneous administration generally provides the longest duration of action, and intravenous injection provides the shortest.

Central Nervous System Stimulation

For many years, selected adrenergic agonists have been used clinically because of their ability to produce stimulation of certain functions of the CNS that result in increased alertness and attention span and decreased sense of fatigue. Another potentially therapeutic effect of these agents is stimulation of the lateral hypothalamus and satiation of the food drive. The principal sympathomimetic drugs that cross the blood-brain barrier are ephedrine, amphetamines, and methylphenidate. Because of the history of abuse of amphetamine-like drugs, their procurement and use are strictly controlled by various state and federal statutes.

A major accepted use of amphetamine and related drugs is for the management of children with attention-deficit/hyperactivity disorder. The use of CNS stimulants, along with

psychotherapy and family counseling, has provided remarkable relief from the restlessness, brief attention span, and impulsiveness that mark this disorder. Methylphenidate has been used most often for the pharmacologic treatment of attention-deficit/hyperactivity disorder. It has a relatively brief duration of action (3 to 5 hours), requiring a second dose that often must be administered by teachers or daycare providers. Alternative agents that have gained wider use in recent years include extended duration formulations of methylphenidate or the combination of amphetamine and dextroamphetamine.[17] Another clinical use of adrenergic CNS stimulants is for the treatment of narcolepsy, a disorder characterized by uncontrollable attacks of sleep in the daytime. Modafinil, a nonadrenergic CNS stimulant, is an alternative therapy with a different adverse effects profile (e.g., higher incidence of headache, less cardiovascular stimulation).

A clinical application that has drawn considerable attention is the pharmacologic suppression of hunger in short-term adjuvant therapy in weight loss programs. Among the drugs that produce anorexia are the amphetamines, diethylpropion, phentermine, and ephedrine. Some states restrict the use of amphetamines for weight loss because these drugs have a relatively high potential for abuse. Ephedrine is not approved for weight loss but was a common component of oral herbal products (ephedra, *ma huang*) and dietary supplements promoted to increase energy and decrease weight. In its first formal action against an herbal remedy, the FDA banned the use of ephedra alkaloids, including ephedrine, in these products.

A limitation to the therapeutic use of these classic sympathomimetic anorexic drugs is that they produce undesired effects, including CNS stimulation, insomnia, anxiety, nervousness, gastrointestinal disturbances, cardiovascular stimulation, and development of psychological dependence. These drugs are also generally without long-term benefit if not accompanied by stringent caloric restrictions. They are often taken to make a rigid diet seem more acceptable. They are contraindicated in patients taking MAO inhibitors and patients with hypertension, cardiac arrhythmias, thyrotoxicosis, or other severe cardiovascular disease.

Treatment of Hypertension

As mentioned earlier and discussed in Chapter 28, four centrally acting α_2-adrenergic receptor selective agonists are used for the treatment of hypertension: clonidine, guanabenz, guanfacine, and methyldopa. They act on central α_2 receptors that are involved in the autonomic regulation of the cardiovascular system. Activation of inhibitory neurons in the brain causes peripheral vasodilation by inhibiting sympathetic outflow from the CNS and decreasing cardiac output through enhanced vagal tone and decreased sympathetic tone. Generally, these drugs do not reduce sympathetic tone as much as do peripherally acting inhibitors of the sympathetic nervous system or its receptors (see Chapter 7).

THERAPEUTIC USES IN DENTISTRY

Vasoconstrictors are widely used in conjunction with local anesthetic solutions. The vasoconstrictor most commonly used in dentistry is epinephrine, with levonordefrin (the *l* isomer of nordefrin) being used less frequently, usually with mepivacaine.

Table 6-3 lists the concentrations and amounts of adrenergic vasoconstrictors contained in commercially available dental local anesthetic cartridges. The concentration listed for levonordefrin is considered approximately equivalent in clinical effectiveness to 1:100,000 epinephrine, as judged by prolongation of dental anesthesia. The maximum recommended strength of the vasoconstrictor is 1:100,000 epinephrine equivalency for routine nerve block anesthesia. When local tissue hemostasis is required for surgical procedures, such as periodontal surgery, the dentist may additionally choose to infiltrate the area with local anesthetic solution containing 1:50,000 epinephrine, but repeated injections of 2% lidocaine with 1:50,000 epinephrine may cause tissue necrosis and microscarring.[2]

Vasoconstrictors serve several useful purposes when used with local anesthetic solutions. First, they prolong the duration of local anesthesia severalfold and may improve the frequency of successful nerve block.[24] Table 6-4 illustrates the effect of vasoconstrictors on duration of local anesthesia. Second systemic toxicity of the local anesthetic may be minimized by reducing the peak blood concentration of the anesthetic agent.[7] Third, when anesthetic solutions are

TABLE **6-3**

Concentrations and Amounts of Adrenergic Vasoconstrictors in Dental Local Anesthetic Cartridges

VASOCONSTRICTOR	DILUTION	AMOUNT PER DENTAL CARTRIDGE (μg/1.8 mL)
Epinephrine hydrochloride	1:200,000	9
Epinephrine hydrochloride	1:100,000	18
Epinephrine hydrochloride	1:50,000	36
Levonordefrin hydrochloride	1:20,000	90

TABLE **6-4**

Effect of Epinephrine on the Duration of Local Anesthesia

		DURATION	
LOCAL ANESTHETIC	VASOCONSTRICTOR	MEAN (min)	MAXIMUM (min)
Lidocaine 2%	None	44	100
Lidocaine 2%	Epinephrine 1:1,000,000	57	130
Lidocaine 2%	Epinephrine 1:750,000	67	145
Lidocaine 2%	Epinephrine 1:250,000	90	175
Lidocaine 2%	Epinephrine 1:50,000	88	210

Note: Data were obtained by oral surgeons from patients undergoing exodontia. The mean and maximum duration of anesthesia was judged by luxation of the tooth and by the use of probes for soft tissue effects. All injections were inferior alveolar nerve blocks; 24 patients were included in each group.

given by infiltration, vasoconstrictors tend to reduce blood loss associated with surgical procedures (see Chapter 16).

Local anesthesia with vasoconstrictors has been implicated with ischemic conditions of the pulp and alveolar bone, the latter being associated with an increased incidence of osteitis after extractions.[5] Local tissue damage at the site of injection is related to or accentuated by the presence of vasoconstrictor adrenergic agonists.

An important issue related to potential toxicity is the systemic effects of vasoconstrictors after intraoral injection. A related question often faced by the dentist is whether to administer a vasoconstrictor-containing local anesthetic solution to a patient with cardiovascular disease. A traditional opinion held that vasoconstrictors contained in dental anesthetic cartridges produced little, if any, clinically significant systemic effects. Some older reports recommend that cardiac patients be given local anesthetics with vasoconstrictors if needed for adequate anesthesia because the benefits of satisfactory pain control were greater than the risks of small amounts of vasoconstrictor.[35] The validity of this statement depends on the level of stress on the patient and the amount, rate, and manner in which the epinephrine-containing solution is injected.

In the last three decades, numerous well-controlled studies have shown that even the small amounts of vasoconstrictor used in dentistry significantly increase resting plasma catecholamine concentrations and alter some measures of cardiac function (e.g., increase stroke volume).[21,26,32,47] As illustrated in Figure 6-5, intraoral injection of lidocaine with 1:100,000 epinephrine for removal of impacted third molars resulted in significantly increased circulating epinephrine compared with injection of a local anesthetic without vasoconstrictor.[48] Although large therapeutic dosages were used in this study, injection of even a single cartridge of local anesthetic with 1:100,000 epinephrine can result in a temporary doubling of the plasma epinephrine concentration.[51] It is often assumed that the amount of epinephrine released from the adrenal medulla during acute stress greatly exceeds that contained in local anesthetic cartridges. With clinically achievable doses, as shown in Figure 6-5, the stress-induced increase in epinephrine concentration in the "no epinephrine" group was only a small fraction (approximately 14%) of that obtained after intraoral injection of eight cartridges of lidocaine with 1:100,000 epinephrine.

With these developments in mind, a joint report of the American Heart Association and American Dental Association concluded that "vasoconstrictor agents should be used in local anesthesia solutions during dental practice only when it is clear that the procedure will be shortened or the analgesia rendered more profound," that "extreme care should be taken to avoid intravascular injection," and that "the minimum possible amount of vasoconstrictor should be used."[22] More recent reports support this recommendation (see General References). An alternative is available; effective local anesthetic preparations without vasoconstrictor agents (e.g., 3% mepivacaine) have been shown to provide clinically effective local anesthesia, especially for nerve block procedures (see Chapter 16).

It is often necessary to produce gingival retraction for operative procedures on teeth and for making impressions. Besides astringents such as zinc and aluminum salts, cotton cord impregnated with racemic (*d* and *l* isomers) epinephrine, containing as much as 1.2 mg of drug per inch of cord, is commercially available. Racemic epinephrine has approximately half the potency of *l*-epinephrine because *d*-epinephrine has approximately $\frac{1}{15}$ the activity of *l*-epinephrine.

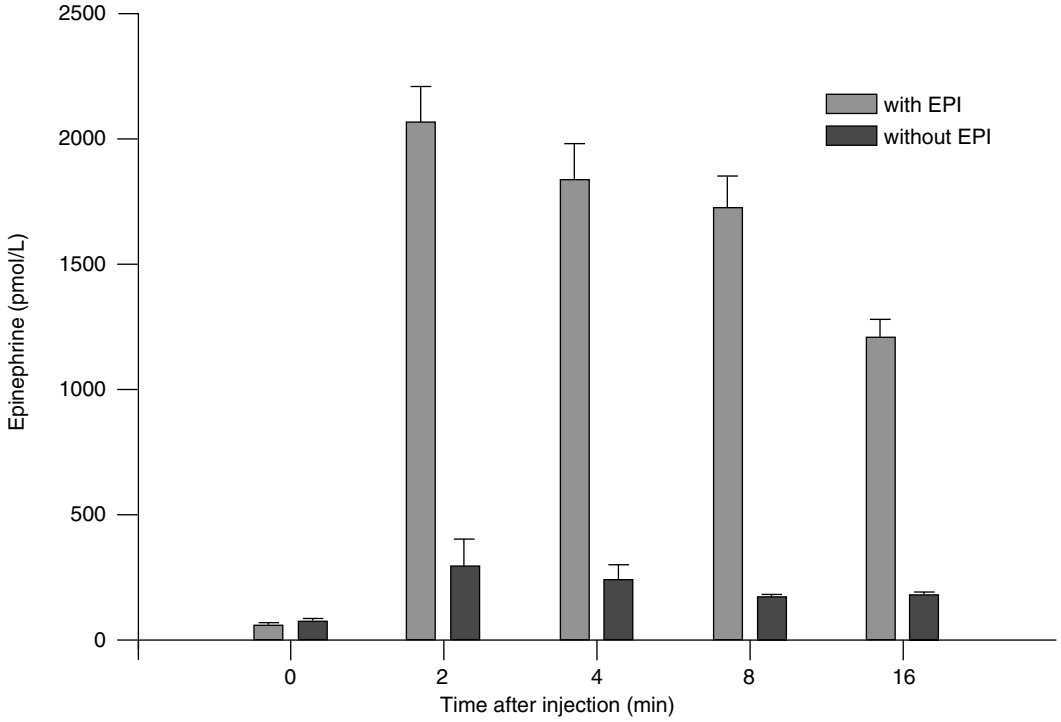

FIGURE **6-5** Effect of intraoral local anesthetic injections on plasma epinephrine. Unsedated oral surgery patients (n = 26) were injected with either 14.4 mL of 2% lidocaine with 1:100,000 epinephrine (*with EPI*, 144 μg epinephrine total dose) or 3% mepivacaine without vasoconstrictor *(without EPI)* under randomized, double-blind conditions. Brackets indicate the standard error. (Adapted from Troullos ES, Hargreaves KM, Goldstein DS, et al: Epinephrine suppresses stress-induced increases in plasma immunoreactive β-endorphin in humans, *J Clin Endocrinol Metab* 69:546-551, 1989.)

Whether these large amounts of epinephrine present a hazard to a normal patient and to patients with cardiovascular disease depends on several factors. Experimental and clinical studies indicate a relatively high absorption of the vasoconstrictor if the epithelium is abraded or the vasculature is exposed, which is common in extensive restorative procedures. Systemic absorption is marked by signs of anxiety, elevated blood pressure, increased heart rate, and occasional arrhythmias. These effects can be extremely serious in a patient with cardiovascular disease or in a patient who is taking medication that reduces the uptake or otherwise enhances the activity of adrenergic agents. Because of this concern, epinephrine-impregnated retraction cord is used much less often than other types of retraction cord.

Various products are available to control capillary bleeding occurring with surgical procedures on gingival tissues. Topical epinephrine hydrochloride (1:1000) and phenylephrine (1:100) are most common. More concentrated solutions have occasionally been recommended, but their use can heighten the risk of cardiovascular problems without producing any significant increased effectiveness in reducing hemorrhage.

ADVERSE EFFECTS

Almost all adverse effects of the adrenergic agonists are dose related. Toxic reactions can result from the administration of too large a dose, accidental intravascular injection, impaired uptake of the drug, a heightened sensitivity or number of adrenergic receptors, or therapeutic doses given to a patient with preexisting cardiovascular disease. Relatively small amounts of epinephrine can cause potentially grave effects in a highly susceptible patient. Generally, serious complications may be expected with doses of epinephrine greater than 0.5 mg, and fatalities are likely to occur with doses of 4 mg or more, although one patient is reported to have survived an injection of 30 mg.[49] Correct dosage calculations, careful reading of labels, and a complete medical history can help reduce accidents. Reviews of the literature indicate that reported adverse reactions attributable to vasoconstrictors used with local anesthetics in dentistry are rare.[6,49]

Most serious of the toxic effects of epinephrine are cardiac disturbances, with increased stimulation of the heart leading to myocardial ischemia, possibly heart attack, and arrhythmias, including ventricular fibrillation. Patients with a history of uncontrolled hyperthyroidism, hypertension, or angina pectoris are particularly susceptible. If epinephrine is administered to a patient who is taking a nonselective β-adrenergic receptor blocking drug such as propranolol (see Chapter 7), unopposed α-receptor stimulation may cause excessive vasoconstriction. The increase in blood pressure from rapid parenteral administration can be severe enough to result in hypertensive crisis, which can cause cardiac disturbances or a cerebrovascular accident.[11] Drugs with primarily α-adrenergic receptor stimulation can cause excessive vasoconstriction in overdose. Local tissue necrosis may result from any vasoconstrictor injected into a region where ischemia is likely, such as the digits of the hands or feet.

CNS reactions to classic sympathomimetic drugs include nervousness, excitability, insomnia, dizziness, and tremors. Long-term use of amphetamines can lead to psychotic symptoms. The most common side effects of centrally acting α_2-agonist antihypertensive agents are dizziness, drowsiness, and xerostomia. The xerostomia seems to be most severe with clonidine and guanabenz. Constipation, sexual dysfunction, CNS disturbances, bradycardia, and excessive hypotension have also been reported. A particularly troubling adverse effect is rebound hypertension of serious proportions if these drugs are withdrawn abruptly.

Unique to methyldopa is the occurrence of drug-induced hepatitis, with a fever that may reach alarming levels (105° F). Withdrawal of the drug usually allows liver function to return to normal. This reaction has been shown to be related to the transformation of methyldopa to reactive compounds that combine covalently with cellular macromolecules.[9] Other adverse effects of methyldopa include parkinsonian signs, hyperprolactinemia, and hemolytic anemia.

ADRENERGIC AGONISTS

Nonproprietary (generic) name	*Proprietary (trade) name*
Ophthalmic products	
Mydriatics	
Hydroxyamphetamine	Paredrine
Phenylephrine	Neo-Synephrine
Decongestants	
Naphazoline	Allerest, Naphcon
Oxymetazoline	Visine L.R.
Phenylephrine	Neo-Synephrine
Tetrahydrozoline	Visine
Antiglaucoma agents (see Chapter 8)	
Respiratory tract products	
Nasal decongestants	
Ephedrine	Pretz-D
Epinephrine	Adrenalin
Naphazoline	Privine
Oxymetazoline	Afrin, Nostrilla
Phenylephrine	Neo-Synephrine, Sudafed PE
Propylhexedrine	Benzedrex
Pseudoephedrine	Sudafed
Tetrahydrozoline	Tyzine
Xylometazoline	Otrivin
Cold remedies	
These preparations consist of antihistamines, analgesics, cough suppressants, other drugs, and one of the following adrenergic agonists:	
Phenylephrine	In Dimetapp Cold & Cough, in Dristan Multi-Symptom Nasal Decongestant
Pseudoephedrine	In Claritin-D, in Sudafed Multi-Symptom Cold & Cough
Bronchodilators	
Albuterol	Proventil, Ventolin, in Combivent
Bitolterol	Tornalate
Ephedrine	Primatene Tablets
Epinephrine	Adrenalin, Primatene Mist
Ethylnorepinephrine	Bronkephrine
Formoterol	Foradil
Isoetharine	Bronkosol
Isoproterenol	Isuprel, Medihaler-Iso

Continued

ADRENERGIC AGONISTS—cont'd

Nonproprietary (generic) name	*Proprietary (trade) name*
Levalbuterol	Xopenex
Metaproterenol	Alupent
Pirbuterol	Maxair
Salmeterol	Serevent
Terbutaline	Brethine, Bricanyl
Cardiovascular system products	
Vasoconstrictors and cardiac stimulants	
Dobutamine	Dobutrex
Dopamine	Intropin
Ephedrine	—
Epinephrine	Adrenalin
Isoproterenol	Isuprel
Levonordefrin	Neo-Cobefrin
Mephentermine*	Wyamine
Metaraminol*	Aramine
Methoxamine*	Vasoxyl
Midodrine	Orvaten, ProAmatine
Norepinephrine	Levophed
Phenylephrine	Neo-Synephrine
Antihypertensive agents	
Clonidine	Catapres
Fenoldopam	Corlopam
Guanabenz	Wytensin
Guanfacine	Tenex
Methyldopa	Aldomet
Methyldopate	—
CNS stimulants and anorexiants	
Amphetamine	in Adderall
Benzphetamine	Didrex
Dexmethylphenidate	Focalin
Dextroamphetamine	Dexedrine, in Adderall
Diethylpropion	Tenuate
Methamphetamine	Desoxyn
Methylphenidate	Methylin, Ritalin
Modafinil	Provigil
Pemoline	Cylert
Phendimetrazine	Bontril, Plegine
Phentermine	Adipex-P, Fastin
Sibutramine	Meridia
Miscellaneous products	
Hemorrhoid treatments	
Phenylephrine sedative	In Hemorid, in Preparation H
Dexmedetomidine	Precedex

CHAPTER 7

Adrenergic Antagonists

MICHAEL T. PIASCIK AND PETER W. ABEL

Understanding of the mechanisms of transmission in the sympathetic nervous system has increased significantly as a result of a better understanding of the actions of drugs; an increased appreciation of receptors and the second messenger pathways used by them; and extensive investigation of important diseases such as congestive heart failure, coronary artery disease, and hypertension. The consequence of this work has been the development of numerous new pharmacologic agents possessing increasingly selective mechanisms of action. Chapter 5 discusses the theoretic mechanisms by which drugs produce effects on the autonomic nervous system (see Table 5-2). The drugs discussed in this chapter all interfere with sympathetic nervous system transmission. Despite having diverse mechanisms of action, these drugs are collectively referred to as *adrenergic antagonists* or *sympatholytics*. Most, but not all, adrenergic antagonists are competitive antagonists of either α-adrenergic or β-adrenergic receptors (adrenoceptors). As a result, these agents block the actions of the endogenous neurotransmitters epinephrine and norepinephrine and exogenously administered adrenergic agonists and are also called *adrenergic receptor blockers*.

A group of agents with sympatholytic activity includes drugs that are agonists at α_2-adrenergic receptors in key brain nuclei controlling cardiovascular function (see Chapter 6). These drugs reduce blood pressure largely by decreasing the outflow of sympathetic nervous system transmission to cardiovascular effectors. Several agents that are mainly of historical interest are known collectively as *adrenergic neuron–blocking drugs*. They act on nerve terminals to produce their sympatholytic effects and are discussed in Chapter 28.

HISTORY

Evidence that drugs could be used to antagonize the actions of other pharmacologic agents was obtained shortly after the isolation and synthesis of epinephrine. In 1906, Dale noticed that certain alkaloids isolated from ergot, produced by a fungus disease of rye grain, blocked the ability of epinephrine to increase systemic arterial blood pressure. After an injection of ergotoxine (a mixture of ergot alkaloids), a hypotensive effect was observed in response to epinephrine treatment; it was aptly named by Dale the "epinephrine reversal" response.[9] These early studies also provided the first example of selective antagonism by showing that ergot derivatives were capable of blocking some, but not all, of the actions of epinephrine. This idea of selective antagonism remains an important aspect of drug development and use.

The pioneering work of Ahlquist[1] in delineating the α-adrenergic and β-adrenergic receptors provided the framework necessary to classify more systematically antagonists of sympathetic nervous system function. Nickerson and Goodman[21] reported in 1947 the development of dibenamine, an agent capable of irreversibly blocking the α-adrenergic receptor, which inhibited certain responses to exogenous epinephrine and to adrenergic nerve stimulation. Selective blockade of α-adrenergic receptors by ergotoxine also explained the epinephrine reversal described by Dale.[9] Phentolamine and related imidazolines were early examples of nonselective, competitive antagonists at α-adrenergic receptors. Selective antagonists of the α_1-adrenergic and α_2-adrenergic receptors have now been developed. Dichloroisoproterenol was the first β-adrenergic receptor blocker developed. The first clinically useful β blocker introduced was propranolol, which blocks β_1-adrenergic and β_2-adrenergic receptors. Selective β_1 antagonists were then discovered. We now know that there are at least nine adrenergic receptors (α_{1A}, α_{1B}, α_{1D}, α_{2A}, α_{2B}, α_{2C}, β_1, β_2, and β_3). Increasingly selective antagonists against each of these receptors are being developed with the goal of obtaining drugs capable of specifically interfering with the receptor involved in a pathophysiologic condition without blockade of other receptors that could lead to unwanted side effects.

In addition to effects on adrenergic receptors, it was found that sympathetic nervous system transmission could also be altered by actions directly on the nerve terminal. The drug bretylium interferes with the release of norepinephrine in response to nerve stimulation.[4] Other drugs were also developed that interfere with neuronal function at the level of the nerve terminal. Reserpine depletes the norepinephrine stored in these nerve terminals.[5] Metyrosine (α-methyl-L-tyrosine) competitively inhibits tyrosine hydroxylase, the rate limiting enzyme in the synthesis of norepinephrine.[11] These sympatholytics are not as therapeutically beneficial as the selective receptor antagonists, however, because their administration is associated with many unpleasant side effects. In the 21st century, the use of these agents has been curtailed, and they have been largely relegated to historical footnotes. Brief descriptions of these drugs are given in Chapters 5, 12, and 28.

SELECTIVE α_1-ADRENERGIC RECEPTOR ANTAGONISTS

As discussed in Chapter 5, α_1-adrenergic receptors are located predominantly on the postjunctional membranes of glands

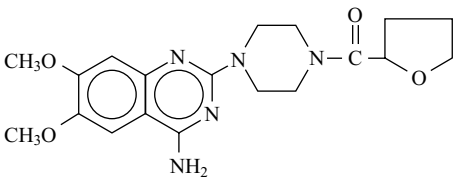
and smooth muscle. The α_1-adrenergic receptors associated with smooth muscle of arteries and veins play an important role in promoting vasoconstriction and in regulating systemic arterial blood pressure and blood flow. The α_1-adrenergic receptors are also important in regulating the tone of nonvascular smooth muscle, such as in the neck of the urinary bladder and capsule of the prostate. More recent evidence has suggested that the α_1-adrenergic receptor plays a role in the regulation of hypertrophic growth, the generation of reactive oxygen species, and apoptotic cell death. Antagonism of these cellular events may also be the reason that α_1-adrenergic receptor blockers are effective in the treatment of benign prostatic hyperplasia. The α_2-adrenergic receptors are found on the prejunctional neuronal membrane, where they play an autoregulatory role in inhibiting norepinephrine release. They are also located postjunctionally on the membranes of pancreatic islet cells, smooth muscle, and blood platelets.[17]

Prazosin and Analogues

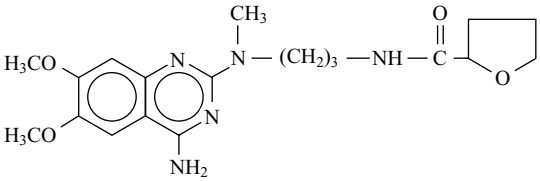
The first antagonists that targeted the α_1-adrenergic receptor were nonselective (see later) and also blocked the α_2-adrenergic receptor. These drugs were unsuitable as antihypertensive agents, presumably because of the α_2-adrenergic receptor blockade. The disadvantages associated with the nonselective blockade of α receptors inspired a search for agents with receptor selectivity.

The first therapeutically useful α_1-adrenergic receptor antagonist developed was prazosin (Figure 7-1).[3] Terazosin and doxazosin are structural analogues that were subsequently introduced. Although these agents differ in pharmacokinetic properties, their mechanism of action is the same. The α_1-adrenergic receptor antagonists prevent the action of sympathetic neurotransmitters and exogenously administered agonists at α_1-adrenergic receptors on effector organs. Prazosin and related compounds have essentially equal affinity for all three subtypes (α_{1A}, α_{1B}, and α_{1D}) of the α_1-adrenergic receptor.

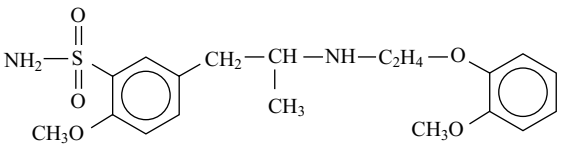
As a result of blocking smooth muscle α_1-adrenergic receptors, prazosin dilates arterioles and veins. Each of these actions contributes to the hypotension seen with this drug. Blockade of arterial smooth muscle produces hypotension by reducing peripheral resistance. The venodilation resulting from blocked venous α_1-adrenergic receptors decreases cardiac preload. Compared with the nonselective α receptor antagonists, prazosin causes less tachycardia, a smaller increase in cardiac output, and less renin release.[3]



Prazosin



Alfuzosin



Tamsulosin

FIGURE **7-1** Structural formulas of three α_1-adrenergic receptor–blocking agents.

Absorption, fate, and excretion

Prazosin is variably absorbed, with 40% to 70% of an oral dose becoming systemically bioavailable. A large percentage of circulating drug in the plasma is bound to α_1-acid glycoprotein. The plasma half-life is approximately 2 to 3 hours, requiring dosing two to three times per day. Most of the drug is demethylated and conjugated in the liver. Some prazosin metabolites are pharmacologically active and contribute to its therapeutic effect. Metabolites are excreted in the bile.

Terazosin is almost completely absorbed after oral administration and thus has a higher bioavailability than prazosin. It is also highly bound to plasma proteins. With a half-life of approximately 12 hours, the drug can be administered once a day. It is extensively metabolized in the liver, with both active and inactive metabolites formed. Approximately 60% of the drug is eliminated in the bile and 40% in the urine.

The systemic bioavailability of doxazosin is 60% to 70% after oral administration. Similar to the other members of this class of compounds, doxazosin circulates highly bound to plasma proteins, is extensively metabolized, and is excreted in the bile and urine. Its half-life is 10 to 20 hours, giving it an extended duration of action.

Therapeutic uses

Prazosin, terazosin, and doxazosin can be used in monotherapy for the treatment of hypertension (see Chapter 28). Terazosin and doxazosin, which are given once a day, may have advantages over prazosin, which requires more frequent administration. Otherwise, the clinical effects of terazosin and doxazosin are similar to the effects of prazosin. Although prazosin and analogues can alleviate the signs and symptoms of congestive heart failure (because of a reduction in preload and afterload), they have not been shown to increase survival in patients with congestive heart failure.[20,23] The doxazosin arm of a more recent clinical trial, the ALLHAT study, was discontinued because of increased cardiovascular risks compared with alternative treatments.[20] This finding has resulted in a significant reduction in the use of prazosin analogues in the therapy of hypertension. These drugs do not have adverse effects on lipids or cholesterol and may be particularly useful in treating patients with hyperlipidemia.[7,18] Prazosin and its analogues are also effective in treating benign prostatic hyperplasia caused by the blocking of the α_1-adrenergic receptors associated with smooth muscle of the bladder neck and prostate. This action reduces pressure on the urethra and improves urine flow. Because of their longer plasma half-lives, terazosin and doxazosin may be preferred over prazosin for this indication.[7,18]

Adverse effects

Orthostatic or postural hypotension is a potential concern with prazosin analogues. The effect is most likely to occur with initial administration and is known as "first-dose" syncope. Hypotension ensues when the systemic arterial blood pressure decreases by more than 20 mm Hg on standing. In this situation, cerebral perfusion decreases, and an individual may become lightheaded, dizzy, or faint. In changing from the supine to the standing position, gravity tends to cause blood to pool in the lower extremities. Several reflexes, including sympathetically mediated venoconstriction, minimize this pooling, however, and maintain cerebral perfusion. If these reflex actions do not occur, orthostatic hypotension can result.

By blocking the α_1 receptors associated with venous smooth muscle, prazosin-like drugs inhibit the sympathetically mediated vasoconstriction associated with postural changes.

Therapy with prazosin and its analogues should be instituted initially with small doses, followed by a gradual dosage increase over time. These drugs may cause fluid retention and edema; it may be necessary to give a diuretic simultaneously. A more recently described adverse effect of the prazosin-type drugs is inoperable floppy iris syndrome (IFIS). IFIS occurs during phacoemulsification cataract surgery. In this procedure, ultrasound is used to break up the cataract so that it can be removed by aspiration. This delicate procedure requires that the pupil be dilated by administration of an α-adrenergic receptor agonist. This pupillary dilation is blocked by prazosin. In addition, the flaccid iris is difficult to manipulate and obstructs the surgical field. Surgery is rendered more difficult, and the risk of complications is increased. Prazosin and its analogues should be withheld before cataract procedures. Other adverse effects include dry mouth, dizziness, headache, nasal stuffiness, and fatigue.

Alfuzosin

Alfuzosin (see Figure 7-1) is an analogue of prazosin that selectively blocks the α_1-adrenergic receptors associated with the prostate gland.[19] Alfuzosin binds to α_1-adrenergic receptors with equal affinity. The reason for its prostate selectivity is not well understood. It seems to be related to the ability of alfuzosin to accumulate selectively in prostate tissue. Because of this prostate affinity, therapeutic doses of alfuzosin have little effect on systemic arterial blood pressure and are much less likely to cause syncope. IFIS remains a concern, however, with the use of alfuzosin. The drug is well absorbed and is available in a once-daily dosage form.

Tamsulosin

Tamsulosin (see Figure 7-1) is the first clinically available antagonist that blocks specific subtypes of the α_1-adrenergic receptor: the α_{1A} and α_{1D} subtypes. The α_{1A}-adrenergic receptor has been shown to mediate the contraction of human prostatic smooth muscle.[26] Because tamsulosin has a high affinity for the α_{1A}-adrenergic receptor, it is effectively used to treat benign prostatic hyperplasia. The selectivity of this compound for the prostate is reflected in the fact that there is little decrease in blood pressure after therapeutic doses of the drug. Tamsulosin is well absorbed after oral administration and circulates tightly bound to plasma proteins. It is extensively metabolized in the liver and excreted as inactive conjugation products in the urine. Tamsulosin is less likely to cause orthostatic hypotension and syncope than other α_1-selective antagonists.[7,18] Similar to the other α_1-adrenergic receptor antagonists, tamsulosin use has been associated with an increased incidence of IFIS. Other adverse effects include nasal stuffiness and skin rash.

NONSELECTIVE α-ADRENERGIC RECEPTOR ANTAGONISTS

The nonselective α-adrenergic receptor–blocking drugs prevent the action of adrenergic transmitters and sympathomimetic agonists at all α-adrenergic receptors. Although many drugs exhibit some α blocking activity, only the imidazolines and haloalkylamines are classified and used clinically as nonselective α-adrenoceptor antagonists.

Imidazolines

Analogues of the imidazoline adrenergic amines were among the first synthetic adrenergic blocking agents to be identified. Phentolamine (Figure 7-2) is the only compound from this class that is still clinically available. It is a competitive antagonist at α_1-adrenergic and α_2-adrenergic receptors. It also evokes histamine release, acts as a cholinomimetic, and blocks 5-hydroxytryptamine (serotonin, 5-HT) receptors. Therapeutically, doses sufficient to achieve adrenergic blockade can produce side effects attributable to these other actions. Nevertheless, adverse responses linked to significant decreases in peripheral vascular resistance—such as hypotension—are the major problems associated with phentolamine use. Reflex tachycardia is a special concern with phentolamine. By blocking prejunctional α_2 receptors, the drug interferes with the negative feedback mechanism (autoregulation) that normally limits the amount of norepinephrine released in response to an acute decrease in blood pressure. This lack of autoregulation leads to excessive transmitter release by sympathetic nerves supplying the heart, which may produce increases in heart rate sufficient to cause myocardial ischemia and cardiac arrest.[27,29]

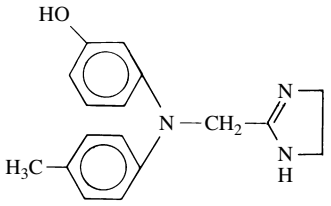


FIGURE **7-2** Structural formula of phentolamine.

In recent years, phentolamine has had very limited therapeutic applications. It has been infused intravenously to control acute episodes of hypertension during anesthesia and in the preoperative and intraoperative management of patients with pheochromocytoma. It has also been used in clonidine withdrawal and in the treatment of hypertensive crises resulting from the interaction of monoamine oxidase (MAO) inhibitors and sympathomimetic amines. Subcutaneous injections of phentolamine are indicated in cases of extravasation of infusions of catecholamines, especially norepinephrine.

Most recently, phentolamine mesylate has been approved for the reversal of soft tissue numbness after administration of local anesthetics with vasoconstrictors for nonsurgical dental procedures. The drug is formulated in dental cartridges (0.4 mg/1.7-mL cartridge) and is injected in the same manner as the local anesthetic when pain relief is no longer needed. The median duration of post-treatment anesthesia in the upper and lower lips of adults[16] and children[31] is reduced by 85 minutes when phentolamine mesylate is injected at the end of restorative and dental hygiene procedures lasting about 45 minutes. Return of normal function (e.g., speaking, smiling, drinking) occurs in concert with return of normal sensation. It is unlikely that the phentolamine is acting by reversing the vasoconstrictor effect of injected epinephrine or levonordefrin, which should have already disappeared from the local tissues. Instead, the phentolamine probably increases local blood flow by blocking sympathetic tone, which hastens the removal of the local anesthetic from local neurons. Doses of phentolamine used for this purpose (0.2 mg to 0.8 mg) are approximately 10 times less than doses injected intravenously for treatment of hypertensive emergencies, and adverse effects have been similar to those reported after sham injection.

β-Haloalkylamines

Phenoxybenzamine is the only currently used member of the β-haloalkylamines. It is classified as an antagonist at α_1-

adrenergic and α_2-adrenergic receptors. Phenoxybenzamine initially binds reversibly to the receptors, but then it undergoes a chemical reaction that allows the drug to become covalently linked. The initial binding is governed by the same chemical binding forces described in Chapter 1. During development of the blockade, the presence of an agonist, or even a competitive α-blocking drug, decreases the blocking activity of phenoxybenzamine by competing for the α-adrenergic receptors. When the block has developed completely, usually in approximately 1 hour, no drug can successfully compete for the receptor because phenoxybenzamine will have formed a stable covalent bond with the receptor. This stage of the block is referred to as irreversible or nonequilibrium and has a half-life of about 24 hours, with effects persisting for several days. Similar to phentolamine, phenoxybenzamine is nonselective and blocks the prejunctional α_2 receptors responsible for regulating the release of norepinephrine. Its adverse effects are largely predicated on its long-lasting, insurmountable blockade of α receptors. In high doses, phenoxybenzamine also inhibits responses to histamine, acetylcholine, and 5-HT, however, and blocks transporter systems responsible for the tissue uptake of norepinephrine.

It was originally hoped that phenoxybenzamine would prove to be a useful antihypertensive. Many nonspecific effects and troublesome side effects have significantly restricted its therapeutic application. Phenoxybenzamine is used in the long-term therapy of pheochromocytoma in preparation for surgery or in patients who are judged to be unsuited for surgery. It rarely has been used to relax the bladder sphincter of patients with motor paralysis of the bladder or obstruction caused by prostatic hyperplasia.

Most of the adverse effects of phenoxybenzamine are shared by other α receptor antagonists; however, they are often more intense and prolonged with phenoxybenzamine because of the irreversible nature of its receptor block. The reduction of blood pressure caused by blockade of postjunctional α_1 and α_2 receptors, coupled with the inhibition of regulatory prejunctional α_2 receptors and possibly norepinephrine reuptake, results in prominent compensatory reflex activity, especially increased cardiac excitability, contractility, rate, and output. Orthostatic hypotension commonly results from the loss of control over the capacitance veins; exaggerated sensitivity to hypovolemia and the hypotensive influences of other drugs is also a common outcome. Symptoms of tachycardia, dizziness, headache, and syncope all are typical. Abdominal distress and diarrhea caused by uncompensated parasympathetic activity are added problems, as are the minor irritants of nasal stuffiness and miosis. In addition, inhibition of ejaculation has made compliance among men extremely poor. The symptoms of therapy with phenoxybenzamine can seem worse than the symptoms of the disease this drug is used to treat.

β-ADRENERGIC RECEPTOR ANTAGONISTS

The β-adrenergic receptor antagonists, also called β-adrenergic receptor blockers, are an important and versatile class of drugs widely used in cardiovascular therapeutics. The β blockers are also used to treat numerous noncardiovascular disease states. Several β blockers are among the most widely prescribed medicines in the United States.

The β-adrenergic receptors are categorized into three subtypes: β_1, β_2, and β_3. Propranolol was the first β blocking drug to be approved in the United States and is considered the prototype for this class of compounds. This drug is a competitive antagonist at β_1-adrenergic and β_2-adrenergic receptors and is referred to as a nonselective β blocker. The beneficial effects of propranolol and other nonselective β blockers are mostly attributable to blockade of the β_1-adrenergic receptor. As discussed subsequently, blockade of the β_2-adrenergic receptor is associated with undesirable effects on the airways, vascular smooth muscle, and endocrine function. Metoprolol, the first selective β_1 receptor antagonist, and its successors (e.g., atenolol, acebutolol, and esmolol) have attracted considerable attention because of their relative freedom from the unwanted effects of β_2-adrenergic receptor blockade. This β_1 selectivity is relative with existing agents, and these drugs lose much of their selectivity at higher doses. Presently, nonselective and selective β_1 blockers are used clinically. Certain β blockers have weak partial agonistic properties; this is referred to as intrinsic sympathomimetic activity (ISA). The value of such drugs is discussed subsequently. The pharmacodynamic and pharmacokinetic properties of propranolol and other selected β blockers are summarized in Table 7-1.

The physiologic role of the β_3 receptor is not as well defined as the roles of the β_1-adrenergic and β_2-adrenergic receptors (which are reviewed in Chapter 5).[15,30] Selective agonists and antagonists of the β_3-adrenergic receptor have been developed. Activation of the β_3 receptor results in a negative inotropic but positive chronotropic effect. Similar to the β_2-adrenergic receptor, activation of the β_3 receptor causes vasodilation.[25] β_3 Receptor stimulation is also being investigated for the treatment of overactive bladder.[34] Activation of the β_3-adrenergic receptor has been shown to stimulate lipolysis, and many β_3 receptor–selective agonists have been developed that are effective in rodent models of obesity. So far, none of the selective β_3 receptor agonists has been shown to be effective in stimulating weight loss in humans.[15,30] There is no current role for antagonists of the β_3 receptor.

Chemistry

As exemplified by the first β blocker, dichloroisoproterenol, halogen substitution of the catechol hydroxyl groups of the β agonist isoproterenol results in a partial agonistic activity at the β receptor. As illustrated in Figure 7-3, the currently available β blocking drugs all possess an ethylamino moiety similar to that seen in β-adrenergic receptor agonists attached through a methoxy linkage to a variant ring structure. β_1 Selectivity is conferred by a benzene ring with a large substitution in the para position.

Pharmacologic Effects

The pharmacologic effects of the β blockers occur as a result of preventing binding and subsequent receptor activation by epinephrine, norepinephrine, and exogenously administered adrenergic agonists in tissues regulated by β-adrenergic receptors.

Drugs that do not have ISA decrease resting heart rate, plasma renin activity, and cardiac output. Because of their partial agonist activity, drugs with ISA, such as pindolol, do not depress resting cardiac function or plasma renin activity to the degree seen with other β blockers. Agonist-driven increases in these parameters are small, however, because of the low intrinsic activity of pindolol. In situations of high sympathetic nervous system activity, β blockers with ISA antagonize the ability of endogenously released epinephrine and norepinephrine (agonists with high intrinsic activity) to increase heart rate, contractility, and renin secretion. Under these conditions, epinephrine and norepinephrine must compete for binding with drugs that have much less intrinsic activity.

Several β blockers can exert a local anesthetic effect in the heart. This activity derives from the blockade of Na^+ channels and results in disruption of electric impulse propagation in the heart. The local anesthetic effect is also referred to as *membrane-stabilizing activity* (see Table 7-1). Membrane-stabilizing activity is especially strong with propranolol.

TABLE **7-1**

Comparison of β-Adrenergic Receptor Blocking Drugs

DRUG	POTENCY OF BLOCKADE (PROPRANOLOL = 1)	MEMBRANE-STABILIZING ACTIVITY	INTRINSIC SYMPATHOMIMETIC ACTIVITY	ORAL BIOAVAILABILITY	HALF-LIFE (hr)	ROUTE OF ELIMINATION	LIPOPHILICITY	DOSING FREQUENCY (times/day)	THERAPEUTIC INDICATIONS
Nonselective ($\beta_1 + \beta_2$)									
Nadolol	1.0	0	0	30	10-24	Renal	Low	1	Angina pectoris; hypertension
Pindolol	6.0	+	++	80	3-4	Hepatic/renal	Moderate	1-2	Hypertension
Propranolol	1.0	++	0	30	3-5	Hepatic	High	2-3	Angina pectoris; arrhythmias; hypertension; hypertrophic subaortic stenosis; migraine prophylaxis; myocardial infarction; pheochromocytoma
Timolol	6.0	0	0	50	3-5	Hepatic/renal	Moderate	1-2	Hypertension; migraine prophylaxis; myocardial infarction; glaucoma
Selective (β_1)									
Acebutolol	0.3	+	+	40	3-4	Hepatic/renal/ nonrenal	Moderate	2-3	Hypertension; ventricular arrhythmias
Atenolol	1.0	0	0	50	6-9	Renal	Low	1-1	Angina pectoris; hypertension; myocardial infarction
Esmolol*	0.02	0	0	—	0.15	Red blood cell esterase	—	—	Supraventricular tachycardias; noncompensatory tachycardias
Metoprolol	1.0	—	0	40	3-7	Hepatic/renal	Moderate	2-3	Angina pectoris; hypertension; myocardial infarction

*Has a very brief duration of action and is given intravenously only.

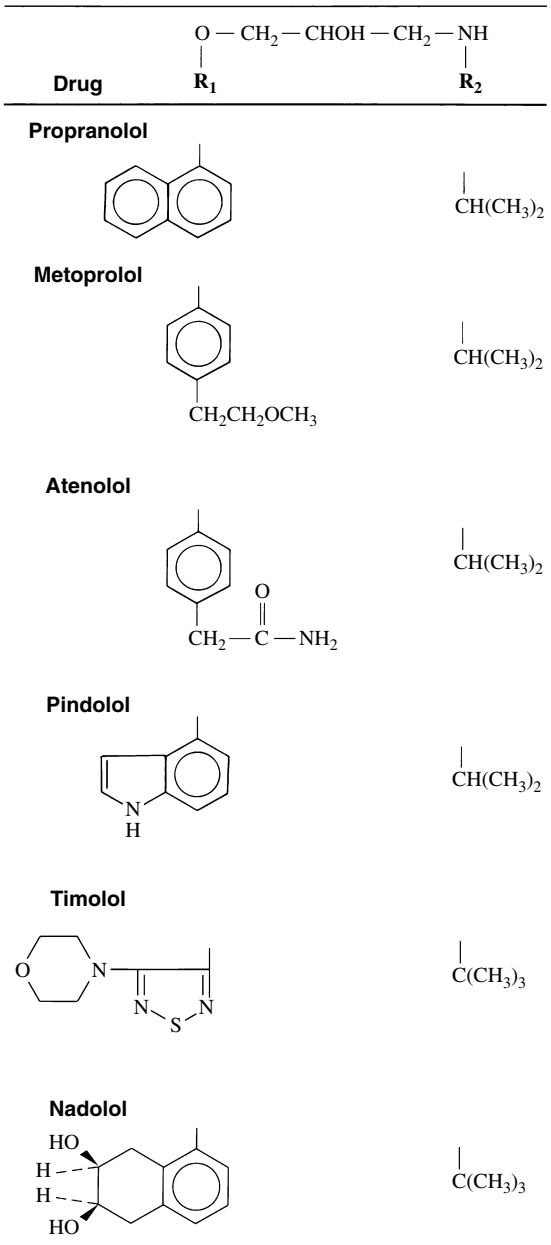

FIGURE **7-3** Structural formulas of some β adrenoceptor–blocking agents. All the drugs share a similar side chain, differing only in the terminal hydrocarbon group (R_2). Considerable variation exists in the ring structures (R_1).

Blockade of Na^+ channels is a property of many antiarrhythmic agents (see Chapter 24). In the case of β blockers, the blockade of Na^+ channels requires higher blood concentrations than the concentrations necessary for receptor blockade.[8] Toxic (but not therapeutic) doses of propranolol can exert effects similar to certain antiarrhythmic drugs, such as quinidine.[10] These effects include a decrease in the slope of the upstroke of the action potential (phase 0) and an increase in the refractory period in ischemic ventricular tissue.

Effects on the cardiovascular system

The β blockers decrease the rate and force of myocardial contraction. The major sites of action for the negative chronotropic effects of the β blockers are the β_1-adrenergic receptors associated with the sinoatrial (SA) node, the atrioventricular (AV) node, and the His-Purkinje system. There is a decrease in SA nodal firing rate, slowed conduction, and reduced automaticity. These actions contribute to the antiarrhythmic efficacy of the β blockers. The decrease in contractile force occurs largely as a result of β_1-adrenergic receptor blockade associated with ventricular (the major site of action) and atrial muscle. Collectively, these changes result in a decrease in cardiac output. The negative inotropic and chronotropic actions lessen the oxygen consumption of the heart and contribute to the usefulness of the β blockers in treating ischemic heart disease. The effects of the β blockers are most pronounced under conditions of heightened sympathetic activity, when there are significant amounts of circulating and neuronally released catecholamines.

In normotensive patients, β blockers do not normally reduce blood pressure; however, they are highly effective in reducing blood pressure in hypertensive patients. These agents reduce blood pressure equally in the supine and standing positions, with no orthostatic hypotension. This attribute was discovered serendipitously while β blockers were being used to treat angina pectoris. Since that time, propranolol and other β blockers, alone or in combination with other drugs, are among the drugs of first choice in the treatment of hypertension. Although the mechanisms by which the β blockers reduce blood pressure are not completely understood, certain facts are known. The reduction in blood pressure is associated only with the *l* isomer, which has a much higher affinity for β-adrenergic receptors than the *d* isomer. When propranolol is first administered to a patient, cardiac output decreases, and peripheral resistance increases. The latter effect may result from β_2 receptor blockade in the vasculature or from a baroreceptor-mediated increase in sympathetic tone. With continued therapy, peripheral resistance also decreases. By blocking renal β_1-adrenergic receptors involved in renin secretion, β blockers cause a reduction of plasma renin concentrations. The reduction in plasma renin activity eventually leads to a reduction in angiotensin II concentrations and aldosterone secretion. Other mechanisms that seem to contribute to the reduction in blood pressure include decreases in heart rate, cardiac output, and central nervous system (CNS) sympathetic outflow[14] and an alteration in baroreceptor responsiveness.

Effects on smooth muscle

By blocking the β_2-adrenergic receptors associated with airway smooth muscle, propranolol and other nonselective β blockers prevent sympathetic stimulation of bronchiolar smooth muscle, while leaving parasympathetic activity and other bronchoconstrictive influences unchecked. This imbalance can lead to a marked increase in airway resistance in patients with bronchospastic disorders such as asthma, chronic bronchitis, and emphysema. Propranolol and other nonselective β blockers are contraindicated in patients with bronchospastic disease. This limitation was a major impetus for development of selective β_1 receptor–blocking drugs. In a similar fashion, nonselective β blockers can also exacerbate peripheral vascular disease by blocking vasodilatory β_2-adrenergic receptors on vascular smooth muscle.

Gastrointestinal tract effects

Similar to other adrenergic antagonists, propranolol tends to produce a relative preponderance of parasympathetic activity in the gastrointestinal tract. The net effect is related to the amount of sympathetic activity that is blocked, but it is usually of little importance.

Metabolic effects

Propranolol and other nonselective β blockers antagonize the β_2-adrenergic receptors responsible for initiating glycogenolysis in the liver and in skeletal muscle. Hypoglycemia may

result from this action, but it is rare in the nondiabetic individual. The release of fatty acids from adipocytes by epinephrine is mediated by β_1-adrenergic or β_3-adrenergic receptors. All clinically useful β-adrenergic antagonists blunt this release. Nevertheless, these drugs also increase triglyceride concentrations and decrease blood concentrations of high-density lipoproteins. This response does not preclude the use of β blockers in patients with elevated serum lipids, including cholesterol.

Ocular effects

While the antihypertensive effects of the β blockers were being studied, investigators noticed that intraocular pressure in patients with open-angle glaucoma was reduced.[35] The production of aqueous humor is decreased by β blockers. Several β receptor blockers are commonly used topically (eye drops) in treating glaucoma and ocular hypertension. The pharmacotherapy of glaucoma is discussed in Chapter 8.

Central nervous system effects

The versatility of the β blockers is reflected in the fact that they can by used to treat a variety of disorders that have CNS involvement, including migraine headache, tremor associated with anxiety (stage fright), and benign essential tremor. Reduction of tremors is also mediated by blocking β_2-adrenergic receptors in skeletal muscle.

As described subsequently, the β blocking drugs can cause various side effects related to their CNS activity. Theoretically, the most hydrophilic β blockers (e.g., nadolol and atenolol) should have the least access to the CNS and be associated with the lowest occurrence of such CNS effects; studies of atenolol tend to confirm this relationship.[32]

Absorption, Fate, and Excretion

Most clinically approved β blockers are available in oral dosage forms. Esmolol, a selective β_1 receptor antagonist with a very brief duration of action, is limited to intravenous use for the treatment of acute hypertension and to control ventricular rate in patients with supraventricular tachyarrhythmias. Levobunolol and metipranolol are available only in solutions suitable for ophthalmic use. Key features of the pharmacokinetic properties of selected β blockers are summarized in Table 7-1.

In its first pass through the liver, approximately 50% of propranolol is metabolized. The first-pass extraction can vary widely among patients, necessitating individualized dosing regimens. Peak plasma concentrations of propranolol occur approximately 90 minutes after oral administration, with 90% of the drug bound to plasma proteins. The half-life after oral administration is 3 to 5 hours; intravenous administration results in a half-life of 1.5 to 2 hours.[22] Nadolol is unique among currently available drugs because it has an elimination half-life of up to 24 hours. The bioavailability of propranolol and metoprolol may be significantly improved if the drugs are taken after a high-protein meal, presumably because the protein reduces first-pass metabolism of the drugs. To minimize variation in drug effects, the dosing schedule should be consistent regarding meals.

Metabolism of propranolol occurs almost exclusively in the liver, with oxidative reactions involving the benzene ring and the side chain. One metabolite, 4-hydroxypropranolol, is as active as the parent compound.[6] Less than 5% of the administered drug is excreted intact in the urine. As noted in Table 7-1, most of the other β-blocking drugs are excreted more extensively by the kidney than is propranolol.

Therapeutic Uses

A brief discussion of the important therapeutic uses of the β blockers follows. Individual indications are also discussed in Chapters 24, 25, 26, and 28.

Hypertension

As described in Chapter 28, β blockers are used as first-line agents in the treatment of hypertension. Numerous studies have shown these agents to be safe and effective at decreasing the morbidity and mortality associated with elevated blood pressure. The β blockers can be used as monotherapy to control hypertension or used in combination with other drugs, such as diuretics, to produce a more vigorous antihypertensive response. Many of the side effects associated with the use of other antihypertensives, such as Na^+ and water retention or the development of tolerance, do not occur with β blockers. The effects of β blockers on blood triglycerides and glucose metabolism described previously do not preclude their use in patients with hyperlipidemia or diabetes. The only systemic β blockers not approved for use in hypertension are esmolol and sotalol.

Ischemic heart disease

The β blockers are widely used to prevent angina pectoris associated with atherosclerotic coronary artery disease. In this condition, there is an imbalance between the oxygen demand of the myocardium and the ability of the partially occluded coronary arteries to deliver oxygen-rich blood to the myocardial muscle. This imbalance leads to cardiac ischemia and development of the characteristic chest pain of angina pectoris. Two of the major determinants of myocardial work and oxygen consumption—the force and rate of contraction—are decreased by β blockade. Although β blocker–mediated reductions in oxygen consumption are efficacious in reducing the incidence and severity of exertional (classic) anginal attacks, they are not helpful in managing vasospastic (variant) angina.

Post–myocardial infarction

The favorable action on cardiac work and on myocardial oxygen consumption is the reason β blockers are used after myocardial infarction. These drugs can limit the likelihood and reduce the severity of reinfarction. The antiarrhythmic activity of the β blockers may also contribute to reducing mortality rates after myocardial infarction.

Congestive heart failure

In patients with left ventricular dysfunction, various sympathetically mediated reflexes are activated that ultimately contribute to the signs and symptoms of congestive heart failure. These sympathetic reflex responses include increases in circulating catecholamines, angiotensin II formation, and peripheral vascular resistance; activation of hypertrophic growth responses; and activation of myocardial β-adrenergic receptors. These activities impair cardiac performance further, which sets in motion a vicious cycle of increasingly compromised ventricular performance (see Chapter 25). Numerous more recent clinical studies have shown that β blockers decrease the morbidity and mortality rates of congestive heart failure.[13,23] These drugs act at several levels to interrupt the sympathetic nervous system contribution to heart failure.

The β_1-adrenergic receptor–mediated increase in renin secretion is blocked, decreasing circulating concentrations of angiotensin II. Angiotensin II not only has the ability to increase peripheral vascular resistance and promote Na^+ and water retention, but it is also a positive signal for the generation of reactive oxygen species and hypertrophic growth responses. The β_1-adrenergic receptor is also a potent stimulant to the generation of reactive oxygen derivatives and hypertrophic growth. In heart failure, chronic activation of the sympathetic nervous system leads to the desensitization and downregulation of the myocardial β_1-adrenergic receptor. The downregulation of this signaling pathway, a pathway vital to producing increases in contractile force, also contributes to contractile dysfunction and the development of heart failure.

Blocking β_1-adrenergic receptors prevents chronic receptor stimulation and the associated downregulation of the β_1-adrenergic receptor signaling pathway. β Blockers may promote the upregulation of β_1-adrenergic receptor signaling in heart failure. Blockade of the β_1-adrenergic receptor inhibits the generation of reactive oxygen species and hypertrophic growth produced by this receptor system. Bisoprolol, carvedilol, and metoprolol have been shown to decrease mortality and morbidity associated with congestive heart failure.[13] It has also been suggested that carvedilol has antioxidant effects independent of β_1-adrenergic receptor blockade.

Treatment of arrhythmias

The β blockers can be used to treat various supraventricular tachyarrhythmias, including atrial flutter and atrial fibrillation. In treating sinus tachycardia, the β_1-adrenergic receptors in the SA node, whose inhibition slows heart rate, are the major focus of action. In atrial flutter and fibrillation, the β_1-adrenergic receptors in the AV node are the site of action. The slowing of conduction and increased refractory period at the AV node protect the ventricle in these conditions from the excessive stimulation caused by the abnormal atrial depolarizations. Sotalol has antiarrhythmic properties not shared by other β blockers and can be used to treat life-threatening ventricular arrhythmias. Acebutolol can be used to treat premature ventricular contractions. Esmolol has a short plasma half-life, which makes it useful in the acute management of supraventricular tachyarrhythmias.

Other uses

The β blockers can be used to treat pheochromocytoma (administered with an α-adrenergic receptor–blocking drug), thyrotoxicosis, migraine headache (prophylaxis only), glaucoma, hypertrophic subaortic stenosis, stage fright, and tremors and to prevent bleeding episodes associated with esophageal varices. Among the β blockers, propranolol has the largest number of approved uses. Timolol, metoprolol, nadolol, and atenolol can be used to treat migraine headaches. Levobunolol and metipranolol are used exclusively as ophthalmics.

Adverse Effects

Many of the adverse effects of the β blockers (Table 7-2) are logical extensions of their pharmacologic effects, which are caused by blockade of β-adrenergic receptors. These effects are most prominently seen on the heart, smooth muscle, brain, and organs that mediate metabolic responses.[28]

Effects on the heart

As an extension of their actions on SA and AV nodal function, β blockers can induce bradycardia and AV block. The abrupt withdrawal of propranolol has been linked to attacks of angina pectoris, myocardial infarction, and sudden death, especially in patients with angina. The chronic blockade of the β-adrenergic receptor may induce β receptor supersensitivity, which contributes to a rebound exacerbation of these clinical problems.[2] Withdrawal from β blocking drugs should be done slowly, over 1 to 2 weeks. In patients with moderate-severe congestive heart failure, β blockers can precipitate bradyarrhythmias, AV nodal conduction abnormalities, severe ventricular dysfunction, and cardiac failure. The risk is higher in patients with preexisting cardiac disease and in patients who take β blockers with cardiac glycosides or other drugs that also slow pacemaker activity and impair AV nodal conduction velocity. A reduction in myocardial contractility is especially great when β blockers are combined with Ca^{++} channel blockers such as verapamil.

Effects on smooth muscle

Because of the blockade of β_2 receptors in blood vessels, nonselective β blockers tend to reduce adrenergic vasodilator responses of the vasculature to epinephrine. This effect is of little consequence in most patients, even though cold hands and feet may result. In patients with peripheral vascular disease, such as Raynaud's disease, worsening of the condition

is likely, and β blockers, especially nonselective ones, are contraindicated in such patients.

Bronchospasm resulting from blockade of β_2 receptors is apt to occur in patients with chronic obstructive airway diseases such as asthma, chronic bronchitis, and emphysema. Drugs selective for β_1 receptors have less effect than nonselective blockers on bronchial smooth muscle. Nevertheless, the risk of bronchoconstriction with these drugs is still present because of their limited selectivity for the β_1 receptor.

Metabolic effects

In a diabetic patient taking hypoglycemic drugs, the effects of compensatory sympathetic stimulation and epinephrine release resulting from reduced blood glucose concentrations may be blocked in patients receiving β blockers. A common warning sign of hypoglycemia to a diabetic patient is an increase in heart rate. Because this action is largely mediated by the β_1-adrenergic receptor, this early sign of hypoglycemia is blunted by all clinically used β blockers.

Central nervous system effects

Patients receiving β blockers may experience CNS depression, weakness, fatigue, sleep disturbances including insomnia and nightmares, hallucinations, dizziness, and depression of mood.

DRUGS WITH COMBINED α-ADRENERGIC AND β-ADRENERGIC RECEPTOR ANTAGONIST ACTIVITY

Labetalol

Labetalol combines nonselective β blocking properties with α_1-adrenergic antagonism. It is five to seven times more potent at blocking β-adrenergic receptors compared to α_1 receptors. These properties are the result of the different receptor-blocking characteristics of the four isomers that make up the drug formulation. Because of actions at β-adrenergic and α_1-adrenergic receptors, labetalol decreases peripheral resistance and blood pressure. The drug has some direct vasodilatory properties because at least one isomer is a partial agonist at β_2 receptors, and at least one isomer may exert vasodilator properties not mediated by inhibition of adrenergic receptors. Administration of labetalol occasionally causes orthostatic hypotension; however, the use of labetalol is usually not associated with decreased cardiac output, severe bradycardia, or congestive heart failure.

Labetalol can be used orally in the long-term treatment of hypertension or administered intravenously for management of hypertensive emergencies (see Chapter 28). It exhibits near-complete oral absorption. Extensive first-pass metabolism significantly decreases the amount of drug that reaches the systemic circulation, however. The adverse effects seen with labetalol are predictable considering the drug is a nonspecific β blocker and an α_1 receptor blocker. Untoward reactions associated with β receptor blockade include bradycardia and AV block, complications in asthmatic and diabetic patients, airway dysfunction, sedation, fatigue, and other CNS manifestations.

Carvedilol

Carvedilol, a racemic mixture of two isomers, is the second drug to be marketed with α_1 and β blocking activities. In contrast to labetalol, carvedilol is without ISA. Carvedilol is also much more selective for β-adrenergic receptors than labetalol. Carvedilol was initially approved for use as an antihypertensive (because of its ability to block α_1 and β receptors), but more recent clinical studies have shown that it is particularly useful in decreasing morbidity and mortality associated with congestive heart failure.[13] The pharmacologic actions that make carvedilol useful in treating heart failure are probably the result of blockade of both α_1-adrenergic and β-adrenergic receptors. The beneficial effects of β receptor blockade in heart failure have been previously discussed. The vasodilatory actions of carvedilol that occur as a result of α_1 receptor blockade decrease peripheral resistance and, as a result, the workload of the heart. There is also evidence that carvedilol exerts antioxidant activity and acts as a free radical scavenger, which could provide benefit in patients with heart failure.[12] Similar to labetalol, carvedilol is metabolized in the liver and undergoes extensive first-pass metabolism. The adverse effects of carvedilol are similar to the adverse effects observed with labetalol.

DRUGS THAT REDUCE SYMPATHETIC OUTFLOW

Centrally Acting Adrenergic Agonists

Several drugs, including methyldopa, clonidine, guanabenz, and guanfacine, inhibit sympathetic outflow through actions within the CNS. These drugs are actually α_2-adrenergic agonists and are discussed in Chapter 6. They interfere with sympathetic nervous system activity by stimulating regulatory α_2 receptors in the CNS. These drugs have largely been supplanted as antihypertensives by safer, more effective therapeutic entities. Clonidine does have clinical uses not associated with cardiovascular therapeutics. Some of the major adverse effects of these drugs are summarized in Table 7-2. The use of drugs that reduce sympathetic outflow from the CNS in the treatment of hypertension is discussed in Chapter 28.

Monoamine Oxidase Inhibitors

MAO inhibitors are capable of inhibiting the intracellular enzyme responsible for inactivation of norepinephrine. By poorly understood mechanisms, MAO inhibitors reduce systemic arterial blood pressure. One such drug, pargyline, was specifically marketed for the treatment of essential hypertension. Currently, MAO inhibitors are occasionally used to treat depression (see Chapter 12). The risks of MAO inhibitor therapy in the treatment of hypertension outweigh its benefits, and its use as an antihypertensive drug is rare.

The most frequent adverse effects are those associated with other adrenergic neuron blocking drugs and with ganglionic blocking drugs, including orthostatic hypotension, dizziness, weakness, xerostomia, and syncope. Tremors and hallucinations have also been reported. Difficulties in micturition and ejaculation are also experienced. Most serious is the hypertensive crisis that can occur after eating or drinking foodstuffs containing substantial amounts of tyramine. Aged cheese, liver, beer, and wines are among the most common of these tyramine-containing foods. Hypertension is the result of three factors: (1) the metabolism of tyramine by MAO that would normally occur in the gastrointestinal tract is blocked by the MAO inhibitors; (2) tyramine is an indirect-acting amine, and causes release of neurotransmitter from the cytoplasmic pool of adrenergic nerve endings; and (3) large amounts of the transmitter accumulate in the cytoplasmic pool of adrenergic nerve endings as a result of the inhibition of MAO. In addition to the typical symptoms of acute hypertension (throbbing headache, flushing, and hyperpyrexia), cerebrovascular accidents and occasionally deaths have occurred.[24] The use of drugs that release catecholamines should be scrupulously avoided with MAO inhibitors. Amphetamines and drugs with mixed sympathomimetic actions such as ephedrine and mephentermine are absolutely contraindicated. The use of the analgesic meperidine is contraindicated in patients

taking MAO inhibitors because a syndrome of CNS excitation, hyperthermia, and convulsions may commonly result. Opioid analgesics unrelated to meperidine (e.g., morphine) should be used cautiously because MAO inhibitors tend to increase the CNS depression from many opioid analgesics and sedatives.

IMPLICATIONS FOR DENTISTRY

Many of the drugs discussed in this chapter are widely used to treat hypertension, ischemic heart disease, congestive heart failure, and cardiac rhythm disturbances. In their daily practices, dental practitioners are likely to encounter patients taking one or more of these drugs. Dentists must pay heed to the potential risks associated with these pathologic conditions and the therapeutic agents used to manage them.

Physical Implications

A consideration for patients being treated with certain sympatholytics is the patient's position during and after dental procedures. Suddenly standing upright after being in a supine position in the dental chair is apt to cause syncope. This problem is particularly likely for the antihypertensive drugs more prone to cause orthostatic hypotension (e.g., α_1-adrenergic receptor blocking drugs and drugs with combined α blocking and β receptor–blocking activity). Accidents ranging from chipped teeth and restorations to fractured mandibles and worse have resulted from falls. Contemporary practice standards require the measurement of blood pressure in dental patients. Blood pressure monitoring is particularly important in hypertensive patients.

Drug Interactions

Because nonselective β blockers inhibit β_2-adrenergic receptor–mediated vasodilation, there is a risk of a hypertensive episode after administration of local anesthetic agents that contain vasoconstrictors.[33] In this situation, the vasoconstrictor actions of epinephrine at α adrenergic receptors are not opposed by the vasodilator actions of β_2-adrenergic receptors, resulting in an exaggerated increase in blood pressure that could be deleterious in patients with hypertension or ischemic heart disease.

Clonidine is well known to cause xerostomia. The use of clonidine-like drugs may result in clinical symptoms related to dry mouth, such as difficulty in swallowing and speech. Long-term use of xerostomia-causing drugs is associated with a higher incidence of oral candidiasis and dental caries. The use of β-adrenergic receptor blockers is likely to alter the composition of salivary proteins. The effects of these changes have not been fully explored; however, there is a concern that they could adversely influence oral health. The effect of drugs that alter the function of adrenergic nerve endings on salivary proteins is also not well explored.

Patients taking MAO inhibitors must not be given drugs that have indirect sympathomimetic activity or are inactivated by MAO. Epinephrine, used in local anesthetic solutions, is not contraindicated because it is a direct agonist and largely inactivated by catechol-O-methyltransferase. Levonordefrin may be used for similar reasons. Nonetheless, in patients taking MAO inhibitors, the avoidance of hemostatic preparations containing high concentrations of epinephrine is recommended.

Opioids and other CNS depressants should be used cautiously, and usually at lower doses in patients who are taking MAO inhibitors. Meperidine is absolutely contraindicated. The dentist should reinforce the physician's instructions to the patient about dietary restrictions and contraindications of several drugs for patients taking MAO inhibitors.

ADRENERGIC ANTAGONISTS

Nonproprietary (generic) name	*Proprietary (trade) name*
α-Adrenergic receptor blockers (selectivity)	
Alfuzosin (α_1)	Uroxatral
Doxazosin (α_1)	Cardura
Phenoxybenzamine (α_1, α_2)	Dibenzyline
Phentolamine (α_1, α_2)	Regitine, OraVerse
Prazosin (α_1)	Minipress
Tamsulosin (α_{1A})	Flomax
Terazosin (α_1)	Hytrin
β-Adrenergic receptor blockers (selectivity)	
Acebutolol (β_1)	Sectral
Atenolol (β_1)	Tenormin
Betaxolol (β_1)	Betoptic, Kerlone
Bisoprolol (β_1)	Zebeta
Carteolol (β_1, β_2)	Cartrol
Esmolol (β_1)	Brevibloc
Levobunolol (β_1, β_2)	AKBeta, Betagan
Metipranolol (β_1, β_2)	OptiPranolol
Metoprolol (β_1)	Lopressor, Toprol XL
Nadolol (β_1, β_2)	Corgard
Nebivolol (β_1)	Bystolic
Penbutolol (β_1, β_2)	Levatol
Pindolol (β_1, β_2)	Visken
Propranolol (β_1, β_2)	Inderal
Sotalol (β_1, β_2)	Betapace
Timolol (β_1, β_2)	Blocadren
Combined α- and β-adrenergic receptor blockers	
Carvedilol (β_1, β_2, α_1)	Coreg
Labetalol (β_1, β_2, α_1)	Trandate, Normodyne

CHAPTER 8

Cholinergic Drugs

FRANK J. DOWD

Cholinergic drugs are agents that mimic the actions of the endogenous neurotransmitter acetylcholine (ACh). As described in Chapter 5, ACh is the primary neurotransmitter released from the nerve terminals of the preganglionic fibers of the parasympathetic and sympathetic nervous systems, the postganglionic fibers of the parasympathetic nervous system (which include most of the postganglionic cholinergic neurons), and some postganglionic fibers of the sympathetic nervous system (mostly fibers to the sweat glands). ACh is also the primary neurotransmitter released from somatic efferents innervating skeletal muscle and from certain central nervous system (CNS) neurons.

Most cholinergic, or cholinomimetic, agonists produce parasympathetic responses by stimulating muscarinic receptors located on tissues innervated by the postganglionic fibers of the parasympathetic nervous system. These drugs are often referred to as *muscarinic* or *parasympathomimetic agonists*. Some cholinergic agonists produce a nonselective stimulation of the parasympathetic and sympathetic branches of the autonomic nervous system by activating ganglionic nicotinic receptors located on the cell bodies of postganglionic fibers. In addition, some cholinergic agonists excite skeletal muscle by activating a separate group of nicotinic receptors located on the motor end plate of the neuromuscular junction. The synapses in the CNS that contain nicotinic and muscarinic receptors can be stimulated by cholinomimetic agonists capable of penetrating the blood-brain barrier.

Drugs that inhibit the hydrolysis of ACh by the enzyme acetylcholinesterase (AChE) produce their cholinomimetic effects indirectly. These anticholinesterases prolong the effective life of ACh released at neuroeffector junctions. As a group, the anticholinesterases are less selective in effect than many direct-acting cholinomimetics, and they are largely without activity in denervated tissues. Nevertheless, their dependence on ACh release confers the potential advantage of retaining neural control over their effects.

CHOLINOMIMETIC AGONISTS

The cholinomimetic agonists directly stimulate cholinergic receptors—muscarinic or nicotinic or both—to cause a pharmacologic response in an effector. These cholinergic drugs are classified into two groups on the basis of their origin and chemical composition: choline esters, which include ACh and its synthetic congeners, and the naturally occurring alkaloids and their congeners, including muscarine, pilocarpine, cevimeline, and nicotine. With few exceptions (e.g., nicotine), all these agents exert prominent parasympathomimetic effects.

Chemistry and Classification

Choline esters

The history of the discovery of ACh and its identification is described in Chapter 5. In 1909, Hunt synthesized the acetyl ester of choline, and earlier Hunt and Taveau[16] reported on the pharmacology of many synthetic congeners of ACh. Interest in the choline esters arose partly out of the hope that some of these compounds would have a longer duration of action than ACh and, at the same time, a greater degree of selectivity. This goal has not been realized completely, and ACh and related drugs generally either are not used therapeutically or are used only in selected instances. The structures of ACh and the three principal synthetic esters of choline—methacholine, carbachol, and bethanechol—are shown in Figure 8-1. Succinylcholine, a diacetylcholine derivative with selective nicotinic receptor effects in skeletal muscle, is discussed in Chapter 10.

Natural alkaloids and congeners

Several alkaloids obtained from various plants possess direct cholinomimetic activity. Muscarine, the prototype muscarinic agonist, is present during certain times of the year in the mushroom *Amanita muscaria* and is especially prominent in several *Inocybe* and *Clitocybe* species. Although a quaternary ammonium compound (Figure 8-2), muscarine has a rapid onset of action after oral ingestion and produces physiologic responses characteristic of profound parasympathetic nervous system stimulation. In severe poisoning, cardiovascular collapse may occur. Pilocarpine is found in the leaves of the South American shrub *Pilocarpus jaborandi*. It is also a selective muscarinic receptor agonist. Pilocarpine remains in the therapeutic armamentarium for a few specific indications and has a specific dental indication. Cevimeline, a synthetic agent, is similar in pharmacology to pilocarpine. Arecoline is the primary alkaloid of betel nuts. It is a euphoretic and stimulates muscarinic and ganglionic nicotinic receptors. Nicotine, an alkaloid found in tobacco leaves (*Nicotiana tabacum*), is important historically as the prototype nicotinic receptor agonist. In the form of cigarettes, nicotine is the most commonly used cholinergic agonist, and it is responsible for the physical dependence associated with smoking. This drug and other drugs selective for nicotinic receptors are discussed in Chapter 10.

Mechanism of Action

Direct-acting cholinomimetic drugs produce their effects by binding to and stimulating muscarinic and nicotinic receptors. As noted previously, these receptors are located in junctional regions of the peripheral nervous system and the CNS. ACh is capable of stimulating muscarinic and nicotinic receptors

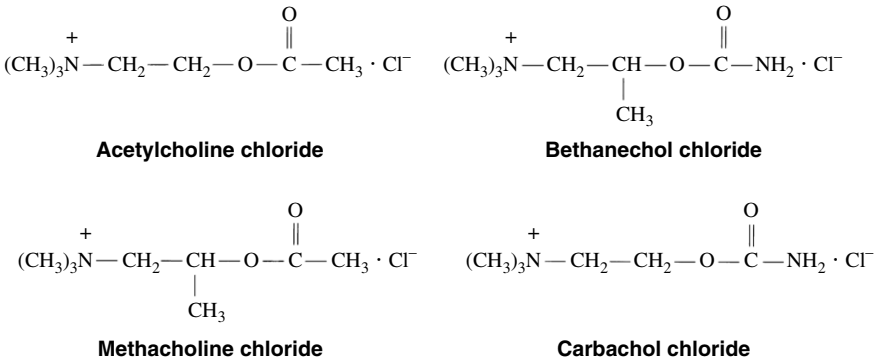

FIGURE **8-1** Structural formulas of acetylcholine and three congeners.

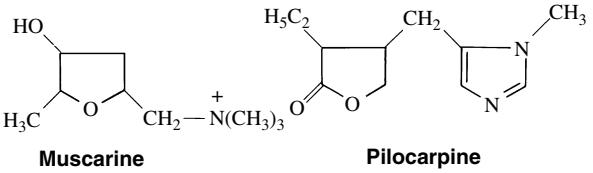

FIGURE **8-2** Structural formulas of muscarine and pilocarpine.

when administered systemically; although muscarinic responses are produced by low doses of ACh, effects on ganglionic and somatomotor transmission require increasingly higher doses. The choline ester bethanechol and the plant alkaloid muscarine produce a relatively selective activation of muscarinic receptors located on autonomic effector tissues (especially in smooth muscle and glandular tissues) and on the cell bodies of unique populations of CNS neurons. Although these muscarinic agonists produce qualitatively similar responses in different organ systems, they vary in their relative potencies in evoking these reactions.

Parasympathomimetic responses to cholinergic drugs are mediated by the stimulation of several populations of muscarinic receptors. A total of five muscarinic receptor proteins (m_1 through m_5, corresponding to the pharmacologically identified receptors M_1 through M_5) have been produced from cloned muscarinic receptor genes, and it has been established that multiple receptor subtypes can coexist in the same organ or tissue. The exact distribution of these receptors and their functional properties are currently areas of active investigation, but a few general concepts have emerged. In the periphery, the M_1 receptor seems to be localized in ganglia, some exocrine gland cells, and the enterochromaffin cells of the stomach (see Chapter 33). The M_2 receptor is the primary subtype found in the heart and is present, along with the M_4 receptor, in the lung. The M_3 receptor is widely distributed and is most prominent in glandular tissue. Although a peripheral distribution of the M_5 receptor has not been identified, it is expressed, as are the other subtypes, in discrete regions of the CNS.

Muscarinic receptors belong to a large family of plasma membrane receptors whose basic structure consists of seven helical segments spanning the membrane and joined by alternating intracellular and extracellular peptide bridges (see Chapter 1). Although the hydrophobic helical segments, which form the ligand-binding site, show considerable structural homology among the muscarinic receptor subtypes, the third intracellular loop, joining helices V and VI, is highly divergent. Biochemical studies suggest that this loop is of primary importance in the coupling between receptor binding and intracellular action.

Stimulation of muscarinic receptors initiates a cascade of intracellular events that ultimately leads to the observed pharmacologic effects. Evidence to date suggests that all muscarinic receptor subtypes regulate the activity of G proteins (see Chapter 5). The G proteins modulate intracellular processes by influencing "second messenger" systems. Agonist-induced activation of M_1, M_3, or M_5 receptors stimulates the enzyme phospholipase C, which produces Ca^{++}-dependent phosphorylation of specific cellular regulatory proteins. The stimulation of M_2 or M_4 receptors inhibits the activity of adenylyl cyclase, decreasing the intracellular concentration of cyclic adenosine 3′,5′-monophosphate. In the heart, this outcome of M_2 receptor activation results in increased K^+ efflux and reduced Ca^{++} influx, leading to characteristic muscarinic receptor–induced changes in cardiac function (see later). The activation of M_2 receptors on the intact vascular endothelium produces a profound vasodilation by stimulating the production and release of nitric oxide, an important endothelium-derived relaxing factor (Figure 8-3).[13,17] Nitric oxide stimulates guanylyl cyclase located in vascular smooth muscle, which catalyzes the formation of cyclic guanosine 3′,5′-monophosphate. This cyclic nucleotide reduces intracellular Ca^{++} concentrations, leading to vascular smooth muscle relaxation and vasodilation. The effect of agonists on the muscarinic receptors of endothelial cells accounts for the vasodilation when these drugs are administered systemically, especially intravenously. This vasodilation occurs despite the lack of nerve innervation to these receptors on endothelial cells.

The systemic administration of high doses of ACh activates nicotinic receptors located on the cell bodies of postganglionic nerve fibers of the autonomic nervous system (N_N receptors) and nicotinic receptors located in the neuromuscular junction (N_M receptors). As described in Chapter 5, nicotinic receptors are composed of five glycoprotein subunits forming a rosette around a central channel spanning the plasma membrane. The α subunits (see also Figure 1-2) contain the ACh-binding sites. When stimulated by ACh, nicotine, or another nicotinic receptor agonist, a conformational change in the protein occurs, allowing Na^+ and, to a lesser extent, Ca^{++} ions to move down their respective concentration gradients. The net ionic movement depolarizes the postganglionic cell body or muscle end plate. Prolonged stimulation of nicotinic receptors with ACh or nicotine results in a phenomenon referred to as "depolarization blockade," in which responses to further stimulation are attenuated and then lost (see Chapter 10).

Pharmacologic Effects

The pharmacologic effects produced by direct-acting cholinergic drugs vary according to the receptors they stimulate, their distribution throughout the body, and their mode of

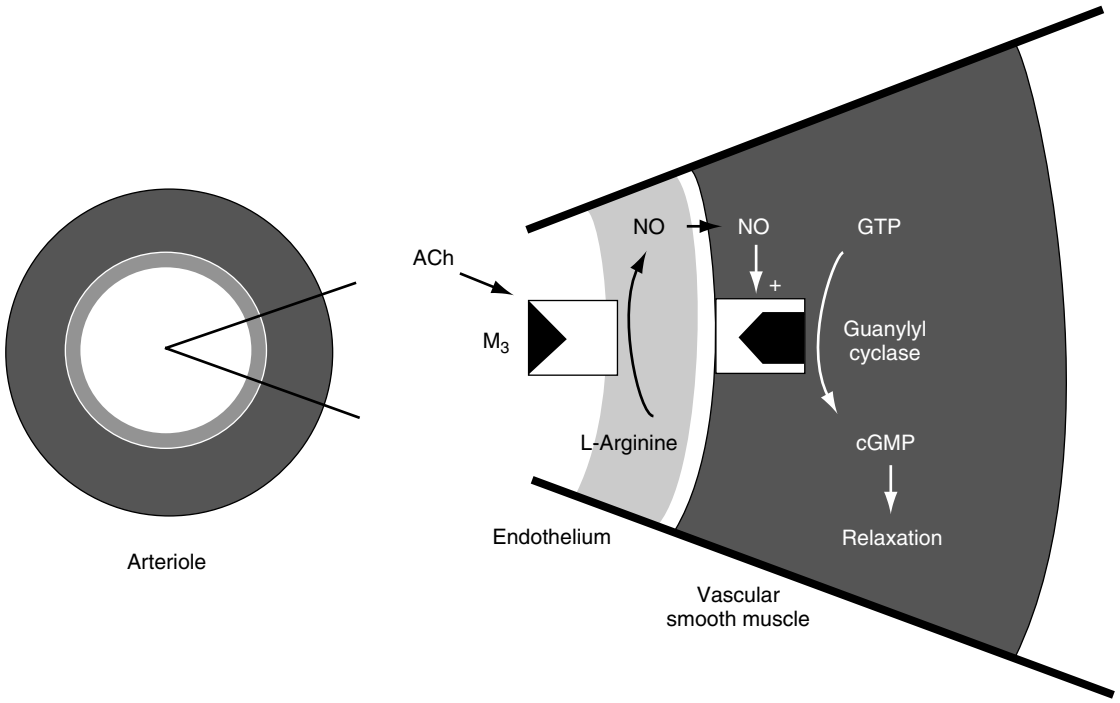

FIGURE **8-3** Mechanism of vascular relaxation by muscarinic receptor agonists. The muscarinic agent acetylcholine (*ACh*) binds to its receptor (M_3) on the intact vascular endothelium. Newly synthesized nitric oxide (*NO*) diffuses into the vascular smooth muscle, where it stimulates the formation of cyclic guanosine 3′,5′-monophosphate (*cGMP*) from guanosine triphosphate (*GTP*).

inactivation. The duration of action of ACh and its congeners is determined by their susceptibility to hydrolysis by AChE and pseudocholinesterase. Methacholine, with some susceptibility only to AChE, has a longer duration of action than ACh. Bethanechol, carbachol, cevimeline, and the natural alkaloids are not affected by the cholinesterases at all and also have longer durations of action than ACh.

Currently available agents exhibit significantly different affinities for muscarinic and nicotinic sites, so that carbachol has more pronounced nicotinic effects than ACh, and bethanechol, muscarine, pilocarpine, and cevimeline have very few nicotinic properties. Differences in effect are also noted regarding various target tissues. Bethanechol and carbachol are very effective stimulants of the gastrointestinal and urinary tracts, whereas ACh and methacholine exert more prominent cardiovascular effects. Some of the limitations of injected ACh arise because the drug is so quickly metabolized that it gains little access to tissues that are not well perfused.

Peripheral muscarinic effects

Cholinergic agonists that stimulate muscarinic receptors produce end-organ responses that mimic parasympathetic nervous system stimulation. Table 5-1 outlines several of the physiologic responses produced by direct electric stimulation of parasympathetic nerves. The following discussion of the specific muscarinic effects of the cholinergic drugs is limited to actions that have some therapeutic application or toxicologic importance; not all of the cholinergic drugs possess all these actions.

Eye. Muscarinic receptor agonists activate the sphincter muscle of the iris and produce constriction of the pupil (miosis). At the same time, there is contraction of the ciliary muscle, so the eye is focused for near vision. Intraocular pressure is decreased, particularly if the tension was elevated initially. There may also be a transient hyperemia of the conjunctiva.

Heart. Direct cardiac effects are similar to the effects associated with vagal stimulation. The heart rate is decreased by drug-induced slowing of the spontaneous depolarization of the sinoatrial node (negative chronotropic effect). There is also a decrease in the force of contraction (negative inotropic effect) of atrial and, to a much lesser extent, ventricular muscle. Although the effective refractory period is shortened in atrial muscle, the refractory period in the atrioventricular node and conducting system of the heart is increased, and conduction is slowed.

These direct effects on the heart are subject to autonomic modification. A baroreceptor-mediated increase in sympathetic nervous system activity may occur if the muscarinic drug produces a significant decrease in blood pressure. In a patient receiving the muscarinic blocking drug atropine, a dose of a cholinergic drug great enough to activate nicotinic receptors in autonomic ganglia and the adrenal gland will promote the release of catecholamines and result in cardiac stimulation.

Vascular smooth muscle. Muscarinic receptor agonists produce a generalized vasodilation that causes a decrease in blood pressure. All vascular beds are affected, which is consistent with pharmacologic evidence that all parts of the vasculature, including pulpal blood vessels, are supplied with muscarinic receptors. The physiologic significance of these receptors is still in doubt, however, partly because much of the vasculature receives no parasympathetic innervation. In the absence of an administered drug, it is likely that vasodilation in local tissues occurs most often in response to autoregulatory factors, such as high carbon dioxide concentrations, low oxygen concentrations, and an acidic pH, and not to stimulation of cholinergic nerves. ACh produced and released locally may facilitate vasodilation in response to local blood flow increases. As noted previously, muscarinic receptor agonists produce their vasodilatory effects by inducing the

vascular endothelium to release nitric oxide into the surrounding vascular smooth muscle, where it produces muscle relaxation.[13,17]

Bronchial smooth muscle. The smooth muscle of the bronchioles is constricted by muscarinic receptor agonists.

Gastrointestinal smooth muscle. Motility, peristaltic contractions, amplitude of contraction, and tone all are increased by muscarinic receptor agonists. Conversely, sphincter muscles are relaxed.

Secretory glands. All glands that are innervated by cholinergic fibers are potentially stimulated by cholinergic drugs, including the salivary, lacrimal, bronchial, sweat, gastric, intestinal, and pancreatic glands. The secretion by sweat glands is controlled by sympathetic nerves, which in this case have cholinergic postganglionic fibers.

Urinary tract. Muscarinic receptor agonists stimulate contraction of the detrusor muscle, which results in decreased bladder capacity and opening of the urethral orifice in the fundus of the bladder. (Micturition is permitted by voluntary relaxation of the urethral sphincter.) Peristaltic activity in ureteral smooth muscle may also be stimulated.

Peripheral nicotinic effects

Several cholinomimetic drugs can stimulate nicotinic receptors. Nicotinic receptor agonists have varying effects at different nicotinic sites; these effects are related to the structure of the molecule,[3] the dosage of the drug, and the location and type of nicotinic receptor activated. As noted earlier, there are at least two major kinds of peripheral nicotinic receptors: those on ganglia (N_N) and those in skeletal muscle (N_M). Although exogenous ACh at low doses stimulates muscarinic receptors selectively, in substantially higher doses it stimulates N_N receptors and, by close intra-arterial injection of high doses, N_M receptors. Carbachol has substantial nicotinic properties at therapeutic doses. Its affinity for nicotinic receptors is higher than that for muscarinic receptors. There is evidence that carbachol not only occupies the postsynaptic cholinergic receptor but also causes the release of ACh from nerve terminals in certain locations by activating presynaptic nicotinic receptors. Muscarinic effects are obtained indirectly through increased ACh release at parasympathetic ganglia and muscarinic neuroeffector sites. Although pilocarpine is essentially muscarinic in action, it has been reported to produce ganglionic stimulation in high doses.

Stimulation of autonomic ganglia leads to a mixture of parasympathetic and sympathetic effects. Because these effects often oppose each other, the resultant outcome is often difficult to predict. In the case of ACh and carbachol, which also exert prominent muscarinic activity, parasympathetic effects predominate; this is likely due to the fact that these drugs have a more difficult time gaining access to nicotinic receptors. The pharmacology of nicotine, which is devoid of direct muscarinic properties, is reviewed in Chapter 10. None of these agents produces clinically useful skeletal muscle stimulation.

Central nervous system effects

As previously mentioned, there are muscarinic and nicotinic receptors in the CNS. ACh, the choline esters, and the cholinomimetic alkaloids all are known to evoke CNS actions when applied directly to brain tissue. Central cholinergic systems have been implicated in central regulation of most physiologic systems (i.e., cardiovascular, respiratory, gastrointestinal, and somatomotor systems) and influence cognition and emotion. The observation that cholinergic agonists affect so many functions indicates that cholinergic receptors play an important role in central neurotransmission. In the intact individual, many cholinergic agents are excluded from the CNS, however, because of their quaternary ammonium constituents. The fact that these drugs may still produce behavioral arousal responses is probably the result of their peripheral influences, which lead to changes in sensory inputs conducted to the brain by visceral afferent fibers.

Absorption, Fate, and Excretion

All the previously discussed cholinergic receptor agonists are absorbed after administration by oral and parenteral routes, although absorption of the quaternary ammonium compounds from the gastrointestinal tract is likely to be unpredictable. Parenteral administration of the choline esters must be done with extreme caution because of the profound effects they may have on cholinergic effectors. ACh is rapidly destroyed by AChE and pseudocholinesterase and exerts an effect measured in seconds if given by bolus intravenous injection. Methacholine, more slowly metabolized than ACh by AChE and immune to pseudocholinesterase, is longer in duration of action. For all practical purposes, carbachol and bethanechol are not affected by the cholinesterases, so they have a much longer duration of action and the potential for producing widespread and prolonged cholinergic effects.

Pilocarpine is well absorbed after oral, subcutaneous, or topical administration. It also gains ready access to the CNS, and it is well distributed through the tissues and organs of the body. A large fraction is excreted unchanged by the kidneys, with an elimination half-life of 0.75 to 1.5 hours. Cevimeline is also well absorbed after oral administration, with peak blood concentrations occurring in 1.5 to 2 hours. Most of the drug is metabolized to sulfoxides and glucuronic acid conjugates, with an elimination half-life of about 5 hours.

Adverse Effects

Generally, adverse reactions to the cholinomimetic drugs are predictable consequences of the stimulation of cholinergic receptors. Patients with increased risk of adverse responses include patients with asthma, cardiovascular disease, and peptic ulcer. Untoward reactions may include a response profile that many autonomic pharmacologists refer to as the *SLUD* response (*s*alivation, *l*acrimation, *u*rination, and *d*efecation). In addition to the SLUD response, muscarinic receptor agonists can produce bronchospasm, hypotension, and arrhythmias. Hypertensive responses to pilocarpine and cevimeline may occur with parenteral injection of large doses; this seemingly atypical effect is the result of sympathetic ganglionic stimulation caused by activation of excitatory muscarinic receptors on postganglionic neurons. Intravenous and intramuscular injection is generally avoided because of the increased possibility for producing cardiopulmonary reactions; toxic reactions generally are reduced by the restricted and often topical use of these agents.

The mushrooms *Amanita pantherina* and *Amanita muscaria* contain muscarine but in amounts that are probably too small to account for the symptoms of poisoning that result from their ingestion. The mushroom *Inocybe lateraria*, with a much higher muscarine content, produces signs and symptoms of intoxication that resemble those produced by muscarine, including profuse salivation and sweating; miosis; bradycardia; severe abdominal pain with vomiting, cramps, and diarrhea; and respiratory difficulties arising from the constriction of bronchial muscle and increased secretion in the respiratory tract. The onset of poisoning is rapid, and treatment consists of the administration of atropine in large quantities, gastric lavage, and appropriate supportive measures. Recovery usually occurs in 1 or 2 days. In many cases of mushroom poisoning, there are delayed symptoms, including violent emesis and diarrhea and damage to parenchymatous

organs (principally the liver), which are not amenable to atropine treatment and are produced by a group of cyclopeptide toxins from the mushroom that inhibit the synthesis of messenger ribonucleic acid.[2]

ANTICHOLINESTERASES

Anticholinesterases are drugs that stimulate cholinergic transmission indirectly by inhibiting the enzyme AChE, which hydrolyzes and inactivates ACh in the synaptic clefts of the autonomic nervous system, the CNS, and the neuromuscular junction of the somatic nervous system. Agents in this class derive their pharmacologic effects from their ability to prolong the life of ACh at receptor sites. These cholinesterase inhibitors are sometimes referred to as indirect-acting cholinergic drugs.

Anticholinesterases can be subclassified as either reversible or irreversible cholinesterase inhibitors. Reversible inhibitors (e.g., edrophonium, neostigmine, and physostigmine) temporarily inactivate the enzyme by forming noncovalent associations with the enzyme or covalent bonds that are readily hydrolyzed. Irreversible cholinesterase inhibitors (organophosphates) inactivate the enzyme by forming a permanent covalent bond with the enzyme.

Physostigmine, or eserine, the earliest known anticholinesterase, has a colorful history. An alkaloid, it is derived from a bean, or nut, known as the Calabar, ordeal, or Esére bean, and it was used in witchcraft trials by certain native tribes in West Africa. The bean was brought to England by a British medical officer stationed in Calabar in the mid-1800s, and its pharmacologic properties were investigated in numerous laboratories, including those of Fraser, who studied its toxicity in the 1860s and noted that its actions were antagonized by atropine. In 1877, physostigmine was used for the treatment of glaucoma, which remains one of its principal uses today. In 1914, noting the extreme brevity of the action of ACh, Dale[8] suggested that an enzyme capable of destroying ACh must exist in the body, and in 1930 it was found that physostigmine could prevent the rapid destruction of ACh.[10]

By the 1930s, the chemical structure of physostigmine had been elucidated, a series of synthetic analogues had been synthesized, and several researchers had reported independently that the derivative neostigmine was effective in the treatment of myasthenia gravis (MG).[23,27] Until the basic mechanism of neurohumoral transmission was elucidated, however, it was not understood that these drugs acted therapeutically as anticholinesterases.

The first organophosphate anticholinesterase was synthesized in 1854, before physostigmine was known, by de Clermont, who made and tasted tetraethyl pyrophosphate (and survived to record the fact). Modern interest in these compounds did not begin until 1932, when Lange and von Krueger[18] synthesized some compounds with a phosphorofluoride linkage and gave a remarkable description of the pharmacologic properties of this group of chemicals. Lange believed that these compounds would prove useful as insecticides, and he offered them to the I.G. Farben Company in Germany. It was some years before this company took an active interest, but they soon realized the potential of these compounds as chemical warfare agents. The manufacture of nerve gas began in Germany in 1940. Related investigations were being carried out in England at the same time, and in the United States diisopropyl fluorophosphate was being studied during World War II. (This agent has been given the official name of isoflurophate.) Two compounds developed by the Germans, tabun and sarin, are among the most toxic nerve gases known. Of the thousands of organophosphates that have been tested, several dozen are widely available as insecticides, and many others have military implications as lethal nerve gases.

Chemistry and Classification

Reversible anticholinesterases include the truly reversible non-ester quaternary ammonium compounds and the esters of carbamic acid, which react covalently with the enzyme surface. The carbamoylated enzyme is regenerated by hydrolysis in about 30 minutes; the continued presence of the anticholinesterase yields a duration of action of several hours. The reversible anticholinesterases may be classified as simple quaternary ammonium compounds (edrophonium) or carbamate ester derivatives, including tertiary amines (physostigmine), quaternary amines (neostigmine), and bisquaternary amines (ambenonium). Three representative reversible anticholinesterases are shown in Figure 8-4.

Irreversible anticholinesterases are organophosphates that result in a phosphorylated enzyme not significantly regenerated by hydrolysis. They have limited therapeutic value, but are of great toxicologic significance. Four examples include (1) isoflurophate, the best known and studied compound of this class; (2) malathion, a widely used insecticide; (3) echothiophate, one of the first compounds in this class to have a therapeutic application; and (4) tabun, one of the most potent and toxic nerve gases. Structures of several irreversible anticholinesterases are shown in Figure 8-5. The anticholinesterases are classified according to their uses in Table 8-1.

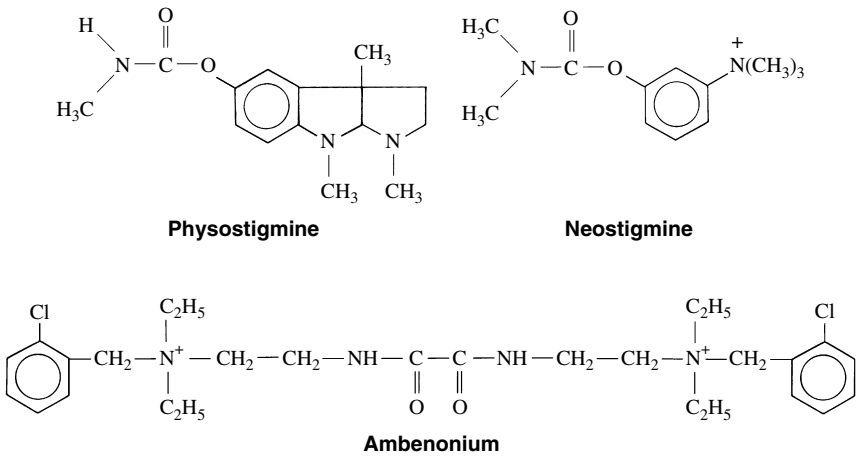

FIGURE **8-4** Representative reversible anticholinesterases.

TABLE **8-1**

Uses of Anticholinesterases

USE	DRUGS
Treatment of glaucoma	Demecarium, echothiophate, physostigmine
Treatment of myasthenia gravis	Ambenonium, edrophonium,* neostigmine, pyridostigmine
Treatment of Alzheimer's disease	Donepezil, galantamine, rivastigmine, tacrine
Reversal of nondepolarizing muscle relaxants	Edrophonium, neostigmine, pyridostigmine
Nerve gas	Sarin, soman, tabun
Insecticides (organophosphates)	Malathion, paraoxon, parathion
Insecticides (carbamates)	Aldicarb, carbaryl, propoxur

*Diagnostic purposes only.

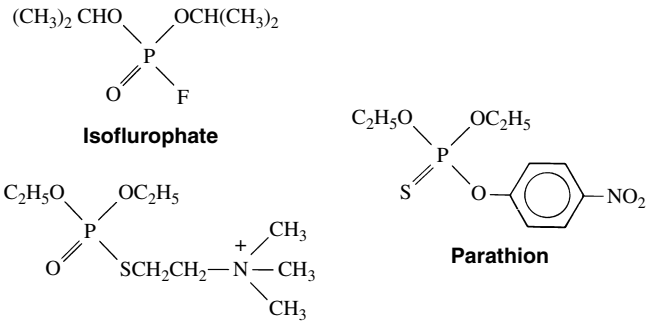

FIGURE **8-5** Representative irreversible anticholinesterases.

Mechanism of Action

In Chapter 5, it is pointed out that AChE hydrolyzes ACh with great rapidity, that the enzyme is localized in the region of the receptor, and that it acts most efficiently when ACh is present in low concentrations. There is also a nonspecific plasma cholinesterase, or pseudocholinesterase (butyrylcholinesterase), which has a greater affinity for butyric esters than for acetyl esters and is more effective when the concentration of ACh and other esters is high.

AChE is composed of protein units that have an individual molecular weight of 70,000 Da. The enzyme exists in synaptic plasma membranes in the form of simple oligomers (single units, dimers, and tetramers). A much larger configuration, present in the outer basal lamina of the synapse (and especially evident in the neuromuscular junction), has tetramers of the catalytic unit attached to a specific collagen (collagen Q) through disulfide linkages to yield a filament 50 nm in length and weighing 106 Da.[22] Clusters of these structures form complex associations with various proteins on the cell surface.

The ACh molecule reacts with the enzyme AChE at two primary sites; these sites are shown, with ACh and several anticholinesterases, in Figure 8-6. AChE is depicted as having a choline-binding site, to which the quaternary ammonium portion of the ACh molecule is attracted, and an esteratic site, with an affinity for the ester portion of the molecule.[26] It is at the esteratic site that the ACh molecule is split, leaving the acetylated enzyme, which is rapidly regenerated by combination with water. The organophosphate anticholinesterases have an affinity chiefly for the esteratic site of the AChE molecule. They produce a very stable covalent attachment; there is virtually no hydrolysis with many of these compounds, and cholinesterase activity remains depressed until new enzyme is synthesized. Because enzyme turnover may take several weeks, the organophosphates are referred to as irreversible in action.

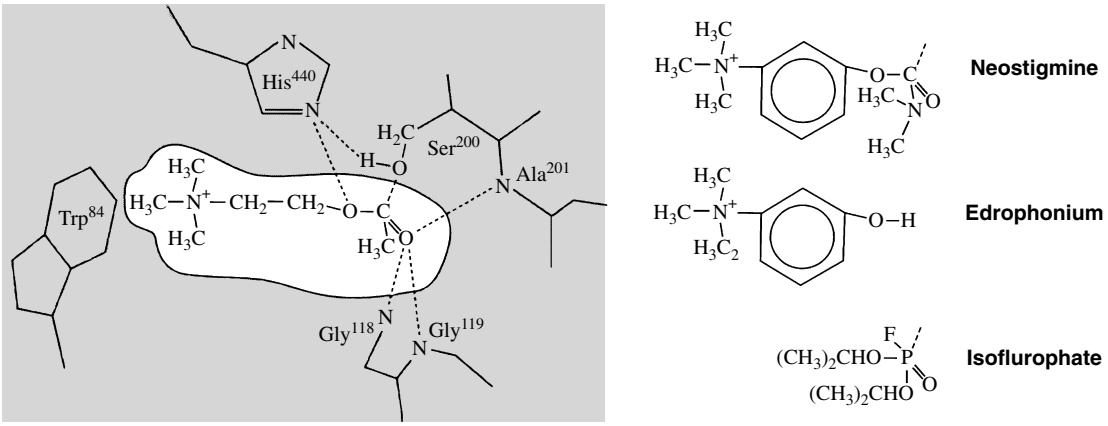

FIGURE **8-6** Interaction between acetylcholine and three anticholinesterases with acetylcholinesterase. The positive charge of the quaternary ammonium group of acetylcholine is attracted to the choline-binding site of acetylcholinesterase by the π electrons of surrounding aromatic amino acids, including the tryptophan (*Trp*^{84}) shown in the illustration. Hydrophobic interactions strengthen the binding of the choline moiety. A covalent attachment occurs with the serine (*Ser*^{200}) residue at the esteratic site. As a result, choline is split off, and the enzyme is briefly acetylated before spontaneous hydrolysis frees the enzyme. Nitrogen from nearby amino acids participates in this process by forming hydrogen bonds with the acetate group. Neostigmine mimics acetylcholine in its binding to acetylcholinesterase; however, the carbamoyl group is not as easily removed from the esteratic site. Edrophonium not only binds primarily to the choline-binding site but also participates in a hydrogen bond with the histidine (*His*^{440}) nitrogen of the esteratic site. The organophosphate isoflurophate reacts only at the esteratic site, where it creates a stable covalent bond. (Reprinted with permission from AAAS. Adapted from Sussman JL, Harel M, Frolow F, et al: Atomic structure of acetylcholinesterase from *Torpedo californica*: a prototypic acetylcholine-binding protein, *Science* 253:872-879, 1991.)

The anticholinesterase agents enjoying the greatest therapeutic use are drugs, such as neostigmine and physostigmine, that interact strongly with both binding sites of the receptor. As with the organophosphates, attachment of such drugs to the serine residue at the esteratic site is achieved by a covalent linkage. This bond is subject to hydrolysis, however, and these drugs are categorized as reversible cholinesterase inhibitors.

The simplest quaternary anticholinesterase, edrophonium (see Figure 8-6), binds AChE in a noncovalent manner. Its inhibition is rapidly reversible, making it useful for situations requiring a short duration of action, such as for diagnostic purposes. The terms *reversible* and *irreversible* denote differences in duration of effect, not in site of attachment.

The anticholinesterases, whether reversible or irreversible, owe their pharmacologic effects chiefly to the fact that they prolong the life of ACh at sites where it is a mediator. Their actions are often identical to the actions of ACh, although much more prolonged and, in most cases, completely dependent on the presence of endogenous ACh in the area of the effector. For this reason, most of the anticholinesterases are ineffective in denervated organs. Exceptions to this generalization are the quaternary ammonium compounds such as neostigmine and pyridostigmine and the bisquaternary amine ambenonium that stimulate nicotinic (N_M) receptors directly. Neostigmine is capable of direct stimulation of the neuromuscular junction and is effective on denervated skeletal muscle. Its pharmacology is the result of a combination of anticholinesterase and cholinomimetic properties.

Pharmacologic Effects

The cholinesterase inhibitors produce muscarinic effects similar to those elicited by the direct-acting cholinergic agonists (described earlier and outlined in Chapter 5). These effects are mediated by increasing the concentration of ACh at the autonomic neuroeffector junction and skeletal muscle neuromuscular junction. The activity of the anticholinesterases is greatest for the organs that receive more or less continuous cholinergic nerve stimulation. As a result, their effects are seen first in the smooth muscles of various ocular structures, the gastrointestinal tract, and the urinary bladder.

An important disparity in action between anticholinesterases and direct-acting muscarinic drugs is that the former do not cause significant muscarinic receptor–mediated vasodilation because many blood vessels receive no parasympathetic innervation, and no ACh is available to be protected against hydrolysis. Instead, vascular effects of high doses of anticholinesterases are largely mediated through their effects on autonomic ganglia and on medullary vasomotor centers. (The latter case occurs primarily with physostigmine, which is not permanently charged and can penetrate the blood-brain barrier.) Cholinesterase inhibitors stimulate, and in high doses subsequently block, N_N and N_M receptors indirectly by increasing the synaptic concentrations of ACh at ganglionic and neuromuscular sites. Hypotensive responses can arise from blockade of sympathetic ganglia. Quaternary cholinesterase inhibitors such as neostigmine are also able to stimulate directly N_M receptors and, to a lesser extent, N_N receptors.

As is the case with cholinomimetic alkaloids, the anticholinesterases are also known to evoke CNS actions. The CNS effects that are seen in anticholinesterase poisoning—confusion, ataxia, respiratory abnormalities, convulsions, coma, and death from respiratory paralysis—provide powerful evidence that cholinergic receptors play an important role in central neurotransmission. As pointed out in Chapter 5, there are muscarinic and nicotinic receptors in the CNS. As already mentioned, quaternary ammonium compounds penetrate biologic membranes poorly, so anticholinesterases that contain a quaternary ammonium group (e.g., neostigmine or edrophonium) are poorly absorbed after oral administration and do not readily pass through the blood-brain barrier. Predictably, they are quite effective at skeletal neuromuscular junctions but have no CNS effects.

Absorption, Fate, and Excretion

Physostigmine is readily absorbed after oral, subcutaneous, and topical administration, and it is destroyed principally through hydrolysis at the ester linkage by plasma esterases, including pseudocholinesterase. The other reversible cholinesterases listed in this chapter, such as neostigmine and pyridostigmine, are quaternary ammonium compounds, which means that they pass through biologic membranes with difficulty. Some of these compounds are broken down by esterases or hepatic microsomal enzymes. These compounds and their metabolites appear in the urine.

The organophosphate anticholinesterases, with the exception of echothiophate, are highly lipid soluble, and they are rapidly absorbed from the gastrointestinal tract, the skin and mucous membranes, and the lungs. These characteristics explain their potential toxicity when used as aerosols, dusts, vapors, or liquids. Most organophosphates are metabolized by A-esterases (paraoxonases) in the plasma and liver and by microsomal oxidation; for a few drugs, enzymatic transformation results in a more toxic product than the original compound. In the case of isoflurophate, approximately 80% of the drug is metabolized and excreted in the urine and feces during the first 24 hours, and approximately 20% remains protein bound in the tissues for a prolonged period.

Adverse Effects

In humans, intoxication from anticholinesterases has resulted from overdosage with drugs used in the treatment of MG and from exposure to toxic amounts of carbamate insecticides or organophosphate in insecticides or chemical warfare agents. Organophosphate insecticides have gained wide use in many countries, and thousands of cases of poisoning are attributable to these compounds, especially parathion. Most of the organophosphates are volatile liquids at ordinary temperatures and are highly lipid soluble. They are readily absorbed through the skin, the respiratory tract, the gastrointestinal tract, and the eyes. The symptoms of anticholinesterase poisoning reflect the role of ACh as a neuromediator at muscarinic and nicotinic receptors located peripherally and in the CNS. In high doses, the reversible anticholinesterases can produce the same symptoms as the irreversible anticholinesterases; the chief difference between these two groups lies in the ready access to the circulation and the longer duration of action of the irreversible anticholinesterases.

The first signs and symptoms to appear, especially after local exposure through aerosols, vapor, or dust, are an intense miosis, an inability to accommodate for far vision, severe rhinorrhea, and a frontal headache attributable to ciliary muscle spasm. The respiratory tract is also affected soon after exposure. In addition to the watery nasal discharge, there is nasal hyperemia, a sensation of tightness in the chest, probably because of bronchoconstriction, and increased bronchial secretion. Audible wheezing may follow, related to the bronchoconstriction and the hypersecretion. Laryngospasm may occur because of the secretory activity, which triggers a reflex spasm of laryngeal muscle. Ventilation can be severely and very rapidly compromised. Other manifestations of muscarinic stimulation include gastrointestinal effects such as salivation, anorexia, nausea, vomiting, severe cramps, diarrhea, and involuntary defecation. Sweating, lacrimation, bradycardia, urinary frequency, and involuntary micturition also occur.

With the onset of muscarinic effects, various nicotinic effects also become apparent. The affected individual shows easy fatigability and generalized weakness, especially on exertion. Involuntary muscle twitching, fasciculations, and muscle

BOX **8-1**

Manifestations of Overdosage With Anticholinesterases

MUSCARINIC EFFECTS (PERIPHERAL)	NICOTINIC EFFECTS* (PERIPHERAL)	CNS EFFECTS
Miosis, frontal headache (brow ache), conjunctival hyperemia, blurred vision	Muscular weakness, twitching, fasciculations	Restlessness, giddiness, tension, anxiety, nausea
Rhinorrhea, nasal hyperemia	Tachycardia	Tremors, electroencephalographic changes
Lacrimation, salivation, sweating	Elevation or depression of blood pressure	Confusion, ataxia, convulsions
Increased bronchial secretions, tightness of chest, bronchoconstriction, wheezing	Death from respiratory failure	Depression of respiratory and circulatory centers, cyanosis, coma, respiratory and circulatory collapse
Anorexia, nausea, vomiting, cramps, diarrhea, involuntary defecation		Death from respiratory failure
Urinary urgency, involuntary micturition		
Bradycardia, hypotension		

*Nicotinic effects include stimulation and inhibition of synaptic or junctional transmission.
CNS, Central nervous system.

cramps follow; then generalized muscle weakness, including the muscles of respiration, increases in severity. Respiratory movements become more shallow and rapid, and respiratory failure may occur in minutes unless artificial respiration is instituted. Respiration is also greatly hampered by the constriction of the airway and the intense secretory activity in the respiratory tract. Sympathetic ganglia may be stimulated and later blocked in moderate to severe intoxication, but this usually does not pose a life-threatening problem. Finally, outstanding CNS manifestations start with tension, restlessness, and jitteriness, and progress to confusion and ataxia, coma, disappearance of reflexes, Cheyne-Stokes respirations, and finally generalized convulsions. The cause of death is respiratory failure resulting from paralysis of the muscles of respiration, central depression of respiration, and airway obstruction. Box 8-1 summarizes the signs of poisoning with the anticholinesterases according to muscarinic, nicotinic, and CNS effects.[6]

The treatment of acute intoxication with an organophosphate should include the following actions:

1. Remove the victim from the source of contamination, or remove the organophosphate-containing contaminant.
2. Administer atropine in very large doses. Atropine does not relieve the neuromuscular blockade produced by these agents, but it does alleviate the effects of excessive muscarinic receptor stimulation, including many of the CNS manifestations of poisoning. Repeated, often very large, doses may be required.
3. Maintain the airway and administer artificial respiration.
4. Inject a benzodiazepine, such as diazepam, if atropine fails to relieve the convulsions.
5. Administer pralidoxime. This drug is one of several oximes that were synthesized in the 1950s as cholinesterase reactivators.

When the mechanism of organophosphate poisoning was fully understood, it became possible to conceptualize a molecule that could reverse the inhibition of AChE. It was reasoned that by attaching a nucleophilic group to a cationic quaternary nitrogen group at a proper atomic distance, the phosphorus group of the alkyl phosphate would be attacked and would be removed from AChE in a displacement reaction. It was reasoned further that the cationic group of this ideal molecule would be attracted to the choline-binding site, and the nucleophilic atom would be directed toward the phosphorus atom. Numerous compounds were synthesized, and one of the most potent was pralidoxime, the structure of which is shown in Figure 8-7. Intravenous administration of the oximes

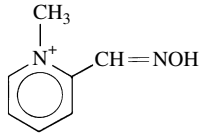

FIGURE **8-7** Structural formula of pralidoxime.

produces a remarkably rapid reactivation of the AChE at neuromuscular junctions in which transmission has failed as a result of poisoning with irreversible anticholinesterases. The reactivation occurs within minutes, but the effect of the oximes is much less dramatic at muscarinic sites and, with few exceptions, negligible in the CNS because many of the reactivators are quaternary compounds and cannot pass the blood-brain barrier. Also, the oximes are most effective when given immediately after exposure to the organophosphate because a process of "aging" of the phosphorylated AChE complex makes the enzyme resistant to reactivation. Therapeutic use of pralidoxime and its congeners is reserved for cases of intoxication with the irreversible anticholinesterases.

In some instances of organophosphate poisoning, the acute cholinergic phase may be followed by delayed peripheral neuropathy. Two types have been described. One appears 2 to 5 weeks after exposure to the organophosphate and involves phosphorylation and inhibition of an enzyme called neurotoxic esterase. The second neuropathy, called an *intermediate syndrome,* has been reported in approximately 10% of patients recently treated for organophosphate poisoning and appears 24 to 96 hours after exposure.[25] This condition, which is unresponsive to atropine and pralidoxime, involves the proximal limb muscles, the neck flexors, certain cranial nerves, and the muscles of respiration. These patients require respiratory support, and several have died of respiratory failure. It is theorized that the intermediate syndrome may be caused by contamination of the organophosphate or an interaction of the organophosphate with some other pesticides.

GENERAL THERAPEUTIC USES

ACh itself has had very little therapeutic application because of the extreme brevity of its action. The synthesis of congeners has solved the duration problem and resulted in drugs with

more selective actions. Although these compounds have limited use in contemporary therapeutics, the choline esters and the alkaloid pilocarpine are still used for some important purposes, as are the reversible anticholinesterases. The irreversible anticholinesterases are principally used as laboratory tools, as insecticides, and therapeutically for ophthalmologic conditions.

Glaucoma

Glaucoma is the name given to a group of diseases characterized by an elevation of intraocular pressure, a progressive atrophy of the optic disk, and a gradual loss in the field of vision. The aqueous humor is produced in the ciliary epithelium, passes into the posterior chamber, and then through the pupil into the anterior chamber. It leaves the eye by two pathways in the anterior chamber angle. In the first, the aqueous humor passes through the trabecular meshwork across the inner wall of Schlemm's canal and then into the venous circulation. In the second route, called the *uveoscleral pathway,* aqueous humor flows across the iris and anterior face of the ciliary muscle and ultimately exits through the sclera. Most forms of glaucoma result from an interference with the drainage from the trabecular meshwork or from closure of the angle by the iris.

Glaucoma is classified as primary, secondary, or congenital, based on characteristics and etiology. Of the primary types, open-angle (wide-angle, chronic simple) glaucoma and narrow-angle (angle-closure, acute congestive) glaucoma are the most common. In open-angle glaucoma, outflow resistance is elevated because there is a disturbance in the trabecular meshwork, or there is high episcleral venous pressure. The disease is slowly progressive, chronic, and often insidious because irrevocable damage can be done to the visual apparatus before symptoms develop. Narrow-angle glaucoma is usually, as its other name, acute congestive glaucoma, suggests, a medical emergency, triggered by an acute elevation of intraocular pressure, usually because iris-lens contact has obstructed the outflow of aqueous humor from the posterior to the anterior chamber. The secondary glaucoma types are associated with various systemic or ocular diseases, trauma, or drugs.

Therapy for glaucoma is directed at stimulating the musculature of the iris and ciliary body, increasing the facility of outflow of aqueous humor, reducing its formation, or extracting liquid from the eye. Although historically the cholinergic agents (in this application called *miotics*) have been the initial and principal drugs used in the treatment of chronic open-angle glaucoma, many other drugs (Table 8-2) are currently used, either alone or in conjunction with the cholinergic miotics. For first-line therapy, β-adrenergic receptor blockers and prostaglandin preparations are now more commonly used.[21]

Pilocarpine and other drugs that stimulate muscarinic receptors reduce intraocular pressure by decreasing resistance to aqueous humor outflow. Pilocarpine is available for topical administration in various solutions, and in a long-acting gel formulation. Carbachol, a slightly longer acting drug, is now used only occasionally.

The long-acting miotics—the anticholinesterases demecarium and echothiophate—are used for patients with chronic open-angle glaucoma who are refractory to the short-acting miotics and the other conventionally used drugs. These agents are quite potent and are administered in the lowest possible concentrations. Long-term administration (≥6 months) of echothiophate has been associated with the development of cataracts. Adverse effects limit their usefulness in the long-term therapy of glaucoma.

TABLE **8-2**

Drugs Used in the Treatment of Glaucoma

CLASS	DRUGS
Cholinergic Receptor Agonists	Carbachol, pilocarpine
Anticholinesterases	
Short-acting	Physostigmine
Long-acting	Demecarium, echothiophate
Adrenergic Receptor Agonists	
α And β agonist	Epinephrine
Prodrug	Dipivefrin
α_2 Agonist	Apraclonidine, brimonidine
β-Adrenergic receptor antagonists	
Nonselective	Carteolol, levobunolol, metipranolol, timolol
β_1 Selective	Betaxolol
Other Drugs	
Prostaglandin $F_{2\alpha}$ analogues	Acetazolamide, bimatoprost, latanoprost, travoprost, unoprostone
Carbonic anhydrase inhibitors	Brinzolamide, dorzolamide
Osmotic agents	Glycerin, isosorbide, mannitol
Combination products	Dorzolamide and timolol; pilocarpine and epinephrine

Xerostomia

Xerostomia can occur at any age, but it is most often seen in elderly individuals. Age-related decreases in salivary gland production, however, are not the reason many older people have dry mouth. Dry mouth may result from several causes, including radiation to the salivary glands, therapy with antineoplastic agents, disease (e.g., Sjögren's syndrome), and treatment with various drugs more common in older patients.[1] Saliva serves several functions in protecting the oral cavity.[11,19] Adequate saliva volume is required for cleaning the teeth and cleansing the oral cavity. Buffers in saliva reduce the effect of acids. Proteins, including mucins, aid in mineralization of dental enamel; reduce wear on the teeth by providing lubrication; have antibacterial, antiviral, and antifungal properties; and provide growth factors for tissue repair.[9,19] Reduced salivary flow rate, which is a major (but not the only) cause of the perception of dry mouth, is a risk factor for oral disease. Xerostomia can be very uncomfortable and is known to be associated with increased caries; oral pain; increased oral infection; and difficulty speaking, chewing, and swallowing.[19,20] Pilocarpine and cevimeline have been approved for the treatment of xerostomia in subjects with functional salivary gland tissue.[12]

A 5-mg to 10-mg dose of pilocarpine elicits significant increases in parotid, submandibular, and sublingual secretion, with maximal flow rates being achieved in 30 minutes and a return to basal rates in approximately 3 hours. The drug is usually given three times daily. The saliva-stimulating effect depends on residual salivary gland function. Generally, at these doses, there is no significant effect on blood pressure, heart rate, or cardiac function. Sweating is a common side effect; chills, nausea, and dizziness have also been reported. Cevimeline is a selective M_1 and M_3 muscarinic receptor agonist also used for the treatment of xerostomia. Because of its receptor preference, this drug is reported to have fewer adverse effects than pilocarpine; however, clinical studies have not been done to confirm this claim. Cevimeline is administered at a dose of 30 mg three times daily. The dentist must carefully determine whether muscarinic receptor agonists should be used to treat dry mouth. Therapy for xerostomia must not compromise other therapy the patient may be

receiving. Risk factors for muscarinic receptor agonists need to be considered.

Oral fluids, including saliva substitutes, may be added for the relief of dry mouth. Oral fluids should be substituted for pilocarpine and cevimeline in patients in whom the drugs are not well tolerated, in patients at risk for adverse effects, such as patients with uncontrolled asthma, in patients for whom pilocarpine or cevimeline would compromise existing therapy, or in patients in whom there is a complete loss of salivary function. Other contraindications are addressed in the section on therapeutic uses in dentistry.

Reversal of Neuromuscular Block

The use of reversible anticholinesterases to terminate the neuromuscular block of curare-like drugs in general anesthesia is discussed in Chapter 10.

Myasthenia Gravis

MG is a disease characterized by weakness and easy fatigability of the skeletal muscles, particularly ocular and oropharyngeal muscles, and by marked variations in severity of symptoms in the course of a single day. The prevalence of the disease is about 14 to 15 per 100,000 population. Approximately 10% of patients die of MG. There is also a neonatal form of MG that tends to be transient. Although the disease was described more than 300 years ago, the underlying mechanisms and suitable treatment were unclear until two investigators, Remen in 1932[23] and Walker in 1934,[27] unknown to each other, administered neostigmine to patients with MG and reported relief of symptoms.

The typical patient with MG initially has ocular complaints—double vision or ptosis or both—and difficulty in chewing and swallowing. Later, dyspnea and other respiratory problems may arise. Approximately 10% of patients with MG have a tumor of the thymus, and approximately 75% have hyperplasia of lymphoid tissue of the thymus. At least 30% of patients with an enlarged thymus have a remission of myasthenic symptoms after thymectomy.

Since the work of Remen[23] and Walker,[27] it has been accepted that the defect in MG is probably at the neuromuscular junction. Investigators showed that although synaptic vesicle diameter is unaltered, the mean nerve terminal area and the postsynaptic membrane are abnormally simple, with clefts that are sparse, shallow, wide, or absent. The favorable response of some patients to thymectomy and certain features of the muscle response in MG have led to the recognition that this disease is an autoimmune disorder. Experimental autoimmune MG is characterized by simplified postsynaptic membrane structures, high concentrations of anti–ACh receptor antibodies in the serum, binding of antibodies to most ACh receptor in the muscle, and reduction of the ACh receptor content to approximately 30% of normal.

MG is currently viewed as an autoimmune disorder in which there is continuous production of antibody to the ACh receptor at the neuromuscular junction. The primary defect in MG is loss of ACh receptor through accelerated destruction of receptors and without a concomitant increase in rate of synthesis, and by complement-mediated focal lysis of the postsynaptic membrane. Other forms of MG may involve other proteins at the neuromuscular junction.

Treatment for MG is now fairly standardized. Diagnosis is made on the basis of a physical and neurologic examination; an elevated titer of ACh receptor IgG antibodies; an improvement in muscle strength after intravenous or intramuscular injection of edrophonium, a short-acting anticholinesterase; and single fiber electromyography. After a positive diagnosis, six methods of treatment are available.[24] In the first method, one of three reversible anticholinesterases (neostigmine, pyridostigmine, or ambenonium) is used to enhance neuromuscular transmission. Second, thymectomy is especially indicated in patients with thymomas. Third, adrenal corticosteroid therapy is presently considered the initial standard therapy for mild-moderate MG. Fourth, other immunosuppressant drugs, such as cyclosporine and azathioprine, are used. Fifth, plasmapheresis to remove offending antibodies is an effective modality used in acute situations. Sixth, high-dose intravenous immunoglobulins also are used in acute situations. (The mechanism of intravenous immunoglobulins has not been well defined.)

Treatment with immunosuppressive drugs is associated with undesirable side effects (see Chapter 41). With azathioprine, toxic effects on the gastrointestinal and hematologic systems are most common, with prominent nausea, vomiting, and abdominal discomfort in the first months. Cyclosporine use is associated with nephrotoxicity, diarrhea, gingival pain, nausea, and headaches. Treatment with corticosteroids is associated with many adverse effects (see Chapter 35). Osteoporosis is a significant risk, and patients routinely are placed on bisphosphonates or other medications to protect bone structure.

Therapy with an anticholinesterase is likely to be complicated by side effects resulting from the accumulation of ACh at cholinergic receptor sites. Some of these effects are characteristically muscarinic—abdominal cramps, diarrhea, sweating, salivation, and lacrimation—and can be well controlled by the administration of atropine and related drugs. Other side effects, such as muscle fasciculations and CNS symptoms, are not controllable by the muscarinic blocking drugs and may be warning signs of an impending cholinergic crisis, which results from overdosage with the anticholinesterases. Cholinergic crisis is characterized by muscle weakness, particularly of the respiratory muscles, resulting from persistent depolarization of the neuromuscular junction. Cholinergic crisis closely resembles myasthenic crisis, the latter of which may occur because of inadequate medication, and it is urgently necessary in such patients to determine quickly which of the two conditions exists. This determination is made by giving, with great caution and with resuscitation equipment immediately available, a very low dose of edrophonium. If the symptoms are relieved, the problem is myasthenic weakness; if muscle strength decreases, cholinergic crisis is established.

Antidote for Atropine Poisoning

All the cholinergic drugs with muscarinic properties should theoretically be useful in antagonizing the effects of atropine, but the most effective drugs for this purpose are the anticholinesterases, and the drug of choice is physostigmine. When the diagnosis of atropine poisoning is confirmed, physostigmine is administered intravenously, and it rapidly relieves the delirium and coma. Neostigmine and other quaternary ammonium compounds are of limited use because they are incapable of counteracting the CNS effects of atropine.

Numerous psychotropic agents (e.g., tricyclic antidepressants, phenothiazines, and antihistamines) share to varying degrees the antimuscarinic effects of atropine. Particularly when used in combination (for intravenous sedation or for other reasons), these agents may induce a central anticholinergic syndrome consisting of confusion, delirium, hallucination, and psychotic behavior. Intravenous physostigmine in doses of 0.5 mg to 2 mg is effective in reversing this syndrome. Because the duration of action of parenteral physostigmine is 1 to 2 hours, repeated administrations may be necessary to avoid recurrence of the syndrome.

Paralytic Ileus and Bladder Atony

After abdominal and pelvic surgery, there is often a failure of normal peristalsis that leads to postoperative abdominal distention and discomfort. Neostigmine has been used in the

treatment of this condition, as has bethanechol, which is preferred to other choline esters because of its reduced cardiac effect. Bladder atony also follows surgery and sometimes parturition. It leads to urinary retention and is treated with bethanechol or neostigmine.

Senile Dementias of the Alzheimer Type

Alzheimer's disease and related senile dementias are progressive and debilitating neuropsychiatric diseases. Alzheimer's disease is manifested by memory loss, language deficits, and other symptoms, and usually terminates in death from some debilitating condition in approximately a decade. Although the cause of Alzheimer's disease remains an active area of investigation, the dementia apparently is a form of amyloid encephalopathy resulting from the deposition of the protein β-amyloid in selective regions of the CNS.[15] The deposition of this protein causes the formation of neurofibrillary tangles, oxidation, inflammation, neuronal cell death from multiple factors, and loss of several different neurotransmitters important in cognition and memory.[7] One central neurochemical affected by Alzheimer's disease, especially early in the course of the illness, is ACh.

Deficits in ACh and in choline acetyltransferase, the enzyme responsible for the formation of ACh from choline and acetyl coenzyme A, have been identified in the brains of patients with Alzheimer's disease. The identification of these deficiencies suggested a treatment strategy for Alzheimer's disease analogous to that used in the pharmacologic therapy of Parkinson's disease—replacement of the missing (in this case cholinergic) agonist.[14] Early experiments with physostigmine showed some transient, although variable, improvement. The AChE inhibitors that are used to treat Alzheimer's disease easily penetrate the blood-brain barrier. Tacrine, a longer acting reversible anticholinesterase, is approved for palliative treatment of mild-moderate forms of Alzheimer's disease; however, tacrine is also capable of producing significant, although reversible, hepatotoxicity at therapeutic doses and is now rarely used. Donepezil, rivastigmine, and galantamine are newer AChE inhibitors used to treat Alzheimer's disease. The AChE inhibitors have shown modest but significant improvement in patients with Alzheimer's disease.[4,5] Their benefit seems to be in temporarily slowing memory loss and loss of function.

Other strategies, aimed mostly at reducing the adverse responses to β-amyloid, are being actively investigated. AChE inhibitors for Alzheimer's disease are often administered with vitamin E, an antioxidant, and memantine, an N-methyl-D-aspartate receptor antagonist.[7]

Other Uses

Methacholine inhalation is sometimes used as a challenge test for the diagnosis of bronchial asthma, and edrophonium has been given intravenously to abort attacks of paroxysmal atrial tachycardia. Both uses have undesirable adverse potentials (bronchoconstriction with methacholine and bradycardia with edrophonium), however, and are indicated only when more established diagnostic or therapeutic approaches have been exhausted.

In addition to the use of organophosphates for insecticides, many carbamate reversible AChE inhibitors are also available as insecticides.

THERAPEUTIC USES IN DENTISTRY

All the cholinomimetic drugs that have an affinity for muscarinic sites are capable of stimulating salivation. Xerostomia is a common problem encountered by dentists in patients with Sjögren's syndrome,[1] patients who have had head and neck radiation, and patients undergoing treatment involving drugs that produce dry mouth. Muscarinic receptor agonists may be useful in stimulating salivary flow when there is functional salivary gland tissue present and when there is no contraindication for their use. Muscarinic receptor agonists should not be administered if they will compromise other therapy that the patient is undergoing. Antimuscarinic therapy for overactive bladder (see Chapter 9) would tend to be compromised by the administration of a muscarinic receptor agonist. (Antimuscarinic drug therapy would likewise reduce the clinical efficacy of pilocarpine or cevimeline.) Muscarinic receptor agonists are contraindicated in urinary tract obstruction, hyperactive airway disease, chronic obstructive pulmonary disease, acute heart failure, gastrointestinal spasms, hyperthyroidism, and acute iritis. Pilocarpine is usually taken at doses of 5 mg or 10 mg three times a day, 30 minutes before each meal. Cevimeline is given at a dose of 30 mg three times daily. As mentioned previously, physostigmine may be valuable in treating certain adverse reactions to antimuscarinic drugs used for intravenous sedation.

CHOLINERGIC DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Cholinomimetics	
Acetylcholine	Miochol-E
Bethanechol	Urecholine
Carbachol	Miostat, Isopto Carbachol
Cevimeline	Evoxac
Methacholine	Provocholine
Pilocarpine hydrochloride	Pilocar, Pilocel, Salagen
Pilocarpine nitrate*	P.V. Carpine Liquifilm
Pilocarpine ocular therapeutic system	Ocusert Pilo-20, Ocusert Pilo-40
Pilocarpine and epinephrine	E-Pilo-1, P_2E_1
Pilocarpine and physostigmine	Isopto P-ES
Anticholinesterases	
Ambenonium	Mytelase
Demecarium	Humorsol
Donepezil	Aricept
Echothiophate	Phospholine
Edrophonium	Tensilon, Reversol
Galantamine	Razadvne, Reminyl
Isoflurophate*	Floropryl
Neostigmine	Prostigmine
Physostigmine	Eserine Sulfate, Isopto Eserine
Physostigmine salicylate	Antilirium
Pyridostigmine	Mestinon
Rivastigmine	Exelon
Tacrine	Cognex
Cholinesterase reactivator	
Pralidoxime	Protopam

CHAPTER 9

Antimuscarinic Drugs

FRANK J. DOWD

Various drugs can interfere with the transmission of nerve impulses at cholinergic junctions. As shown in Table 5-2, some drugs prevent the uptake of choline by the nerve terminal or the release of acetylcholine (ACh) from the terminal; other drugs block at ganglia or, by a competitive or depolarizing form of blockade, at neuromuscular junctions. The drugs presented in this chapter block responses in muscarinic receptors and are essentially without effect except at inordinately high doses at nicotinic receptors. These drugs are known as *antimuscarinic* or *muscarinic receptor–blocking drugs*; the term *anticholinergic,* although often used for this class of drugs, is inaccurate because these drugs, for the most part, are selective for muscarinic receptors but not nicotinic receptors. They are also termed *atropine-like* because of their derivation from or relation to the oldest and best-known member of the group. Because peripheral muscarinic receptors are the primary targets of ACh released by postganglionic cholinergic neurons, the effects achieved by the antimuscarinic drugs are chiefly on smooth muscle, cardiac muscle, and glands that are innervated by these neurons.

The natural alkaloids are derived from numerous plants, including *Atropa belladonna* (deadly nightshade); *Datura stramonium,* also known as jimsonweed or Jamestown weed; *Hyoscyamus niger* (henbane); and mandragora, among others. Datura was used in India in ancient times—its name comes from the Sanskrit. These drugs are mentioned in the Ebers papyrus (circa 1550 BC), in the Greek herbal of Dioscorides, and by Galen. In Western civilization, the drugs were used by professional poisoners in the Middle Ages for slow poisoning because of the obscure symptoms and the slow course of illness. The Swedish botanist Linné named the shrub *Atropa belladonna* after Atropos, one of the three Fates, who cuts the thread of life. The term *belladonna* comes from the Italian and means "beautiful woman"; this term was used because instillation of one of these drugs into the eyes was said to make women more attractive. Atropine, scopolamine, and related natural chemicals are also referred to as *belladonna alkaloids*.

CHEMISTRY AND CLASSIFICATION

Antimuscarinic drugs fall into four categories, as follows:

1. Naturally occurring belladonna alkaloids—atropine and scopolamine—which are organic esters. Atropine and scopolamine are composed of an aromatic acid (tropic acid) and a complex organic base (tropine or scopine). Atropine is a racemic mixture of *d*-hyoscyamine and *l*-hyoscyamine; the *l* isomer is the active form and is often used separately.
2. Semisynthetic derivatives, such as homatropine, which is produced by combining tropine with mandelic acid, and the quaternary ammonium derivatives of atropine, scopolamine, and homatropine (atropine methylnitrate, methscopolamine bromide, and homatropine methylbromide).
3. Synthetic quaternary ammonium compounds, such as methantheline, propantheline, and ipratropium.
4. Synthetic antimuscarinic drugs that are not quaternary ammonium compounds, such as benztropine, trihexyphenidyl, and cyclopentolate.

A prototypic chemical structure of each of these types is shown in Table 9-1, and a more extensive list is at the end of the chapter.

MECHANISM OF ACTION

The antimuscarinic drugs—whether the naturally occurring alkaloids or the semisynthetic or synthetic derivatives—are competitive antagonists of ACh at muscarinic receptors. (Review Figure 5-1 for the principal location of muscarinic receptors.) They have an affinity for muscarinic receptor sites but lack intrinsic activity.[1] They occupy the receptor sites and prevent access of ACh, creating a blockade that is generally reversible by increasing the amount of ACh in the area of the receptor, as would occur after the administration of an anticholinesterase drug. Because atropine can antagonize the muscarinic effects of the anticholinesterases and vice versa, each drug can be used as an antidote for the other in case of poisoning. The antimuscarinic drugs are capable of blocking responses to parasympathetic nerve stimulation, to sympathetic nerve stimulation of thermoregulatory sweat glands, to ACh protected from hydrolysis by anticholinesterases, and to direct-acting muscarinic agents, although their capability for inhibiting the latter two is greater than for the first two.

Several explanations have been offered for why atropine is more effective in blocking the pharmacologic effects produced by muscarinic receptor agonists than in blocking physiologic responses evoked by parasympathetic nervous system stimulation. One possibility is that ACh released into the restricted environs of a junctional cleft may overwhelm the antagonist by the high, although temporary, concentrations achieved. A second possibility is that the antimuscarinic drugs facilitate ACh release from cholinergic neurons by blocking presynaptic muscarinic receptors that limit evoked ACh release. A third explanation arises from the fact that physiologic responses to parasympathetic nervous system stimulation are mediated by several neurotransmitters in addition to ACh. Direct electrical stimulation of the parasympathetic nervous system causes the release of ACh and several other

TABLE **9-1**

Chemical Structures of Representatives of the Four Classes of Antimuscarinic Drugs

TYPE OF COMPOUND	EXAMPLE	CHEMICAL STRUCTURE
Naturally occurring alkaloid	Atropine	Semisynthetic derivative of alkaloid	Methscopolamine	Synthetic quaternary ammonium compound	Propantheline	Synthetic but not quaternary ammonium compound	Benztropine	
TABLE **9-2**

Relative Effects of Atropine and Scopolamine on Various Effectors

	IRIS	CILIARY BODY	SECRETION: SALIVA, SWEAT, BRONCHIAL	BRONCHIAL MUSCLE	GASTROINTESTINAL MUSCLE	HEART	CENTRAL NERVOUS SYSTEM
Atropine	+	+	+	++	++	++	+
Scopolamine	++	++	++	+	+	+	++

neurotransmitters from the postganglionic nerve terminal.[7] ACh and adenosine triphosphate (ATP) are released from postganglionic parasympathetic nerves. In this setting, ATP, acting on nucleotide receptors, functions as a cotransmitter with ACh.[9]

Although atropine is a highly effective antagonist at all muscarinic receptors, evidence has accumulated that there are five muscarinic subtypes, M_1 to M_5, each with different affinities for certain muscarinic agonists and antagonists, different anatomic distributions, and different second messenger signaling mechanisms (see Chapters 5 and 8). The relatively selective affinity of the tricyclic benzodiazepine pirenzepine for M_1 receptors versus M_2 and M_3 receptors gives it stronger antimuscarinic properties in certain sites (e.g., corpus striatum, cerebral cortex, and enterochromaffin cells) compared with others (e.g., heart and ileum). Pirenzepine, which is available outside of the United States, was the first clinically useful selective muscarinic receptor antagonist. Darifenacin is a selective antagonist at the M_3 receptor and is available for treatment of overactive bladder.[14] The characterization of different muscarinic receptor subtypes continues to provide an impetus for development of selective antagonists.

PHARMACOLOGIC EFFECTS

Therapeutic doses of antimuscarinic drugs produce effects attributable to the blockade of peripheral muscarinic receptors and similar receptors in the central nervous system (CNS) located within the medulla and higher cerebral centers. In the following discussion, atropine and scopolamine, which have always been considered the prototypes for this class of drugs, are principally reviewed, but (1) atropine and scopolamine differ in the relative intensity of their antimuscarinic effects on specific organs (Table 9-2); (2) there is a difference in the susceptibility of various effectors to antimuscarinic agents in general (Table 9-3); (3) because of differences in chemical structure, some antimuscarinic drugs pass readily into the CNS, whereas others do not; (4) there are some major differences among antimuscarinic drugs

TABLE **9-3**

Order of Susceptibility of Effectors to Increasing Doses of Antimuscarinic Agents

RESPONSE	DOSE
Secretion (saliva, sweat, bronchial)	Low
Mydriasis, cycloplegia, tachycardia	↓
Loss of parasympathetic control of urinary bladder and gastrointestinal smooth muscle	↓
Inhibition of gastric secretion	High

TABLE **9-4**

Onset and Duration of Cycloplegia Induced by Some Topical Antimuscarinic Drugs

DRUG	ONSET (min)	DURATION
Atropine	30-40	≥6 days
Scopolamine	20-30	3-6 days
Homatropine	40-60	1-3 days
Cyclopentolate	25-75	6-24 hr
Tropicamide	20-35	2-6 hr

in the onset and duration of their actions (Table 9-4); and (5) muscarinic receptor subtypes have differing affinities for specific antimuscarinic drugs.

Peripheral Nervous System Actions

The antimuscarinic drugs possess peripheral nervous system and CNS actions, but the nature and intensity of these vary with the individual drug and the dose administered. Most peripheral nervous system effects are caused by an interruption of parasympathetic impulses to a given effector. This interruption results in control of the tissue or organ by the sympathetic nervous system, which often exerts effects opposite to those of the parasympathetic nervous system. An important exception is where the sympathetic effect acts through muscarinic receptors, most notably in the sweat glands. The sympathetic effect of sweating is inhibited by antimuscarinic drugs. The pharmacologic effects observed depend largely on the existing activity of postganglionic cholinergic neurons. Inhibition of sweating and hyperthermia are likely to be observed on a hot day, but no effect on thermoregulation is apparent in a cold environment. Generally, atropine-like drugs block the salivation, lacrimation, urination, and defecation response to cholinergic drugs described in Chapter 8 and the hypotensive and bradycardic effects of muscarinic receptor stimulation. The effects of antimuscarinic agents on specific tissues are described next.

The eye

Atropine-like drugs block muscarinic receptors in the sphincter of the iris and in the ciliary muscle, leading to dilation of the pupil (mydriasis) and paralysis of accommodation (cycloplegia). Photophobia and fixation of the lens occurs for far vision, and vision for near objects is blurred. Intraocular pressure is not significantly affected except in the case of narrow-angle (or angle-closure) glaucoma, for which administration of these drugs may cause a dangerous increase in intraocular pressure. The onset and duration of the mydriatic and cycloplegic effects differ, as shown for cycloplegia in Table 9-4, and to some extent the choice of an agent for an ophthalmologic procedure is influenced by these differences.

Respiratory tract

After administration of antimuscarinic drugs, the bronchial smooth muscle is left under the sole control of the sympathetic nervous system and is relaxed. This relaxation of the smooth muscle decreases airway resistance. Sometimes there is an increase in respiratory minute volume resulting from an increase in the physiologic dead space and medullary stimulation. The bronchoconstriction caused by muscarinic agonists, sulfur dioxide, and certain other bronchial spasmogens is easily reversed by atropine, but bronchoconstriction caused by histamine, 5-hydroxytryptamine, and the leukotrienes is resistant.

Secretion of all glands in the nose, mouth, pharynx, and respiratory tree is inhibited. This suppression of secretory activity in the respiratory tract is the underlying reason for the effectiveness of antimuscarinic drugs in preventing laryngospasm during general anesthesia; these agents are incapable of directly blocking contraction of the laryngeal muscle.

Salivary glands

Parasympathetically mediated salivary secretion is abolished in a dose-dependent manner, whereas salivary gland vasodilation is much less affected. The mouth and throat become unpleasantly dry, to the point that speech and swallowing may become difficult. Dry mouth or xerostomia can lead to numerous adverse effects on the oral cavity (see Chapter 8).

Gastrointestinal tract

Although antimuscarinic drugs are quite effective in preventing the expected motor and secretory responses of the gastrointestinal tract to administered cholinergic drugs, their effects on vagal stimulation are more ambiguous. Antimuscarinic drugs have a marked inhibitory effect on motility throughout the gastrointestinal tract. Interference with the normal parasympathetic impulses to the gastrointestinal tract, as would occur with antimuscarinic drugs and ganglionic blocking agents, causes a profound decrease in the tone of gastrointestinal smooth muscle and in the frequency and amplitude of peristaltic contractions. Regarding secretion, gastric secretory activity in humans is inhibited only at very high doses of belladonna alkaloids, when essentially all other parasympathetic function has been blocked and the patient has an extremely dry mouth, blurred vision, an increased heart rate, and marked inhibition of gastrointestinal motility. At these high doses, atropine reduces gastric acidity, pepsin secretion, and total gastric secretion.

The fact that the gastrointestinal tract, particularly the secretory apparatus, is resistant to belladonna alkaloids and the fact that the therapeutic use of these drugs as antiulcer and antispasmodic agents has been disappointing underscore the finding that transmitters in addition to ACh are involved in the regulation of secretion and motor activity in the gastrointestinal tract (see Chapter 33). Two of these transmitters are ATP and histamine. At high doses, atropine has antihistaminic (H_1) activity, and the antihistamine diphenhydramine has marked antimuscarinic activity, one manifestation of which is xerostomia.

Cardiovascular system

The effects of antimuscarinic drugs differ according to the dose administered and whether the subject is in the erect or recumbent position. With oral doses used to limit salivation (e.g., 0.4 mg to 0.6 mg of atropine in adults), mild bradycardia often results. At these low doses, a selective blockade of prejunctional muscarinic receptors augments ACh release from postganglionic parasympathetic fibers innervating the heart. In most cases, however, the heart rate increases significantly in humans given more than 0.4 mg intravenously or 1 mg orally. In a standing or upright patient, there is little or no change in cardiac output. As implied in Table 9-2, doses of

scopolamine that cause mydriasis rarely cause tachycardia, whereas atropine administered systemically in doses sufficient to have ocular effects inevitably accelerates the heart rate.

Genitourinary tract
The ureters and the urinary bladder (detrusor muscle) are relaxed by atropine.[3] The sphincter and trigone muscles are contracted by atropine. These effects are due to muscarinic receptor blockade. Together these changes in the bladder cause urinary retention in humans. This retention is particularly likely in the presence of prostatic hypertrophy.

Body temperature
Belladonna alkaloids suppress sweating because the sweat glands (other than the apocrine sweat glands as found on the palms of the hand) are innervated by cholinergic fibers of the sympathetic nervous system. The receptors at the neuroeffector sites in the sweat glands are muscarinic. The increase in body temperature that can follow the administration of large doses of atropine or scopolamine may have a CNS component, but the primary cause is the peripheral inhibition of sweating. It is also the most serious and life-threatening result of an overdose of one of these drugs.

Central Nervous System Effects
CNS effects are produced only by antimuscarinic drugs that can penetrate the blood-brain barrier. The quaternary amines, such as methscopolamine and propantheline, have little or no effect on the CNS.

Medulla and higher cerebral centers
Scopolamine and atropine produce complex effects on the CNS. With conventional therapeutic doses of atropine, there is direct stimulation of the CNS, which is generally manifested only as a mild stimulation of respiratory centers located in the vagal nuclei of the medulla. At therapeutic doses, scopolamine usually produces effects ranging from decreased psychological efficiency to drowsiness, sedation, euphoria, and amnesia, but it can also cause excitement, restlessness, hallucinations, and delirium. Atropine is much less active in this respect than scopolamine.

Antitremor activity
Belladonna alkaloids were first used in the treatment of Parkinson's disease in the mid-1800s, long before their mechanism of action was understood and before the biochemical nature of the defect of parkinsonism had been elucidated. Their effectiveness in suppressing tremor was later suggested to result from a "central atropine-ACh antagonism," and more recently it has become apparent that the striatum is the site of cholinergic systems that in parkinsonism are released from an inhibitory balance mediated by dopamine (see Chapter 15).

Vestibular function
Since ancient times, belladonna alkaloids have been the basis of various remedies to treat motion sickness.[11] Scopolamine is more effective than atropine. It acts on several areas of the brain, including the vestibular apparatus and the cortex.

ABSORPTION, FATE, AND EXCRETION

Belladonna alkaloids and their tertiary derivatives and analogues are readily absorbed from all parts of the gastrointestinal tract except the stomach, as would be expected with alkaloids that form acid salts. Absorption is more rapid from subcutaneous tissue or muscle than it is from the gastrointestinal tract. The drugs are distributed throughout the body, including the CNS. The fate of most of these drugs in humans is not well studied, but the kidneys provide the main route for excretion of atropine in changed and unchanged form. Within 24 hours, 27% to 94% of a dose of labeled atropine is excreted, and very little is excreted after 24 hours. A third of the atropine appears as unchanged atropine, and the remainder appears as a metabolite of uncertain identity.[8] Rabbits possess a genetically determined enzyme, atropinesterase, which explains their singular ability to tolerate large doses of atropine. Various idiosyncratic responses or variations in sensitivity to one or another of the actions of these drugs are not uncommon. Young individuals show a high incidence of idiosyncratic responses; individuals with Down syndrome are more sensitive to the mydriatic effects; and African American individuals develop more exaggerated tachycardia.

Antimuscarinics with a quaternary ammonium structure are incompletely absorbed after oral ingestion and are often given by nonenteral routes. These drugs are largely excluded from the CNS.

GENERAL THERAPEUTIC USES

The therapeutic uses of antimuscarinic drugs all are based on the peripheral and central pharmacologic effects already discussed. It is difficult to obtain a high degree of selectivity in the organ or organs to be affected, however, because antimuscarinic drugs tend to affect many muscarinic sites. Nevertheless, certain drugs are more effective and potentially more useful in a particular therapeutic role than others. The quaternary ammonium compounds, two of which are shown in Table 9-1, differ from atropine and scopolamine in many important respects. Two important differences are (1) they do not readily pass the blood-brain barrier because they are ionized at physiologic pH and they have little or no effect on the CNS, and (2) they have greater ganglionic blocking properties than the nonquaternary compounds. This latter difference may explain why orthostatic hypotension and impotence are sometimes encountered in patients being treated with these drugs.

Ophthalmology
By local administration of antimuscarinic drugs, it is possible to produce mydriasis and cycloplegia of very long duration (atropine), medium duration (scopolamine), and very short duration (tropicamide). Mydriasis is necessary for a thorough examination of the retina and optic disk; cycloplegia is necessary for measurement of the refractive powers of the lens. Mydriasis can be produced alternately with miosis for the purpose of breaking up adhesions that may have developed between the lens and the iris. The topical use of these drugs is strongly contraindicated in patients with a predisposition to narrow-angle glaucoma, and although systemic anticholinergic drugs are usually safe for patients with open-angle glaucoma, they may precipitate a first attack of acute angle-closure glaucoma. Homatropine, cyclopentolate, and tropicamide are the major mydriatics used. The duration of effects ranges from 1 to 3 days for homatropine to 6 hours or less for tropicamide.

Respiratory Tract
Belladonna alkaloids previously were commonly used for the treatment of bronchial asthma, but liabilities, including limited effectiveness and a tendency to inhibit secretions, which often led to the retention of a viscid residuum further obstructing airflow, resulted in their abandonment as soon as replacement therapies became available. Subsequently, the quaternary ammonium compound ipratropium was marketed in aerosol form for the treatment of chronic obstructive pulmonary disease. It is highly effective for patients with chronic bronchitis and has been used in acute asthma and status asthmaticus in patients unresponsive to β_2-adrenergic receptor

agonists, although it is considered a secondary drug in the treatment of acute asthma.[5] The inhalation route limits systemic side effects and reduces the risk of inhibiting bronchial secretion.

As antimuscarinic drugs, ipratropium and similar drugs are unique in their preservation of ciliary motility in the bronchial mucosa, an important benefit in preventing the formation of mucous plugs.[2,17] Tiotropium is a drug similar in action to ipratropium. It also is given by inhalation, but has a longer duration of action than ipratropium and can be administered once a day.[12,15] The ability of atropine-like drugs to suppress secretion throughout the respiratory tract is advantageous during the administration of general anesthesia because these drugs produce a dry field, lessen the danger of pulmonary aspiration, and help prevent laryngospasm.

Salivary Secretion

Antimuscarinic drugs are widely used to diminish salivary secretion before oral procedures and before surgery, particularly oral surgical procedures. The use of antimuscarinic drugs for this purpose provides a dry oral cavity and diminishes the salivary response during surgery. Atropine is occasionally used to reduce excessive salivary secretion in heavy metal poisoning and parkinsonism.

Gastrointestinal Tract

Antimuscarinic drugs have been used extensively as antispasmodics, as antiulcer agents, and for various disorders characterized by the term *spasticity*. Although their use is often attended by symptomatic relief, they have proved of questionable benefit in the treatment of peptic ulcer, severe dysenteric illnesses, and so-called spasticity syndromes. It has become popular to substitute the synthetic quaternary ammonium compounds for the naturally occurring alkaloids for these therapeutic goals on the questionable basis that side effects would be less severe with the synthetic compounds. As shown in Table 9-3, if reduction in intestinal peristalsis is a therapeutic aim with this kind of drug, tachycardia, blurring of vision, and dryness of mouth must be accepted as inevitable side effects. Pirenzepine, an M_1-selective muscarinic receptor antagonist, has been found to suppress resting and stimulated acid and pepsin secretion without producing as many effects on the heart, bladder, or ocular structures—all locations where receptors other than M_1 muscarinic receptors predominate.

Cardiovascular System

The application of antimuscarinic drugs to the treatment of cardiovascular disorders is limited. They can be used during anesthesia and surgery to prevent vagal reflexes, in cases of myocardial infarction in which there is excessive vagal tone causing sinus or nodal bradycardia, in cases of a hyperactive carotid sinus reflex producing bradycardia and syncope, and in certain cases of digitalis-induced heart block. Some other forms of heart block are also amenable to atropine therapy.

Genitourinary Tract

Belladonna alkaloids have been used to treat various urologic disorders, including renal colic (usually in combination with opioids), nocturnal enuresis, and overactive bladder associated with urge incontinence and urinary frequency. Because the bladder is less susceptible than some other tissues to the action of muscarinic drugs (see Table 9-3), nonselective antimuscarinic drugs have not proved very useful in the treatment of these disorders. Drugs that have additional direct relaxant effects on smooth muscle, such as flavoxate and oxybutynin, are more useful for symptomatic relief of dysuria, urgency, and incontinence associated with inflammatory or neurogenic conditions. Tolterodine, trospium, darifenacin, and solifenacin are additional antimuscarinic drugs used to treat these conditions.[14,16,18] They apparently have some selectivity for the urinary bladder.[3] For treating nocturnal enuresis in children, tricyclic antidepressants (see Chapter 12) and the antidiuretic hormone analogue desmopressin (see Chapter 34) are more commonly used than antimuscarinic drugs.

Preanesthetic Medication

Belladonna alkaloids also are used for preanesthetic medication. Scopolamine in particular provides the CNS effects of euphoria, amnesia, and sedation, in addition to the inhibition of salivary and other secretions and the protection that this inhibition furnishes against laryngospasm.

Central Nervous System

Other uses for the CNS effects of antimuscarinic drugs are to prevent motion sickness and to treat Ménière's disease. Scopolamine is an effective drug for severe, brief motion sickness when given prophylactically. It is not particularly effective in preventing nausea and vomiting from most other causes, such as radiation sickness. Scopolamine has been prepared in a transdermal system for the prevention of motion sickness. The patch has an adhesive surface that, when placed on the skin behind the ear, delivers 1.5 mg of scopolamine over 3 days. An effective concentration of the drug in the blood is achieved in about 4 hours. Delivered transdermally, the usual effects of cholinergic blockade are minimized, although there is occasional dryness of the mouth and drowsiness.[13]

In Parkinson's disease (see Chapter 15), the anticholinergics are the oldest drugs used for this condition, and they are still considered useful in the early stages of the disease and in combined therapy with levodopa and other antiparkinsonian drugs. Antimuscarinic drugs are also used to treat Parkinson-like adverse effects of antipsychotic drugs. The antimuscarinic drugs favored for treating Parkinson's disease or Parkinson-like symptoms are the nonquaternary synthetic compounds that gain ready access to the brain and have greater CNS effects than peripheral nervous system effects. These drugs include benztropine, biperiden, trihexyphenidyl, and antihistamines such as diphenhydramine that also have antimuscarinic properties (see Chapter 15).

Antidote to Anticholinesterases

Toxicity from anticholinesterases may result from their use in the treatment of myasthenia gravis (particularly in the early phase of therapy when the patient is not as tolerant to the muscarinic effects of these drugs) or from exposure to an organophosphate insecticide or anticholinesterase nerve gas. These anticholinesterases typically produce a spectrum of peripheral muscarinic and nicotinic effects and CNS effects. Atropine is effective in antagonizing the effects at muscarinic sites and relieves the hypersecretion of salivary, lacrimal, and respiratory glands; bronchoconstriction; gastrointestinal symptoms; sweating; various other manifestations of muscarinic stimulation; and some CNS actions. It does not interfere with the desired effects of anticholinesterases at neuromuscular junctions when these drugs are being used for myasthenia gravis or to reverse neuromuscular blockade induced by curare-like agents (see Chapter 10); atropine also does not prevent the neuromuscular stimulation, followed by respiratory failure, characteristic of excessive nicotinic stimulation. For treatment of acute toxicity with anticholinesterases, very large doses of atropine are used; for treatment of milder symptoms of muscarinic stimulation, as in the treatment of myasthenia gravis, much smaller doses suffice.[6]

Antidote to Poisoning by Mushrooms Containing Muscarine

As stated in Chapter 8, the mushroom *Inocybe lateraria* is poisonous because of its high content of the alkaloid muscarine. Atropine is a specific antagonist of antimuscarinic chemicals found in this and other plant sources.

ADVERSE EFFECTS

Atropine and related drugs, despite wide availability and defined toxicity, have produced few fatal cases of poisoning in adults. Children are more sensitive to atropine, and most reported fatalities have involved children who accidentally ingested eye drops or other medicines that contained atropine or scopolamine. Children are more susceptible to hyperthermia and other toxic effects of atropine; dosages need to be carefully controlled. The colloquialism "hot as a hare, red as a beet, dry as a bone, blind as a bat, and mad as a hatter" vividly conveys the symptoms of atropine intoxication, which are predictable extensions of the pharmacologic effects of this group of drugs. Present are dryness of the mouth, extreme thirst, a burning sensation in the throat, and difficulty in swallowing; dilation of the pupils and cycloplegia with severe impairment of vision and photophobia; flushing of the skin, vasodilation of skin vessels, absence of sweating, and an increase in body temperature in warm environments to 40.5° C (105° F) or greater; urinary retention; and derangements of CNS activity. Toxic CNS effects of atropine and homatropine in children include ataxia that becomes so severe that the patients are unable to sit or stand unassisted; a dysarthric quality of speech; restlessness with constant muttering, shouting, and singing; great confusion; visual hallucinations; and violent, aggressive, and maniacal behavior.

Mild toxic reactions may subside in a few hours, whereas most patients require a day or more for complete recovery. Therapy for atropine poisoning includes physostigmine, which is useful in increasing the amount of ACh in the vicinity of the receptors and acts rapidly to terminate the atropine blockade. Antianxiety drugs such as diazepam may be used to control CNS excitation. Therapy also includes supportive care.

A more recent practice of drug abuse in young adults in certain locales of the United States is the chewing of seeds from the moonflower plant (*Datura inoxia*). Patients present with typical signs of antimuscarinic drug poisoning because of the high level of scopolamine in the plant. These signs include hallucinations; dry, hot, and flushed skin; dry mouth; and tachycardia.[4]

Topical use of antimuscarinic drugs in the eye is absolutely contraindicated in cases of suspected or diagnosed narrow-angle glaucoma. Systemic doses of anticholinergic drugs can be used in patients with open-angle glaucoma but not in patients with narrow-angle glaucoma. As previously mentioned, use of these drugs may precipitate the first attack of acute intraocular hypertension. In prostatic hypertrophy, anticholinergic drugs may cause urinary retention.

DRUG INTERACTIONS

The anticholinergic effect of atropine-like drugs is potentiated by antihistamines (which particularly accentuate the xerostomia), the tuberculostatic drug isoniazid, monoamine oxidase inhibitors, tricyclic antidepressants, and several other drugs. Phenothiazines tend to potentiate the CNS effects of the antimuscarinic drugs. When atropine is given in the presence of propranolol, it is likely to antagonize the slowing of the heart and the increased duration of the atrioventricular nodal refractory period for which propranolol may have been prescribed to achieve. Atropine may also block the vagal actions of the digitalis glycosides.

BOTULINUM TOXIN

Botulinum toxin prevents the release of ACh from nerve endings. It is sometimes used to prevent drooling in certain disease states.[10] It is also used to relieve muscle spasm and cosmetically to smooth facial wrinkles and frown lines. Botulinum toxin is discussed in Chapter 10.

TABLE **9-5**

Preparations and Oral Dosages Used in Dentistry

DRUG	DOSE	TIME OF ADMINISTRATION*
Atropine sulfate	0.4-1.2 mg	30-60 min
Glycopyrrolate	1-2 mg	30-45 min
Hyosycamine sulfate	0.125-0.5 mg	30-60 min
Propantheline bromide	15-30 mg	30-45 min

*Time before the procedure when the drug is administered.

THERAPEUTIC USES IN DENTISTRY

The principal use of anticholinergic drugs in dentistry is to decrease the flow of saliva during dental procedures. Small doses given orally or parenterally approximately 30 minutes to 2 hours before the procedure are effective, but these drugs may also produce side effects that may be objectionable to some patients. The same dose may also be used to diminish salivary flow in heavy metal poisoning. Table 9-5 lists four preparations and oral dosages used in dentistry. Atropine is often selected because it is well absorbed from the gastrointestinal tract.

Atropine and glycopyrrolate are frequently used in oral surgery as intraoperative antisialagogues. They are administered intravenously in doses of 0.4 mg to 0.6 mg and 0.1 mg to 0.2 mg. Because it is a quaternary amine, glycopyrrolate has fewer CNS effects than belladonna alkaloids. Compared with atropine, it is a more selective antisialagogue and less likely to promote tachycardia in conventional doses. During general anesthesia, anticholinergics also diminish secretions in the respiratory tract, reducing the likelihood of laryngospasm, and help prevent reflex vagal slowing of the heart.

IMPLICATIONS FOR DENTISTRY

Not only do dentists occasionally have reason to use antimuscarinic drugs, but also dentists often encounter patients who are taking these agents for any one of the reasons enumerated. Drugs of several different pharmacologic classes have substantial antimuscarinic effects. The most characteristic effects of these drugs that concern dentists are xerostomia and the discomfort that this brings to the patient and the deterioration in oral health. Small doses of pilocarpine often are effective in stimulating salivary flow; however, this strategy is complicated by the fact that pilocarpine may also counter the therapeutic benefit being achieved by the antimuscarinic drug. In cases in which using a muscarinic receptor agonist may antagonize therapy involving an antimuscarinic drug, patients can be advised to drink water, suck on noncariogenic lemon drops, and irrigate the mouth with saliva substitutes to alleviate xerostomia. As discussed in Chapter 8, if saliva flow is reduced, patients need to pay scrupulous attention to oral hygiene, and caries control needs to be more aggressive. If there is progressive deterioration in oral health, consultation with the patient's physician may be helpful in identifying suitable therapeutic alternatives without as much xerostomia. The use of antimuscarinic drugs should be avoided in patients with prostate

hypertrophy and patients with atony in the urinary or gastrointestinal tract.

ANTIMUSCARINIC DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Naturally occurring alkaloids	
Atropine	Atropisol, Sal-Tropine
Belladonna (tincture and extract)	—
Hyoscyamine	Anaspaz, Levsin
Levorotatory alkaloids of belladonna	in Bellamine
Scopolamine	Isopto Hyoscine, Scopace
Scopolamine (transdermal therapeutic system)	Transderm Scōp
Semisynthetic derivatives	
Atropine methylnitrate*	—
Homatropine	Isopto Homatropine
Methscopolamine	Pamine
Synthetic quaternary ammonium compounds	
Anisotropine*	Valpin 50
Clidinium	Quarzan
Glycopyrrolate	Robinul
Hexocyclium*	Tral Filmtabs
Ipratropium	Atrovent
Isopropamide*	Darbid
Mepenzolate	Cantil
Methantheline*	Banthine
Propantheline	Pro-Banthine
Tiotropium*	Spiriva
Tridihexethyl*	Pathilon
Synthetic nonquaternary ammonium compounds	
Benztropine	Cogentin
Biperiden	Akineton
Cyclopentolate	Cyclogyl, in Cyclomydril
Dicyclomine	Bentyl, Byclomine
Flavoxate	Urispas
Oxybutynin	Ditropan
Procyclidine	Kemadrin
Propiverine*	Detrunorm
Tolterodine	Detrol
Trihexyphenidyl	Artane
Tropicamide	Mydriacyl, Tropicacyl
Tricyclic benzodiazepine	
Pirenzepine*	Gastrozepine

*Not currently available in the United States.

CHAPTER 10

*Drugs Affecting Nicotinic Receptors**

XI-QIN DING

Early in the sixteenth century, Spanish explorers of the New World encountered a plant extract used by South American natives to poison the tips of their hunting arrows. This extract, known as *curare*, was brought back to Europe, and its lethal action was quickly found to depend on muscular paralysis. Further understanding of the actions of curare did not occur for many years.

In 1856, Bernard reported that the site of action of curare was the junction between nerve and muscle. He found that although curare blocked neuromuscular transmission, it did not impede conduction of impulses along the motor nerve or contraction of a directly stimulated muscle. The active substance used by Bernard in his studies, *d*-tubocurarine, was subsequently purified, and in 1942 it was administered for the first time to a patient undergoing surgery for appendicitis to relax the abdominal musculature. Drugs that block neuromuscular transmission have since found widespread acceptance for their ability to produce muscular flaccidity and are frequently administered as adjuncts to general anesthesia during surgery.

In 1889, Langley showed that nicotine could "paralyze" transmission at autonomic ganglia, and in 1905 he showed that nicotine could stimulate muscle when applied to the motor end plate and that curare could block this effect. These findings led to the adoption of the term *nicotinic* to refer to the receptors present at autonomic ganglia and the neuromuscular junction.

The discovery of curare[4] led to developments in two different directions: to drugs that affect transmission at nicotinic cholinergic receptors and to drugs that interfere with the mechanisms of skeletal muscle contraction. These two topics are the subjects of this chapter.

DRUGS AFFECTING GANGLIONIC TRANSMISSION

Ganglionic Transmission

Nicotinic receptors (see Chapter 1) play a crucial role in the transmission of autonomic impulses across the ganglionic synapse. As described in Chapter 5, acetylcholine (ACh) is the primary neurotransmitter at sympathetic and parasympathetic ganglia, where it is released by preganglionic neurons and stimulates postganglionic neurons by activating nicotinic N_N receptors. Although it is sometimes convenient to think of autonomic ganglia as simple relay stations between the central nervous system (CNS) and effector tissues, the existence of other receptors and neurotransmitters within the ganglia indicates that some modulation of the primary nervous inputs may occur. It is also evident that transmission is not the same in sympathetic and parasympathetic ganglia even though N_N receptors are the primary receptors in both cases.

Various pharmacologic and electrophysiologic studies on sympathetic ganglia have led to models of ganglionic transmission that involve at least four classes of receptors: cholinergic nicotinic, cholinergic muscarinic, α-adrenergic, and peptidergic.[8] Muscarinic and peptidergic receptors mediate slow and late slow excitatory postsynaptic potentials, which seem to facilitate the transmission of high-frequency impulses through the primary nicotinic receptor pathway. Catecholamine-containing (dopamine or norepinephrine) interneurons have been proposed for sympathetic ganglia[12] but are not found in parasympathetic ganglia.[21] As shown in Figure 10-1, these interneurons may be stimulated by preganglionic muscarinic activity to release catecholamines that hyperpolarize the postganglionic neuron, producing an inhibitory postsynaptic potential. These secondary events of ganglionic transmission only modulate the primary depolarization, by making it more or less likely to occur. Conventional N_N receptor antagonists can inhibit ganglionic transmission completely, but muscarinic antagonists, α-adrenergic antagonists, and peptidergic antagonists cannot do so.

There are two important facts in ganglionic transmission. First, the autonomic ganglia contain neuronal components that are not protected by a structure analogous to the blood-brain barrier, which means that they are affected by many drugs and chemicals that never gain access to central synapses. Second, ACh is the primary transmitter of the ganglionic synapse, and any drug that interferes with the synthesis, release, or inactivation of ACh or with its interaction with the N_N receptor has the capacity to interfere with ganglionic transmission.

Ganglionic Stimulating Drugs

Nicotine

Nicotine, as indicated in Chapter 8, is the principal psychoactive ingredient in tobacco products. As a selective depolarizing drug at nicotinic receptors, this alkaloid stimulates transmission at autonomic ganglia and at nicotinic synapses in the CNS. It also activates various sensory fibers equipped with nicotinic receptors, including mechanoreceptors in the lung, skin, mesentery, and tongue; nociceptive nerve endings; and chemoreceptors in the carotid body and aortic arch. Stimulation of nicotinic receptors in skeletal muscle is easily shown in the laboratory, but it is not evident normally in humans

*The author wishes to recognize Dr. Joel D. Schiff for his past contributions to this chapter.

because initial stimulation is soon followed by inhibition at these nicotinic sites. Nicotine has a dual effect on ganglionic transmission—initial stimulation and subsequent depression (see later).

An important feature of nicotinic receptors is their tendency to become desensitized (i.e., unresponsive) on continuous exposure to agonists or depolarizing antagonists (e.g., succinylcholine, as described later). The actions of nicotine are highly time and concentration dependent, and complex patterns of stimulation and depression are observed. The heart rate may be increased by stimulation of sympathetic ganglia and the adrenal medulla or by inhibition of vagal transmission in the heart, or both. Conversely, blockade of sympathetic transmission to the heart and stimulation of parasympathetic transmission can cause bradycardia. The heart rate may also be affected by central influences and by actions at peripheral sensory sites.

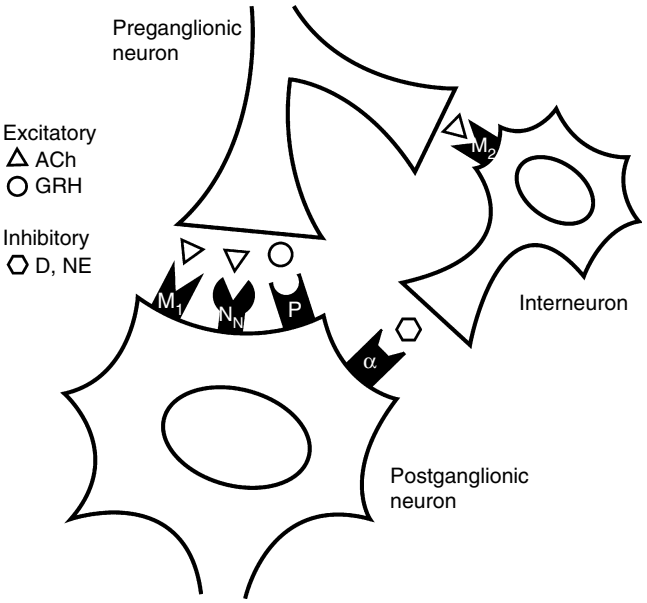

FIGURE **10-1** Synaptic connections in the mammalian superior cervical ganglion. The principal pathway involves nicotinic receptor transmission *(N_N)* sensitive to conventional ganglionic blocking drugs. Muscarinic receptors (M_1 and M_2), sensitive to atropine blockade, support and inhibit depolarization of the postganglionic neuron. As shown, a catecholamine-containing interneuron may participate in causing inhibition. Corelease of peptides such as gonadotropin-releasing hormone *(GRH)* produces long-lasting facilitation of transmission. α, α-Adrenergic receptor; *ACH*, acetylcholine; *D*, dopamine; *NE*, norepinephrine; *P*, peptidergic receptor.

Generally, usual amounts of nicotine absorbed during cigarette smoking cause mild cardiovascular stimulation, increased gastrointestinal activity, and CNS stimulation accompanied in regular users by a feeling of well-being and decreased irritability. With long-term use, tolerance and physical dependence occur. The addictive nature of nicotine is thought to result from its action on the reward pathway—the circuitry in the brain that regulates feelings of pleasure and euphoria.

Acute overdose of nicotine causes nausea and vomiting, abdominal pain, dizziness and confusion, and muscular weakness. If untreated, death may ensue from cardiopulmonary collapse. Nevertheless, the primary health issues regarding nicotine stem from the chronic use of tobacco products. An increased incidence of cancer and cardiovascular and pulmonary disease has been well documented.[20] In dentistry, tobacco use has been linked to oropharyngeal carcinoma, leukoplakia, acute and chronic periodontal disease, delayed wound healing, halitosis, and tooth staining.[5]

The only therapeutic use of nicotine is as an adjunct in tobacco cessation programs. Nicotine is administered in multiple forms (Table 10-1) to maintain pharmacologic concentrations of the alkaloid and to prevent tobacco cessation from triggering an acute withdrawal syndrome, which includes irritability, anxiety, sleep disturbances, and cognitive impairment. It also dissociates the self-administration of nicotine from the social, tactile, and oral and olfactory components of tobacco smoking, weakening the psychological link between satisfaction of the nicotine craving and the physical actions of tobacco use. The nicotine dose is reduced in a stepwise fashion over several months, during which time the patient ideally receives continued counseling and motivational assistance to remain abstinent.

Because of the deleterious effects of smoking and smokeless tobacco on oral health, the dentist is encouraged to participate actively in helping patients quit tobacco use.[5] Such participation may include—in addition to prescribing a

TABLE **10-1**

Nicotine-Containing Smoking Deterrents

PRODUCT	PROPRIETARY (TRADE) NAME	NICOTINE CONTENT PER DOSE FORM (mg)	DAILY NICOTINE DOSE (mg)	DURATION (wk)*
Nicotine inhalation system	Nicotrol Inhaler	4 (delivered)	≤64	≤24
Nicotine gum	Habitrol, Nicorette, Nicotrol, Thrive	2 and 4†	≤80	12
Nicotine lozenge	Commit	2 and 4†	≤80	12
Nicotine transdermal system (skin patch)‡	NicoDerm CQ	114	21	6
		76	14	2
		38	7	2
Nicotine nasal spray	Nicotrol NS	0.5§	≤40	≤14

*For the gum, lozenge, and inhalation dosage forms, the number of units used per day is gradually decreased, beginning after 6 weeks of therapy (12 weeks for the inhalation system). The transdermal system uses a sequential schedule, beginning with the strongest patch for individuals smoking more than 10 cigarettes per day (as shown). For individuals who smoke 6 to 10 cigarettes per day, the patch delivering 14 mg/day should be used for 6 weeks, followed by the 7-mg dose for 2 weeks.

†The 2-mg dose is used for individuals who smoke less than 25 cigarettes per day.

‡Patch is worn 16 to 24 hours a day.

§Dose per actuation; 1 to 2 sprays in each nostril (1-mg to 2-mg total dose) is recommended.

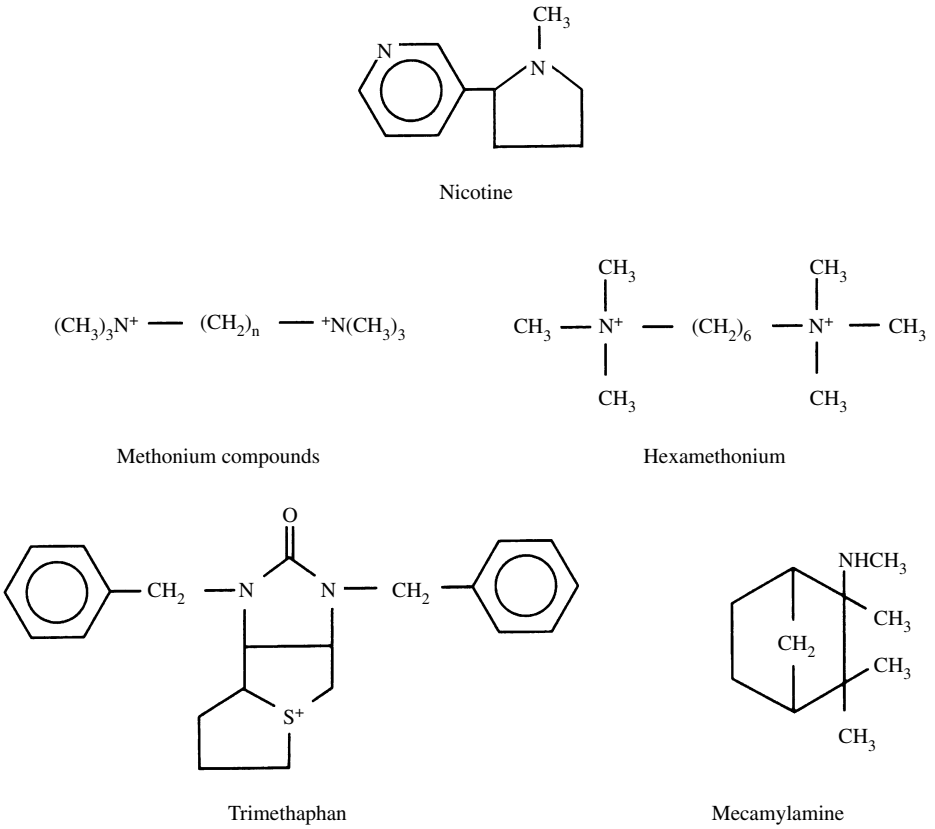

FIGURE **10-2** Structural formulas of nicotine and some nondepolarizing ganglionic blocking agents.

nicotine product—procedures to promote fresh breath and tooth bleaching to remove tobacco stains from teeth, which may provide additional positive psychological feedback to encourage abstinence from tobacco use.

Other ganglionic stimulants

Tetramethylammonium and dimethylphenylpiperazinium are also ganglionic stimulants. They differ from nicotine primarily in the fact that the stimulation is not followed by pronounced ganglionic depolarization blockade. Dimethylphenylpiperazinium is about three times more potent and slightly more ganglion-selective than nicotine.

Ganglionic Blockers

Between 1895 and 1926, numerous compounds having the generic structure shown in Figure 10-2 and termed *methonium compounds* were synthesized. In 1915, Burn and Dale described the ganglionic blocking action of tetraethylammonium. In the 1940s, an entire series of diiodide and dibromide derivatives of these methonium compounds were synthesized; in 1946, Acheson and Moe published a systematic and extensive pharmacologic study of tetraethylammonium. Interest in these drugs arose because they could be used as pharmacologic tools for exploring various aspects of autonomic pharmacology and because, at least at first, they offered the promise of being useful therapeutic agents in the treatment of hypertension, peptic ulcers, and other diseases that seemed to have an autonomic component and that had not yet yielded to therapeutic measures then available.

Classification

Ganglionic blocking agents can be classified on the basis of their chemical structure or mechanism of action into three groups, as follows:

1. Depolarizing drugs, such as nicotine, which produce initial stimulation and varying degrees of subsequent block through a mechanism analogous to that of succinylcholine (see later). At higher doses, these agents can stimulate and block other cholinergic receptors, such as those at the neuromuscular junction and in the CNS.
2. Competitive drugs, such as trimethaphan and tetraethylammonium, which interfere with the binding of ACh to the nicotinic receptor.
3. Noncompetitive agents, such as hexamethonium (C6) and mecamylamine, a secondary amine. Hexamethonium interferes with ganglionic transmission by blocking ion channels that have been opened by ACh, whereas mecamylamine seems to share properties associated with hexamethonium and the competitive blocking agents.

Pharmacologic effects

The discussion in this section is restricted to the pharmacology of the competitive and noncompetitive nondepolarizing blocking agents because clinically used ganglionic blockers belong to these two groups. Nicotine has been discussed previously regarding its ganglionic stimulating properties and its use in tobacco cessation programs.

All the ganglionic blocking drugs, regardless of their structure or their mechanism of action, have the same basic pharmacology, although many of them have additional actions at sites other than ganglionic receptors. An ideal ganglionic blocking agent would be a compound that interferes only with ganglionic transmission, blocks without previous excitation, and does not influence the release of transmitter. Hexamethonium is a prototype agent that meets these criteria.

The pharmacology of the ganglionic blocking drugs is predictable because all parasympathetic and sympathetic

TABLE **10-2**

Usual Predominance of Sympathetic or Parasympathetic Tone at Various Effector Sites, with Consequent Effects of Autonomic Ganglionic Blockade

ganglia are blocked by most of the available agents. Ganglia are not equally sensitive to the blocking drugs, however, and some effects are easier to block than others. The effects of ganglionic agents are profoundly influenced by the background tone; that is, the effect of blocking a ganglion is proportional to the rate of nerve transmission through that ganglion at any given time. If vascular tone is high, as it would be in a standing individual, the ganglionic blocking agents would produce a profound decrease in blood pressure, much greater than they would in a recumbent individual, in whom vascular tone would be lower. Finally, as is shown in Table 10-2, because these drugs block sympathetic and parasympathetic actions, the direction and magnitude of their effects are related to which autonomic division provides the dominant baseline control for a given organ.

The eye. Parasympathetic neurons play a dominant role in the regulation of pupillary diameter and activity in the ciliary muscle. Blockade of autonomic ganglia leads to partial, but not maximal, dilation of the pupil and to paralysis of accommodation.

Salivary glands. The salivary glands are predominantly under the control of the parasympathetic nervous system. Ganglionic blockade results in marked xerostomia.

Cardiovascular system. Ganglionic blocking drugs cause a decrease in blood pressure that depends on posture. Normotensive recumbent subjects show the least change; the most prominent alteration in blood pressure occurs in sitting or standing subjects because vascular reflexes play an important role in the maintenance of blood pressure in these circumstances. The blood pressure may decrease by 35%. Changes in heart rate depend on the existing vagal tone, but generally cardiac rate increases slightly in humans. Cardiac output tends to decrease, mainly because of poor venous return and pooling of blood in the extremities. Localized blood flow alterations depend on the location of the vascular bed. In the skin, there is an increase in blood flow that manifests as an increase in surface temperature and a pinkness of the skin. The effects on coronary, pulmonary, muscle, renal, cerebral, and splanchnic circulation are inconsistent because, although vascular resistance may decrease in some of these organs, the reduced cardiac output may not permit a concomitant increase in blood flow.

Respiratory tract. There is inhibition of secretory activity in the respiratory tract and slight bronchial relaxation, but ganglionic blocking drugs do not directly affect respiration.

Gastrointestinal tract. The volume and acidity of gastric secretions that occur spontaneously are strongly inhibited by the ganglionic blocking agents, but there is little effect on secretion induced by histamine. Vagal stimulation is inhibited, and marked inhibition of motility occurs throughout the gastrointestinal tract, leading to paralytic ileus and causing constipation. Sympathetically maintained sphincter tone is also lost, and so the constipation may alternate with diarrhea.

Urinary tract. The parasympathetic component of the efferent arm of the spinal reflex normally responsible for micturition is blocked. As a result, distention of the bladder does not trigger the voiding response, and urinary retention develops because of incomplete bladder emptying.

Sweat glands. Sympathetic stimulation of the eccrine sweat glands is inhibited, so the skin becomes dry and warm and flushed from the vasodilation of skin blood vessels.

Central nervous system. In therapeutic doses, the cationic blocking drugs, including hexamethonium and its congeners, do not gain ready access to the CNS, and they usually have no direct CNS effects. Mecamylamine and other secondary and tertiary amine blocking agents have been reported to produce such effects as tremor, choreiform movements, mental aberrations, and convulsions.

Absorption, fate, and excretion

For ganglionic blocking agents, the question of absorption, fate, and excretion is an academic one because only one drug, mecamylamine, is available in an oral formulation and it is seldom used because of its numerous side effects. Trimethaphan has been administered by intravenous drip; it has a rapid onset and short duration of action.

General therapeutic uses

Because of their multiple side effects, ganglionic blockers are rarely used. For most patients these effects are intolerable except for acute use in recumbent patients. Trimethaphan was used in the past as an adjunct during anesthesia

to produce controlled hypotension and in hypertensive emergencies.

Adverse effects

As is true of other autonomic drugs, toxicity from the ganglionic blocking agents is an extension of their known pharmacologic effects. Some of these effects, such as xerostomia, blurring of vision, and constipation, are annoying but bearable. Other side effects, such as orthostatic hypotension, urinary retention, and sexual impotence, present more significant problems. More severely, the ganglionic blocking agents can produce peripheral circulatory collapse with cerebral and coronary insufficiency, paralytic ileus, and complete urinary retention. The toxic liabilities of the drugs are the major reason for their abandonment in the treatment of hypertension.

Implications for dentistry

The ganglionic blocking agents are no longer in wide use; patients with problems stemming from ganglionic blockade that might ordinarily prove troublesome to the dentist, such as xerostomia and orthostatic hypotension, are not likely to be encountered.

DRUGS AFFECTING NEUROMUSCULAR TRANSMISSION

Neuromuscular Transmission

Nervous control of skeletal muscle contraction is mediated by ACh. In response to a motor neuron action potential, ACh is released from the terminal region of the nerve fiber. The transmitter diffuses across the junctional cleft and binds with the nicotinic N_M receptor on the postjunctional membrane (end plate) of the muscle fiber. As with other nicotinic receptors the N_M receptor has two binding sites for cationic ligands, and the binding of two molecules of ACh to the receptor brings about an increase in the cation permeability of the end plate membrane and a consequent depolarization (excitatory end plate potential) of the junctional region of the muscle fiber. Under normal conditions, the depolarization is sufficient to trigger an action potential in the electrically excitable muscle fiber membrane, and muscular contraction follows.[10] Figure 10-3 shows the physiologic events that occur in a nerve, neuromuscular junction, and skeletal muscle that lead to contraction of muscle and indicates points along the pathway at which drugs can block these events.

Neuromuscular Junction Blockers

Neuromuscular blocking drugs interfere with the ability of ACh to evoke end plate depolarization at the nicotinic N_M receptor. They are generally separated into two groups according to whether the agents themselves bring about end plate depolarization in the course of their action. The depolarizing and the nondepolarizing blocking agents differ in the mechanisms through which they produce neuromuscular blockade (discussed subsequently).

Nondepolarizing agents

Nondepolarizing, or competitive, neuromuscular blocking drugs include tubocurarine (*d*-tubocurarine) and several other benzylisoquinolines (e.g., atracurium, cisatracurium, and mivacurium); aminosteroids such as pancuronium, rocuronium, and vecuronium; and a few unrelated drugs.[19] Tubocurarine, rocuronium, and vecuronium are monoquaternary amines with a second nitrogen that is partially ionized at physiologic pH; the other clinically available drugs are bisquaternary compounds. Commonly, these drugs incorporate two cationic nitrogen sites into a rigid molecular structure (Figure 10-4). The rank order of potency at the N_M receptor correlates highly with the clinical dose needed to produce 50% twitch depression of the adductor muscle of the thumb (adductor pollicis).[16]

All these drugs act by occupying the end plate N_M receptor sites of the muscle fiber, blocking access to these sites by ACh. The drugs themselves do not cause end plate depolarization. Inhibition of neuromuscular transmission is essentially competitive, with the blocking agent and ACh competing for receptor sites on the muscle fiber. By interfering with nervous excitation of muscle without themselves producing any excitation, the nondepolarizing blocking agents cause flaccid paralysis. Because of the very large safety margin in neuromuscular transmission, which results from the 6-fold to 10-fold excess of ACh released from the motor neuron terminal and from the large number of postjunctional receptor sites (resulting in a highly coupled stimulus-response system as described in Chapter 1), about 70% of the ACh receptors must normally be blocked to produce any clinically apparent effect on muscle function.

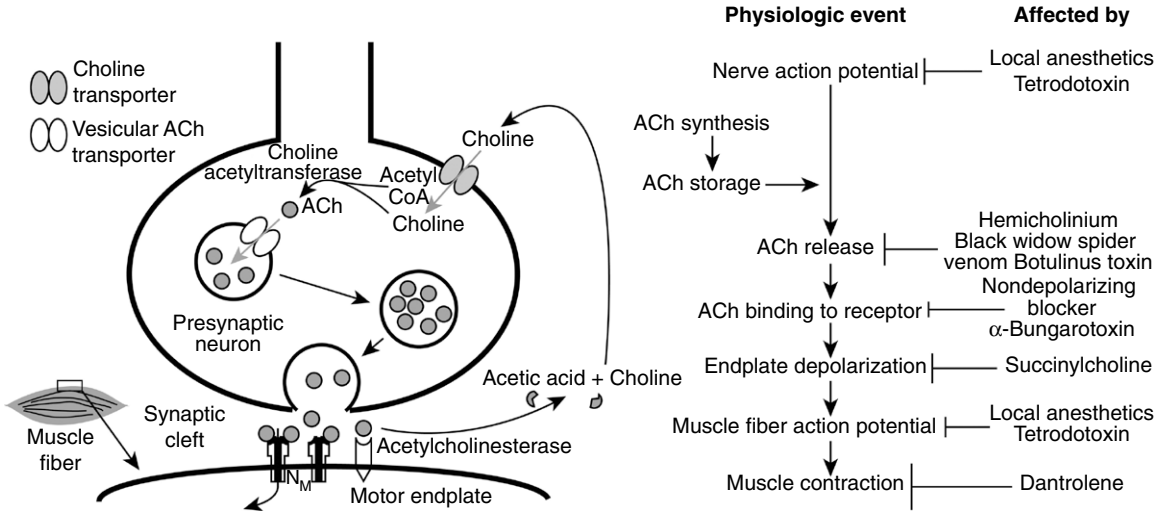

FIGURE **10-3** Physiologic events that occur in a motor nerve, neuromuscular junction, and skeletal muscle, leading to contraction of the muscle, and drugs that can block these events. *ACh*, Acetylcholine.

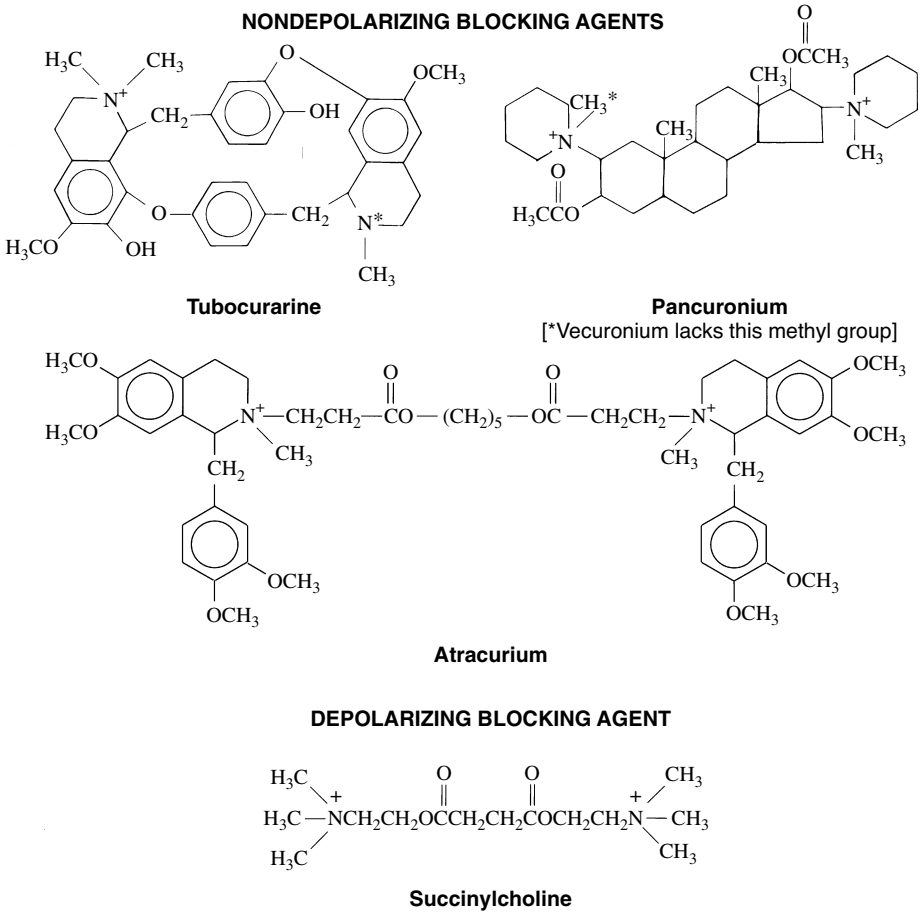

FIGURE **10-4** Structural formulas of some neuromuscular blocking agents.

Although tubocurarine, which was first isolated as the primary active ingredient from arrow poisons used by South American Indians, has the longest history of use and can be thought of as the prototype of this category of drugs, it is no longer used because of its tendency to evoke undesirable side effects. The major side effect seen with curare is hypotension. The excessive hypotension is the result of (1) blockade of autonomic ganglia and (2) release of histamine from mast cells. Histamine release may cause bronchoconstriction in asthmatic patients. Newer congeners with more selective neuromuscular blocking effects are preferred because they are largely devoid of these problems.[19]

Depolarizing agents

Similar to most nondepolarizing blockers, succinylcholine (also known as suxamethonium chloride and scoline), the major depolarizing agent, is a bisquaternary compound. In contrast to the nondepolarizing agents, succinylcholine is a much smaller molecule, composed simply of two ACh molecules attached at the acetyl ends (see Figure 10-4). Succinylcholine has a flexible chain linkage between its cationic moieties.

Succinylcholine acts by binding to the cholinergic receptor at the muscle end plate. As the class name suggests, the initial effect of the binding of this agent is a depolarization of the muscle fiber. During the early phase of its action, there is a period of excitation during which the sensitivity of the muscle to ACh is increased. It is common for the drug-induced depolarization to be great enough to trigger action potentials and fasciculations (i.e., spontaneous twitching) in the muscle fibers. It is believed, however, that the fasciculations reflect activation of prejunctional N_M receptors, causing motor neuron depolarization and ACh release. Postjunctional stimulation by succinylcholine is responsible for an increased muscle tension observable with some muscles, especially the masseter. When exaggerated, masseteric tone can occasionally complicate endotracheal intubation.

The depolarization produced by the blocking agent gradually diminishes, but the end plate membrane potential does not completely return to its resting level. After the transient excitation, and during the period in which end plate depolarization is still prominent, neuromuscular transmission is blocked in what is referred to as a *phase 1 block*. Here, continued depolarization of the motor end plate traps surrounding voltage-gated Na^+ channels in an inactivated state (see Chapter 16 for a discussion of Na^+ channel states) refractory to further stimulation until the membrane potential is restored to normal. Recovery from this form of neuromuscular paralysis occurs quickly after cessation of succinylcholine administration. With continued drug infusion, however, the end plate slowly repolarizes despite the presence of succinylcholine, and there is a gradual transition to a longer lasting *phase 2*, or *desensitization block*. Recovery in this situation is delayed beyond the removal of the depolarizing agent and depends on return of N_M receptors from the desensitized to the resting state.

TABLE **10-3**

Pharmacologic Properties of Neuromuscular Receptor–Blocking Agents

DRUGS	ED_{95} (mg/kg)*	ONSET (min)	DURATION OF ACTION (min)†	GANGLIONIC BLOCKADE	VAGAL BLOCKADE	HISTAMINE RELEASE
Ultrashort-Acting						
Succinylcholine	0.3	1-1.5	5-8	–	–	+
Short-Acting						
Mivacurium	0.08	3-4	12-18	0	0	+
Intermediate-Acting						
Atracurium	0.23	3-4	35-45	0	0	+
Cisatracurium	0.05	4-6	35-45	0	0	0
Rocuronium	0.3	1.5-3	30-40	0	0	0
Vecuronium	0.05	3-4	35-45	0	0	0
Long-Acting						
Pancuronium	0.07	3-4	60-120	0	++	0
Tubocurarine	0.5	2-4	60-120	++	0	++

*The ED_{95} is the dose that reduces the twitch tension in the adductor pollicis by at least 95% in 50% of individuals. Usual intubating doses are two to three times the ED_{95}.
†The duration of action is the time from onset of paralysis to return of 25% of the twitch tension in the adductor pollicis.
++, Moderate effect; +, slight effect; –, opposite effect (i.e., stimulation of ganglionic and vagal transmission); *0,* no effect.

Succinylcholine is administered intravenously to produce a short-acting depolarizing block of skeletal muscle lasting about 5 to 10 minutes (Table 10-3). This short action is related to metabolism by plasma and liver pseudocholinesterases to succinic acid and choline. The short duration of action of this compound has made it one of the drugs of choice to relax the laryngeal muscles before intubation and as an adjuvant before electroconvulsive shock therapy. Succinylcholine also stimulates autonomic ganglia and may cause a mild elevation of blood pressure and bradycardia due to ganglionic effects. Rarely, succinylcholine contributes to a syndrome termed *malignant hyperthermia*, which may be related to the initial intense muscular contractions. Succinylcholine tends to elevate ocular, cerebrospinal fluid, and gastrointestinal pressure and may be contraindicated in glaucoma patients, in patients suspected to have brain tumors, and in patients immediately after meals. Succinylcholine is perhaps the leading agent given for anesthetic management in causing anaphylaxis, with a reported incidence of one or two cases per 10,000 administrations.

Pharmacologic effects

The major pharmacologic actions of neuromuscular blocking agents are on the motor end plate of skeletal muscle, and all the therapeutic applications of these drugs stem from those actions. Nevertheless, neuromuscular blocking agents affect many other body systems. Some of the more important of these actions on other sites must be considered when choosing blocking drugs to administer, and additional precautions in their use must be observed.

An ideal neuromuscular blocker would be rapid in onset, consistent in duration of action (even in patients with advanced renal or hepatic disease), and readily reversible in effect. It would be a nondepolarizing drug so that it would not cause muscle fasciculations; it would be free of autonomic and cardiovascular effects; and it would not liberate histamine from muscle or other tissues. Additionally it would not induce tachyphylaxis, so prolonged blockade could be maintained without the need to increase the dosage over time. None of the existing neuromuscular blocking agents fulfills all these expectations; however, cisatracurium, vecuronium, and rocuronium are notable for their relative lack of effects other than neuromuscular blockade (see Table 10-3).[3]

Neuromuscular junction. On slow intravenous infusion, depolarizing and nondepolarizing neuromuscular blocking agents first affect the facial muscles and then the other muscles of the head and neck. In a conscious subject, this action produces diplopia, dysarthria, and dysphagia; because of dysphagia, secretions accumulate in the throat, and breathing becomes difficult. In addition, there is an uncomfortable sensation of warmth. As the blockade progresses, the small muscles of the hands and body are affected. Paralysis of the intercostal muscles forces breathing to become entirely diaphragmatic. Finally, complete flaccid paralysis, including paralysis of all respiratory muscles, occurs.

This sequence of effects occurs when maximal doses of neuromuscular blocking agents are administered gradually; lower doses may produce only the earlier manifestations and spare the respiratory muscles from becoming paralyzed. In addition, there is some evidence that succinylcholine preferentially blocks transmission in white muscles, such as the muscles of the limb musculature, with less effect on the slower red muscles, including the muscles of respiration.

Rapid intravenous injection of full paralyzing doses, as is generally performed clinically, produces a different temporal pattern of blockade. In this situation, the upper airway muscles (larynx, tongue, jaw) and the diaphragm are blocked before peripheral muscles, such as the adductor pollicis. The respiratory muscles also recover much more quickly. The faster onset in this case may result from increased blood flow or higher temperature in these muscles; the faster recovery is in keeping with the differential sensitivity to neuromuscular blockade already described.

Central nervous system. None of the neuromuscular blocking drugs described here has any apparent influence on the CNS. The reason for this is the inability of these compounds, all of which are permanent cations with low lipid solubility, to cross the blood-brain barrier.

Neuromuscular blockade does not provide anesthesia or analgesia but can make it impossible for a patient to show outward signs of pain. When these drugs are used as adjuncts to general anesthesia, the depth of the anesthesia must be monitored closely to prevent conscious awareness in a paralyzed patient.

Autonomic nervous system. Because of their selectivity for the N_M receptors of the muscle end plate, neuromuscular blocking drugs as a group have no major influence on the autonomic nervous system. Individual drugs of this category do exert certain specific autonomic influences, however (see Table 10-3).

As mentioned previously, tubocurarine exerts partial blocking activity at autonomic ganglia. Pancuronium is notable for its tendency to increase the heart rate, in part by inhibiting vagal activity and by increasing norepinephrine release in the heart. This side effect has been beneficial in counteracting the bradycardia associated with high doses of opioids used in cardiac surgery. Succinylcholine causes a transient bradycardia as it is administered, probably through a vagomimetic action on the muscarinic receptors of the heart. After administration of succinylcholine, there is a longer period of tachycardia that seems to be the result of muscarinic receptor stimulation of sympathetic ganglia.

Histamine release. Several neuromuscular blocking agents, most prominently tubocurarine, cause the release of histamine from mast cells into the circulation (see Table 10-3). These drugs are capable of producing the histamine-mediated effects of hypotension, edema, bronchospasm, and increased salivary flow. The last two actions may introduce complications during performance of controlled respiration and can be prevented by prior administration of antihistamines. Histamine-related effects can be minimized by avoiding rapid intravenous injection. Neuromuscular blocking drugs with a steroid nucleus (pancuronium, rocuronium, vecuronium) are free of this side effect; cisatracurium is the only currently available benzylisoquinoline without this clinical liability.[7] Histamine release is generally thought to be a direct result of stimulating nicotinic receptors on the mast cell membrane.[2,22]

Cardiovascular system. Although none of the neuromuscular blocking drugs has any direct effect on vascular tone, all can produce hypotension by a combination of indirect actions. The release of histamine, as described earlier, causes edema and vasodilation. The loss of skeletal muscle tone as a result of neuromuscular blockade eliminates the skeletal muscle pumping action on the veins of the extremities; there is pooling of blood in capacitance veins and a concomitant reduction in venous return to the heart. In addition to these physiologic effects on the circulation, another factor is the use of assisted or controlled ventilation during the period of muscular paralysis. The increased intrathoracic pressure produced by the respirator during its positive-pressure phase further reduces venous return to the heart. In this respect, alternating positive-pressure and negative-pressure respirators are less problematic than intermittent positive-pressure devices because of the increased venous return in the negative-pressure phase of the former. These causes of hypotension can be treated by positioning the patient with the lower extremities elevated slightly above the heart and by administering isotonic fluids intravenously, possibly in combination with sympathomimetic vasoconstrictors.

Absorption, fate, and excretion

Neuromuscular blocking agents are generally administered intravenously. Intramuscular administration of large doses is effective for most of the agents discussed and may be used in treating some pediatric patients in whom intravenous injection might present difficulties, but this route does not offer the precision of control or the rapidity of onset of action afforded by the intravenous route. The drugs discussed in this chapter are ineffective when given orally. This was known to be the case for tubocurarine by South American hunters, who readily ate prey felled by arrows laden with the drug.

All the clinically useful blocking agents show their effects within a few minutes after administration (see Table 10-3). Succinylcholine provides excellent intubating conditions (vocal cord relaxation) within 60 to 90 seconds after intravenous injection and gives its maximal effect within 2 minutes. Recovery is apparent after 5 to 10 minutes. The nondepolarizing blockers exhibit slower onsets and longer durations of action. The speed of onset for these drugs is inversely related to blocker potency, presumably because fewer drug molecules of highly potent agents are available to initiate blockade. Rocuronium, the least potent competitive blocker currently available, has been found to produce intubating conditions almost as rapidly as succinylcholine in children, and it is the best alternative to succinylcholine currently available when rapid intubation is required.

Mivacurium, a short-acting agent, has a clinical duration of action of only 15 to 20 minutes after an intubating dose. Here, the clinical duration is defined as the time from onset of muscle blockade until the point at which the twitch response of the adductor pollicis to a supramaximal electrical stimulus has returned to 25% of baseline. (Full recovery does not occur until much later.) Comparative durations for intermediate-acting and long-acting blockers (as classified in Table 10-3) are 30 to 45 minutes and 60 to 120 minutes.[1] With any of the drugs, blockade may be prolonged either by repeated injection or by continuous intravenous infusion.

Succinylcholine and mivacurium are hydrolyzed by plasma pseudocholinesterase, which explains their brief durations of action. Mivacurium is broken down to inactive metabolites, whereas succinylcholine is first converted to succinylmonocholine, a much weaker depolarizing blocking agent, and then to succinic acid and choline. It is possible to inhibit the plasma pseudocholinesterase with hexafluorenium, after which the action of succinylcholine is prolonged much longer.

In some individuals with atypical plasma cholinesterase, succinylcholine and mivacurium persist in the body for several hours. Some of these patients can be identified before drug administration by a cholinesterase activity assay. Purified cholinesterase has been injected intravenously before treatment to obtain a neuromuscular blockade of short duration in these patients.

Long-acting neuromuscular blockers are to a large extent excreted unchanged in the urine and bile; their actions may be greatly prolonged in patients with renal or hepatic failure, and they are largely contraindicated in such patients. Intermediate-acting neuromuscular blockers are also eliminated in the urine and bile. The primary reason for the shorter duration of action of intermediate-acting drugs compared with long-acting agents is their greater redistribution potential. Vecuronium is partially metabolized by the liver; one of its metabolites, the 3-OH derivative, is about 60% as potent as the parent compound. Some of the parent drug and most of the metabolites are excreted by the biliary-fecal route. Vecuronium is suitable for use in patients with renal insufficiency, but it is contraindicated in patients with cirrhosis. Atracurium is hydrolyzed by nonspecific tissue esterases and degraded nonenzymatically by a process known as *Hofmann elimination*. This latter process converts the quaternary nitrogens to the tertiary form, cleaving the molecule and yielding laudanosine, a metabolite with CNS stimulatory properties in high concentrations. Because atracurium is almost completely

inactivated by nonhepatic metabolism, it is useful in patients with reduced hepatic and renal function. Cisatracurium, the most potent of the 10 stereoisomers that compose atracurium, is similarly inactivated; however, its much greater potency means that comparatively less of the laudanoside metabolite is produced.

General therapeutic uses

Since the first clinical use of tubocurarine in 1942, several applications for neuromuscular blocking agents have gained wide acceptance.

Endotracheal intubation. To secure a patent, protected airway, an endotracheal tube is often inserted in patients receiving general anesthesia or patients who are otherwise unconscious or in need of respiratory assistance (or both). Succinylcholine has long been the drug of choice because of its fast onset of action. Rocuronium is the only currently available nondepolarizing blocking drug to approach the rapidity of onset of succinylcholine. This attribute is one reason why rocuronium is currently the most commonly used nondepolarizing blocking drug in clinical use.

Surgery. Neuromuscular blocking agents, especially intermediate-acting competitive blockers, are frequently used as adjuncts to general anesthesia during surgical procedures. The most common indication is to relax the abdominal wall musculature during abdominal surgery. This application is especially useful in procedures such as appendectomy, in which the underlying condition has produced reflex splinting of these muscles. During brain or cerebrovascular surgery in which the patient is sedated but conscious, neuromuscular blockade may be used to suppress cough and sneeze reflexes so that the field of operation remains immobilized.

Tetanus. In mild cases of tetanus, the patient is generally able to sustain respiration except during intermittent spasms. Here, neuromuscular blocking agents are administered to reduce the severity of these spasms. In severe cases of tetanus, in which the rigor of the patient extends to the respiratory musculature, neuromuscular blocking drugs are administered to induce flaccidity so that a mechanical respirator may be used.

Electroconvulsive therapy. In the treatment of depressive illness with electroconvulsive therapy, the therapeutic result is a consequence of the electrical stimulation of the CNS; the massive muscle spasm that accompanies such treatment is of no therapeutic benefit and has the potential for producing bodily injury. Neuromuscular blockade is induced by injection of succinylcholine before the electrical stimulation of the brain. Succinylcholine is used because of its short duration of action and lack of residual side effects.

Other uses. Succinylcholine is used to produce a short-lived muscular relaxation to permit numerous brief nonsurgical manipulations, such as bronchoscopy. In cases of laryngospasm, succinylcholine, often in subintubating doses, may be needed to relax the vocal cords and permit ventilation.

Nondepolarizing blockers facilitate the setting of fractures of extremities or the mandible. Despite the fact that only a brief blockade is needed for such a procedure, succinylcholine is unsuitable because the fasciculations and increased motor tone it can cause may compound the fracture-associated injury.

Nondepolarizing neuromuscular blocking agents are sometimes used in the intensive care unit to facilitate mechanical ventilation of patients. Because this application is associated with a wide range of problems, including deep venous thrombosis, unrecognized inadequate sedation or analgesia, and prolonged paralysis after stopping the agent, this use should be minimized whenever possible.

Adverse effects

The major risk of overdosage with neuromuscular blocking agents is death from respiratory failure. When any neuromuscular blocking drug is administered, the practitioner must be prepared for the loss of respiratory function and have equipment immediately available for assisted or controlled respiration. In cases of respiratory arrest, ventilation must be maintained with external devices, generally with an endotracheal tube. Paralysis from nondepolarizing agents may be reversed to some extent through administration of an anticholinesterase (e.g., neostigmine), generally accompanied by an antimuscarinic drug (e.g., atropine) to prevent excessive muscarinic receptor–mediated sequelae to the anticholinesterase. The use of an anticholinesterase to reverse the phase 2 block of succinylcholine is also possible; however, with nondepolarizing drugs available covering a wide range of action durations, there should be no need for patient exposure to succinylcholine for a period long enough to produce a phase 2 block.

Arrhythmogenic effects of the neuromuscular blocking drugs stem from their ability to influence autonomic transmission in the ganglia and heart. Of the commonly used drugs, pancuronium is notable for its tendency to increase heart rate. Conversely, transient bradycardia is a known feature of succinylcholine, especially in small children. After a second dose of succinylcholine, bradycardia is more pronounced, and cardiac asystole has been reported. Atropine is administered before succinylcholine to ameliorate this effect. Arrhythmias have also resulted from the tendency of succinylcholine to cause hyperkalemia, especially in burn patients and patients with certain neuromuscular deficits. Sudden death may occur in children with undiagnosed muscular dystrophy. Hypotension and responses to drug-evoked histamine release have been reviewed previously.

Succinylcholine, as the only depolarizing neuromuscular blocking agent in clinical use, initially stimulates muscle contraction. Muscle pain is a common result, especially in ambulatory patients. Masseter spasm occurs in 1% of children and may complicate endotracheal intubation. In rare individuals, masseter spasm may be an early indicator of malignant hyperthermia, which is discussed in the section on dantrolene.

Drug interactions

Many different classes of drugs are capable of interacting either positively or antagonistically with the neuromuscular blocking agents (Table 10-4). The following sections describe the actions of drugs likely to be administered in conjunction with neuromuscular blockers and their effects on the activities of the blocking agents.

Anticholinesterases. Inhibitors of acetylcholinesterase, by blocking the enzymatic hydrolysis of ACh at the motor end plate, increase the amount of transmitter available at the receptor sites. These drugs antagonize the blockade produced by the nondepolarizing blocking agents, which act by competing with ACh for occupancy of receptor binding sites. Their effect when administered in conjunction with succinylcholine is more complex; after a brief period of antagonism, during which the blockade is reduced, they act to intensify the depolarizing neuromuscular blockade. Organophosphates such as echothiophate inhibit plasma cholinesterase and acetylcholinesterase. Systemic absorption of organophosphates prolongs the action of succinylcholine and mivacurium and reduces the effects of the nondepolarizing blocking agents in general. Neostigmine and pyridostigmine, but not edrophonium, also inhibit plasma cholinesterase.

TABLE **10-4**

Effect of Various Agents on the Depth of Blockade Produced by Nondepolarizing Blocking Agents and Succinylcholine

AGENT	NONDEPOLARIZING BLOCKER	SUCCINYLCHOLINE
Nondepolarizing blocker	+	–
Succinylcholine	–, +	+
Anticholinesterase	–	+
Hexafluorenium	0*	+
Halothane, isoflurane	+	+
Aminoglycosides	+	+
Phenytoin, carbamazepine (long-term use)	–	0
Magnesium salts	+	+

*May intensify the blockade by mivacurium.
+, Intensification of the blockade; –, reversal or lessening of the blockade; *0,* no major effect.

Hexafluorenium, which specifically inhibits plasma pseudocholinesterase without affecting the end plate acetylcholinesterase, prolongs the presence of succinylcholine in the circulation. This action extends the duration of the neuromuscular blockade by succinylcholine, and presumably mivacurium, and decreases the dose necessary to obtain that blockade. In addition to its inhibitory effect on plasma cholinesterase, hexafluorenium is itself a weak nondepolarizing neuromuscular blocker and may slightly potentiate the blockade induced by other nondepolarizing blocking agents.

Sugammadex. Sugammadex is a γ-cyclodextrin derivative designed to encapsulate rocuronium and reverse its neuromuscular blockade.[14] The sugammadex molecule resembles a truncated, hollow cone with a hydrophobic interior capable of binding steroidal blockers such as rocuronium and a hydrophilic exterior that permits intravenous injection. Endogenous steroids lack the quaternary ammonium moiety of rocuronium and are poorly reactive with sugammadex. Vecuronium, which is significantly more potent than rocuronium, is also easily reversed despite reduced binding affinity for sugammadex. The U.S. Food and Drug Administration decided not to approve sugammadex in August 2008 because of concerns regarding allergic reactions. Phase III clinical trials have been allowed to proceed to address the safety of sugammadex further.

General anesthetics. Anesthetics that stabilize excitable membranes, most prominently ether and the halogenated inhalation agents, tend to interact positively with nondepolarizing blocking agents. When ether was used for general anesthesia, doses of tubocurarine had to be reduced by 50% or more.[15] A similar reduction is necessary with isoflurane and pancuronium, but a more modest interaction occurs with sevoflurane and vecuronium.

Antibiotics. Some antibiotics, such as the aminoglycosides, reduce the amount of ACh released by the motor nerve terminal in response to an action potential and augment the muscle relaxation caused by nondepolarizing neuromuscular blocking drugs.[6,18] Succinylcholine is also potentiated. Other antibiotics that may reduce dosage requirements for neuromuscular blocking agents include the tetracyclines, clindamycin, and the polymyxins.

Sympathomimetics. Catecholamines and other sympathomimetic agents may increase the amount of ACh released from the motor neuron and antagonize the blockade produced by nondepolarizing blocking agents.

Lithium. Lithium salts, used for the prophylaxis and treatment of manic-depressive illness, can slow the onset of neuromuscular blockade caused by succinylcholine but not that caused by the competitive blockers. Lithium also intensifies the blockade by pancuronium but not that by tubocurarine or succinylcholine, and it prolongs the effect of succinylcholine and pancuronium but not that of tubocurarine.

Neuromuscular blocking agents. Administration of a nondepolarizing blocking agent to a patient under the influence of the same drug or a different nondepolarizing blocking drug augments the blockade. This augmentation is usually additive; however, some combinations, such as an aminosteroid with a benzylisoquinoline, exhibit supra-additive effects.[23] This drug interaction is used clinically; a small "priming" dose of one nondepolarizing blocker may be given to hasten the onset of the subsequent paralyzing dose of another.

Administration of a second dose of succinylcholine to a patient already treated with the drug may lighten the blockade for a brief interval, which would correspond to the period of early transient fasciculation that follows administration of any of the depolarizing drugs. The ultimate effect of the second dose is augmentation of the neuromuscular blockade, however. Some tachyphylaxis occurs with repeated administrations.

Combinations of depolarizing and nondepolarizing neuromuscular blocking drugs are generally antagonistic and have little clinical value. Use has been made of this antagonism, however, in the administration of a low dose of nondepolarizing blocker before paralyzing the patient with succinylcholine. In this case, the nondepolarizing agent prevents the fasciculations normally caused by succinylcholine. It is also a frequent practice to use succinylcholine to induce a rapid blockade for tracheal intubation before the production of a long-term blockade with a nondepolarizing agent. The short lifetime of succinylcholine in the body effectively prevents any significant antagonism between the two drugs. Subsequent administration of the nondepolarizing drug generally provides evidence of enhanced neuromuscular blockade.

Applications in dentistry

Dental practice has few indications for the use of neuromuscular blocking agents. Among the situations in which use of these drugs might be appropriate are mandibular fractures, when muscle relaxation is needed to permit manipulation of bone fragments, and trismus, when no more conservative means exist to permit mouth opening for diagnosis and treatment. In addition, succinylcholine or a relatively short-acting nondepolarizing blocking drug is used to aid the insertion of

an endotracheal tube when the use of general anesthesia makes intubation appropriate. In any office where general anesthesia is used, succinylcholine should always be available to treat otherwise intractable laryngospasm.

Other Agents Affecting Neuromuscular Transmission

Many substances, synthetic and of biologic origin, have been found to act by affecting one or more of the processes involved in normal neuromuscular transmission. Some of these drugs are used to treat various conditions of muscular spasms including spasms associated with stroke, multiple sclerosis, and cerebral palsy. These drugs are termed *spasmolytics*. Diazepam, baclofen, tizanidine, and cyclobenzaprine are discussed in Chapter 13.

Diazepam

Diazepam, a benzodiazepine compound, facilitates inhibition of γ-aminobutyric acid (GABA) in the CNS. It has potential action on the $GABA_A$ receptor and acts in part at the level of the spinal cord. It is effective in treating all types of muscle spasms. The major limitation is sedation seen at muscular relaxant doses.

Baclofen

Baclofen is an orally effective agonist for the presynaptic CNS $GABA_B$ receptor. When activated, the presynaptic $GABA_B$ receptor causes a decrease in release of excitatory amino acids (i.e., glutamate) and a corresponding decrease in skeletal muscle tone. Patients experience less sedation than with diazepam. This GABA analogue is used for relief of spasticity caused by multiple sclerosis and traumatic spinal cord injury.

Tizanidine

Tizanidine is a clonidine-like α_2-adrenoceptor stimulant that reduces skeletal muscle spasticity by a CNS inhibitory action, but with less hypotension than seen with clonidine. Other side effects include sedation, asthenia, and dry mouth.

Cyclobenzaprine

Cyclobenzaprine is related to the tricyclic antidepressants. It is used for short-term (2 to 3 weeks) treatment of muscular spasms associated with musculoskeletal conditions. The mechanism of action of cyclobenzaprine may be to increase brainstem-mediated noradrenergic inhibition of spinal cord neurons. Side effects include atropine-like responses and effects produced by inhibition of catecholamine uptake.

Hemicholinium

Most of the choline produced by the enzymatic hydrolysis of ACh is returned to the motor nerve terminal by a specific transport system and is used in the synthesis of new transmitter. Hemicholinium, by blocking the neuronal uptake of choline, interferes with the synthesis of ACh and acts to deplete the nerve terminal of this substance. The resulting blockade of neuromuscular transmission is gradual in onset but is accelerated by increased motor neuron activity. Because hemicholinium inhibits choline transport in all peripheral cholinergic nerves, it affects transmission at all cholinergic synapses and junctions. Hemicholinium has no clinical applications at present.

Botulinum toxin

The toxin produced by *Clostridium botulinum* acts on the motor nerve terminal to prevent the release of ACh in response to the arrival of an axonal action potential. The toxin interferes with the influx of extracellular Ca^{++} into the nerve terminal. Ca^{++} influx during the action potential is necessary for ACh release. Botulinum toxin affects all peripheral cholinergic nerves.

Botulinum toxin is used in ophthalmology in the treatment of strabismus and certain ocular deviations (tropias). The toxin, applied focally, can produce long-lasting (weeks to months) paralysis of an excessively contracting extraocular muscle, and the hope is that, as function gradually recovers, CNS adaptation will maintain the correction. The toxin is also used to relieve severe blepharospasm. It is injected into the orbicularis oculi, where it blocks spasmodic contractions for 3 months. Another serologically distinct form of botulinum toxin is used for certain types of skeletal muscle dystonias, such as cervical dystonias. In a cosmetic application, botulinum toxin is used to inhibit activity of certain facial muscles, such as those of the forehead, whose contractions cause skin wrinkling.

α-Bungarotoxin

α-Bungarotoxin isolated from the venom of the banded krait and the similar if not identical neurotoxin from the venom of the cobra are capable of binding avidly to the cholinergic receptor proteins of the muscle end plate. The toxin does not cause end plate depolarization, and its effect, although essentially irreversible, is similar to that of nondepolarizing blocking agents. The ability of radiolabeled α-bungarotoxin to bind stoichiometrically with skeletal muscle nicotinic receptors makes it possible to locate and count receptor sites; this has provided a useful technique for research on numerous subjects ranging from denervation supersensitivity to myasthenia gravis.

Tetrodotoxin

Tetrodotoxin, found in many tissues of the puffer fish, or fugu, prevents the propagation of peripheral axon and skeletal muscle action potentials by interfering with electrically activated Na^+ conductance. Saxitoxin, which is produced by certain strains of dinoflagellates and has been implicated in the occasional contamination of shellfish that consume these organisms, has a similar effect on Na^+ channels. The mechanism of action of these toxins is similar to that of local anesthetics, but their potencies are a millionfold greater, and they act for 1 day or more after a single exposure.

Dantrolene

Dantrolene (Figure 10-5) is an agent that acts within the skeletal muscle fiber rather than on the neuromuscular junction. Its site of action is the sarcoplasmic reticulum, where it inhibits the depolarization-induced release of Ca^{++} from the cisternae of the sarcoplasmic reticulum into the cytoplasm, interfering with excitation-contraction coupling. The principal therapeutic applications of dantrolene are for the relief of spasticity associated with upper motor neuron disorders and for the prophylaxis and treatment of malignant hyperthermia.[9]

Spastic movements, clonus, and rigidities that result from stroke or cerebral palsy are often relieved by dantrolene; the spasticity of multiple sclerosis is relieved to a lesser extent, possibly because the lesions of this condition are more widespread.[17] Dantrolene is strongly contraindicated in amyotrophic lateral sclerosis because the muscular weakness associated with this condition, when exacerbated by the drug (see later), can lead to respiratory difficulty.[17]

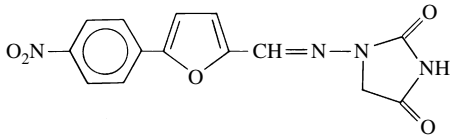

FIGURE **10-5** Structural formula of dantrolene.

Malignant hyperthermia is a genetically transmitted condition in which there is an apparent reduction in the threshold for Ca^{++} release from the sarcoplasmic reticulum of skeletal muscle, often because of a mutation in the ryanodine receptor that forms the Ca^{++}-release channel.[11,13] Under normal conditions, Ca^{++} is released from the sarcoplasmic reticulum in response to an all-or-none action potential propagating down the transverse tubular system. Because there are no partial depolarizations physiologically, the actual threshold for Ca^{++} release by the sarcoplasmic reticulum is unimportant. A depolarizing neuromuscular blocking drug does produce such a partial depolarization, however, of the muscle fiber membrane.

Succinylcholine and the volatile general anesthetics such as isoflurane, which may also lower the release threshold, can trigger an attack of malignant hyperthermia in which the increased release of Ca^{++} into muscle cytoplasm causes contracture and an enormous acceleration of the cellular metabolism of muscle; the latter generates heat (body temperature can increase by 1° C every 5 minutes and reach 43° C), carbon dioxide (arterial tensions > 100 mm Hg), and lactic acid (arterial blood pH <7.0). The hyperthermia, hypoxemia, and acidosis cause muscle edema and structural damage. In addition, the hyperthermia and resultant sympathetic reflex response increase heart metabolism fivefold to eightfold and can lead to arrhythmias. Before dantrolene, attacks of malignant hyperthermia were frequently (70%) fatal. Dantrolene, by blocking the precipitating event, the release of Ca^{++} from the sarcoplasmic reticulum, can prevent or halt an attack of malignant hyperthermia and has reduced the mortality rate to less than 10%.

Side effects of dantrolene include muscle weakness and hepatotoxicity. The muscle weakness, which is simply an extension of the drug's therapeutic action, generally does not occur at dosages used for treatment of spastic movements, although doses high enough to produce this effect are sometimes needed to achieve symptom remission. Doses of dantrolene that produce muscle weakness are sometimes used in prophylaxis of malignant hyperthermia before surgery on patients with a family history of the condition.

Hepatotoxicity of varying degrees has been reported in approximately 1% of patients taking dantrolene for 60 days or longer. Hepatic function should be monitored during long-term therapy with dantrolene.[17] The minimal effective dose should be used.

Dantrolene is effective when administered intravenously or orally; in the latter case, approximately 20% is absorbed, largely through the small intestine.[17] Metabolism of dantrolene occurs in the liver, largely by 5-hydroxylation of the hydantoin moiety.

AGENTS AFFECTING NICOTINIC TRANSMISSION

Nonproprietary (generic) name	*Proprietary (trade) name*
Ganglionic stimulants	See Table 10-1
Ganglionic blockers	
Hexamethonium*	—
Mecamylamine	Inversine
Trimethaphan*	Arfonad
Neuromuscular blockers	
Nondepolarizing	
Atracurium	Tracrium
Cisatracurium	Nimbex
Mivacurium*	Mivacron
Pancuronium	Pavulon
Rocuronium	Zemuron
Tubocurarine*	—
Vecuronium	Norcuron
Depolarizing	
Succinylcholine	Anectine, Quelicin
Miscellaneous agents	
Baclofen	Zanaflex
Botulinum toxin type A	Botox
Botulinum toxin type B	Myobloc
Cyclobenzaprine	Flexeril
Dantrolene	Dantrium
Diazepam	Valium
Hexafluorenium*	Mylaxen
Sugammadex*	Bridion
Tizanidine	Lioresal

CHAPTER 11

*Introduction to Central Nervous System Drugs**

VAHN A. LEWIS

Drugs that alter synaptic function are likely to have considerable impact on neuronal activity. An understanding of these fundamental mechanisms permits appreciation of the therapeutic actions and side-effect profiles of many of the central nervous system (CNS) drugs in the brain and in the spinal cord. The interested student is encouraged to seek several excellent reviews in this area.[23,30] The pharmacology of specific CNS drugs is discussed in greater detail in Chapters 12 through 21 and Chapter 23.

INVESTIGATION OF THE BRAIN

Early research on nervous system function involved behavioral studies in whole organisms. Observing the effects of damage to regions of the nervous system provided clues to the function of various nerve and brain structures. The development of the microscope and its use produced an explosion of interest in the cellular anatomy and structure of the normal and diseased brain. Santiago Ramón y Cajal received an early Nobel Prize in Physiology or Medicine (1906) for his use of the microscope to study the brain.

When electronic amplifiers were developed, it became possible to study the collective electrical action of many neurons (e.g., with electroencephalography or stimulus-evoked potential recordings) and individual neurons with extracellular or intracellular electrical recordings. Using these techniques, it became possible to understand the electrical properties of single nerves and synapses and to consider how these actions related to the action of the whole organism engaged in various behaviors. Hodgkin, Huxley, and Eccles shared a Nobel Prize in Physiology or Medicine in 1963 for their work on action potentials and synaptic connections.

Using these techniques, physiologists, chemists, and pharmacologists began to investigate the chemical nature of neurotransmission and brain function. Chemists produced novel agonists that were used by physiologists and pharmacologists to gain additional information about how the brain functions. With such studies, the basis for chemical neurotransmission and its regulation was explored. The biochemistry of the brain has been gradually revealed. The Nobel Prize for Physiology or Medicine in 1970 was awarded to Katz, von Euler, and Axelrod for their discoveries in the area of chemical neurotransmission.

In the last two decades the pace of discovery has accelerated considerably. Experiments that previously took years can often be performed in days. Genomic approaches allow tens of thousands of biochemical reactions to be studied simultaneously. A key development was the polymerase chain reaction by Mullis at Cetus Corp. Mullis shared the Nobel Prize in Chemistry in 1993 for his part in the invention. The invention of the gene microarray is another technology that is important in this respect.[32] The data from these experiments are analyzed using computers rather than manually. These techniques are beginning to reveal how networks of genes, amino acids, proteins, lipids, sugars, and other chemicals interact to mediate the various functions of the brain. A genomic study of tissue from a patient with epilepsy revealed that the seizures were associated with excess glutamate release from the astrocytes.[27]

Future investigations of the brain may reveal that many chronic brain disorders result from tissue inflammation or breakdown, rather than dysregulation of a particular neurotransmitter. This hypothesis seems to be true in the case of schizophrenia and Alzheimer's disease.[32,37] In 2008, the Nobel Prize in Chemistry was awarded to Shimomura, Chalfie, and Tsien for the development of the green fluorescent protein technique, which has facilitated understanding of genetic modifications in dense tissue such as the brain. Other powerful techniques applicable to brain research are continually being developed.

The CNS integrates sensory information from the external and internal environments; maintains homeostasis through visceral and somatic secretory and motor activity; and generates memory, thoughts, and emotions. Many common diseases have their origins in CNS dysfunction, including Alzheimer's disease, epilepsy, stroke, anxiety, psychoses, movement disorders, mental impairment, and some forms of chronic pain. In addition, the therapeutic effects or side effects of many drugs arise from alterations in CNS activity. Approximately 20% of the most frequently prescribed medications have their principal sites of action within the CNS (e.g., opioid-containing analgesics, benzodiazepines such as alprazolam, antidepressants such as sertraline and fluoxetine, and sleep aids such as zolpidem), and it is virtually certain that every practicing dentist will perform dental treatment on patients taking these drugs. This chapter reviews the anatomic, cellular, and biochemical organization of the CNS from the perspective of drug actions in the CNS. Table 11-1 lists representative drugs that act on the CNS to produce their therapeutic effects.

ANATOMIC ORGANIZATION OF THE CENTRAL NERVOUS SYSTEM

Several excellent texts are available that provide comprehensive descriptions of the organizational structure and pharma-

*The author wishes to recognize Drs. Kenneth M. Hargreaves, Douglass L. Jackson, and Mark T. Roszkowski for their past contributions to this chapter.

TABLE **11-1**

Selected Drug Actions in the Central Nervous System

DRUG CLASS	EXAMPLE DRUG	MAJOR SITE(S) OF ACTION*	MECHANISM†	PHARMACOLOGIC EFFECT
Drugs Commonly Used in Dentistry				
Opioids	Morphine	Deep cortex, PAG, medulla, spinal cord, skin	Presynaptic inhibition	Analgesia
Benzodiazepines	Diazepam	Limbic system, cerebral cortex	GABA potentiation	Anxiety reduction, sedation
Local anesthetics	Lidocaine	Nonselective	Na^+ channel blockade	Convulsions, anesthesia
Other Commonly Used Drugs				
Antihypertensives	Clonidine	Medulla	α_2-Adrenoceptor stimulation	Reduced sympathetic activity
Inhalation anesthetics	Isoflurane	Reticular formation	Ion channel blockade	General anesthesia
Antiparkinson agents	Levodopa	Basal ganglia	Increased dopamine synthesis	Reduced motor symptoms
Antipsychotics	Haloperidol	Limbic system, reticular formation	Dopamine receptor antagonism	Control of schizophrenia

*Several of these drugs have more than one site of action in the central nervous system.
†Drugs may exert different mechanisms through activation of multiple receptors (see text).
GABA, γ-Aminobutyric acid; *PAG*, periaqueductal gray matter.

cology of the CNS.[13,23,30,31] This section reviews only the key structural elements of the CNS most pertinent to understanding drug actions and effects.

Cerebral Cortex

Anatomy

The cerebral cortex consists of two hemispheres with deeply enfolded grooves termed *gyri*. The extensive folding of the cerebral cortex increases its surface area. The major divisions of the cortex are the motor cortex (which initiates and coordinates somatic muscle activity); somatosensory cortex (which processes sensory information); frontal, parietal, and temporal association/integration areas; and visual and auditory areas. More recent imaging studies have focused additional attention on deeper cortical structures, such as the cingulate, the midline cortex (the face of the cortex between the two hemispheres), the insula, and the opercular cortex (buried behind the lateral sulcus). Several of these areas are important for experiencing pain and pleasure. Together, cortical regions are involved with voluntary movement and integration of sensation, consciousness, abstract thought, memory, and learning.

A primary organizational feature of the cerebral cortex is its arrangement as a series of densely packed columns of interconnected cells. The columnar organization of the cerebral cortex is probably a major factor in the integration of neural activity. Each column is approximately 0.5 mm to 1 mm in diameter and includes 10,000 to 50,000 interconnected neurons. The classic studies by Penfield and Rasmussen[40] determined the somatic representation of the human body surface on the sensory cortex (the "sensory homunculus"). These studies indicated that approximately 75% of the sensory cortex processes afferent input from orofacial structures, including the lips, jaws, tongue, and teeth. This predominant cerebral processing of orofacial sensation may contribute to the aversive anxiety that many patients have during the course of dental care.

Pharmacology

Drugs that alter cerebral cortical activity include general anesthetics, antianxiety drugs, sedative-hypnotics, anticonvulsants, antidepressants, and antipsychotics. As detailed subsequently (and in later chapters), the sites of action and the precise biochemical mechanisms for many of these drugs are still incompletely understood. The clinical consequence of a reduction in cortical activity is generally sedation or unconsciousness, however. Administration of the inhalation anesthetic halothane reduces cerebral activity in the frontal cortex during the induction of general anesthesia.[14] Opioids produce analgesia in part by binding to the cingulate and insular cortex, which play a role in registering the aversive qualities of stimuli.[5]

Limbic System

Anatomy

Another major organizational component of the CNS is the limbic system. It is composed of the amygdala, septum, hippocampus, hypothalamus, olfactory lobes, basal ganglia, and portions of the thalamus. These interrelated structures act to coordinate affective (i.e., emotional) sensations with motor, visceral, and endocrine functions. Many of these structures are reciprocally connected with the cerebral cortex, and some are arranged in loops. Such loops integrate the functions of different parts of the brain but can also play a role in brain disease when disturbances develop along a loop. These loops may play a role in Parkinson's disease and drug abuse. In addition, many behavioral functions ascribed to the limbic system are linked functionally to the reticular formation. Hyperexcitation of the amygdala has been associated with panic attacks.[41] The hypothalamus is important for endocrine function, but it is also an important regulator of cyclic functions such as waking and sleeping, monthly ovulatory function, and longer cycles such as yearly hibernation in animals. The study of these periodic phenomena is termed *chronobiology*.

Pharmacology

Many drugs act in part by modifying the activity of the limbic system. Benzodiazepines act at several discrete sites within this system to potentiate the effects of the neurotransmitter γ-aminobutyric acid (GABA), resulting in a reduction of anxiety and the development of sedation (see Table 11-1).[50] Benzodiazepines also reduce seizure activity. Endogenous ligands for the benzodiazepine receptor may be involved in the pathogenesis of epilepsy because epileptic patients have a significant reduction in benzodiazepine receptors in the cortex

and limbic system.[46] If administered in excess, local anesthetics such as lidocaine and the antibiotic penicillin may induce seizure activity.

A major hypothesis for some forms of mental dysfunction (e.g., schizophrenia) proposes an excess in dopaminergic activity. Several antipsychotic drugs are dopamine receptor antagonists and are thought to act at various sites in the limbic system and reticular formation. The clinical consequence of dopamine receptor blockade in these patients is the amelioration of psychotic behavior. Parkinson's disease is associated with a chronic reduction of dopamine activity in the basal ganglia complex.[55] This disease is commonly managed by the administration of drugs such as levodopa (L-dihydroxyphenylalanine, the amino acid precursor to dopamine) that increase dopamine activity. Dopamine is an important neurotransmitter in the brain reward circuitry located in the basal ganglia, and it plays a role in the development of drug dependence to cocaine and amphetamines and indirectly to other drugs.[12,19]

Many drugs have a site of action in the hypothalamus and related structures. The estrogens contained in many birth control formulations act in part by inhibiting release of the hypothalamic gonadotropin-releasing hormone and luteinizing hormone and follicle-stimulating hormone, preventing ovulation. In addition, alcohol-induced diuresis results from inhibition of the release of antidiuretic hormone (also known as vasopressin). Diabetes insipidus is the clinical disease caused by chronically diminished release or activity of antidiuretic hormone.

Midbrain and Brainstem

Anatomy

The midbrain and brainstem regions consist of the mesencephalon, pons, medulla, reticular activating system, and most of the cranial nerve nuclei, including the trigeminal nuclei. This region processes sensory information from the viscera, coordinates visceral (i.e., cardiovascular, pulmonary, and gastrointestinal) systems, and integrates various reflexes (e.g., swallowing and vomiting). In addition, the reticular activating system is implicated in the maintenance of arousal and development of sleep. Damage to small areas of the brainstem can be lethal if they interfere with cardiovascular or respiratory control. The reticular activating system is sensitive to many drugs, including most CNS depressants.[7]

Pharmacology

Several drugs have major sites of action within midbrain and brainstem structures. Opioids such as morphine produce analgesia in part by activating opioid receptors located in the periaqueductal gray region, locus coeruleus, and nucleus raphe magnus. In addition, the antihypertensive drug clonidine is an α_2-adrenergic receptor agonist whose therapeutic effect results in part from stimulating α_2-adrenergic receptors in the medulla oblongata.

Not all drug effects in the CNS are considered therapeutic. Opioid-induced emesis is caused by activation of receptors located in the chemoreceptor trigger zone of the medulla. This side effect is especially prominent in ambulatory patients, whose walking increases activity in the vestibular system. This interaction between drug effect and neural input is the rationale for instructing patients in acute pain receiving opioid analgesics to avoid excessive motion to minimize nausea and vomiting.

Spinal Cord

The spinal cord is involved with the processing and modulation of general sensory information (e.g., touch, heat, cold, pressure, and pain), somatic motor activity, and skeletal and visceral reflexes. Numerous drugs are thought to activate spinal cord mechanisms. Opioids produce analgesia in part by stimulating receptors located in the spinal dorsal horn. (An analogous site of action for opioid inhibition of trigeminal pain involves interaction with receptors located in the medullary dorsal horn, as mentioned in Chapter 20.) This site of action is the basis for the administration of opioids through epidural catheters to elicit spinal analgesia. In addition, the epidural administration of local anesthetics such as bupivacaine is commonly used for the production of regional anesthesia in surgical and obstetric procedures. More recent studies suggest that nonsteroidal anti-inflammatory drugs produce analgesia after intrathecal injection, suggesting that these drugs have both central and peripheral sites of action.

Blood-Brain Barrier

The CNS is isolated from the rest of the body by the blood-brain barrier. Endothelial cells of the brain capillary system are modified by numerous tight junctions and are surrounded with extensive perivascular astrocytic processes. These modifications prevent the free diffusion of many substances into the CNS. Lipid solubility is a key factor in dictating the CNS actions of many drugs. Drugs that are highly lipophilic (e.g., thiopental, diazepam, nicotine, and heroin) easily cross the blood-brain barrier and have a rapid onset of action. In contrast, hydrophilic drugs (e.g., dopamine and some antibiotics) are largely excluded by the blood-brain barrier, minimizing their therapeutic effects in the CNS. Many drugs are "relatively" excluded from the brain, meaning that their onset of action may be delayed, but they eventually cause significant CNS effects. Morphine is relatively excluded from the brain and reaches a peak effect about 1 hour after administration.

There are some holes or "windows" in the blood-brain barrier. One such site is near the area postrema. This area is near the vomiting center, and drugs or other chemicals in the blood can quickly pass to the center and produce nausea and vomiting. Other "windows" include the subfornical organ and the organum vasculosum of the lamina terminalis.

Transporter proteins can accelerate the movement of some molecules into or out of the brain. The treatment of Parkinson's disease provides an example. An amino acid transport through the blood-brain barrier transports hydrophilic levodopa into the brain.

The blood-brain barrier is not completely developed at the time of birth, and many drugs administered to neonates achieve greater concentrations in the CNS than occur in older children or adults.[29] Numerous other conditions can produce a temporary breakdown of the blood-brain barrier, which can increase the penetration of drugs such as morphine and antibiotics into the brain. Some of these conditions include hypertension, inflammation, hypercapnia, osmotic stress, multiple sclerosis, and hyperthermia.

Brain Imaging

Assessment of brain function in health and disease is important for understanding and treatment of various nervous system conditions. Early techniques for assessing brain disorders included x-ray images of the head and monitoring electrical activity on the scalp using electroencephalography. Computer-assisted tomography visualization of the interior of the skull became feasible with the advent of powerful and inexpensive computers. McCormick, who was credited with the development of mathematical algorithms for reconstruction of brain images in the 1960s, shared the 1979 Nobel Prize in Physiology or Medicine with Hounsfield, who developed a working computed tomography (CT) machine, which he used to study the brain. CT allowed the interior of the head to be represented as shades of gray, which basically represent the structures inside the head. Swollen ventricles or hematomas are readily apparent.

Tomographic reconstruction was subsequently extended to other forms of detectable energy. Chemicals labeled with positron emitting isotopes can be visualized based on the geometry of their emitted radiation, which permits back calculation of the point of origin. This technique is referred to as positron emission tomography (PET); a less expensive variant is single-photon emitted computed tomography (SPECT). Most of the energy in the brain is needed for the Na^+,K^+-ATPase pumps that maintain the membrane potential. Monitoring glucose, oxygen, or adenosine triphosphate (ATP) permits functional assessment of the activity in the brain.[49] An early functional PET scan used fluorodeoxyglucose to follow glucose use.[4] Labeling compounds that bind selectively to known proteins, such as the dopamine uptake transporter, permitted the visualization of its brain binding sites.[55] In Parkinson's disease, these techniques show a loss of dopamine uptake in the basal ganglia. Although these results were exciting, they also were limited to fuzzy images.

Another kind of radiation, radio waves, can be induced to be transmitted from the brain by placing the brain in a powerful magnet that causes the nuclei of atoms to align. When a probing radiofrequency signal is applied, the nuclei shift to an energized state, and when the radio signal is turned off, the nuclei return to a lower energy state and emit radiofrequency radiation that can be localized with greater precision than with earlier techniques. This imaging technique is known as magnetic resonance imaging (MRI). MRI carries additional information about the environment of the molecule releasing the radiation, and water, oxygen, and fatty tissues can be distinguished with MRI. A further refinement of this technique is known as functional MRI. With functional MRI, the function of the tissue (the neural work) can be represented. One popular functional MRI technique is blood oxygenation level dependent (BOLD) functional MRI. BOLD detects levels of oxygen saturation in regions of the brain that vary with brain activity. A further application of the MRI signal is diffusion tensor imaging (DTI). With DTI, it is possible to map nerve pathways within the living brain. This technique uses the constraints in movement of water molecules in long skinny neurons. This technique can be used to determine if damage has occurred to the nerve tracts.

Functional MRI and DTI are primarily experimental techniques at this time but are likely to move into the clinic.[33] One problem with these techniques is temporal resolution; they require a few seconds to get enough information for an image. Magnetoencephalography is a new technique with a temporal resolution of 2 msec and may be useful when faster techniques are needed.

Structural Features of the Neuron

Typically, neurons are composed of three primary regions: the soma, or cell body; the dendrites, which are projections that primarily receive synaptic input from other neurons; and the axon, which transmits information from the cell body to other neurons. Similar to other cells in the body, the soma contains the nucleus and the Golgi apparatus. The various vesicles and proteins that are needed by the cell are primarily synthesized in the cell body and distributed to the other parts of the cell by transport processes. A critical region of the neuron is the axon hillock, the junction between the cell body and the axon. The axon hillock region (initial segment) has enriched numbers of voltage-gated Na^+ channels and is typically the site at which the action potential depolarization begins. The terminal end of the axon may contain arborizations of the axon termed the *telodendria*. This region determines the extent to which the information sent on the axon spreads out (collateralizes) as the signal reaches its target.

Communication within the CNS incorporates digital and analog encoding.[13,30] The digital encoding consists of the frequency of action potential depolarizations that are conveyed along the plasma membrane of the axon. Axon potentials are termed *all or none*, meaning that when the threshold for triggering an action potential is reached, the cell generates a complete action potential, whose maximal voltage is consistent for its travel down the axon. The major pharmacologic intervention for this form of signal encoding is the use of drugs that block ion channels, preventing the initiation and conduction of action potentials. The blockade of Na^+ channels by local anesthetics is a primary example. The CNS effect is the basis for many of the toxic effects of local anesthetics (e.g., sedation, convulsions).

Typically, axons contain voltage-gated ion channels. These are needed for a patch of the neuron to carry an action potential, a regenerating electrical signal. Regenerating action potentials enable the neuron to send information over long distances without degradation. The sciatic nerve projects from the spinal cord to the tip of the toes, a distance that is equal to thousands of axon diameters. Axons can be unmyelinated or myelinated. Unmyelinated axons act like a burning fuse; the signal is passed from one region of the membrane to the next by the voltage from an active region exceeding the threshold for "depolarization" of the next region causing it to produce its own action potential. This is a relatively slow conduction process. Myelinated axons have regions of the nerve membrane covered by lipid layers that act as electrical insulators. In between the myelinated patches are nodes of Ranvier, which are short gaps of exposed nerve membranes enriched in voltage-gated ion channels. In myelinated neurons, the action potential "hops" down the axon (saltatory conduction) skipping the myelinated regions but depolarizing the nodes. This movement produces a faster nerve conduction rate and saves energy needed to repolarize the nerve membrane.

In the CNS, dendrites typically do not have the components needed to produce action potentials. These regions of the cell typically conduct information by analog (or passive) potentials. Analog signals are voltages developed on the nerve membrane that spread out on the membrane as though it were a leaky cable following Ohm's law. Typically, these signals are large near their source but decline exponentially with distance from the source of the electrical stimulus. For dendrites the source of the electrical stimulus is typically synaptic connections. Analog signals in the dendrites can combine additively so that the voltage wave that reaches the initial segment is an integrated value of all of the signals applied to the dendrites.

Active membrane and passive membrane regions of neurons are distributed by functional need, rather than by the structure of the neuron. Typical neurons in the CNS include the pyramidal cells of the cortex or the cerebellum. These neurons have extensive dendritic arborizations that receive axonal input from many other cells. The integrated information on the dendritic tree is conducted by passive potentials to the cell body and axon hillock. When these potentials reach a depolarization threshold, the axon hillock depolarizes, and the action potential rapidly conducts the signal down the long axon to the telodendria inducing the release of neurotransmitter from the presynaptic nerve endings.

In most cases, the dentist will be concerned with sensory primary afferent neurons. Here the structure is quite different. These cells are termed *bipolar cells* or *pseudobipolar cells*. The part of the neuron that conducts the information from the innervated tissue to the CNS is the axon; the cell body is displaced from the projecting axon by a short stalk in the trigeminal or dorsal root ganglion and is not essential for integrating information. Instead the information is conducted directly from the periphery to the dorsal horn of the spinal cord. For these sensory nerves, the neuron is specialized for

transferring signals from the periphery to the spinal cord with minimal opportunity for integration or crosstalk.

The cell body is the primary source of organelles and transmitter molecules needed by the neurons. Ion channels and other essential molecules need to be transported from the cell body to other parts of the cell by transport processes. The transport process in the neuron is analogous to a toy train. Filaments or microtubules (e.g., tubulin, actin) in the cells act as miniature tracks. Molecules similar to muscle proteins act as tiny locomotives termed *Kinesins*. Organelles or their subunits are attached to the Kinesins and are pulled along the tracks using ATP for energy. By a similar process, the peripheral part of the nerve can also send cargo back to the nucleus. To return materials from the nerve ending to the nucleus (retrograde transport), a different locomotive is used (dynein proteins).

Uncharacteristic of a pyramidal neuron in the brain, the primary afferent neuron releases biologically active compounds at both ends of the cell—that is, within the brainstem but also at the sites of sensory input.[43] In the brainstem, these chemicals (glutamate, substance P, calcitonin gene–related peptide) are considered neurotransmitters. These substances are also transported to the site of an injury, however, and mediate inflammation and chemotaxis of inflammatory cells. Similarly, the transient receptor potential vanilloid 1 receptor, a nonspecific ion channel that mediates the burning pain associated with hot chili peppers,[54] is present in the dorsal root ganglia and transported to the peripheral nerve ending and the spinal cord.[26]

The use of local anesthetics helps to relieve pain by reducing the release of proinflammatory-mediators and hyperalgesia-mediating chemicals. Neurotrophins (e.g., nerve growth factor and brain-derived neurotrophic factor) are synthesized in the skin and macrophages where they bind to receptors at the dermal end of the peripheral nerve. This receptor-neurotrophin complex is engulfed by the nerve ending, and the complex is transported, in a retrograde manner, to the cell body where the complex modulates DNA transcription.[21,44] Nerve growth factor acutely promotes hyperalgesia (more pain) but, after a delay, stimulates the cell body to produce ion channels, substance P (a pain mediator), and opioid receptors (pain reducers),[36] with some increases continuing for days. For this response to occur, the neurotrophins need to be transported to the nucleus, the cell elements synthesized, and the elements transported back to the peripheral nerve, producing the delay. When these mechanisms are activated, they may continue for various periods; durations in the range of days are not uncommon.

These transport systems are significant in many diseases the dentist may encounter. In compressive trigeminal neuralgia, the flow of organelles down the nerves is obstructed, which can cause accumulation of cell elements at the constriction; these are referred to as neuromas and may produce spontaneous pain because of the elevated ion channels present. Herpesvirus is also thought to be transported from the peripheral skin retrogradely to the neuronal cell body where it lodges. Later, often in association with some stressor, the virus blooms and then is transported in an anterograde direction to the skin.[16] In neuropathic pain, action potentials contribute to the induction of $\alpha_2\delta$ Ca^{++} channels in the cell body, which are transported to other cell regions and are associated with mediating the pain.[10] Microtubular-associated proteins are of considerable interest in some serious brain disorders such as Alzheimer's disease. The tau protein is a cross-linking protein between microfilaments that is found in plaques in the brains of these patients.[3]

Glia

Glia, including oligodendroglia, astroglia (i.e., astrocytes), and microglia, in the brain participate in many functions, including myelination, regulation of various chemicals such as K^+ and neurotransmitters, regulation of immune function, supporting the blood-brain barrier, and facilitating connections between the nerve cells and their blood supply. A specific example of glial function in the brain is the regulation of glutamine, glutamate, and GABA. Glutamine is the precursor of the neurotransmitter glutamate, and glutamate is the precursor of the neurotransmitter GABA, and the astrocytes regulate the concentrations of these compounds.[48] Disturbance of this function may play a role in epilepsy.

Brain Blood Supply

Another important component of the brain is its blood supply. Without a blood supply, brain function would be rapidly lost. Strokes, which compromise the normal supply of blood to the brain, can produce ischemia, inflammation, scarring, cell death, and loss of function of the affected tissues. It is suspected that even microstrokes can accumulate and eventually contribute to neurologic disorders by producing inflammation.[28,30] Microstrokes can result from infections and injuries to the head. Lipid-lowering drugs (e.g., HMG-CoA reductase inhibitors) have been found to reduce the incidence of Alzheimer's disease and Parkinson's disease, suggesting that chronic defects in blood flow may contribute to these disorders.[39,52]

SYNAPTIC ORGANIZATION OF THE CENTRAL NERVOUS SYSTEM

Information Encoding

At the synapse (Figure 11-1), diffusible chemicals contained in synaptic vesicles are released from the presynaptic neuron to activate receptors located on the postsynaptic neuron. A variable (or analog) response at the postsynaptic membrane occurs because a variable number of vesicles may be released. Factors that alter the number of vesicles released include the frequency of action potential depolarizations that arrive at the presynaptic membrane, its preexisting membrane potential, and its metabolic status. Presynaptic receptors can augment or inhibit neurotransmitter release. It is not uncommon for a neuron to release multiple transmitters such as peptides, amino acids, and others. Postsynaptically there is a confluence of transmitters that determine the response. It has been proposed that numerous transmitters act in reverse (i.e., from the postsynaptic side back to the presynaptic neurons). Some candidates that work "in reverse" are nitric oxide and anandamide (an endogenous cannabinoid).

In addition to chemically mediated signals, direct electrical signaling between neurons and glia is possible (e.g., by gap junctions),[51] but this form of communication is generally of lesser importance in pharmacotherapy. There may be a role for such electrical connections in the action of drugs that modify rapid eye movement sleep and wakefulness, such as anesthetics or modafinil.[6,20] The understanding of the relationship between glial and neuronal function is incomplete.

Chemical communication between neurons is well suited for mediating either inhibitory or excitatory signals and permits flexible neuronal processing in response to environments that are constantly changing. Another important quality of chemical transmission is the potential for amplification of the signal from a single presynaptic cell to numerous postsynaptic neurons by extensive collateral axonal synaptic connections.

In contrast to the small number of drugs that modulate digital neuronal encoding, numerous drugs modulate analog encoding. Most CNS drugs with a known mechanism of action seem to act primarily by altering synaptic activity. This list includes most receptor agonists and antagonists, catabolic enzyme inhibitors, and drugs that alter the reuptake of neurotransmitters. Before exploring the pharmacologic actions

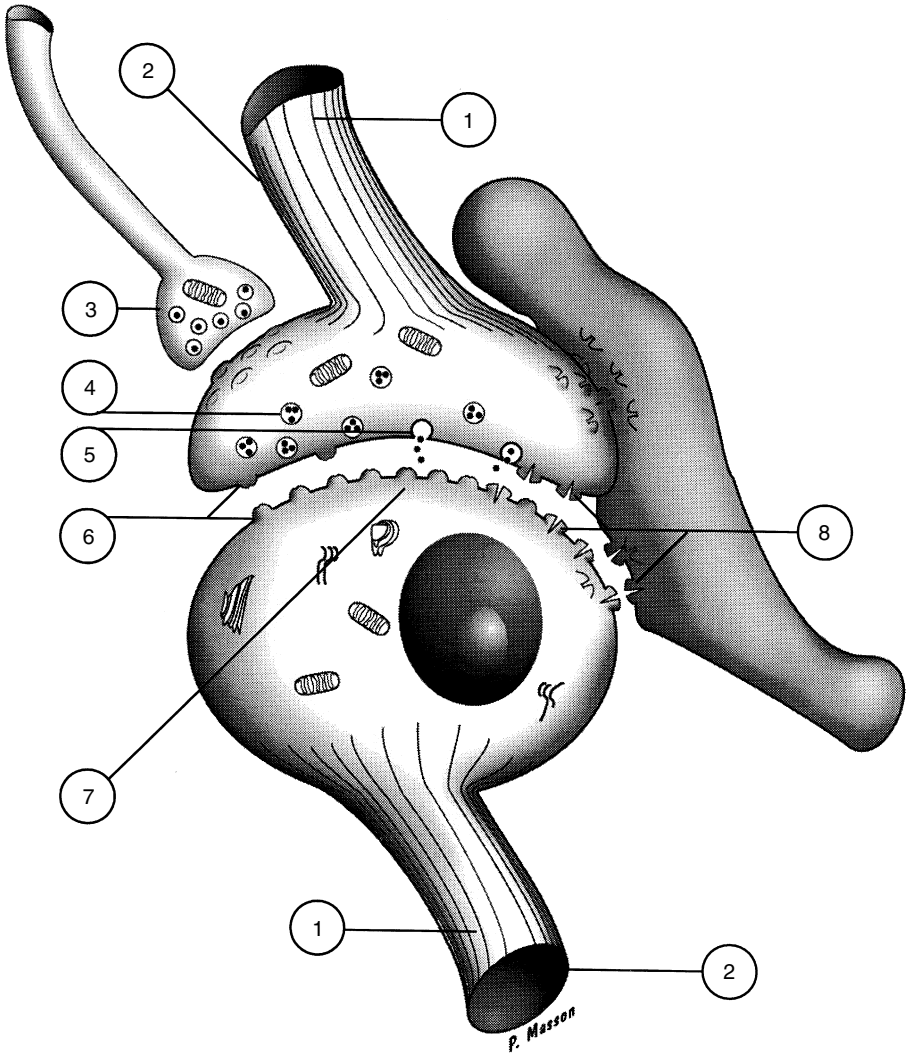

FIGURE **11-1** The major elements involved in synaptic communication, including several sites of drug action. *1*, Microtubules are involved in transporting proteins synthesized in the cell body; drugs such as colchicine can disrupt microtubular transport. *2*, The neuronal membrane potential is normally negative with respect to the extracellular surface. Depolarization is a major form of digital communication and can be blocked by local anesthetics. *3*, Presynaptic neuronal processes can inhibit or facilitate activity of presynaptic neurons. Many drugs, such as opioids, may act in part by presynaptic inhibition. *4*, The synthesis or storage of neurotransmitters can be altered by numerous drugs (e.g., levodopa, which serves as a dopamine precursor). *5*, The secretion of neurotransmitters is the major component of analog signaling. Drugs such as amphetamine acutely increase release of norepinephrine from a cytoplasmic source. *6*, Receptors can exist on presynaptic and postsynaptic membranes and can be affected by either agonists or antagonists. *7*, Signal transduction mechanisms mediate receptor events and can be classified as either metabotropic or ionotropic in nature. Drugs such as the methylxanthines (e.g., caffeine) can increase intracellular cyclic adenosine 3′,5′-monophosphate concentrations by inhibiting phosphodiesterase. *8*, Neurotransmitters are inactivated either by metabolic mechanisms or by uptake into neurons or glia. Drugs can alter synaptic activity by inhibiting reuptake (e.g., tricyclic antidepressants inhibit reuptake of norepinephrine and 5-hydroxytryptamine) or by inhibiting degradation (e.g., physostigmine, which blocks the metabolism of acetylcholine by acetylcholinesterase).

of CNS drugs, it is important to understand the physiologic system of chemical communication between neurons, including neurotransmitters and their synthesis, release into the extracellular space, actions on target cells, and termination of effects.

Synapses take various forms. The typical synapse is described as a small swelling on the end of an axon (a "button") that comes close to the postsynaptic cell structures that contain many receptors. The presynaptic and postsynaptic components are typically axons onto dendrites. All combinations of synapses between axons, neuron cell bodies (the soma), and dendrites are known (e.g., axoaxonic, dendrodendritic, axosomatic).

For many bioamine transmitters, the presynaptic nerve looks like a beaded necklace, with the synaptic vesicles being observed in the beads. The receptor tissue is not close to the transmitter release points. These synapses are described as *en passant* ("in passage") and seem to be specialized for changing

the function of a region of neurons, rather than a specific cell. A more recently describe synapse is seen in several sensory receptors (retina and auditory apparatus) and is described as a ribbon synapse. The presynaptic nerve ending has many synaptic vesicles lined up near a "ribbon" that seems to regulate their release. These synapses are thought to be specialized for producing prolonged and tonic transmitter release.[56]

Organizational Features of the Synapse

A schematic representation of chemical communication is presented in Figure 11-1. Because the neuron cell body contains all the intracellular organelles necessary for protein synthesis (nucleus, ribosomes, endoplasmic reticulum, and Golgi apparatus), microtubular transport plays an important role in carrying newly synthesized proteins (e.g., enzymes, neuropeptides, and receptors) to the nerve terminals. Drugs that block microtubular transport, such as colchicine, could play an important role in the inhibition of neuronal function, but this effect is primarily associated with adverse drug actions. Presynaptic modification of synaptic activity is a major form of neuronal signal processing. Presynaptic terminals may inhibit or facilitate synaptic activity by altering the membrane potential. Opioids and cannabinoids are thought to act at least in part through a presynaptic mechanism. Activation of opioid receptors reduces the release of neurotransmitter across the synapse. Additional sites for pharmacologic manipulation include the synthesis, release, action, and inactivation of various neurotransmitters. These mechanisms are considered in further detail in the following section.

BIOCHEMICAL ORGANIZATION OF THE CENTRAL NERVOUS SYSTEM

Neurotransmitters

Generally, several criteria must be fulfilled for a substance to be considered a neurotransmitter.[13,30] The substance must be synthesized in the presynaptic nerve, stored in synaptic vesicles, released by nerve stimulation, and rapidly inactivated. In addition, exogenous application of the substance should mimic the actions of the endogenous transmitter. By some estimates, nearly 100 substances have partially or completely fulfilled these criteria. They can be classified, on the basis of their chemical structure, as amino acids, small organic compounds, large organic complexes, hormones, lipids, small peptides, and gases. Within the CNS, acetylcholine, monoamines, amino acids, peptides, purines, fatty acids, and hormones represent the main classes of chemicals involved in neuronal signaling. Table 11-2 lists important CNS neurotransmitters and important receptor subtypes.

Acetylcholine

Since the discovery that acetylcholine acts as a peripheral neurotransmitter, considerable research has elucidated its role as a CNS neurotransmitter. Lower motor neurons are cholinergic, as are other local circuit neurons in the cerebral cortex, limbic system, and thalamus. Muscarinic and neuronal nicotinic receptor subtypes have been identified in the CNS. Acetylcholine is thought to modulate waking and dream states, respiration, motor activity, pain, vertigo, and memory. Many cholinergic antagonists have prominent CNS effects, such as sedation, amnesia, and hallucinations. Antimuscarinic drugs are used as adjunctive therapy in the management of Parkinson's disease or as a prophylactic treatment to prevent motion sickness. The anticholinesterase physostigmine is used to manage certain acute delirium reactions. Several other anticholinesterases (including donepezil, tacrine, and rivastigmine) have been approved to improve memory in early phases of Alzheimer's disease.

Monoamines

The monoamines, otherwise known as the biogenic amines, constitute a major class of neurotransmitters. Dopamine, norepinephrine, epinephrine, 5-hydroxytryptamine (5-HT), and histamine are the primary members of this class. Dopamine is a major CNS neurotransmitter, functioning in areas of motor control, behavior, waking, sleep, mood, and perception. Dopamine constitutes more than 50% of the total CNS content of catecholamines. The importance of this neurotransmitter is also shown in its critical role in such debilitating CNS diseases as Parkinson's disease, Huntington's disease, and schizophrenia. MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), a by-product of illicit opioid manufacture, has been shown to produce a parkinson-like syndrome in addicts by causing selective destruction of nigrostriatal dopaminergic neurons (see Chapter 15).[25]

Norepinephrine is the next most common catecholamine (approximately 30% of total CNS catecholamines) and is a neurotransmitter of brainstem neurons within the locus coeruleus, with projections to the cortex, cerebellum, and spinal cord. In addition, norepinephrine is the neurotransmitter of postganglionic neurons of the sympathetic nervous system. Norepinephrine is thought to modulate affective disorders, learning, reward, sleep, and pain perception.

In contrast to dopamine and norepinephrine, concentrations of epinephrine in the CNS are quite low (approximately 5% to 17% of the norepinephrine content) and are localized primarily in cell bodies of the reticular formation. The precise roles of epinephrine in the CNS are still under active investigation.

Neurons containing 5-HT are found primarily near the midline raphe nuclei of the brainstem and project to the cortex, cerebellum, and spinal cord. 5-HT is thought to modulate sleep and waking, pain, and affective states. Neurochemical evidence also reveals another monoamine, histamine, in the hypothalamus and histamine-binding sites in various brain regions, and it is thought to mediate wakefulness, weight control, and attention. Blockade of these binding sites is thought to account for the drowsiness experienced by many individuals who take antihistamines such as diphenhydramine and hydroxyzine.

Amino acids

An additional major class of neurotransmitters consists of amino acids.[18,23] Research on the neurotransmitter roles of amino acids has been difficult because these substances are integral components of general intermediary metabolism and are present in numerous cell types. Many studies now suggest, however, that amino acids are quantitatively the major neurotransmitters in the CNS. These amino acids can be divided into those that are excitatory, capable of depolarizing neurons (glutamic acid, aspartic acid, cysteic acid, and homocysteic acid), and those that are inhibitory, capable of hyperpolarizing neurons (GABA, glycine, taurine, and β-alanine).

Glutamate is found in high concentrations within the brain and has been shown to have potent excitatory effects. Current evidence indicates that this excitatory amino acid has possible roles in memory, sensory perception, upper motor neurons, and excitatory neuronal damage. Studies conducted in experimental animals suggest that glutamate receptor antagonists may protect against neuronal death and may have therapeutic potential for reducing neuronal damage in stroke victims, patients with Parkinson's disease, and patients with Alzheimer's disease.

CNS-acting drugs, such as the dissociative anesthetic ketamine, are known to affect glutamate neurotransmission by binding to a site on the N-methyl-D-aspartate (NMDA) receptor and impeding the flow of Ca^{++} through the channel of the receptor. The NMDA receptor requires activation by two

TABLE **11-2**

Important Central Nervous System Transmitters and Their Receptor and Signaling Characteristics

TRANSMITTER	RECEPTOR SUBTYPE(S)	SIGNALING MECHANISM	EFFECTOR MECHANISM	COMMENTS
Acetylcholine	Nicotinic (muscle, ganglionic, CNS)	Ionotropic	$\uparrow Na^+$, $\uparrow K^+$ conductances	Heterotropic pentamer
	Muscarinic (M_1, M_3, M_5)	G_q protein	PLC-IP_3-DAG, and $\downarrow K^+$ conductance	
	Muscarinic (M_2, M_4)	G_i protein	$\uparrow K^+$, $\downarrow Ca^{++}$ conductances	
Cannabinoid: anandamide, 2AG	CB_1, CB_2	$G_{i/o}$ protein	$\downarrow$cAMP, and $\downarrow K^+$, $\downarrow Ca^{++}$ conductances	Presynaptic, marijuana site of action
Dopamine	D_1, D_5	G_s protein	$\uparrow$cAMP	
	D_2, D_3, D_4	$G_{i/o}$ protein	$\downarrow$cAMP, $\uparrow K^+$ conductance	
Norepinephrine	α_1	G_q protein	PLC-IP_3-DAG, Ca^{++}	
	α_2	G_i protein	$\downarrow$cAMP	Mostly presynaptic
	β_1	G_s protein	$\uparrow$cAMP	
GABA	$GABA_A$	Ion channel	$\uparrow Cl^-$ conductance	Heterotropic pentamer
	$GABA_B$	$G_{i/o}$ protein	$\uparrow K^+$, $\downarrow Ca^{++}$ conductances*	
Glutamate-aspartate	NMDA	Ion channel	$\uparrow K^+$, $\uparrow Na^+$, $\uparrow Ca^{++}$ conductances	Allosteric (Gly-Glut) triggered heterotetramer (composed of two NR_1 and two NR_2 subunits)
	AMPA	Ion channel	$\uparrow K^+$, $\uparrow Na^+$ conductances	Heterotetrameric receptor
	m-$GluR_1$, m-$GluR_5$	G_q protein	$\uparrow K^+$, $\uparrow Na^+$ conductances	
	m-$GluR_{2\text{-}4}$, m-$GluR_{6\text{-}8}$	$G_{i/o}$	Decrease glutamate release	Presynaptic
Glycine	GlyR	Ion channel	$\uparrow Cl^-$ conductance	Heterotropic pentamer
Nitric oxide	Guanylate cyclase	cGMP	Protein kinase G	Presynaptic
Opioid peptides	μ, δ, κ, NOP (or ORL 1)	$G_{i/o}$	Many	Heterodimers possible; presynaptic and postsynaptic
Prostanoids (e.g., prostaglandins)	DP_1, DP_2, $EP_{1\text{-}4}$, FP, IP, TP	G_s, G_i, G_q, G_q, G_s, G_q	Varied	
5-HT (serotonin)	$5\text{-}HT_{1A\text{-}F}$	$G_{i/o}$ protein	$\downarrow$cAMP, and $\uparrow K^+$ conductance	$5\text{-}HT_{1B}$ is presynaptic
	$5\text{-}HT_{2A\text{-}C}$	$G_{q/11}$ protein	$\downarrow K^+$ conductance	
	$5\text{-}HT_3$	Ion channel	$\uparrow Na^+$, $\uparrow K^+$ conductances	Heterotropic pentamer
	$5\text{-}HT_4$, $5\text{-}HT_6$, $5\text{-}HT_7$	G_s protein	$\uparrow$cAMP	
	$5\text{-}HT_5$	$G_{i/o}$ protein	$\downarrow$cAMP	

*Responses vary depending on tissue.

Purine and several peptide neurotransmitters and their receptors are not listed. Acetylcholine and norepinephrine receptors are discussed extensively in Chapters 5 to 10. Other receptor classes are discussed in subsequent chapters. Not all receptor subtypes are listed.

2AG, 2-Arachidonoylglycerol; *5-HT,* 5-hydroxytryptamine; *AMPA,* α-amino-3-hydroxy-5-methyl-4-isoxazole propionate; *cAMP,* cyclic adenosine 3′,5′-monophosphate; *GABA,* γ-aminobutyric acid; *Glut,* glutamate; *Gly,* glycine; *NMDA,* N-methyl-D-aspartate; *PLC-IP_3-DAG,* phospholipase C—inositol trisphosphate—diacylglycerol.

transmitters simultaneously; glycine and glutamate must bind to activate the receptor. This is termed *allosteric binding*. A second interesting property of the NMDA receptor is that the nerve membrane needs to be already partially depolarized to activate it. When sufficiently depolarized, Mg^{++} ion is expelled, opening the channel to ions, especially Ca^{++}. In addition, there are numerous modulatory binding sites for other agents (polyamines). The NMDA receptor may be essential for learning and memory and participates in the phenomena of long-term potentiation. The AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionate) glutamate receptor also responds to glutamate with depolarization, but these receptors act more like typical ion channels, such as nicotinic receptors, through which flow Na^+ and K^+ across the membrane. There are also several metabotropic glutamate receptors.

GABA and glycine are believed to be the major inhibitory neurotransmitters in the CNS. GABA is found in high concentrations in the mammalian brain and spinal cord. When GABA binds to the $GABA_A$ receptor, the result is hyperpolarization of the postsynaptic neuron, mediated by the inward flow of Cl^-. Antianxiety drugs such as benzodiazepines are thought to function as allosteric facilitators of GABAergic transmission in the CNS. The existence of the allosteric binding sites suggests that there may be endogenous molecules that can modulate this receptor. Several other compounds may also bind to this site, and some of these agents are referred to as *inverse agonists* (β-carbolines, diazepam-binding inhibitor)—they decrease Cl^- conductance and can induce seizures. Allopregnanolone (a metabolite of progesterone) binds to another site on the Cl^- ion channel, and it is speculated that this steroid may play a role in increased benzodiazepine side effects in young women.

Glycine is thought to function primarily in the spinal cord, the lower brainstem, and perhaps the retina. High concentrations of glycine are found in the ventral horn of the spinal cord, producing an inhibitory feedback effect on the interneurons

and motor neurons in this region. Convulsions induced by the administration of strychnine are thought to occur because of inhibition of glycine receptors. Alcohol, barbiturates, and some anesthetics facilitate GABA-stimulated Cl^- conductance, but these drugs also inhibit AMPA-stimulated, glutamate-stimulated, and acetylcholine-stimulated ion conductances.[24]

Neuropeptides

Numerous pharmacologically active peptides have been found in neurons. These peptides are capable of causing excitation and inhibition when applied to target tissues. Many neuropeptides are classified into distinct families that share a common amino acid sequence. The opioid peptides constitute an important example. This neuropeptide family includes the endomorphins, endorphins, enkephalins, and dynorphins. With the exception of the endomorphins, members of this family with opioid activity contain the amino acid sequence tyrosine-glycine-glycine-phenylalanine (Tyr-Gly-Gly-Phe).[9]

Peptides differ from the low-molecular-weight neurotransmitters in several regards. The primary difference occurs in their synthesis. In contrast to the low-molecular-weight transmitters, which can be synthesized anywhere within the neuron by cytoplasmic enzymes, peptides depend on mechanisms concentrated in the cell body (e.g., transcription, translation, post-translational processing). Post-translational processing involves splitting of the precursor protein into smaller peptides. A single precursor molecule can yield multiple copies of the active peptide (e.g., proenkephalin) or even several different active peptides (e.g., proopiomelanocortin).[1] In addition, alternative splitting of the precursor may occur in different tissues, in which the precursor may be cleaved in different locations, yielding completely different peptides with totally unrelated functions. This response is tissue-specific and driven by different splicing enzymes.

The neuroactive peptides leave the Golgi apparatus in secretory vesicles that also contain enzymes capable of converting peptides to the final active form. These vesicles are transported to the nerve terminal by axonal transport mechanisms and are released in response to action potentials. The phenomenon of colocalization of such neurotransmitters as amino acids, monoamines, or acetylcholine with neuropeptides and ATP is common, with each chemical exerting a slightly different effect on the target tissue, provided that receptors exist for each mediator.

Purines

ATP, found in purinergic nerves or colocalized with catecholamines or acetylcholine, may act as a neurotransmitter and may modulate the effect of other neurotransmitters. Adenosine also seems to act as an inhibitory neurotransmitter, and its receptors are blocked by the stimulant caffeine.

Fatty acids

Prostaglandins are formed in the CNS from cell-related lipids by the enzymes phospholipase A_2 and cyclooxygenase. As in the periphery, prostaglandins are often synthesized in association with inflammation. Prostaglandins act through G protein–coupled receptor systems to modify various cellular reactions.[57] Cannabinoid receptors (the receptors that mediate the actions of cannabis [marijuana]) are activated by endogenous lipid-related molecules (anandamide and 2-arachidonoylglycerol). Most of the CB1 (brain cannabinoid) receptors are located presynaptically. For this particular system it seems that the postsynaptic receptor is linked to release of agonist, which modulates the function of the presynaptic neuron.[47] Research has suggested that there may be interactions between these two fatty acids, with anandamide being a substrate for cyclooxygenase to produce modified cannabinoid agonists.[45]

Gases

Several endogenously synthesized gases are thought to play a role in neurotransmission and other functions in the brain. The best studied is nitric oxide. This gas is synthesized by nitric oxide synthetase from L-arginine. This synthesis is triggered postsynaptically after a neurotransmitter such as glutamate or acetylcholine induces Ca^{++} currents in the postsynaptic cell. The generated nitric oxide diffuses to the presynaptic neuron where it modulates the action of cyclic guanosine monophosphate to alter the release of neurotransmitters.[17] Nitric oxide synthetase is often found to coexist with GABA in neurons. Nitric oxide synthetase can be identified in the brain and in vasculature by immunohistochemical techniques. It is present early in development and may play some role in tissue differentiation. Later, it is found in important brain structures such as the cerebellum, hippocampus, basal ganglia, and basal forebrain.[22] There is some concern that, by forming reactive peroxynitrites, it may contribute to various disorders, such as atherosclerosis, Parkinson's disease, and brain aging.[11,35] Other gases such as carbon monoxide[15] and hydrogen sulfide[42] are proposed to act as neurotransmitters sometimes.

Hormones

Hormones such as thyroid hormone, glucocorticoids, testosterone, and estrogens can produce behavioral side effects. Receptors for these hormones are found in the brain. Hormones are generally thought to act by a genomic action—that is, binding to an intracellular receptor and then altering DNA transcription (usually at many DNA sites). Several hormones have been found, however, to have immediate or nongenomic actions as well. An example is the metabolite of progesterone, allopregnanolone, which binds to the GABA Ca^- channel receptor producing sedation.[8]

RELEASE OF NEUROTRANSMITTER

The release of neurotransmitter from the neuron is mediated by membrane potentials. Membrane depolarization activates voltage-gated Na^+ channels, allowing an influx of Na^+ into the presynaptic cell. The resulting depolarization of the presynaptic terminus activates voltage-gated Ca^{++} channels that exist in greater abundance at the nerve terminal. This Ca^{++} current is known as the secretory potential and initiates mechanisms leading to the release of transmitter from the presynaptic neuron during membrane depolarization.[30] Repolarization of the nerve terminal occurs as the Na^+ channels become inactivated and K^+ channels open, leading to an efflux of K^+ out of the presynaptic cell.

Research indicates that there is a clustering of synaptic vesicles at the nerve terminal. The number of vesicles at this site of the neuron is much greater than in other areas of the cell. The vesicles aggregate adjacent to areas of presynaptic membrane thickening known as dense bars. This region of the nerve terminal is termed the *active zone* because it is the site where the neurotransmitter is released from the synaptic vesicles by exocytosis. In response to an action potential, synaptic vesicles fuse with the presynaptic membrane, releasing their contents into the extracellular space of the synapse. The actual mechanics of neurotransmitter release occurs in stages. Synaptic vesicles first must dock with the plasma membrane. After docking, a priming reaction occurs that prepares the vesicle to fuse with the plasma membrane when an action potential is present at the terminal. With the arrival of the action potential and the subsequent increase in Ca^{++} in the terminal, the vesicle fuses with the plasma membrane and releases the vesicle contents into the synapse. The events leading to the fusion of synaptic vesicles to the plasma

membrane occur very quickly (within a fraction of a millisecond) and depend on the presence of a Ca^{++} influx. Changes in the duration of the action potential and the pattern of firing of the action potentials can alter the amount of intracellular Ca^{++} and can affect the number and type of vesicles released, triggered by Ca^{++}.

Many important proteins have been implicated in the process of vesicle docking and fusion. Synaptobrevin, syntaxin, and SNAP-25 are three molecules that are integral to the process and are collectively referred to as the *SNARE complex*. The SNARE complex is necessary for membrane fusion and exocytosis.[34,53] Three other proteins play crucial roles in this process: SM protein, complexin, and the Ca^{++} sensor synaptotagmin.[53] Numerous regulatory proteins, including Rab GTPases, have been implicated in the process of exocytosis. The process described previously is representative of the mechanism for neurotransmitter release from the small clear vesicles that primarily contain the low-molecular-weight neurotransmitters. The larger dense core vesicles, which contain the monoamines and peptides, are thought to release their contents by essentially similar mechanisms, which also depend on the influx of Ca^{++}. Additionally, some of the neurons that release monoamines and peptides do not possess active zones, and the transmitter substances are released at nonspecialized sites of the presynaptic membrane.

One consequence of this mechanism is that the presynaptic membrane gradually gets larger because of the added vesicle membranes. There is a sequestration process of the excess presynaptic membrane that engulfs membrane and materials from the extracellular space (molecules or viruses) (i.e., pinocytosis).

RECEPTOR BINDING AND SIGNAL TRANSDUCTION

The various types of receptors for neurotransmitters, hormones, and drugs that act on the CNS are discussed in the broader context of general receptor pharmacology in Chapter 1. Table 11-2 identifies several neurotransmitters and receptors that are uniquely or closely associated with the CNS.

Many of the receptors can be classified as ion channels, and their action is termed *ionotropic*. These receptors tend to produce an immediate response. All of these ionotropic receptors are formed from protein subunits, which often exist in multiple isoforms. $GABA_A$ receptors are pentamers. The choices for the pentamer composition include six α, four β, one δ, four γ, one ε, one π, and three ρ subunit isoforms in potentially thousands of combinations. Although this many receptor types have not yet been observed, it does suggest that there may be many variants.[38] Some $GABA_A$ receptor variants are seen in infants and in epileptic patients.

G protein–coupled metabotropic receptors tend to produce effects that last longer than the ionotropic receptors. It is not uncommon for a single transmitter to combine with ionotropic and metabotropic receptors to produce an immediate and more prolonged action in the cell. See Chapter 5 for detailed information on events that follow stimulation of G protein–linked receptors.

A sequence of events follows the agonist binding to receptors linked to G_s. Adenylyl cyclase is stimulated, and cyclic AMP (the second messenger) is generated. Cyclic AMP stimulates the activity of protein kinase A. Protein kinase A can phosphorylate many proteins. One of the products of protein kinase A phosphorylation is the phosphorylated form of cyclic AMP response element binding protein ($CREB\text{-}PO_4$). This phosphorylation enables CREB to modulate DNA transcription, similar to the way an intracellular receptor does. By these intermediary metabolic pathways, a neurotransmitter can alter the immediate activity of the cell through ion channels, the sensitivity of the cell by phosphorylation, and the long-term function of the cell through alteration of protein synthesis. Pathways such as these provide insight into the mechanisms by which drug tolerance or sensitization may occur.

TERMINATION OF NEUROTRANSMITTER EFFECT

Termination of the neurotransmitter signal is important for efficient functioning of the signaling process. If the neurotransmitter were to remain at the synapse and continue to bind to its receptor, new signals could not get through. Desensitization or downregulation of the receptor would also result from continued exposure to the neurotransmitter. Three mechanisms are involved in signal termination: uptake of the neurotransmitter back into the presynaptic neuron, enzymatic degradation of the neurotransmitter, and diffusion out of the synapse.

Reuptake

Reuptake of the neurotransmitter into the presynaptic cell is an important mechanism for terminating the effects of many transmitters. The existence of high-affinity uptake systems has been shown for norepinephrine (the norepinephrine transporter NET), dopamine (the dopamine transporter DAT), GABA (the GABA transporter GAT), 5-HT (the 5-HT transporter 5-HTT), glycine (the glycine transporter GlyT), and glutamate (the excitatory amino acid transporters EAAT1, EAAT2, and EAAT3). These uptake mechanisms are selective for specific neurotransmitters and rely on carrier or transporter proteins that span the plasma membrane. The transporters depend on the exchange of ions (primarily Na^+) or the hydrolysis of ATP to drive the system. Many antidepressants function by inhibiting the uptake of neurotransmitters such as norepinephrine and 5-HT, leaving a greater concentration of transmitter at the synapse and prolonging its duration of action.

Blockade of uptake mechanisms is also responsible for the effects seen with cocaine administration. Cocaine is a powerful inhibitor of the uptake of norepinephrine and dopamine from the synaptic cleft. Augmentation of dopaminergic transmission in the nucleus accumbens region of the brain has been linked to the euphoria produced by cocaine. A similar increase in synaptic concentrations of norepinephrine over long periods results in several cardiovascular side effects seen with cocaine abuse, such as dysrhythmia and hypertension. The danger of administering exogenous catecholamines to an individual intoxicated with cocaine should be readily apparent.

Enzymatic Degradation

Enzymatic degradation is an efficient method for terminating the effect of neurotransmitters such as acetylcholine and ATP. The enzymes involved in metabolizing acetylcholine and ATP are found primarily on the extracellular face of the plasma membrane of the postsynaptic neuron. The degradation of acetylcholine by acetylcholinesterase on the cell surface in the synaptic cleft is a prototypic example of the regulation of transmitter effect. Anticholinesterases (e.g., physostigmine) are used clinically to inhibit this degradation, increasing the amount of acetylcholine present within the synaptic cleft. Enzymes for metabolizing many other neurotransmitters are found in neurons. Enzymatic inactivation occurs after the neurotransmitter is taken up into the neuron, usually the presynaptic neuron.

The intracellular regulation of neurotransmitter concentrations is tightly controlled and compartmentalized, as shown by the monoamine oxidase system. This enzyme is found on the surface of mitochondria and degrades catecholamines and 5HT in the cytoplasmic pool (see Chapter 5). The monoamine oxidase inhibitors used to treat depression (e.g., isocarboxazid) function by blocking the degradation of the

monoamines within the presynaptic neuron, resulting in an increase in the amount of cytoplasmic monoamines. This effect leads to chronic adaptive receptor changes, which are discussed in Chapter 12.

Receptor-Transmitter Complex Postsynaptic Internalization

An interesting feature of G protein–coupled receptors is that after binding with the transmitter, the receptor is often internalized into the postsynaptic nerve. In some cases, β-arrestin and clathrin-coated pits mediate the receptor endocytosis. When internalized, the receptor can be metabolized in the lysosomes, returned to the cell surface, or possibly transported to the nucleus, as illustrated in Figure 1-12. Removal of the β adrenoceptor from the membrane is thought to be a mechanism for tachyphylaxis (rapid tolerance). Receptors that are internalized after agonist binding include β adrenoceptors, opioid receptors, and receptors for the tachykinins (substance P and the neurokinins).

Diffusion

Diffusion and removal by bulk flow are the simplest methods of terminating the neurotransmitter effect. The kinetics of diffusion depends on the concentration gradient of the neurotransmitter through the synaptic cleft and the affinity of the ligand for its receptor. Diffusion occurs at all synapses to some degree depending on the geometry of the synapse; its relative importance in terminating neurotransmitter action is inversely related to the combined influence of local metabolism and uptake.

TERMINATION OF THE EFFECTS OF CENTRAL NERVOUS SYSTEM DRUGS

Drugs acting in the CNS are largely metabolized to inactive products in the liver, and little metabolism occurs in the brain. Reduction in metabolism by the liver or blockade of the excretion of a drug or its active metabolites by the kidney can prolong the actions of CNS drugs. The CNS receives a high blood flow (estimated at about 750 mL/min), which translates into rapid delivery of drugs from the blood to the brain. Intravenously administered drugs or inhaled drugs can produce effects within seconds of administration.

The blood-brain barrier isolates the brain from the plasma, forming a barrier to the free passage of hydrophilic drugs and creating a separate environment with the pH of the cerebrospinal fluid being slightly acidic (pH 7.3). The brain contains more than double the amount of lipid molecules compared with muscle. This contributes to the high concentration of lipid-soluble drugs in the brain.

The action of highly lipid-soluble drugs in the CNS is often terminated by drug redistribution. After intravenous or gaseous administration, the high blood perfusion of the brain presents large amounts of a lipid-soluble drug to the brain. The drug readily enters the brain because of the blood-brain concentration difference and the high solubility of the drug in the brain lipids, producing a rapid effect. After equilibrium of the concentration of the drug between the plasma and the brain, the drug can be "redistributed" out of the brain to muscle, which is less lipoidal than the brain and less well perfused but has a larger volume than the brain, and then fat, which has a much lower blood flow than does the brain but a considerably larger volume. When this happens, the concentration in the brain may decrease to below a behaviorally effective level before the drug is actually cleared (metabolized or excreted) from the body.

In this case, CNS drugs can show multicompartment elimination. The rapid (or α-phase) elimination is associated with redistribution, followed by a slower, "metabolic" (or β-phase) elimination. When referring to pharmacokinetic tables for CNS drugs, generally only the slow (β-phase) elimination rate is tabulated; this can lead to confusion by practitioners when the behavioral action is much shorter than the metabolic half-life. In these cases, the redistribution out of the brain determines the clinical offset. On repeated administration, the remaining unmetabolized drug can contribute to the total effect of the second dose (or subsequent doses), however, because it may increase the blood concentrations to a point well above the threshold concentration for a behavioral effect. In some cases, redosing can lead to overdosing when the practitioner is unaware of the phenomenon. This type of toxicity has been an issue with drugs such as thiopental and fentanyl.

Because of the pharmacokinetic impact of the blood-brain barrier and high blood flow to the brain, behavioral responses to drugs acting on the CNS follow a pattern that is illustrated by the barbiturates. Highly lipid-soluble barbiturates enter the brain rapidly, come to a rapid peak of action, and then redistribute out of the brain quickly. This pattern of action leads to a rapid effect; the anesthetic thiopental is a good example (see Figure 2-9). Other examples of drugs with similar pharmacokinetics include the benzodiazepine midazolam and the opioid fentanyl. These agents are also used as intravenous anesthetics based on their pharmacology and pharmacokinetics.

Relatively hydrophilic drugs get into the brain more slowly and tend to peak after a delay. The removal of their CNS effects more closely mirrors their metabolism and excretion. These CNS drugs may be used for daytime sedation or for seizure control because the more stable blood concentration tends to produce a flat, consistent effect. Compared with fentanyl, morphine is relatively hydrophilic. It gets into the brain slowly, has a delayed and lower peak action, and produces a prolonged and less profound level of analgesia compared with fentanyl.

Drugs that diffuse too slowly through the tight junctions of the blood-brain barrier may never reach behaviorally effective concentrations. Drug manufacturers can take advantage of this quality to limit CNS side effects. Histamine contributes to wakefulness. Lipid-soluble H_1 receptor antihistamines (e.g., diphenhydramine) enter the brain easily and block the action of histamine in the brain and produce drowsiness. To reduce this effect, less lipid-soluble antihistamines were developed. These drugs penetrate the blood-brain barrier slowly and only minimally. They are marketed as "nonsedating" antihistamines.

Some drugs that bind tightly to their CNS receptors may continue to act, even though the plasma concentrations of the drugs have virtually returned to zero. The action of irreversibly binding drugs is usually terminated only by receptor turnover. Tight, although not irreversible, binding has been observed for drugs such as morphine-6-glucuronide, pimozide, and alprazolam. Morphine-6-glucuronide is an active metabolite of morphine that is 100 times more potent than morphine, but is excluded from the brain except in cases of renal failure. In renal failure, it enters the brain and may become trapped there because of the blood-brain barrier. There it can produce analgesia and sedation even in the absence of detectable drug or metabolite in the plasma.[2]

Active transport mechanisms for terminating the actions of drugs in the CNS have been confirmed. As described in Chapter 2, multiple drug resistance proteins (including P-glycoproteins) and related transporters are proteins elaborated by the endothelium of the brain vasculature, kidney, intestines, and liver that facilitate export of molecules out of these organs and out of the body. These transport resistance proteins export several drugs of medical interest, such as β-adrenergic antagonists, anticancer drugs, anticonvulsants, human immunodeficiency virus protease inhibitors, and opioids. Drugs of particular interest to dental practice that

undergo active elimination include morphine, fentanyl, pentazocine, erythromycin, tetracycline, and glucocorticosteroids. Erythromycin and ketoconazole can inhibit these systems, possibly prolonging the CNS actions of other drugs. These transport proteins can be induced by several drugs, including some anticonvulsants, some anticancer drugs, and St. John's wort. Activation of the pregnane xenobiotic receptor can induce P450 oxidative enzymes, phase II synthetic enzymes, and P-glycoprotein simultaneously.

The hypothalamus is important for regulation of circadian and other rhythms, including sleep-wake and reproductive cycles. Drugs administered to patients can interact with these natural hormones and cycles; understanding the chronobiology of hormones may improve the understanding of the effects of drugs administered at different times. Some examples are the observations that anti-inflammatory adrenocorticotropic hormones and analgesic endogenous opiates are released at peak amounts in the morning. Patients often complain more of pain late in the day or at night, and overdose deaths with opioids are more common in the morning.

Pharmacodynamic processes can also affect the duration of action of CNS drugs. Decreased action of a drug with repeated administration of an agent is termed *tolerance* (e.g., opioid tolerance). Tolerance can have many causes, including reduced availability of neuron membrane receptors, modification of the sensitivity of the receptors, altered postreceptor systems (e.g., G proteins, second messengers, phosphorylation of receptors), or changes in gene transcription leading to changes in receptors in nerve synapses. Conversely, the increased action of a drug with repeated administration is termed *sensitization* (e.g., cocaine sensitization). Metabolic tolerance or sensitization can result from induction or inhibition of the metabolic enzymes in the liver, resulting in a change in the amount of drug getting to the brain.

The selection of a CNS drug should be based on the goals of therapy and an understanding of the pharmacology, especially the pharmacodynamics and pharmacokinetics, of the agent.

CHAPTER 12

*Psychopharmacology: Antipsychotic and Antidepressant Drugs**

VAHN A. LEWIS

According to the National Institutes of Mental Health, 20% of the population have a diagnosable mental disorder in their lifetime.[35] The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) classifies many types of mental disorders.[10] Schizophrenia, which affects 0.5% to 1% of the population, is the most severe of the psychiatric disorders, and disturbances of mood (affective disorders) are the most common. Approximately 10% to 25% of women and 5% to 12% of men have at least one major depressive episode during their lifetimes. Schizophrenia and affective disorders are episodic and progressive disorders. Although appropriate treatment tends to improve the course of a disorder, it rarely produces a cure.

Psychotherapeutic drugs have contributed much to our understanding of mental illness and have reduced hospital bed occupancy by mental patients to a tenth of what it was before their use. Pharmacotherapy has permitted individuals who would otherwise have been hospitalized long-term to be more integrated into society. The Surgeon General's report on mental health has indicated that more people could benefit from treatment with psychotropic agents than are currently being treated.[35] In daily practice, the dentist can expect to treat patients taking psychotherapeutic agents for various mental disorders. These agents may contribute to oral pathology or become a factor when rendering dental care.[17] Many patients being treated for mental illness report poor oral health, but it is not all due to their treatments; poor oral health is also correlated to older age, race, unemployment or financial strain, and smoking behavior.[27]

Brain imaging, molecular biology, and genetic studies promise to improve the understanding of psychotic disorders. Results from such research have identified changes that may relate to the pathology of these conditions. Key findings include the observation of genetic, structural, and functional changes in schizophrenia, bipolar disorder, and depression. Inconsistencies between the symptoms and observable signs still exist that challenge our understanding and treatment of psychiatric disorders. Brain imaging studies have shed some light on this variability. Imaging has shown that the onset of schizophrenia is associated with a patchy loss of cerebral cortex that progresses to a more global and severe loss.[37] The symptoms seen in a particular patient may vary depending on where the process starts and how far it continues. For children with early-onset schizophrenia, the cell loss is found in most areas of the cortex 5 years after diagnosis.[52] Difficulties in categorizing these illnesses can result in inconsistent treatment outcomes.

Psychotic states such as schizophrenia are treated with antipsychotic drugs, sometimes also referred to as *neuroleptics*; depression is treated with antidepressant drugs, and manic illness (and bipolar disorder) is treated with lithium salts and some anticonvulsant drugs. Neuroses (e.g., anxiety), which are less severe psychiatric disorders, are treated with antianxiety agents and are discussed in Chapter 13. Selective serotonin reuptake inhibitor (SSRI) antidepressants are also effective in treating several anxiety disorders, including obsessive-compulsive disorder, panic disorder, post-traumatic stress disorder, and social anxiety disorder. These drugs may be referred to as delayed action antianxiety agents because the effect develops slowly over several weeks. Sympathomimetic stimulants are effective treatments for attention-deficit/hyperactivity disorders and narcolepsy, and they are discussed in Chapter 6. New results from imaging and gene microarray studies reveal differences and similarities between the classification of brain disorders. In an individual patient, various agents may be needed for the particular spectrum of symptoms. Because of the perceived stigma associated with psychiatric illness, the psychiatric disorder itself (which may lead to poor self-insight), or the effects of the psychotropic drugs, patients may forget or be reluctant to discuss their disorder with dentists or to provide complete information regarding their treatment.[56]

MAJOR PSYCHIATRIC DISORDERS

Schizophrenia

In schizophrenia, the patient's ability to function is markedly impaired because of disturbances in thought processes. These disturbances increase the likelihood of adverse social outcomes, such as unemployment, poverty, social isolation, and suicide.[4]

Schizophrenic patients have positive or negative symptoms, or both and memory disorders. Positive symptoms include hallucinations (false perceptions), delusions (false beliefs), and agitation. Negative symptoms include interpersonal withdrawal, loss of drive, and flattened affect (restricted range of emotions). Positive symptoms respond more favorably to the antipsychotic drugs that were developed first (typical or "classic" antipsychotics), whereas negative symptoms are better correlated with demonstrable structural abnormalities in the brain and may be more responsive to newer "atypical" antipsychotic drugs (see later). Schizophrenic patients also have subtle changes in process planning and memory, but these continue to be resistant to treatment.

Neither the etiology nor the pathogenesis of schizophrenia is known. Current thinking suggests that a genetic predisposition and early injury (in utero or early childhood) may set

*The author wishes to recognize Dr. Leslie Felpel for his past contributions to this chapter.

TABLE **12-1**

Therapeutic and Adverse Effects Associated with Some Receptors Bound by Common Antipsychotic and Antidepressant Drugs

RECEPTOR OR PROCESS BLOCKED	THERAPEUTIC EFFECT OF BLOCK	ADVERSE EFFECTS RESULTING FROM BLOCKADE OF RECEPTOR OR PROTEIN
Histamine (H_1)	Sedation, anxiolysis, antiallergy effect	CNS depression, hypotension, dry mouth, weight gain
Muscarinic	Reduction of extrapyramidal side effects	Dry mouth, blurred vision, sinus tachycardia, constipation, urinary retention, memory dysfunction
Adrenoceptor		
α_1-Adrenergic		Memory dysfunction, postural (orthostatic) hypotension, reflex tachycardia, epinephrine reversal, dizziness, dry mouth, weight gain, priapism
α_2-Adrenergic	Blockade of presynaptic autoregulation, increasing CNS 5-HT and NE	Priapism
Dopamine (D_2)	Amelioration of the positive signs and symptoms of psychosis	Extrapyramidal movement disorders, sexual dysfunction, dry mouth, weight gain
5-HT reuptake	Reversal of depression	Gastrointestinal disturbance, sexual dysfunction, activating effects, dry mouth
NE reuptake	Reversal of depression	Dry mouth, urinary retention, erectile dysfunction, CNS stimulation, tremor, proconvulsant
Dopamine reuptake	Antidepressant effect (?)	Psychomotor activation, psychosis, proconvulsant action (?), dependence

5-HT, 5-Hydroxytryptamine; *CNS,* central nervous system; *NE,* norepinephrine.

the stage for neurodevelopmental changes that ultimately manifest as behavioral difficulties later in life (often in early adulthood) and that may be triggered by a stressful lifetime event.[35] For the disease to manifest itself, the effects of several cumulative factors likely combine to result in the clinical disorder.[4] Evidence from brain imaging suggests that broad areas of the brain can lose cell mass in this disorder, suggesting a problem in regulation of brain growth, repair, or cell pruning, rather than dysregulation of a single neurotransmitter. Genetic survey chip studies have also identified differences in neuronal structure and function (e.g., myelination, neuroimmune and mitochondrial genes) suggesting a neurodegenerative cause rather than a specific transmitter disruption.[31]

Dopamine hypothesis

The classic "dopamine hypothesis" for schizophrenia, which suggests that schizophrenia is caused by hyperactivity of central dopamine pathways, has been a dominant theme since the early 1960s. Most antipsychotics are dopamine antagonists in various experimental conditions, and agents that release dopamine (e.g., amphetamine) can induce an acute psychotic state similar to schizophrenia. Loss of balance between cerebral cortex inhibition and dopamine-mediated arousal may promote dysregulated thought. The hypothesis does not explain why the therapeutic effect of the antipsychotics takes several weeks to develop, although dopamine blockade is known to occur within hours; why some schizophrenic patients are refractory to antipsychotics; and why some drugs that affect neurotransmitters other than dopamine may have antipsychotic activity.

The role of dopamine in schizophrenia has been complicated by the identification and cloning of several dopamine receptor subtypes and the discovery that other neurochemicals, either independently or by regulating dopamine, may be involved in the disease process. Dopamine innervation is extensive and contributes to the activity in the basal ganglia, cerebral cortex, hippocampus, amygdala, thalamus, and cerebellum. Hyperactive dopaminergic neural pathways offer a simple and attractive mechanism to explain schizophrenia, but this is an incomplete explanation for the disease. It is justified to assume, however, that the parkinson-like motor disturbances, which are common side effects of the antipsychotics, result from blockade of dopamine transmission in the basal ganglia (Table 12-1). Five dopaminergic cell groups are considered important either for the therapeutic actions of antipsychotic drugs or for side effects of the antipsychotic agents. Table 12-2 summarizes these dopamine cell groups and their proposed relationship to activity.

TABLE **12-2**

Dopaminergic Cell Groups and Their Relationship to Actions and Side Effects of Antipsychotic Drugs

CELL GROUP	RELATIONSHIP/ACTION
Mesolimbic and mesocortical	Considered the major therapeutic targets for antipsychotics
Nigrostriatal	Essential for motor function, related to the motor side effects of antipsychotics
Tuberoinfundibular	Regulation of hormones, especially inhibition of prolactin secretion; thought to mediate side effects such as galactorrhea and infertility
Chemoreceptor trigger zone	Receptors thought to mediate the antiemetic actions of antidopaminergic drugs
Medullary-periventricular	May mediate the actions of antidopaminergic drugs on appetite

Other neurotransmitters

Other neurotransmitters have been implicated in psychotic behavior and are of interest regarding the cause of psychotic symptoms. Phencyclidine-induced psychosis is proposed to be an even better model for schizophrenia than the dopamine hypothesis. The predominant action of phencyclidine is

thought to be blockade of N-methyl-D-aspartate (NMDA)–type glutamate (glutamatergic) receptors. NMDA receptors are polyagonist receptors, involving glutamate, glycine, and polyamines. Stimulation of NMDA by glutamate can be therapeutically problematic. There is more recent interest, however, in glycine transporter blockade as a possible indirect alternative to the use of glutamate receptor agonists for therapy for schizophrenia.[30] The hallucinogens lysergic acid diethylamide and mescaline can induce hallucinations and delusions and are thought to produce their actions through 5-hydroxytryptamine type 2 (5-HT_2) receptors.[2] Anticholinergics, cannabinoids, and sigma receptor agonists are other drugs that can induce psychosis-like reactions.

Anatomic changes

Modern brain imaging techniques have identified numerous volume or functional changes in the brain in psychosis. Particular attention has been focused on areas of the association cortex (e.g., frontal, parietal, temporal association areas) or fiber bundles connecting the association cortex. More recent imaging evidence shows, however, that these are not the only areas of the brain involved. Sensory, motor, visual, auditory cortex, and olfactory cortex may be involved. Corticostriatothalamic loops may be involved because of their intimate connection to the cerebral cortex. These loops make numerous connections with limbic structures, such as the amygdala, hippocampus, nucleus accumbens, and basal ganglia, which are connected with the thalamus and back to the cortex. These same areas are involved in mood and thought processes. Dopamine may act as a regulator or modulator of function in many of these structures. If dysfunction of dopaminergic systems were to occur, it is reasonable to expect that alterations in mood, personality, and thought processes would follow.

Genetic and developmental vulnerability

There is evidence for a genetic predisposition to schizophrenia. If both parents are schizophrenic, 46% of the children are likely to become schizophrenic, and if one parent is schizophrenic, 18% of the children show the disorder compared with 1% of the general population. The possibility of early (in utero or childhood) stresses such as infection, exposure to toxic elements, winter birth, starvation, migration travel, or radiation has been correlated to increased vulnerability to the disease.

Affective Disorders

The affective illnesses are expressed as dysregulations of mood. There are many types of affective disorders categorized in DSM-IV, but for purposes of this discussion it is sufficient to consider only depression and mania. Most individuals have had reactive, or secondary, depression with feelings of sadness or grief associated with a personal loss.[10] In normal circumstances, such reactions are related to specific causes, are not incapacitating, and are generally short-lived (1 to 2 weeks). In contrast, for a mentally ill patient, depression is a severe, disabling disorder characterized by reclusiveness and nonverbalization that may last for extended periods (2 to 5 weeks). The patient is sad most of the day; gains little pleasure from activities; and may have other signs, such as weight loss, irritability, insomnia, feelings of guilt, agitation, or difficulty in concentrating.[10]

A serious consequence of depression is an increased risk of suicide. Depression is also a risk factor or is comorbid with other diseases, such as sleep disorders, weight changes, sexual disorder, pain disorders, anxiety disorders (and panic attacks), drug abuse, psychoses, myocardial infarction, and coronary artery disease. This kind of depression is called primary, endogenous, unipolar, or major depressive disorder. A variant of depression is seasonal affective disorder, which is triggered by changes in seasons and can respond to treatment with intense lights.[10]

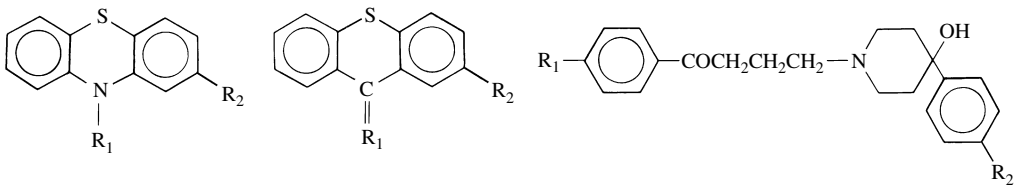
Unipolar depression tends to be more common in women, but the risk of suicide is greatest in elderly men. Triggering factors for depression in women and men overlap, but women tend to be more strongly affected by interpersonal factors, whereas men tend to be more greatly affected by job loss or legal problems. In women, the factors of poor relationships with parents, early marriage, incomplete education, divorce, and financial difficulties can contribute to repeated stressful life events (cycle of adversity). The incidence of mood disorders in women is greatest at times of life when shifts of ovarian hormones occur. A higher incidence of depression can occur at the beginning of menstruation, after childbirth, and in the perimenopausal period. Depression may be more likely during the progesterone-dominated components of the menstrual cycle. Estrogens tend to be antidepressant and facilitate neuronal repair. A genetic risk is evident for mood disorders but so far is not clearly understood. Concordance rates for mood disorders are 46% in monozygotic twins and 20% for dizygotic twins.

Patients with mania exhibit a distinct period of abnormally elevated, expansive, or irritable mood, sometimes requiring hospitalization. Three or more of the following symptoms also suggest a manic episode: (1) inflated self-esteem, (2) decreased need for sleep, (3) talkativeness, (4) flight of ideas, (5) distractibility, (6) increased goal-directed activity, and (7) excessive interest in pleasure.

Manic individuals may also have alternating periods of severe depression, in which case the disorder may be referred to as bipolar (manic-depressive) illness. The first episode of psychopathology is often depression, sleep disorders, or anxiety, but psychopathology later progresses to include manic episodes.[11] The incidence of bipolar disorder may be 5% of the population and 45% of community mental health patients.[3] Three forms of bipolar disorder have been distinguished. Bipolar I involves cycles of mania and depression. Bipolar II involves cycles of hypomania and depression. Hypomania is a less severe form of mania that does not have psychotic features (e.g., hallucinations). Bipolar III is mania associated with the use of antidepressants. Bipolar II patients only rarely convert to bipolar I, and patients with bipolar II disorder may have the highest risk for suicide.

There is great interest in identifying the underlying brain processes that may help explain depression and bipolar disorders. Heterogeneity in the expression and causes of depression has made this process challenging, however. As shown by imaging, the brain structural changes in depression include changes in the prefrontal cortex, the cingulate[49] the insula, and the temporal lobe. The hippocampus and amygdala have been implicated.[36] Cerebral blood flow and tissue glucose use are poorly correlated with depression in wide regions of the cortex, in contrast to the case for bipolar or normal subjects.[12] In light of these imaging results, it is unlikely that depression is due to a change in a single neurotransmitter. Paradoxically, gene survey results suggest that bipolar disorder is similar to schizophrenia because both are viewed as degenerative disorders,[49] whereas major depressive disorder may involve a more specific cause—glutamate/γ-aminobutyric acid imbalance.

Environmental and genetic factors have a role in precipitatimg depression. Environmental factors (stresses) may act as triggers for depressive episodes by altering the release of mineralocorticoids and glucocorticoids, which under some conditions can predispose to brain damage. Depressive episodes tend to increase the likelihood of further depressive episodes, a phenomenon referred to as *kindling*. Individuals who also have a genetic predisposition for depression act as though they are "prekindled." Their episodes of depression are less related



Phenothiazine nucleus **Thioxanthene nucleus** **Butyrophenone nucleus**

FIGURE **12-1** Structural formulas of representative antipsychotic drugs.

to precipitating stressful causes, are more serious, and are seen more often in younger patients. Late-onset depressions are less related to genetics or stresses and may involve damage in subcortical white and gray matter from disease states such as arteriosclerosis or Parkinson's disease.

Although bipolar disorder shares some characteristics with unipolar depression, there are several differences: the treatment is different for bipolar versus unipolar depression, bipolar disorder has a stronger genetic involvement, and bipolar disorder is thought to involve different observable brain structural changes. Currently, treatment is aimed at the manic phase first, which is treated with lithium salts and anticonvulsants. In addition, these agents may exert a neuroprotective effect and can reduce the extent of brain structural changes occurring in bipolar disease.

Monoamine hypothesis

As in the case of schizophrenia, various theories have been offered to explain the cause of affective disorders, with attention focusing on putative neurotransmitters. The classic monoamine hypothesis (also called the biogenic amine hypothesis or simply amine hypothesis) of affective disorders proposes that depression results from a deficiency of norepinephrine (NE), 5-HT, or both at central synaptic sites. Although little evidence exists that directly substantiates this hypothesis, it is indirectly supported by the fact that most antidepressant drugs increase synaptic concentrations of one or more monoamines, either by blocking the reuptake of monoamine into the presynaptic nerve terminal or by preventing its catabolism by the enzyme monoamine oxidase (MAO) in the nerve terminal after reuptake.

Although these findings are consistent with the monoamine hypothesis of affective disorders, there are several discrepancies. One of the findings most difficult to reconcile with the monoamine hypothesis is that the blockade of amine reuptake by antidepressants and of amine metabolism by MAO inhibitors can be shown almost immediately after drug administration, but full therapeutic effects are not observed until the drugs have been taken continuously for several weeks. In addition, some antidepressants, such as mirtazapine, do not have a significant effect on either monoamine reuptake or MAO inhibitor activity.

Because of these and other findings, new possibilities have been investigated to explain the action of antidepressants. Attention is focusing on presynaptic and postsynaptic structural mechanisms as evidence mounts that the reuptake inhibitors, MAO inhibitors, atypical antidepressants, and even electroconvulsive therapy all produce consistent changes in the relative density or sensitivity of certain receptor processes. The classic monoamine hypothesis is too limited and needs to be modified in accordance with new research findings. Changes in biochemistry of 5-HT, NE, dopamine, acetylcholine, glutamate, γ-aminobutyric acid (GABA), orexin, histamine, dopamine, corticotropin-releasing factor and corticosteroids, ovarian hormones, substance P, and omega-3 fatty acids have been shown. Depression may involve neural degenerative components as well, but these have not yet been well researched.

Historical Development of Antipsychotic and Antidepressant Drugs

Most of the psychotherapeutic properties of the psychoactive drugs were discovered by accident. In 1950, while attempting to develop antihistaminic agents, the Rhône-Pauline Laboratories in France synthesized the phenothiazine chlorpromazine (Figure 12-1). The unusual neuroleptic property of chlorpromazine was noted, and the drug was used to treat schizophrenic patients in 1952. The discovery of chlorpromazine and other phenothiazines made possible the outpatient treatment of psychotic disorders.

A characteristic of many antipsychotic drugs is interference with multiple neurotransmitter systems. In addition to blocking dopaminergic receptors, many can block α-adrenergic and serotonergic receptors and alter functions of cells. These drugs have many side effects that can be related to these multiple receptor actions (see Table 12-1). The next phase of development focused on drugs with selective drug receptor binding. In the case of antipsychotic drugs, action at multiple receptor types may provide therapeutic advantages. The current challenge is to identify which combination of actions is most beneficial.

The antidepressant properties of MAO inhibitors were discovered when it was observed that isoniazid, an antituberculosis drug, produced a euphoric state in patients and was found to be an MAO inhibitor. There are two forms of MAO: MAO-A is present in catecholamine-containing neurons, and MAO-B is found in 5-HT–containing neurons and astrocytes. Selective antidepressant MAO inhibitors inhibit the MAO-A form.

The tricyclic antidepressants (TCAs) were synthesized in an attempt to produce more specific antipsychotic agents (note in Figures 12-1 and 12-5 the chemical similarity of TCAs and phenothiazines). It was soon recognized, however, that imipramine, a prototypic TCA, was more beneficial in treating depression than in treating schizophrenia. TCAs were the mainstay for treating depression for many years. Their use has been limited, however, by the numerous side effects resulting from their actions on many nontherapeutic receptor sites. Efforts to develop better agents have been rewarded with a newer class of drugs, SSRIs, with fewer adverse effects than TCAs and fewer drug interactions than MAO inhibitors. These drugs have revolutionized the use of antidepressant medication. Subsequently, the selective serotonin and NE reuptake inhibitors and the selective NE reuptake inhibitors were developed.[26]

St. John's wort is a botanical remedy with a long history of use for depression. It is now thought that the active principle is the compound hyperforin (instead of hypericin as had been believed).[9] It has been characterized as a weak super–reuptake inhibitor with effects on NE, serotonin, dopamine, glycine, GABA, and glutamate reuptake.

Although the psychoactive properties of lithium salts were noted in 1949,[6] lithium carbonate was not developed and widely recognized as an effective treatment for manic-depressive illness until 1970. More recent studies have focused on a possible neuroprotective role for lithium salts. The anti-

convulsant drugs carbamazepine and valproic acid were investigated for treatment of mania (bipolar disorder) in the early 1980s, and since that time their use and that of other anticonvulsant drugs has been increasing. When used for this purpose, these drugs are referred to as *mood stabilizers*.

Many adjunctive treatments are being evaluated for use in subgroups of patients with depression. Some of the agents used include glucocorticoid inhibitors, estrogens, thyroid, lithium, anticonvulsants, stimulants (e.g., modafinil), yohimbine, sildenafil, bupropion, pramipexole, buspirone, and antipsychotic agents.

ANTIPSYCHOTIC DRUGS

The principal drugs effective in the treatment of schizophrenia are dopaminergic receptor antagonists. Five dopamine receptors (D_1 through D_5) have been cloned. Some of these receptors express extra long or short variants. The possibility that each of these receptors may subserve a different physiologic function illustrates the complexity of the dopaminergic system. D_1 and D_5 have similar actions and often increase cyclic 3′,5′-adenosine monophosphate synthesis, whereas D_2, D_3, and D_4 are thought to decrease cyclic 3′,5′-adenosine monophosphate synthesis. Interest has now focused on the relative specificity and affinity of the antipsychotic agents for each of the dopamine receptors. The older typical antipsychotics (e.g., phenothiazines) and the atypical agents (e.g., clozapine) are dopamine antagonists. Clinical potency as an antipsychotic drug relates most closely to blocking D_2 receptors (Table 12-3). The affinity of clozapine for the D_1 and D_4 receptors relative to D_2 is proportionally greater, however, than that of the older agents. In postmortem brain samples from schizophrenic patients, there is an increase in the number of D_2 receptors but not D_1 receptors.

Aripiprazole acts by a unique mechanism: it is a partial dopamine agonist, which produces limited dopamine action, but prevents additional stimulation by endogenous dopamine. This drug has been reported to produce fewer extrapyramidal side effects than dopamine antagonists.

Although there is little doubt that dopamine is involved in schizophrenia, other neurotransmitter systems may also play a crucial role in this disease. In addition to dopamine, neurotransmitters such as 5-HT, glutamate, NE, glycine, and GABA have been implicated in schizophrenia, suggesting that this is a very complex and multifaceted illness and that many mechanisms may be involved in the disease process.[2] Preliminary gene chip microarray analysis has shown changes in signal transduction, transcription, and metabolic enzymes associated with altered regulation of certain genes in schizophrenia.[31]

Chemistry and Structure-Activity Relationships

Of the several classes of antipsychotics, some are closely related structurally, others share a stereochemical resemblance, and still others seem to be chemically unrelated. The term *typical antipsychotic* is used for drugs that improve chiefly positive symptoms, whereas *atypical psychotic* is used for agents that cause fewer extrapyramidal side effects or improve positive and negative symptoms.

Phenothiazines and thioxanthenes

The basic ring structure of the phenothiazines is illustrated in Figure 12-1. Substitutions at R_1 divide the phenothiazine antipsychotics into three major groups. One group, represented by chlorpromazine, has an aliphatic chain at C_1. Compounds such as chlorpromazine with three carbons in the chain linked to an amine ($–CH_2–CH_2–CH_2–N(CH_3)_2$) have antipsychotic properties, whereas compounds with only two carbons, such as promethazine, are usually more antihistaminic or anticholinergic in nature and possess few antipsychotic effects. A second group, represented by thioridazine, has a piperidine ring at R_1 attached to the carbon chain. These phenothiazines are usually less sedating than the aliphatic agents but more sedating than the next group. A third group, represented by prochlorperazine, contains a piperazine ring on the carbon chain at R_1. Drugs in this group are the most potent of the three as antipsychotic agents but are also the most likely to produce extrapyramidal side effects. Minor changes in the structure of these molecules can increase or abolish antipsychotic activity. The thioxanthene antipsychotics, represented by thiothixene, are closely related to the phenothiazines and are formed when the nitrogen of the central ring is replaced by a carbon atom.

Butyrophenones

The butyrophenone antipsychotics are not chemically related to the phenothiazines, but contain a stereochemically related nucleus (see Figure 12-1). The only butyrophenone antipsychotic available in the United States is haloperidol. Droperidol, another butyrophenone, is marketed as an antipsychotic in some countries, but is occasionally used in the United States primarily to reduce nausea and vomiting associated with anesthesia and surgery. Combined with the opiate fentanyl, it is also used to achieve deep sedation (see Chapter 48).

Dihydroindolones

The structure of molindone is shown in Figure 12-2. This compound is not structurally related to the phenothiazines,

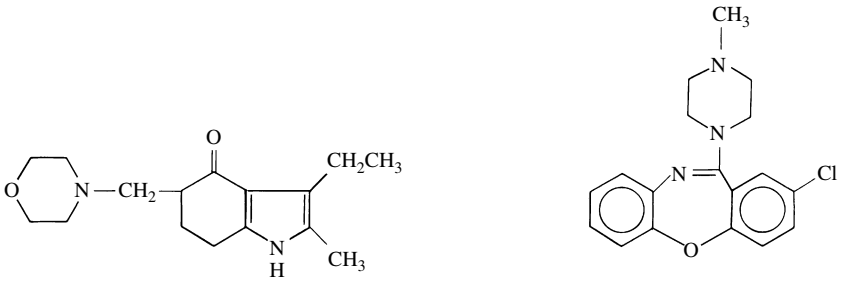
TABLE **12-3**

Comparison of Relative Receptor Antagonist Affinities of Typical and Atypical Antipsychotic Drugs

DRUG	AFFINITY ORDER						
Chlorpromazine	$\alpha_1 \geq$	5-HT_2 >	**D_2** >	D_1 >	M >	α_2	
Haloperidol	sigma =	**D_2** >	$D_1 = D_4$	α_1 >	5-HT_2		
Clozapine	M >	5-$HT_{2,6,7}$ =	H_1 =	α_1 =	α_2 =	D_4 >	D_1
Olanzapine	5-HT_2 >	M_1 >	α_1 =	**D_2** =	H_1 >	D_1	
Risperidone	5-HT_{2A} >	**D_2** =	α_1 =	α_2 >>	M		
Quetiapine	α_1 =	H_1 =	**D_2** =	5-HT_2 >	D_1		
Ziprasidone	5-HT_{2A} =	5-HT_{1A} (agonist) >	**D_2** >	α_1 >	H_1		
Aripiprazole	**D_2** (partial agonist) >	5-HT_{1A} (partial agonist) >	5-HT_{2A} >>	5-HT_{2C} >	D_4 >	α_1 >	H_1

The relative affinity for D_2 receptors is shown. Binding to other receptors has also been reported for some of the other drugs. D_2 receptors are **bold** for emphasis.

5-HT, 5-Hydroxytryptamine; *α*, α-adrenergic; *D*, dopaminergic; *M*, muscarinic; *H*, histaminergic; =, equal to the following receptor type; ≥, greater than or equal to the following receptor type; >, greater than the following receptor type; >>, much greater than the following receptor type.



Molindone **Loxapine**

FIGURE **12-2** Structural formulas of molindone and loxapine.

thioxanthenes, or butyrophenones. The pharmacologic and clinical profile of molindone resembles that of the piperazine group of phenothiazines very closely. Ziprasidone, another dihydroindolone, is pharmacologically an atypical antipsychotic and is discussed subsequently.

Dibenzoxazepines

Loxapine (see Figure 12-2) is the only dibenzoxazepine available in the United States. The structure of this compound contains seven members in its central ring and resembles a TCA. Loxapine does not seem to have antidepressant activity, however. Similar to molindone, this drug has a clinical and pharmacologic profile similar to that of piperazine phenothiazines.

Diphenylbutylpiperidines

Pimozide, a diphenylbutylpiperidine derivative, is a modified butyrophenone in which a keto group in the side chain has been replaced with a 4-fluorophenyl moiety. Pimozide is a selective dopamine D_2 antagonist that has antipsychotic properties and typical Parkinson-like side effects. The U.S. Food and Drug Administration (FDA) approved pimozide for the treatment of Tourette's syndrome, a condition characterized by phonic and motor tics, but it has been used in Europe to treat schizophrenia. Penfluridol, another diphenylbutylpiperidine, is undergoing clinical trials in the United States for the treatment of Tourette's syndrome. Both of these agents have long half-lives.

Dibenzodiazepines

Clozapine (Figure 12-3) is the only dibenzodiazepine available in the United States. Its chemical structure closely resembles that of loxapine, but in contrast to loxapine, it is classified as an atypical antipsychotic in light of its low risk for producing extrapyramidal side effects. Clozapine is reported to improve positive and negative symptoms of schizophrenia and may reverse the progression of schizophrenic symptoms. Clozapine also has muscarinic, 5-$HT_{2,6,7}$, α_1-adrenergic, and D_1, D_2, and D_4 receptor blocking properties. Use of clozapine can be accompanied by significant toxicity, especially agranulocytosis, seizures, and hypotension. Myocarditis and cardiomyopathy may rarely occur.

Thienobenzodiazepines

Olanzapine (Figure 12-4) is an atypical antipsychotic approved for clinical use. Its inhibitory actions at monoamine synapses are similar to the actions of clozapine except that olanzapine has a higher affinity for D_2 receptors (see Table 12-3). It is associated with fewer adverse effects than clozapine, particularly agranulocytosis.

Benzisoxazoles

Risperidone is a neuroleptic agent that combines antagonist action at D_2 and 5-HT_2 receptors (sometimes referred to as a serotonin-dopamine antagonist). This addition to the antipsychotic armamentarium provides therapeutic effects similar to haloperidol, but in low doses it is considered to be atypical because of its relative freedom from extrapyramidal effects. Paliperidone is an active metabolite of risperidone with a pharmacologic profile similar to risperidone.

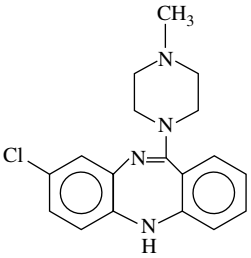


FIGURE **12-3** Structural formula of clozapine.

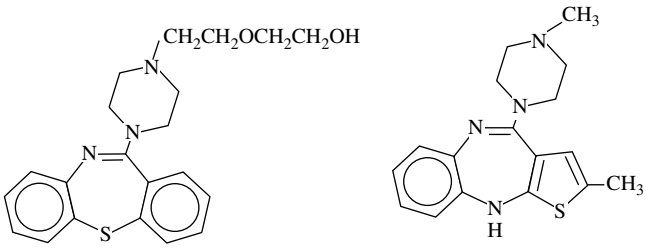

Quetiapine **Olanzapine**

FIGURE **12-4** Structural formulas of quetiapine and olanzapine.

Other drugs expressing atypical antipsychotic activity

Other atypical antipsychotic drugs are available. Quetiapine (a dibenzothiazepine) (see Figure 12-4) is effective for positive and negative symptoms. Ziprasidone (a dihydroindolone) has actions similar to risperidone. Ziprasidone carries warnings for inducing long QT syndrome. Aripiprazole is a dihydrocarbostyril derivative with a unique spectrum of action. Aripiprazole has been found to act as a partial agonist at D_2, D_3, and 5-HT_{1A} receptors and to act as an antagonist at 5-HT_{2A} receptors. It is reported to produce minimal side effects commonly associated with antipsychotic drugs. This seems to be a matter of degree because typical dopamine-blocking side effects are seen in a few patients.

Miscellaneous antipsychotics

Experimental drugs that show the greatest potential for clinical use are drugs that are highly selective for various receptors or are selective for receptors in specific areas of the brain. The

benzamide derivatives sulpiride, remoxipride, and amisulpride may preferentially block D_2 receptors in the mesolimbic system rather than in the striatum, which may account for their clinical effectiveness with low incidence of extrapyramidal side effects. Sulpiride has been available for use as an antipsychotic in Europe for several years but is still in clinical trials in the United States. Numerous drugs are being used as antipsychotics even though their primary indication is for other conditions, and still others are not currently approved for use in the United States.

The benzodiazepines are primarily used as antianxiety and hypnotic drugs, but more recently the clinical indications for this drug group have been expanded to include some psychotic disorders. Diazepam, chlordiazepoxide, alprazolam, clonazepam, and lorazepam all have found clinical usefulness in the treatment of some symptoms of schizophrenia, schizoaffective disorders, assaultiveness, agitation, and delirium. The benzodiazepines seem to have marginal antipsychotic properties when used alone and may be most useful as adjuncts to standard antipsychotic agents.

Pharmacologic Effects

Chlorpromazine is a classic typical antipsychotic drug. Typical antipsychotics include phenothiazines, thioxanthenes, haloperidol, molindone, loxapine, and pimozide. They have similar neuropharmacologic properties and adverse effects. The adverse effects vary in their frequency and severity, however, depending on the drug group. The prototype for the atypical antipsychotics is clozapine.

Antipsychotic effects

Although the precise mechanism of action of antipsychotic drugs is unknown, they all share the ability to block dopamine receptors in the brain. For typical antipsychotic agents, the dose required to alleviate positive symptoms of psychosis is most closely related to affinity of the drug for blocking the D_2 receptor.

There are several dopaminergic pathways in the central nervous system (CNS) (see Table 12-2) that, when antagonized by the antipsychotics, can explain their therapeutic efficacy and some of their side effects. The antipsychotic action may be ascribed to blockade of the mesolimbic/mesocortical tract, which plays an important role in behavior, arousal, salience (i.e. alerting, significance), positive reinforcement, cognitive function, communication, and psychological responses. Although blocking mesolimbic/mesocortical dopamine is thought to be central to antipsychotic efficacy, the inhibition of positive reinforcement may contribute to the high rate of discontinuation of treatment, which averages 74% over 18 months of therapy. Extrapyramidal motor dysfunction results from blockade of the nigrostriatal pathway, and endocrine disorders (amenorrhea, dysmenorrhea) result from the blockade of the hypothalamic-adenohypophyseal system. Two effects of antipsychotics may relate to blockade of dopamine receptors in the brainstem. Blockade of dopamine receptors in the medullary chemoreceptor trigger zone is thought to contribute to the antiemetic actions of antipsychotic drugs. Blockade of dopamine receptors in the medulla or brainstem may also play a role in appetite dysregulation. There are also dopamine interneurons in the olfactory bulb and retina. Olfactory changes occur in schizophrenia and Parkinson's disease, but these have not yet been related to dopamine. In the retina, dopaminergic cells may regulate light adaptation.[55]

Compared with older drugs, atypical antipsychotic agents seem to be more effective for the negative symptoms of schizophrenia and tend to produce fewer extrapyramidal side effects. In addition, these drugs (e.g., clozapine) apparently are more effective in treating patients with schizophrenia resistant to other drugs. Exactly why they are more effective in these cases is not known. Although the typical antipsychotics block nearly all central dopamine pathways, the atypical antipsychotic clozapine may selectively block mesolimbic and mesocortical dopaminergic pathways. This selectivity may explain its effectiveness in the treatment of schizophrenia and the relative absence of extrapyramidal and endocrine side effects.

Several hypotheses are proposed for this selectivity. The first relates the action of these drugs to binding of specific dopamine receptors. Clozapine has a stronger binding to D_1 and D_4 receptors than the classic antipsychotics. D_4 receptors are enriched in the mesolimbic parts of the brain. Some studies have suggested, however, that selective D_4 receptor blockade does not confer atypical properties. Other atypical and classic antipsychotics have significant affinity for the D_3 receptor. The D_3 receptor is also found to be enriched in the mesolimbic brain. The affinity of antipsychotic drugs for the D_3 receptor is generally less, however, than that for the D_2 receptor, and the contribution of the D_3 receptor to schizophrenia is also difficult to assess.

A second hypothesis is that other receptor types, in combination with dopamine blockade, may contribute to the atypical profile of clozapine. Clozapine has various effects on 5-HT receptors. Clozapine is a potent 5-HT_{2A} antagonist, with an affinity greater than that for D_2 receptors. This binding is thought to contribute to the ability of clozapine to relieve the negative symptoms of schizophrenia. Limited affinity for D_2 receptors and greater blockade of 5-HT_2 receptors are common findings for newer agents characterized as atypical antipsychotic drugs (serotonin-dopamine antagonists). Clozapine also binds to muscarinic receptors, which may help reduce extrapyramidal side effects; to histaminergic receptors, which may help reduce anxiety; and to α-adrenergic receptors, which may reduce blood pressure.

A third hypothesis is that by blocking only a fraction of the D_2 receptors, a drug has an atypical spectrum. Patients with Parkinson's disease do not exhibit typical extrapyramidal side effects until approximately 80% of the dopamine neurons in the striatum are damaged. If an antipsychotic agent is effective in reducing psychotic symptoms at doses that occupy less than 70% of the dopamine receptors, it would produce fewer extrapyramidal side effects.

A fourth (but related) hypothesis is that partial dopamine agonists may produce a limited dopaminergic tone to avoid typical side effects but still prevent excessive receptor activation by occupying and competing with endogenously released dopamine that promotes psychotic symptoms. Dopaminergic transmission would be brought into balance. Aripiprazole is the best example of this kind of agent currently available. It has reduced side effects and is being investigated for new indications.

Finally, a fifth hypothesis for atypical antipsychotic action states that the newer agents may rapidly dissociate from the D_2 receptor, which accounts for their atypical effects. Aripiprazole is a partial agonist at D_2, D_3, and 5-HT_{1A} receptors and an antagonist at 5-HT_2 receptors.

The potent anticholinergic activity of clozapine, the 5-HT_{2A} receptor–blocking effect, and the limited occupation of D_2 receptors (<60%) at therapeutic doses all may contribute to its atypical profile. Olanzapine, risperidone, and paliperidone have lower D_2 receptor binding and higher 5-HT_2 receptor binding and are relatively free of dyskinesias.[25] Quetiapine has a therapeutic effect and a side-effect profile similar to olanzapine.

Sedative actions

Phenothiazines and related antipsychotics produce sedation on initial administration, but tolerance develops in 1 to 4 weeks, so the patient becomes progressively more alert as

treatment continues. Sedation is the most commonly reported side effect of clozapine. Tolerance does not seem to develop to the antipsychotic action of these drugs. In contrast to sedatives such as barbiturates, chlorpromazine does not depress the reticular formation. It does raise the threshold for incoming sensory stimuli at the level of the reticular formation, however, so that the output of the reticular formation in response to sensory stimuli is depressed. Because schizophrenia may in part be a result of continual "flooding" of the brain by afferent input, reduction of this input by antipsychotics may partly explain their clinical efficacy.

Extrapyramidal effects

The extrapyramidal side effects produced by antipsychotic drugs include acute dystonias, a Parkinson-like syndrome, akathisia, and tardive dyskinesia. The different types of phenothiazines produce varying degrees of extrapyramidal side effects; in descending order of most to least potent are the piperazines, aliphatics, and piperidines. These compounds follow the reverse ranking order regarding their anticholinergic potency, which may explain why fluphenazine and haloperidol, weak anticholinergics, commonly produce extrapyramidal side effects, whereas thioridazine, a more potent anticholinergic drug, produces fewer motor disturbances. More recently, the role of 5-HT_2 receptors in reducing extrapyramidal symptoms and dystonias has been considered. As can be seen in Table 12-3, chlorpromazine is a more potent inhibitor of 5-HT_2 than it is for the muscarinic receptor. In addition, many newer antipsychotic drugs having atypical properties also block 5-HT_2 receptors. Molindone and loxapine are similar to chlorpromazine in their potential for causing extrapyramidal reactions. Haloperidol may have some unique effects on motor function. It is metabolized to a potentially neurotoxic metabolite, which may adversely affect the dopaminergic cells in the substantia nigra, inducing Parkinson's disease. Haloperidol also blocks sigma receptors. Sigma receptors in the red nucleus have been shown to participate in the generation of dystonias (oculogyric crisis and torticollis) associated with neuroleptic use. This observation may be particularly important for facial dystonias because sigma receptors are also expressed in cranial nerve nuclei.

Anti-Parkinson drugs (see Chapter 15) may be used to antagonize certain antipsychotic-induced motor disturbances, but levodopa is not helpful in this regard. Because dopamine receptors are blocked by the antipsychotic drugs, levodopa, the precursor of dopamine, is less effective in treating drug-induced parkinsonism than the anticholinergics, antihistamines, and amantadine, which act through other mechanisms.

Tardive dyskinesia is an extrapyramidal disorder that manifests after long-term antipsychotic therapy. Most of the extrapyramidal side effects of antipsychotic drugs occur during drug administration and disappear when the agent is withdrawn, but tardive dyskinesia develops after prolonged use and may be irreversible. This condition is thought to reflect the development of supersensitive dopamine receptors in the basal ganglia in response to their chronic blockade. Tardive dyskinesia has been estimated to occur in 15% to 20% of patients receiving long-term typical antipsychotic drug therapy. Tardive dyskinesia consists of abnormal, rapid, and alternating movements of the tongue (thrusting) and perioral areas; facial grimacing; tics; nose twitching; and other abnormal movements. It sometimes involves the extremities and torso, and may become severe enough to disrupt eating and breathing patterns. In contrast to other extrapyramidal side effects, tardive dyskinesia does not regress on reduction of the dose or withdrawal of the drug.

This side effect is frequently not seen until the antipsychotic drug is either withdrawn or reduced in dosage. The only consistently effective treatment for tardive dyskinesia has been increasing the dose of the antipsychotic that caused it in the first place. Such a procedure leads to a vicious cycle and a serious therapeutic dilemma. Typical antipsychotics cause this side effect. Clonazepam may be helpful in mild cases, and botulinum toxin may allow control of overactive muscle groups.[50] Atypical agents such as clozapine, risperidone, and aripiprazole seem to have a reduced liability for tardive dyskinesia. Aripirazole may be helpful for treating some cases, but long-term experience is not yet available. The low incidence of extrapyramidal side effects and the apparent absence of tardive dyskinesia are additional reasons for the interest in the atypical antipsychotic drugs.

Seizure threshold

Most of the antipsychotics, including clozapine, reduce the seizure threshold. The incidence of antipsychotic-induced seizures is approximately 1%, but nearly 7% in epileptic patients who receive antipsychotics. The convulsion is usually of the generalized tonic-clonic type. Chlorpromazine is more likely to cause this effect than fluphenazine, thiothixene, or molindone. The reduction of the seizure threshold seems to be inversely related to the antipsychotic potency of the drug and may depend on the particular dopamine receptor blocked (D_1 versus D_2) or possibly on the blockade of sigma receptors or changes in receptor sensitivity associated with long-term dosing. Seizures are more likely in patients with a history of seizures or under conditions where seizures are more likely, such as during withdrawal of sedative-hypnotic drugs.

Other central nervous system actions

Although medullary respiratory centers can be depressed by chlorpromazine, therapeutically active doses normally elicit little or no effect. If a sedative-hypnotic, antianxiety, or opioid drug is given to a patient receiving antipsychotic medication, however, summation of the depressant effects may result in clinically evident respiratory depression. Elderly patients may be more susceptible, and there is an elevated risk of pneumonia and death in elderly patients taking antipsychotics, with "typical" agents having at least as much risk as "atypical" agents. Antipsychotics, including clozapine, may disrupt thermoregulation by an action on the hypothalamus. Either hypothermia or hyperthermia may occur, depending on the ambient temperature.

Antiemetic action

Chlorpromazine is an effective antiemetic and previously was commonly used for this purpose. (Neuroleptics that are still used to treat nausea include prochlorperazine and droperidol.) The antiemetic action is exerted on the chemoreceptor trigger zone rather than on the vomiting center. Motion sickness is less responsive to dopamine antagonists than to anticholinergics and antihistamines.

Endocrine system

Endocrine system alterations result partly from actions on the hypothalamus. Most of the endocrine effects of antipsychotics are related to disturbances in the secretion of pituitary hormones. Particularly prominent is hyperprolactinemia elicited by blockade of dopamine receptors. Stimulation of dopamine receptors in the adenohypophysis normally inhibits prolactin release. Chlorpromazine may cause lactation and amenorrhea or delay ovulation and menstruation in women and cause gynecomastia and impotence or decreased libido in men. For atypical agents, risperidone has the highest incidence of these effects, and clozapine and aripiprazole have the lowest.[48] The urinary excretion of estrogens, progestins, and 17-hydroxycorticosteroids is decreased by chlorpromazine. Diuretic and antidiuretic effects have been shown in animals and humans, although a weak diuresis seems to be the predominant effect

in humans. The relative lack of effect of clozapine on dopamine receptors of the anterior pituitary accounts for its mild endocrine side effects. Weight gain and diabetogenic effects have been observed for several atypical antipsychotic agents. Olanzapine is most likely to produce weight gain.

Autonomic nervous system

The following side effects of the phenothiazines may result from their antimuscarinic properties: blurring of vision; constipation; and decreased sweating, salivation, gastric secretion, and intestinal tone. Phenothiazines also have antihistaminic, antitryptaminergic, and antiadrenergic properties that complicate further the overall pattern of their CNS and peripheral activities. Dry mouth associated with a series of neuroleptics was found to correlate significantly with their blocking potency at α_1-adrenergic, H_1-histaminergic, and D_1-dopaminergic receptors.[45] The autonomic effects of haloperidol, molindone, and loxapine are similar, although weaker, than the effects of the phenothiazines. Clozapine and olanzapine have the reported side effect of hypersalivation.[47] Often this phenomenon is most prominent during sleep; the mechanism responsible for it is unknown. Although the autonomic effects of antipsychotics can be annoying, tolerance usually develops to these reactions.

Cardiovascular system

Orthostatic hypotension is a result of CNS and peripheral (α-adrenergic receptor blocking) actions of antipsychotics (see Table 12-1), whereas tachycardia and increased coronary blood flow derive from central compensatory cardiovascular reflexes. The aliphatic and piperidine phenothiazines and clozapine are the most likely, and the piperazines the least likely, to cause orthostatic hypotension (Table 12-4). In the emergency treatment of phenothiazine-induced vasomotor collapse, epinephrine is contraindicated because the α-adrenergic receptor–blocking action of the phenothiazines may cause "epinephrine reversal" and an even greater reduction in blood pressure. NE or phenylephrine, both of which lack significant β_2-adrenergic receptor stimulation, is preferred in these circumstances. Chlorpromazine has a direct depressant effect on the heart and an antiarrhythmic action that may be caused in part by its local anesthetic effect. Vascular reflexes mediated by vasomotor centers of the brainstem are depressed by chlorpromazine. Haloperidol rarely causes pronounced hypotensive effects, but tachycardia is a common side effect.

Many antipsychotic and antidepressant agents have been found to cause or exacerbate the condition known as long QT syndrome (see Chapter 24). This syndrome is associated with increased likelihood of torsades de pointes, an arrhythmia that is potentially fatal. The condition is often produced by decreasing the function of cardiac K^+ channels responsible for cardiac repolarization (see Chapter 24). Phenothiazines, butyrophenones, pimozide, thioridazine, mesoridazine, and several atypical antipsychotic agents have been implicated (see Table 12-4). Ziprasidone may have a greater risk for this side effect. Clozapine is also known to block D_4 receptors, which are abundant in the heart. This action may contribute to the cardiovascular risk seen with clozapine.

Absorption, Fate, and Excretion

Metabolism of antipsychotic drugs is complex.[43] Most agents are metabolized by the P450 isoforms CYP2D6 or CYP3A4.[12] Other isoforms may also participate (1A2, 2B6, 2C9), and flavin monoxygenases contribute in the liver and in the brain (Table 12-5). Olanzapine is primarily glucuronidated and may possess advantages when oxidative metabolism is reduced. The P450 isoforms CYP2D6 and CYP1A2 are known to have genetic polymorphisms, and preliminary investigations suggest that patients who are poor metabolizers may have more antipsychotic toxicity than normal metabolizers. Although metabolites for many antipsychotic drugs are active, their antipsychotic effects are usually not as potent as the effects of the parent compounds. The plasma half-lives of the antipsychotic drugs are not true indicators of their long durations of action. Half-lives for the phenothiazines range from 20 to 40 hours, yet the lipid solubilities of the drugs and their metabolites allow them to remain in tissues for prolonged periods.

Adverse Effects

The most troublesome side effects of the antipsychotic agents, particularly the phenothiazines and butyrophenones, are the extrapyramidal disorders consisting of tremor, akathisia, dystonia, bradykinesia, and dyskinesia. Therapy may have to be terminated in patients exhibiting pronounced and intractable motor disturbances. Use of atypical agents may help reduce this problem. The use of an anticholinergic drug, antihistamine, or amantadine can reduce Parkinson-like symptoms and less readily the motor restlessness of akathisia without compromising antipsychotic therapy. Acute dystonic reactions (e.g., torticollis, facial grimacing, oculogyric crisis) are also treated with centrally acting antihistamines and antimuscarinic drugs such as diphenhydramine and benztropine.

Tardive dyskinesia is a problematic neurologic disorder because of its disabling effect and resistance to pharmacologic management. The adverse effect is irreversible or only slowly reversible. The low incidence of extrapyramidal responses to clozapine and atypical agents has given new hope that these disturbing side effects of the antipsychotics can be separated from their therapeutic effect.

Other adverse effects may also be serious enough to necessitate adjustment of the dosage or withdrawal of the medication. These reactions may be manifested as cholestatic jaundice, blood dyscrasias, or dermatologic responses. The latter may take the form of contact dermatitis, urticaria, or photosensitivity.

Clozapine can produce some serious adverse reactions. It was initially withdrawn from the market because it was discovered to cause agranulocytosis in approximately 1% of the patient population. The drug was reintroduced with the provision that all patients receiving it be continually monitored for hematologic changes. Clozapine is also associated with a higher incidence of seizures than the other antipsychotic drugs.[20] Orthostatic hypotension and cardiovascular and respiratory collapse have also been documented. Some predisposing factors have been proposed. Excessive sedation and respiratory collapse may be associated with concomitant use of depressant agents, including benzodiazepines. Epinephrine reversal (caused by α-adrenergic receptor blockade by clozapine) can contribute to declines in blood pressure. These toxicities may be more likely during rapid changes in blood concentrations, which may occur from adjustment of drug dosing or the use of other drugs that may displace clozapine from binding sites or alter the metabolism of clozapine.

Normally, less severe side effects of antipsychotics include orthostatic hypotension and syncope, xerostomia, nasal stuffiness, urinary retention, constipation, and alterations in body temperature (usually hypothermia). In prolonged, high-dose therapy with phenothiazines, a blue-gray pigmentation may occasionally occur in skin exposed to direct sunlight.

A potentially debilitating gain in weight has been observed with schizophrenic patients taking antipsychotic agents. This side effect is of increased concern for patients taking the newer atypical agents.[7] Nearly all the antipsychotics cause weight gain and associated increases in cholesterol and triglycerides (see Table 12-4). Although this weight gain is rarely a severe side effect, it frequently leads to noncompliance.

TABLE **12-6**

Interactions of Antipsychotic Drugs* with Other Drugs

DENTAL DRUG OR OVER-THE-COUNTER DRUG	POSSIBLE RESPONSE WHEN COMBINED WITH ANTIPSYCHOTIC DRUG
Promethazine	CNS depression
Barbiturates	CNS depression
Benzodiazepines	Cardiovascular and respiratory collapse with clozapine
General anesthetics (inhalation and intravenous)	CNS depression (especially respiratory depression)
Ethanol	CNS depression
Opioid analgesics	CNS depression, respiratory depression (especially with meperidine), miosis
Antihistamines	CNS depression, anticholinergic effect
Epinephrine	Epinephrine reversal, orthostatic hypotension
Anticholinergics	Anticholinergic toxicity: arrhythmias, hallucinations, gastrointestinal inhibition
Metabolic inhibitors (erythromycin, clarithromycin)	Elevation of antipsychotic blood concentrations
Protein-bound drugs	Displacement of clozapine might result in adverse reactions

*Primarily the phenothiazines, thioxanthenes, butyrophenones, molindone, and loxapine.
CNS, Central nervous system.

Clozapine and olanzapine may be the most likely, and molindone and ziprasidone the least likely, to cause this effect.[32] The cause of the weight gain is unknown, but may be associated with the blockade of histamine or dopamine receptors.

A rare but sometimes fatal idiosyncratic effect, usually associated with potent antipsychotics such as haloperidol and fluphenazine, is neuroleptic malignant syndrome. It is characterized by sustained and widespread muscular contractions, fluctuating levels of consciousness, autonomic abnormalities, and fever. Treatment for neuroleptic malignant syndrome includes immediate withdrawal of the drug and supportive measures. Some benefit may be gained from the skeletal muscle relaxant dantrolene. Bromocriptine, a dopaminergic agonist, may also be helpful. Physical cooling to reduce fever may be necessary. It is generally believed that the risk of developing neuroleptic malignant syndrome with clozapine is low, but some cases have been reported. Drug interactions for antipsychotic drugs are summarized in Table 12-6.

The partial agonist antipsychotic aripiprazole is reported to have a low incidence of many of the side effects associated with typical antipsychotic drugs. Aripiprazole is associated with reduced extrapyramidal effects, reduced release of prolactin, minimal weight gain, and little effect on the QT interval.

General Therapeutic Uses

Currently, antipsychotic drugs are primarily used for the treatment of psychotic states. The wide variety of pharmacologic effects of the phenothiazines has led, however, to their use as antiemetics, preoperative medications to relax and calm the patient, antihistamines, and antihelmintics (in veterinary preparations). Antipsychotics may be used to control the manic phase of bipolar disorder. Other applications of the phenothiazines include the control of hallucinations associated with acute alcohol withdrawal and the treatment of intractable hiccough. As mentioned previously, pimozide has special application in the treatment of Tourette's syndrome.

Because of the perceived reduced side effects and improved efficacy of the atypical antipsychotic drugs, an expansion of indications for these agents can be anticipated. Many new indications for these drugs in children have been proposed, including autism, disruptive disorder, juvenile treatment-resistant schizophrenia, and pervasive developmental disorder of childhood. Additional indications in adult patients include borderline personality disorder, delusional disorder, first-episode schizophrenia, mood disorders with psychotic features (aripiprazole), obsessive-compulsive disorder, polydipsia syndrome, schizoaffective disorders, and personality problems. Atypical antipsychotic agents should be used with great caution in dementia-related psychosis in elderly patients because their use has been associated with an increased risk of death in this population.[24] There are few controlled studies to support these indications except for the use of olanzapine for the treatment of acute mania.

Although dose requirements of antipsychotic drugs for most patients usually fall within a narrow spectrum, dosage may vary considerably. Adjustments in dose are frequently made depending on the patient's clinical response and side effects. Effective plasma concentrations vary widely among patients, and their determination is not helpful. Generally, treatment with antipsychotic agents is uninterrupted and indefinite in duration.

Long-acting depot antipsychotic preparations, such as fluphenazine enanthate, fluphenazine decanoate, and haloperidol decanoate, are convenient in patients for whom compliance is a problem. These injectable forms are effective for 2 to 3 weeks after therapeutic blood concentrations are obtained and stabilized. A reduced total drug dose is frequently possible because problems with absorption from the gastrointestinal tract are bypassed. Generally, depot forms are safe for younger patients in good physical condition. A disadvantage to this mode of administration is that the drug cannot be withdrawn if side effects occur, and therapeutic levels are sometimes difficult to stabilize.

Antipsychotics such as the phenothiazines, thioxanthenes, and butyrophenones were the drugs of choice for decades in the treatment of schizophrenia. Olanzapine, quetiapine, and possibly low doses of risperidone are now the preferred agents

and are of particular use in cases of schizophrenia refractory to older antipsychotics or when administration of other antipsychotics results in unacceptable adverse effects. Because molindone and ziprasidone result in less weight gain than other agents, they may have application when weight gain is a special concern. Clozapine is considered to be a second-line drug primarily because of its propensity to cause agranulocytosis.

Implications for Dentistry

Because many people in the United States at some point in their lives receive pharmacotherapy for mental illness, the dentist inevitably encounters these patients in practice. Many patients are receiving more than one drug for their condition, and they may be taking various other drugs (e.g., alcohol, cough remedies, aspirin, dietary supplements) that may not be revealed in a medical history questionnaire. Many antipsychotics can add to the CNS depressant effects of sedative-hypnotics, antianxiety agents, anesthetics, or opioid analgesics used in the course of dental treatment. Chlorpromazine is known to potentiate the effects of general anesthetics and the respiratory depressant response to opioids (see Table 12-6). The cardiac effects of thioridazine can be potentiated by hydroxyzine, and other antihistamines may pose similar concerns. Antipsychotic and antihistaminic drugs have substantial antimuscarinic activity and may contribute to the long QT syndrome.

Tardive dyskinesia has important implications in dentistry because the facial musculature is prominently involved in the disorder. The abnormal movements of tardive dyskinesia often start in the orofacial musculature, particularly the tongue, which alternately protrudes, retracts, and undergoes a rolling movement. Because the orofacial muscles are primarily affected in the early development of tardive dyskinesia, the patient often believes that the dentist can correct the problem.

Individuals who require treatment with the phenothiazine antipsychotics usually take these drugs for an extended period or for life. Prolonged phenothiazine use can sometimes cause a reduction in leukocyte count, which rarely predisposes the patient to infection and frequent oral candidiasis. The tendency of clozapine to cause agranulocytosis is a factor that can lead to serious susceptibility to infection.

The reduced salivary flow caused by antipsychotics can result in xerostomia and an increased incidence of dental caries. Clozapine and olanzapine may induce hypersalivation, however. This condition is likely to be most pronounced at night. Several treatments have been proposed. Anticholinergics with central (atropine, amitriptyline), peripheral (glycopyrrolate), or local action (sublingual ipratropium) have been proposed. Central inhibition of salivation using clonidine patches (an α_2-adrenergic receptor agonist) has been tried with some success. In difficult cases, botulinum toxin injections, which block neuron transmission to the parotid gland, have been proposed.[42] These treatments could contribute to the risk of xerostomia-related dental problems.[44]

ANTIDEPRESSANTS

Numerous mechanisms are responsible for the actions of the known antidepressant drugs (Table 12-7). Most clinically used antidepressants increase the synaptic concentrations of 5-HT or NE or both in the brain, and this relationship has given support to the monoamine hypothesis of affective disorders.[8] The increase in neurotransmitters can be measured in a few hours from the time that the medications are administered.

Studies of diets deficient in tryptophan, the precursor amino acid for 5-HT, have found that depressed patients taking SSRIs have a return of symptoms of depression within a few hours after eating a tryptophan-deficient diet. Women seem to be more sensitive to tryptophan restriction. Tryptophan restriction does not reverse the effects of NE-selective antidepressants, however. Selective inhibition of NE synthesis with metyrosine triggers symptoms of depression in patients treated with NE reuptake-blocking antidepressants and in untreated patients with latent depression. Patients responding to SSRIs do not exhibit depressive symptoms when taking metyrosine. Normal patients do not show depressive symptoms after either tryptophan depletion or metyrosine treatment. Altogether, these studies suggest 5-HT, NE, or both may play a role in depression; the predominant factor may vary in different patients.

A significant challenge to the monoamine hypothesis is the time required for full antidepressant activity to be expressed, which may vary from 2 to 8 weeks in clinical practice. This time lag is long enough for considerable rearrangement of cellular structure to occur. Part of this delay may simply be related to the pharmacokinetics of the antidepressants, which have half-lives averaging 24 hours. To reach plasma equilibrium, the drugs need, on average, to be taken for at least 4 to 5 days; however, this does not explain the entire delay. The action of antidepressants is closely linked to the neurotransmitters 5-HT and NE. Information on 5-HT in the CNS is particularly instructive about mechanisms of antidepressant action. The raphe nuclei contain the bulk of the 5-HT–synthesizing neurons in the brain, and these project to wide areas of the brain (Table 12-8).[29]

In the awake animal, raphe 5-HT–containing neurons are generally tonically active with a firing rate of approximately 5 Hz, which is maintained by depolarizing Ca^{++} and hyperpolarizing K^+ currents. These cells may also respond to phasic activity such as loud sounds. Afferent inputs to the 5-HT cells include tonic excitatory input from catecholamines (NE from the locus coeruleus [LC] and dopamine from the ventral tegmental area) and phasic excitatory glutamate inputs. Noradrenergic input is thought to activate excitatory α_1 receptors on the raphe 5-HT neurons. Extracellular 5-HT is also present and may originate from raphe collateral feedback or possibly from a nonsynaptic source, which might be "leakage" from 5-HT neurons themselves.[40] A GABA inhibitory afferent input is also known.

TABLE **12-7**

Mechanisms of Antidepressant Drugs

MECHANISM	DRUG EXAMPLES
Block 5-HT reuptake	TCAs, most second-generation and third-generation drugs, SSRIs
Block NE reuptake	TCAs, most second-generation and third-generation drugs
Inhibit MAO	MAO inhibitors, St. John's wort*
Block presynaptic autoreceptors	Mirtazapine
Block dopamine reuptake	Bupropion
Block Na^+ gradients needed for many neurotransmitter reuptake transports	St. John's wort
Neuroprotective actions	SSRIs, anticonvulsants, Li^+
Facilitate GABA	Alprazolam
Hormone adjustment	Estrogens, levothyroxine

*Only at high doses.
5-HT, 5-Hydroxytryptamine; *GABA,* γ-aminobutyric acid; *MAO,* monoamine oxidase; *NE,* norepinephrine; *SSRIs,* selective serotonin reuptake inhibitors; *TCAs,* tricyclic antidepressants.

TABLE **12-8**

Key Serotonergic Pathways in the Action of Selective Serotonin Reuptake Inhibitors (SSRIs)

MIDBRAIN (RAPHE) PROJECTION TO	POSSIBLE SSRI EFFECT	SIGNS OF DYSREGULATION
Prefrontal cortex	Relief of depression	Depression
Hippocampus, limbic cortex	Alleviation of panic disorder	Anhedonia, anxiety, panic, sexual dysfunction
Basal ganglia	Alleviation of obsessive-compulsive disorder	Agitation; extrapyramidal side effects, including akathisia, parkinson-like tremor, and rigidity
Hypothalamus	Alleviation of eating disorder	Bulimia and binge-eating disorders, prolactin dysregulation
Spinal cord (pontine-medullary cell bodies)	Sexual dysfunction	Inhibited ejaculation and orgasm

A current hypothesis to explain some of the therapeutic delay follows. Antidepressant drugs produce an increased serotonergic tone in the raphe nuclei. Because of abundant presynaptic autoregulatory receptors (autoreceptors), however, the release of 5-HT is acutely "turned off" in the raphe nuclei. With continued exposure to the antidepressant drugs, the autoreceptors desensitize or downregulate, allowing increased 5-HT release at the synaptic terminals ("turned on"). This increased release may lead to a downregulation of some terminal field postsynaptic 5-HT receptors. In the brainstem, the raphe nucleus reciprocally innervates the LC and may reciprocally innervate dopaminergic areas such as the ventral tegmental area and cortex. These innervations hint at additional layers of control and interaction. Additionally, the delay in onset of antidepressant action suggests that some form of cellular remodeling may occur.

NE has long been suspected to have involvement with depression. A large amount of the NE in the brain is found in the LC, whose neurons project as far as the forebrain. The LC neurons not only respond to various phasic external stimuli and stress-related stimuli ("fight or flight") but also participate in tonic brain states, including the sleep-wake cycle and arousal. The LC may be involved in mediating anxiety, depression, panic attacks, and post-traumatic stress disorder. Although numerous peptides can alter the activity of the LC, one of the most interesting influences may be the increased LC firing rate induced by corticotropin-releasing hormone (which may mediate the involvement of corticosteroids in the response to stressful conditions).

NE actions are mediated by several receptor types (α_1, α_2, β_1 adrenoceptors) (see Chapter 6). Changes in noradrenergic systems that are linked to depression include alterations in α_2-receptor number and function in the brain and platelets of depressed patients and decreased cell counts and tyrosine hydroxylase in the LC of suicide victims. Clonidine, an α_2 agonist, can increase the release of growth hormone and thyroid-stimulating hormone in normal patients. In depressed patients, the magnitude of these hormone responses are reduced to approximately 50% of control subjects. The clonidine test may identify the depressive trait.

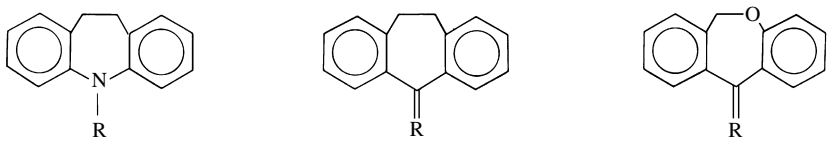
Long-term antidepressant use reduces postsynaptic β adrenoceptors in the brain without significantly affecting postsynaptic α_1 adrenoceptors. This change apparently occurs because the increases in synaptic NE resulting from presynaptic effects of antidepressants (downregulation of autoregulatory α_2 adrenoceptors) are able to affect adrenoceptors differently (β adrenoceptors downregulate and α_1 adrenoceptors do not). Exactly how these changes benefit a depressed patient is still being investigated; however, the increase in synaptic NE coupled with a change in postsynaptic adrenoceptor profile is likely to be the basis for the therapeutic effects of antidepressant drugs. TCAs, SSRIs, and electroconvulsive therapy all lead to similar changes. The effect of the antidepressant drugs on 5-HT dynamics is analogous to that on NE dynamics. The mechanism by which antidepressants act seems to depend on differential changes among various receptors and receptor-signaling processes. Although this hypothesis is useful for explaining the actions of several classes of antidepressant drugs, it is not a complete explanation for the actions of all antidepressants.

Efforts to speed up the onset of action of antidepressants based on some of these finding are being investigated. Strategies have included attempts to block somatodendritic 5-HT_{1A} autoreceptors with pindolol (a clinically available β blocker that coincidentally blocks 5-HT_{1A} receptors),[5] and use of antidepressants that block α_2-adrenergic or β-adrenergic receptors. Currently, only a few studies have reported efficacy with these approaches.[6] Early morning sleep deprivation has also been found to produce a rapid, but temporary, reversal of depression and the depression of bipolar disorder. Not all patients respond, however. There have been attempts to prolong the beneficial effect by using bright light therapy. These observations have so far defied explanation.

TCAs and MAO inhibitors, sometimes referred to as first-generation antidepressants, share many characteristics: they are effective in a broad spectrum of depressive syndromes (although 20% to 30% of patients remain unresponsive to pharmacotherapy); they have a delayed onset of therapeutic effect; and they have troublesome side effects. Newer drugs (second-generation and third-generation antidepressants), such as amoxapine, maprotiline, bupropion, trazodone, nefazodone, and mirtazapine, were introduced to overcome the disadvantages of first-generation compounds. This heterogeneous group of agents share antidepressant efficacy but vary in their particular actions, which are listed in Box 12-1.

SSRIs are an important addition to the pharmacologic armamentarium for the treatment of depression. As the group name implies, these drugs have greater pharmacologic selectivity than TCAs and have the potential for therapeutic effectiveness with fewer side effects. SSRIs also require 2 to 3 weeks before therapeutic efficacy is noted. The first drug of this class approved for use in the United States was fluoxetine. Fluoxetine quickly became a very popular drug because it is effective in major depression and refractory depression. It also has fewer side effects compared with previous drugs. More recently approved SSRIs—sertraline, fluvoxamine, paroxetine, and citalopram—exhibit a similar pharmacologic profile, differing from fluoxetine primarily in their pharmacokinetic properties. Because of the relative safety of these agents, investigations of their efficacy in a wide array of behavioral disorders have led to broadened indications for their use. SSRIs may be more beneficial in women, and TCAs may be more beneficial in men.

Although they block 5-HT uptake preferentially, venlafaxine and duloxetine are classified as selective agents that block NE and 5-HT reuptake (selective serotonin and norepinephrine reuptake inhibitors). Atomoxetine and reboxetine are



Dibenzazepine **Dibenzocycloheptadiene** **Dibenzoxepine**

Actions of Antidepressant Drugs

Drugs That Inhibit Reuptake of NE and 5-HT with Similar Potencies (20-fold Difference or Less)
Amitriptyline
Amoxapine*
Atomoxetine
Clomipramine
Desipramine
Doxepin
Duloxetine
Imipramine
Nefazodone
Nortriptyline
Protriptyline

Drugs That Inhibit 5-HT Reuptake with Greater Potency (>50-fold More than NE Reuptake)
Citalopram
Fluoxetine
Fluvoxamine
Paroxetine
Sertraline
Trazodone†
Venlafaxine†

Drug That Inhibits NE Reuptake with Greater Potency (Approximately 500-fold More than 5-HT Reuptake)
Maprotiline

Drugs That Have Little Effect on Either 5-HT or NE Uptake
Bupropion
Mirtazapine

*Also blocks dopamine uptake.
†Not classified as a selective serotonin reuptake inhibitor.
5-HT, 5-Hydroxytryptamine; *NE*, norepinephrine.

norepinephrine reuptake inhibitors. St. John's wort has a unique action blocking the reuptake of 5-HT, NE, dopamine, GABA, glycine, and glutamate, but with no known receptor-blocking actions.

Tricyclic Antidepressants

Chemistry and structure-activity relationships

A small modification of the phenothiazine ring structure resulted in an entirely new group of drugs, the TCAs. The name of these compounds is derived from the triple-ring structure consisting of two benzene moieties connected through a seven-membered ring (Figure 12-5).

The prototype for TCAs is imipramine, a dibenzazepine derivative. Structural analogues of imipramine include the dibenzocycloheptadienes, in which a carbon atom is substituted for the nitrogen of the central ring, and the dibenzoxepines, in which an oxygen atom replaces one of the methylene groups of the center ring of the dibenzocycloheptadiene molecule. A prototype drug for the dibenzocycloheptadienes is amitriptyline, and for the dibenzoxepines, doxepin.

Substitutions at R (see Figure 12-5) usually consist of aminopropyl groups that may be either dimethyl or monomethyl amino derivatives. Compounds such as imipramine, amitriptyline, and doxepin have two methyl moieties on the nitrogen atom of the side chain and are tertiary amines. Desipramine, nortriptyline, and protriptyline have one methyl group and are secondary amines.

Pharmacologic effects

Similar to antipsychotic drugs, TCAs have therapeutically useful effects on the CNS and various side effects. Common properties of the antidepressant drugs are blockade of the 5-HT reuptake transporter or NE reuptake transporter or both, histaminergic receptors (H_1), muscarinic receptors, and α_1-adrenergic receptors, and a local anesthetic action.

Central nervous system. When administered to a normal individual, TCAs initially produce drowsiness, lethargy, and often an increased feeling of anxiety. With continued administration, the individual may have thought disorders and become increasingly confused. Conversely, after TCAs have been administered for approximately 2 to 3 weeks to depressed patients, they become less confused and have an elevation of mood. Untoward CNS effects include dizziness, lightheadedness, and delirium and hallucinations.

All TCAs seem to have in common the ability to inhibit the reuptake of NE or 5-HT or both into central presynaptic nerve terminals. Normally, most of the transmitter is recycled into the presynaptic terminal, stored, and made available for reuse (see Chapter 11). TCAs, by blocking this reuptake, increase the concentrations of NE or 5-HT or both at critical central synapses. This increase in concentration of these biogenic amines leads to the receptor changes discussed earlier and an antidepressant effect.

Autonomic nervous system. TCAs are more potent anticholinergics than their phenothiazine analogues. Dry mouth, constipation, urinary retention, and ophthalmologic changes (blurred vision and mydriasis) are commonly observed, especially with the tertiary amines.[38] Paradoxically, excessive sweating is also sometimes reported, although in a large overdose the skin is dry. Sexual dysfunction (including loss of libido, impaired erection and ejaculation, and anorgasmy) is an additional side effect that may lead to patient noncompliance. Peripheral cholinergic and α-adrenergic blockade have been associated with sexual dysfunction. Excess serotonergic tone at some 5-HT receptors may also be responsible for the sexual side effects of these agents (see Table 12-1).

Cardiovascular system. TCAs can cause hypotension and compensatory tachycardia. TCAs affect the heart in a manner similar to the class I antiarrhythmics such as quinidine and procainamide.[18] Prolongation of the QT interval, flattening of

the T wave, and various arrhythmias have been reported. Postural hypotension, particularly in elderly patients, is common, probably because of α_1-adrenergic receptor blockade. Because TCAs block the reuptake of catecholamines, they can increase the response to endogenously released catecholamines or directly acting sympathomimetic drugs that are actively transported into adrenergic nerve terminals.

Absorption, fate, and excretion

TCAs are readily absorbed from the gastrointestinal tract. The drugs are distributed throughout the body and are tightly bound to plasma and tissue proteins. Many pharmacologically active metabolites are formed in the liver by microsomal oxidation reactions, including N-demethylation. Subsequent glucuronidation inactivates the agents and promotes their excretion. Approximately two thirds of a single dose is eliminated in the urine and one third in the feces over several days. TCAs are metabolized by several isoforms of P450, with particular involvement of CYP1A2, CYP2C19, CYP2D6, and CYP3A4.[15]

Adverse effects

TCAs may initially cause anxiety or feelings of fatigue and weakness (Table 12-9), but tolerance develops to these effects. Although these agents do not elicit the extrapyramidal side effects of the antipsychotic agents, mild tremor may sometimes occur. In some individuals, tics, ataxia, and incoordination have been reported. The anticholinergic effects cause dryness of the mouth, mydriasis, and urinary retention and may contribute to cardiovascular disturbances. Amitriptyline is one of the most potent anticholinergic TCAs; it is about one eighth as potent as atropine.

Acute overdosage, sometimes self-inflicted by suicidal patients, is a potentially life-threatening situation and is characterized by CNS excitation and depression, anticholinergic effects, and cardiovascular complications. Life-threatening cardiac arrhythmias are a potential consequence of acute overdose. Even in conventional doses, the incidence of sudden death from myocardial infarction or ventricular arrhythmias is increased in patients with cardiac disease. Several TCAs produce long QT syndrome, which can lead to torsades de pointes. Fatalities have also occurred in children with no apparent preexisting cardiac defect. Blood dyscrasias, skin rashes, photosensitization, and cholestatic jaundice, many of which are manifestations of allergic reactions, have been reported but are less frequent than with the phenothiazines. TCAs may also increase the risk for seizures, with clomipramine among the most likely to produce this effect. The

likelihood of seizures is directly related to the dose taken and a history of previous seizure disorders.[41]

Adverse drug interactions are another potential problem for patients treated with antidepressants. Coadministration of TCAs with MAO inhibitors may cause anxiety, vomiting, tremor, convulsions, coma, and death. TCAs may also obtund the antihypertensive action of guanethidine and the sympathomimetic action of amphetamine and tyramine by preventing their uptake into nerve terminals. The effects of clonidine (an α_2 agonist) are also inhibited. Drug interactions that the dentist must consider are discussed subsequently and are similar to interactions listed in Table 12-6.

Monoamine Oxidase Inhibitors

MAO inhibitors include many chemically unrelated compounds that share the ability to antagonize the action of MAO, the enzyme responsible for the metabolic degradation of the naturally occurring monoamines epinephrine, NE, dopamine, and 5-HT. Some of these inhibitors, such as tranylcypromine, are structurally related to amphetamine.

Pharmacologic effects

Similar to TCAs, MAO inhibitors increase the concentration of NE and 5-HT in the CNS. By preventing the catabolic action of MAO, MAO inhibitors allow the buildup of monoamines in the presynaptic nerve terminals (see Chapters 6 and 11). This effect apparently leads to adaptive changes in receptors similar to the changes seen with TCAs. Although these effects are compatible with the monoamine hypothesis of depression, MAO inhibitors are not specific for MAO because they affect other enzymes and have nonenzymatic actions as well. A clear understanding of the mechanism of the antidepressant action of this group of drugs does not exist. The existence of at least two forms of MAO (MAO-A and MAO-B) in the brain and selective inhibitors of MAO-A and MAO-B suggests, however, that selective inhibition of specific forms of MAO will be of potential use in the future. Moclobemide and brofaromine, selective inhibitors of MAO-A, are effective antidepressants; in contrast to most other MAO inhibitors, they are reversible inhibitors of MAO and have many advantages because of their selectivity and shorter duration of action.

MAO inhibitors are generally considered to be less effective and to have more serious side effects and drug interactions than TCAs. These drugs are making a comeback, however, with the discovery that they are effective for atypical depression and that in some of the early studies inappropriate dosages were used. Similar to SSRIs, MAO inhibitors also have antiobsessional, antipanic, and anxiolytic effects. Nevertheless, numerous precautions, particularly regarding drug interactions and dietary restrictions, must be observed with the clinical use of these compounds.

The most prominent autonomic effects of MAO inhibitors are exerted on the cardiovascular system. Hypotension occurs because of reduced NE release from peripheral adrenergic nerves (except in the presence of indirectly acting sympathomimetic drugs). Tachycardia, dry mouth, sweating, hot flashes, diarrhea, constipation, difficulty in micturition, and impotence may also occur. MAO inhibitors antagonize transmission of nerve impulses through autonomic ganglia, and evidence suggests that sympathetic ganglia are more severely affected.

Absorption, fate, and excretion

MAO inhibitors are rapidly absorbed from the gastrointestinal tract. The metabolic fate of MAO inhibitors is not fully known, but the drugs are apparently rapidly metabolized and excreted. The long duration of action (weeks) results from an irreversible inactivation of MAO and can be of concern when adding new therapies after an MAO inhibitor has been discontinued.

Adverse effects

Most of the original MAO inhibitors have been withdrawn from the market because of their serious side effects. An important adverse reaction to the remaining MAO inhibitors (and a major problem with the original drugs) is hepatotoxicity. MAO inhibitors may also cause orthostatic hypotension and, in overdosage, central excitatory manifestations of insomnia, agitation, hyperreflexia, and convulsions.

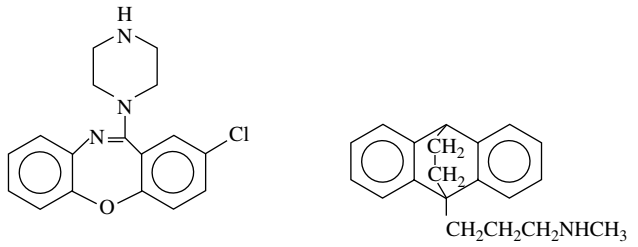
Drug interactions are of particular concern with MAO inhibitors because they are likely to be serious and potentially fatal. Among the drugs with which MAO inhibitors interact are TCAs and SSRIs, other classes of antidepressants, opioid analgesics (especially meperidine), alcohol and other CNS depressants, indirect-acting or mixed-acting sympathomimetics such as amphetamine or ephedrine, sympathomimetics metabolized predominantly by MAO such as phenylephrine (commonly used in over-the-counter preparations as a nasal decongestant), and monoamine precursors such as levodopa.

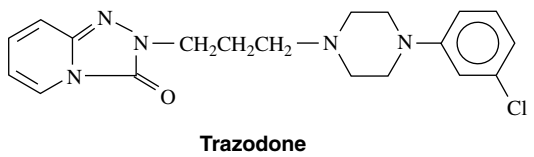
In addition to drug interactions, acute hypertensive crises have been precipitated by the ingestion of foods containing naturally occurring pressor amines, such as tyramine, which release NE from nerve endings. Patients treated with MAO inhibitors have elevated stores of NE available for release. In addition, ingested tyramine, which is normally metabolized by enteric and hepatic MAO, reaches the systemic circulation in increased amounts. Foods containing sympathomimetic amines that should be avoided include aged cheeses (especially cheddar and Swiss), fermented alcoholic beverages (particularly Chianti wine), canned fish products, snails, liver, nuts, broad beans, citrus fruits, coffee, and almost any product made with yeast. Hypertensive crises precipitated by such foods are characterized by severe headaches, often localized in the occipital region, and fever. This type of drug interaction is likely to become less important as more selective or reversible MAO inhibitors are developed. The reversible and selective MAO-A inhibitor moclobemide has been reported to produce less of this "cheese effect."

MAO inhibitors are contraindicated with SSRIs. This combination may precipitate the "serotonin syndrome," which consists of hyperthermia, facial flushing, dizziness, confusion, headache, sweating, fever, rigidity, myoclonus or tremor, respiratory disturbances, gastrointestinal upset, and mental status changes ranging from delirium to coma. This drug interaction may occur several weeks after termination of fluoxetine because of its slow elimination from the body (half-life of 250 hours for active metabolites of SSRIs).

Second-Generation and Third-Generation Antidepressants

The second-generation and third-generation antidepressants (or atypical antidepressants) include a diverse array of drugs. Amoxapine (Figure 12-6), a dibenzoxazepine resembling TCAs in chemical structure, is the N-demethylated metabolite of the antipsychotic loxapine. Amoxapine shares many properties with the atypical antipsychotic agents and has been shown to have atypical antipsychotic and antidepressant effects, making it useful for patients with psychotic and mood disturbances. Maprotiline is related to the TCAs, but contains a tetracyclic ring structure (see Figure 12-6). Trazodone and nefazodone (see Figure 12-6) are triazole derivatives, trazodone being noted for having 5-HT_2 blocking activity in addition to its reuptake-blocking action. Bupropion, an aminoketone, is structurally dissimilar to all other antidepressants (Figure 12-7). Bupropion is a weak reuptake inhibitor of dopamine and 5-HT and a weak α_2-adrenergic receptor





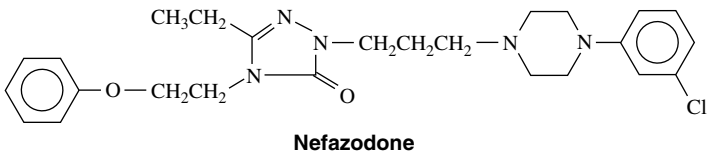


FIGURE **12-6** Structural formulas of amoxapine, maprotiline, trazodone, and nefazodone.

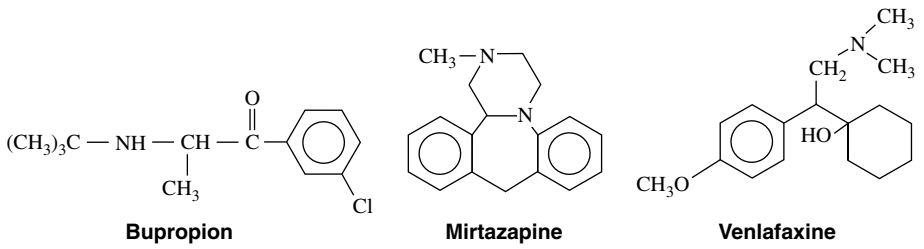

FIGURE **12-7** Structural formulas of bupropion, mirtazapine, and venlafaxine.

blocker. Mirtazapine (see Figure 12-7), a piperazinoazepine, is not thought to block amine reuptake, but is reported to block several additional receptors (histamine H_1, 5-HT_2, 5-HT_3, α_2-adrenergic). There has been some interest in using these agents as adjunct therapy to SSRIs.

Pharmacologic effects

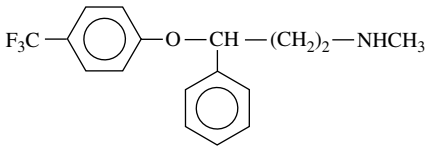
These compounds differ significantly in their selectivity of action on monoamine uptake and neurotransmitter receptors.[51] Amoxapine resembles the secondary amine TCAs in pharmacologic activity, but it also blocks dopamine and 5-HT_{2A} receptors, accounting for its atypical antipsychotic effect. Differences in potency in inhibiting 5-HT and NE transport are summarized in Box 12-1. Mirtazapine is not consistently effective as an antidepressant agent.[54]

Absorption, fate, and excretion

All second-generation agents are well absorbed from the oral route. Peak concentrations of the drugs are reached in approximately 1 to 3 hours. Amoxapine is almost completely metabolized (one hydroxylated metabolite retains pharmacologic activity) and excreted in the urine over several days. Several active metabolites of trazodone are formed, and 70% to 75% of an ingested dose is excreted in the urine within 72 hours after administration. The metabolite *m*-chlorophenylpiperazine, a 5-HT_2 agonist, is metabolized by CYP2D6 and is more likely to accumulate if CYP2D6 activity is low or inhibited. Bupropion also yields two active metabolites (including hydroxybupropion) that may accumulate and contribute to antidepressant activity by acting on NE reuptake. Peak action is seen in 3 hours, with a half-life of approximately 21 hours. Bupropion is metabolized by CYP2B6, which may cause the drug to have an important drug interaction profile. Smoking does not alter its kinetics. Nearly 80% of an orally administered dose is excreted as inactive metabolites in the urine. Mirtazapine is metabolized to several metabolites by several P450 isozymes and is primarily excreted in the urine (75%). Venlafaxine is metabolized to an active metabolite, O-desmethyl venlafaxine, and is eliminated by renal and hepatic routes. The elimination half-life is approximately 5 hours. The antihistamine diphenhydramine has been found to inhibit the metabolism of venlafaxine.

Adverse effects

Amoxapine, maprotiline, trazodone, mirtazapine, and nefazodone share common side effects, including sedation, antimuscarinic and cardiovascular effects, and skin rashes (see Table 12-9). The incidence and severity of these reactions vary considerably, however, among the drugs. Amoxapine is approximately equal to TCAs in cardiotoxicity, whereas maprotiline has less effect on the heart and, in contrast to TCAs, causes a slight bradycardia and a decrease in blood pressure. Bupropion has minimal cardiovascular effects and only infrequently produces orthostatic hypotension. Venlafaxine can cause dose-related hypertensive effects, QT interval prolongation, insomnia, nausea and vomiting, xerostomia,



Fluoxetine

mydriasis, and sexual side effects. It may also increase the likelihood of seizures.

Each of the second-generation and third-generation agents has some unique side effects that can limit clinical usefulness. Because of its antidopaminergic activity, amoxapine produces extrapyramidal side effects and can increase prolactin secretion and cause amenorrhea, gynecomastia, and galactorrhea. Trazodone sometimes produces persistent priapism requiring surgical detumescence, which can result in permanent impotence. Priapism may be related to α_1-adrenergic and α_2-adrenergic receptor blockade or 5-HT_{2C} receptor stimulation (by *m*-chlorophenylpiperazine).

Maprotiline and bupropion may trigger seizure activity. Drugs that block the reuptake of catecholamines seem to have a higher incidence of seizures. Bupropion is especially likely to cause convulsions. Bupropion was withdrawn from the market after its initial introduction because of seizures; it was reintroduced at lower recommended doses. Bupropion is contraindicated in patients with epilepsy and in patients who have had bulimia or anorexia nervosa because of an increased risk of seizures in these patients. This drug is marketed (for different purposes) under two trade names, Wellbutrin and Zyban, so patients should not accidentally be given both because of dose-related increased risk for seizures. Other side effects of bupropion include headache and dry mouth, tremor, insomnia, and the possible induction of psychosis. Less commonly, bupropion generates rashes or erythema multiforme (Stevens-Johnson syndrome).

Nefazodone and some of its metabolites are potent inhibitors of CYP3A4, and nefazodone is capable of blocking the metabolism of numerous drugs. Mirtazapine has been associated with agranulocytosis and seizures developing in a few patients. It should not be given with MAO inhibitors. Weight gain is a common side effect of antidepressants and, in many instances, contributes to noncompliance (see Table 12-9). Mirtazapine and maprotiline, along with the TCAs doxepin, trimipramine, and amitriptyline, are among the most potent blockers of histamine receptors, producing marked sedation and weight gain. The second-generation and third-generation antidepressants produce fewer sexual dysfunctional side effects compared with TCAs or SSRIs. Levodopa and MAO inhibitors increase bupropion toxicity. Ritonavir, an antiviral agent metabolized by CYP2B6, increases bupropion actions. Carbamazepine reduces bupropion blood concentrations.

Selective Serotonin Reuptake Inhibitors

Fluoxetine, fluvoxamine, sertraline, paroxetine, citalopram, and escitalopram (Figure 12-8) are the SSRIs currently approved for use in the United States.

Pharmacologic effects

The selectivity of SSRIs for 5-HT provides a theoretic basis for greater specificity in various depressive states and fewer side effects, and to a significant extent this has been realized clinically. By selectively inhibiting 5-HT reuptake, these drugs cause downregulation of presynaptic inhibitory 5-$HT_{1B/D}$ autoreceptors, which facilitates 5-HT transmission; this leads to postsynaptic changes analogous to those seen with TCAs. Similar to TCAs, SSRIs have been reported to cause downregulation of central β-adrenergic receptors, but this is not a consistent finding. Nevertheless, it again illustrates the complexity of depression and the pharmacologic similarities of effective antidepressants.

Several serotonergic pathways account for various effects of SSRIs (see Table 12-8). SSRIs have been found to be useful for other psychiatric disorders in which 5-HT is thought to play a role, such as obsessive-compulsive disorders, panic disorders, various eating disorders, migraine, social phobia, posttraumatic stress disorder, generalized anxiety disorder, social anxiety disorder, and premenstrual distress disorder.

Absorption, fate, and excretion

The major difference among SSRIs is their pharmacokinetic profile. The elimination half-life of fluoxetine is approximately 45 hours compared with 26 hours for sertraline, 21 hours for paroxetine, and 14 hours for fluvoxamine. Generally, these drugs are metabolized by CYP2D6 and CYP3A4 isozymes. Fluoxetine is metabolized to norfluoxetine, an active metabolite with an extended half-life (7 days) that is also an inhibitor of CYP2D6 and CYP3A4. Paroxetine has active metabolites that contribute to its pharmacologic effect, whereas the metabolites of sertraline and fluvoxamine are inactive. The long half-lives of these compounds, particularly fluoxetine, become clinically relevant when considering drug interactions.

Adverse effects

Compared with TCAs, SSRIs have minimal anticholinergic effects and produce less sedation and less lethality in overdosage. Because they have only mild anticholinergic effects, SSRIs may be especially useful in elderly patients.

Side effects have been categorized as early onset or late onset (Box 12-2). The most prominent early side effect of SSRIs is gastrointestinal upset (diarrhea, nausea, vomiting); tolerance to this effect develops over 4 to 6 weeks. Patients may also have anxiety, agitation, and sleep disturbances. Tolerance to sleep disturbances may not occur. Late-onset side effects include weight gain, sexual dysfunction (e.g., anorgasmy and decreased libido), asthenia (weakness), and drug withdrawal symptoms. The intensity of the long-term side effects varies among the SSRIs. Sexual dysfunction is more common with sertraline than fluoxetine.

There have been some reports of dose-related motor side effects, including akathisia, dystonia, dyskinesia, tardive dyskinesia, parkinsonism, and bruxism.[13] $5\text{-HT}_{1\text{-}4}$ receptors are located in the basal ganglia or related structures and may participate in regulating dopamine release. Hyponatremia has been reported in elderly patients, which may reflect the effect of 5-HT on mineralocorticoid function. After prolonged use, patients may have drug withdrawal symptoms. These are more common with shorter acting agents and are lessened by reducing doses slowly over time.

Reports of fluoxetine-induced suicidal contemplation have been given widespread coverage in the media, but this problem has never been confirmed in controlled studies. Baseline (untreated) suicide rates in adolescents are higher than those for adults, and this may contribute to the concern. Suicide rates tend to be reduced by relieving the depression.[14,19,46] During initiation of therapy, careful monitoring and counseling may be needed.

Drug interactions

The potential for a life-threatening drug interaction (5-HT syndrome) exists with SSRIs and MAO inhibitors. An interaction of this nature would be particularly problematic clinically when switching from fluoxetine to an MAO inhibitor because of the long duration of action of fluoxetine. Numerous drug interactions are possible because certain SSRIs compete with other drugs for metabolism by the CYP2D6 or CYP3A4 isozymes. Drugs such as cimetidine can interfere with the metabolism of fluoxetine, and fluoxetine can impair the biotransformation of drugs such as propranolol and carbamazepine. Fluoxetine decreases the metabolism of TCAs when used in combination and significantly prolongs their half-life. Increased bleeding has been reported in patients taking warfarin, but this problem is not associated with inhibition of warfarin metabolism.

Other selective amine inhibitors

Venlafaxine, duloxetine, atomoxetine, and reboxetine. Venlafaxine, duloxetine, atomoxetine, and reboxetine are more selective drugs than the TCAs but have actions that also include inhibition of NE reuptake. Venlafaxine and duloxetine inhibit serotonin reuptake more than NE, whereas atomoxetine and reboxetine inhibit NE reuptake more than serotonin. Venlafaxine (see Figure 12-7) acts selectively on 5-HT reuptake at low doses, but blocks NE reuptake at higher doses.[51] Duloxetine inhibits serotonin and NE reuptake but has little effect as a receptor blocker. Both drugs are structurally similar to fluoxetine. Agents that block NE reuptake may improve the antidepressant spectrum of duloxetine and venlafaxine. These agents also are used for relieving chronic pain states. Duloxetine was approved by the FDA for treating major depressive episode and diabetic neuropathy. It is also being promoted for the treatment of fibromyalgia. Atomoxetine is approved for the treatment of attention-deficit disorder.

Absorption, fate, and excretion. Venlafaxine, duloxetine, and atomoxetine are metabolized primarily by CYP2D6. Some are mild inhibitors of CYP2D6. Venlafaxine is metabolized to an active metabolite O-desmethylvenlafaxine whose half life is about twice that of the parent drug. Reboxetine is primarily metabolized by CYP3A4.

Adverse effects. Side effects include dry mouth, insomnia, blurred vision, sweating, and constipation. Reboxetine and atomoxetine can increase heart rate and systolic blood pressure. These drugs can also reduce salivary secretion to approximately one half of control.[38] Mixed or pure NE reuptake inhibitors may have reduced sexual side effects. Drug interactions with SSRIs, MAO inhibitors, TCAs, dextromethorphan, and pentazocine and with numerous other substrates of CYP2D6 or CYP3A4 have been reported with these antidepressants. Drug interactions with epinephrine have not yet been reported, although the actions of ephedrine have been increased in some cases.

St. John's Wort

St. John's wort, a traditional herbal remedy, is helpful for treating mild to moderate depression. In ancient Greece and Rome, St. John's wort (*Hypericum perforatum*) was placed above icons for its mystical powers (*hyper* means "above"; *eikon* means "icon"). St. John may refer to the flowering time of the plant around June 24, the Christian feast of the birth

of St. John the Baptist. The drug is available as an herbal preparation from health food stores and pharmacies in the United States and outsells fluoxetine in Germany.

St. John's wort has many biologically active components, including hypericin, hyperforin, and some flavinoids.[9] Commercially available capsules contain approximately 3% to 5% hyperforin and 0.3% hypericin. It has only more recently been understood that hyperforin may be the most active constituent, so labeling may still refer to hypericin as the active agent.

St. John's wort blocks the reuptake of 5-HT, NE, dopamine, GABA, and glycine with approximately equal potency, a unique therapeutic property. These neurotransmitter symporters use the Na^+ gradient produced by the Na^+, K^+-ATPase pump to transport neurotransmitters into the cell. When a neurotransmitter is in the cell, proton-dependent antiporters pump it into the synaptic vesicles. Hyperforin may reduce the Na^+ gradient on which the symporters depend, decreasing neurotransmitter uptake.[9]

St. John's wort reaches peak plasma concentrations in approximately 4 hours and has a half-life of approximately 9 hours. There is disagreement as to the relative clinical effectiveness of St. John's wort, despite evidence of an antidepressant action. Commonly noted side effects include gastrointestinal upset, fatigue, dizziness, dry mouth (but less than with other antidepressants), and restlessness. The drug seems to be relatively free of the typical autonomic side effects associated with TCAs. A rare, but possibly dose-related, toxicity is phototoxicity. Cows that eat too much St. John's wort can get severe phototoxic blisters attributed to hypericin. The eye may be susceptible to increased cataract formation because of a related effect.

Drug interactions are of possible concern with St. John's wort and can result from multiple mechanisms. St. John's wort can activate the pregnane X receptor, a member of the steroid/thyroid family of gene promoters that increases CYP3A4 transcription.[9] This induction is thought to be caused by hyperforin. St. John's wort can inhibit certain cytochrome P450 enzymes. Another mechanism for drug interactions is the induction of intestinal P-glycoprotein, which may reduce absorption of other drugs such as cyclosporine and indinavir. Drug interactions may involve other antidepressants that elevate brain biogenic amines. St. John's wort can also block MAO-A and MAO-B, but this is thought to occur only at higher than therapeutic doses. Drug interactions with cyclosporine, oral contraceptives, warfarin, indinavir, digoxin, nefazodone, sertraline, and paroxetine have been reported.

Potential Antidepressants and Antidepressant Potentiators

Benzodiazepines, although not approved for use as antidepressants, are increasingly being prescribed for affective disorders (anxiety disorders can be comorbid with affective disorders). Alprazolam, a triazolobenzodiazepine marketed as an antianxiety agent, seems to have definite antidepressant properties. It is commonly used for the treatment of mild cases of depression and for panic attacks. Clonazepam, an anticonvulsant, is also used sometimes in the treatment of panic attacks (see Chapter 13), and lorazepam, an antianxiety drug, may be effective against mania. The response of panic attacks to benzodiazepines suggests that doses higher than those recommended for anxiety are required. Benzodiazepines are less effective than TCAs in severely depressed patients. The disinhibitory effect of the benzodiazepines can provoke paradoxic aggression and suicide attempts in some patients.

Buspirone, a partial 5-HT_{1A} agonist and an effective antianxiety agent (see Chapter 13), is being evaluated for the treatment of depression. Other drugs of this class under investigation for relief of depression and anxiety are gepirone and ipsapirone. Clinical trials indicate that gepirone possesses antianxiety and antidepressant activity.

Ovarian hormones can induce biochemical changes in the brain. Estrogen can alter 5-HT, acetylcholine, and catecholamine function, whereas progesterone may alter function at GABA receptors. These effects can lead to changes in mood and memory. In some cases, mood disorders in women can be treated with steroidal hormones. In other cases, steroidal hormones may be useful adjuncts that improve the efficacy of traditional antidepressants.

Drugs such as lithium salts, usually associated with the treatment of bipolar disorder, are sometimes used in unipolar depression when conventional therapy is insufficient. Thyroid replacement therapy may enhance antidepressant therapy in 50% of patients.[20] Thyroid hormone can affect the function of catecholamines. Thyroxine is converted to triiodothyronine in the cells of the locus coeruleus. In the cortex, triiodothyronine may be released as a cotransmitter with NE.

Many antidepressant drugs are investigational only or have been approved for use outside the United States. These compounds vary in mechanism of action, side effects, and efficacy. The diversity of the chemical structures and pharmacologic activities of antidepressant drugs suggests that clinical depression is caused by various biochemical alterations. Paradoxically, the drug tianeptine, a selective serotonin reuptake enhancer, is already being marketed in other countries. These drugs are likely to enhance medical care and provide a better understanding of the underlying causes of depression.

General Therapeutic Uses

Antidepressants are primarily indicated for the treatment of depression. The clinician is confronted with various treatments but relatively few absolute indicators of which approach is ideal for each patient. Psychotherapy can be provided as initial therapy and is frequently beneficial; however, it usually takes longer than drug treatment to be effective. A combination of drugs and psychotherapy may be more effective than either treatment alone. Drug selection is ideally based on efficacy, side effects, and cost. Patients may be started on an SSRI (fewer side effects) or on a TCA or other antidepressant if some factor favoring its use over an SSRI is identified. If the patient responds, no further adjustment is necessary. If the patient responds partially or not at all, a different class of drug can be tried. If treatment is still unsatisfactory, combination therapy with antidepressants of different classes may be effective. If all these fail, a trial of electroconvulsive therapy may prove beneficial. Other therapies such as antipsychotic agents, vagal stimulation therapy, and transcranial magnetic stimulation may be tried in extremely resistant cases.

TCAs and newer mixed selective amine agents are used in the treatment of chronic pain, which is a common codiagnosis in depressed patients. Although analgesia may result from the antidepressant effect, a direct analgesic action is suggested by the fact that analgesia can be obtained in patients free of depressive illness and at lower doses than those required for relief of depression. Common types of chronic pain syndromes possibly amenable to TCAs include headache, diabetic neuropathy, neuralgias, postherpetic neuralgia, arthritis, and atypical facial pain (see later). Antidepressants should be used with special caution in elderly patients because of the possible exacerbation of cardiovascular disease. In patients older than 50 years, initial doses should be one third of the normal recommended dose, with increases made gradually over a 7- to 14-day period.

The FDA recognizes additional indications for several of these agents. Amitriptyline is indicated for delusions, doxepin for alcoholism, and desipramine for attention-deficit/hyperactivity disorder. Imipramine may be prescribed for the manage-

ment of nocturnal enuresis in older children and incontinence in adults. Although effective, no mechanism has yet been shown for these indications[23]; however, their clinical efficacy is greater than that of anticholinergic agents.

Second-generation and third-generation antidepressants may have advantages in some patients. Because of its sedative property, trazodone is useful in agitated depression and in depressed patients who have insomnia. Trazodone, nefazodone, and bupropion may also be of special use in elderly patients because these drugs have mild cardiovascular and anticholinergic side effects. Trazodone has been associated with ventricular dysrhythmias, however, in some patients with cardiac disease. Most second-generation and third-generation antidepressants produce less sexual dysfunction than SSRIs. Nefazodone is indicated for panic disorder and post-traumatic stress disorder. Amoxapine may have special use in psychotic depression, where its activity as a dopamine antagonist may prove beneficial.

Similar to SSRIs, bupropion has very low potential for causing sedation and is useful when daytime alertness is desired. Bupropion (Zyban) is used for smoking cessation[22] and may be successful in 44% of patients. (Nicotine formulations are also used for smoking cessation; clonidine and nortriptyline are second-line treatments.) Bupropion, as Zyban, is available in an extended-release dosage form and is effective in doses up to 300 mg/day in divided doses. Treatment is usually continued for 7 to 12 weeks. Other uses for bupropion include attention-deficit/hyperactivity disorder and post-traumatic stress disorder.

MAO inhibitors may be particularly effective in the treatment of atypical affective disorders (e.g., depression with hysteria), panic attacks, and depression coupled with somatic anxiety, and in patients whose conditions are refractory to the other antidepressants. They have been largely replaced, however, by safer, more effective drugs. Moclobemide, a reversible MAO-A-selective drug, produces fewer side effects than older MAO inhibitors.

SSRIs are currently the most commonly prescribed antidepressants. Clinical trials and case reports also suggest that these drugs may be useful in the treatment of obsessive-compulsive disorders (the FDA has approved fluoxetine and paroxetine), bulimia (fluoxetine), panic disorders (paroxetine and sertraline), social phobia (paroxetine), and poststroke depression (citalopram). Post-traumatic stress disorder may also be an indication. To date, these drugs have been found to be effective antidepressants while producing fewer side effects than previous agents. Depression associated with other medical illness or surgery is common. This depression may contribute to adverse treatment responses. SSRIs are effective for treatment of depression in patients with myocardial infarction, diabetes, and Parkinson's disease. SSRIs are generally less effective in chronic pain syndromes than drugs that block NE and 5-HT uptake, although SSRIs may be effective in diabetic neuropathy (citalopram) and migraine pain (paroxetine).

As with the antipsychotics, antidepressants must be administered over a long period and are often continued for several weeks after clinical remission to guard against relapse. Several weeks to 2 months of continuous drug administration are usually necessary before therapeutic effects are noted. This slow onset in effect may be related to alterations in brain neurochemistry or receptors. Drug treatment should continue for at least 6 months. If the patient has had more than one previous depressive episode, treatment should be continued for at least 2 years and in some cases indefinitely. Although it has been claimed that some of the newer agents have a more rapid onset of action than TCAs, this assertion has yet to be consistently confirmed in clinical studies. Similar to other antidepressants, SSRIs may precipitate mania, especially in the bipolar patient.

Tricyclic antidepressants

The anticholinergic side effects of TCAs have important dental implications. Reduced salivary flow increases the risk of dental caries, oral candidiasis, and oral functional abnormalities. Three quarters of patients taking imipramine may report dry mouth compared with one third of patients taking the SSRI sertraline.

Anticholinergic agents should not be administered with TCAs because additive effects can result in toxic reactions (e.g., confusion, agitation, hyperthermia, tachycardia, urinary retention). The use of antianxiety agents, barbiturates, and other sedatives should be carefully controlled in patients receiving TCAs because of additive depressant effects on the CNS. The duration of action of barbiturates may be prolonged by TCAs, but the long-term use of barbiturates can reduce half-lives of TCAs by microsomal enzyme induction. Propoxyphene, which has been reported to interfere with several P450 isozymes, may inhibit the metabolism of TCAs and increase their half-lives.

Similar to the antipsychotic agents, the risk of long QT syndrome and torsades de pointes is increased by many antidepressants, so adding other agents that increase this risk should be avoided. These include several of the macrolide (erythromycin, clarithromycin) and fluoroquinolone (moxifloxacin, gatifloxacin) antibiotics, imidazole antifungal agents (ketoconazole, itraconazole), antihistamines, and cholinergic agonists.

Because of the cardiotoxic effects of TCAs and their potentiation of adrenergic drugs, high doses or accidental intravascular injection of local anesthetic solutions may precipitate arrhythmias and hypertension. The use of TCAs is not a contraindication, however, for the use of epinephrine with local anesthetics as long as care is taken not to inject the vasoconstrictor intravenously or in large doses.

Abrupt termination of an antidepressant may lead to withdrawal symptoms. Such patients may exhibit hypersensitivity to touch and pain and may have paresthesias, headache, and muscle spasms.

Monoamine oxidase inhibitors

Various drug interactions involve MAO inhibitors, particularly the irreversible nonselective type. Interactions most relevant for the practicing dentist include the prolongation and enhancement of the CNS effects of the opioid analgesics, barbiturates, and other CNS depressants. MAO inhibitors given in conjunction with meperidine cause potentially fatal reactions, including hyperthermia, excitement, and seizures, in addition to reactions that resemble an opioid overdose. This interaction requires that meperidine not be used concurrently with MAO inhibitors or for several weeks after therapy with MAO inhibitors has ceased. Other opioids, which are not similar chemically to meperidine, may be used with caution.

Hypotension can develop with the concomitant use of general anesthetics and MAO inhibitors. It is prudent to discontinue the use of MAO inhibitors for 2 weeks before surgery. Neither epinephrine nor levonordefrin is potentiated by inhibition of MAO activity.

Second-generation and third-generation antidepressants

Although second-generation and third-generation antidepressants may have fewer side effects than TCAs, their anticholinergic and sedative properties should be kept in mind. Bupropion is exceptional in that central stimulation is more likely than sedation. This side effect may aggravate the condition of an already nervous patient. The drug is reported to produce dry mouth in approximately 25% of patients who use it, including patients in smoking cessation programs. The dentist should recognize that bupropion, although generally

safe, occasionally can produce severe reactions such as seizures or Stevens-Johnson syndrome. The drug should be avoided in patients who pose a risk for these reactions. Long-term success rates in smoking cessation programs, even with pharmacotherapy, are low.

Amoxapine can cause extrapyramidal side effects that can affect prosthodontic care. Drug interactions involving amoxapine and maprotiline are similar to interactions involving first-generation TCAs. Mirtazapine has potential for side effects and drug interactions. Because of its ability to block H_1 histamine receptors, it is sedating and can produce weight gain and xerostomia.

Selective serotonin reuptake inhibitors

The high incidence of gastrointestinal disturbances, particularly nausea and vomiting, during initial treatment with SSRIs can pose clinical problems. Postponement of clinical procedures to a later date may be advisable because tolerance develops to these side effects. Fluoxetine (or its metabolite norfluoxetine) prolongs the duration of action of certain benzodiazepines, probably by decreasing their metabolism. This inhibition may lead to protracted sedation, especially in light of the long half-lives of fluoxetine and its active metabolite. The interaction is most pronounced with benzodiazepines (alprazolam, midazolam, and triazolam) that are metabolized by CYP3A4-catalyzed α hydroxylation on the triazolo ring of these drugs.

Implications for Dentistry

Untreated depression has been correlated with numerous intraoral changes that may predispose depressed patients to dental or oral disease. Known factors include reduced salivary flow, preference for carbohydrates (possibly because of decreased brain 5-HT), higher oral lactobacillus counts, and decreased motivation and interest in oral health maintenance.[17] Depressed patients may be more likely to have periodontitis. Chronic facial pain, burning sensations in the mouth, and temporomandibular joint disorders may be associated with depression.

All drugs used to treat depression have been reported to produce varying degrees of xerostomia and may increase the likelihood for dental caries and other oral health problems.[27] Estimates of degree of dry mouth vary widely in the literature for the same drug. The reasons for this variability may include differences in dosage, duration of therapy, and underlying physical status among patients. Although antimuscarinic action has been a principal explanation for dry mouth, other drug actions may also contribute. Changes in salivary function can reflect actions of drugs on the salivary glands, the cardiovascular system, immune function, or the CNS centers controlling these functions. The relative likelihood of xerostomia is much greater with TCAs than with other antidepressants. Other common oral side effects of antidepressants include altered taste sensation, stomatitis, and glossitis.[17]

Amitriptyline and other antidepressants are among the more commonly used drugs for facial pain, including atypical facial pain and facial arthromyalgia (Costen's syndrome and temporomandibular joint dysfunction syndrome). Drug responses vary from patient to patient. Although effective doses are lower than the doses required for the treatment of depression, the same delayed onset to effect (several weeks) has been reported. Similar results have been obtained with dothiepin, an investigational thio derivative of amitriptyline. Dothiepin may have analgesic efficacy for treating idiopathic fibromyalgia, rheumatoid arthritis, and atypical facial pain. The selective NE reuptake blockers such as duloxetine or reboxetine may also be useful in the treatment of chronic pain. Because duloxetine and reboxetine block the reuptake of NE, concurrent use of vasoconstrictors in dental carpules could produce exaggerated cardiovascular responses.

ANTIMANICS

Manic disorder or bipolar disorder is a unique diagnostic condition. A genetic component is suspected. Numerous biochemical pathways seem to be altered in manic or bipolar patients in the brain and blood elements. Elevated concentrations of Ca^{++} have been observed in brain cells, platelets, and lymphocytes. Brain mitochondrial function and intracellular pH are decreased, choline/creatine-phosphocreatine ratios are higher than normal, and phosphocreatine and *N*-acetyl aspartate concentrations are decreased in specific brain regions. These results indicate possible neuronal damage and impaired function. Abnormalities on several chromosomes are suspected, and there is an increased maternal transmission rate with several mutations of mitochondrial DNA associated with increased risk of the disorder.

Lithium salts are important for treating mania, but Li^+ alone may be inadequate treatment for half of patients exhibiting bipolar disorder. In addition to the antimanic effects of Li^+, evidence suggests Li^+ may also exert neuroprotective actions that may be prophylactic in unipolar and bipolar disorders and possibly in neural degenerative disorders such as Alzheimer's disease.[39] Other agents can be used to control manic patients temporarily while Li^+ therapy is being instituted and to treat individuals for whom Li^+ alone proves ineffective. Typical and atypical antipsychotic drugs are used in 85% of patients during initiation of therapy.[53] Interest has been directed toward the use of established anticonvulsants (valproate and carbamazepine), several new anticonvulsants, omega-3 fatty acids,[40] Ca^{++} channel blockers, thyroid-stimulating hormone, and thyroid hormone as adjunctive agents in the treatment of bipolar disorder. Ultimately, a variety of drugs is available if needed.

Lithium Salts

Li^+ was observed to be effective for mania by Cade in 1949, but was not generally embraced until the late 1960s.

Pharmacologic effects

The mechanism of action of Li^+ is not established. Many changes resulting from Li^+ administration have been documented, including effects on plasma membrane cation channels, plasma membrane ion pumps, and exchange systems and positive and negative effects on neuronal release of various neurotransmitters.

Although the mechanism of action of Li^+ remains unresolved, two effects of Li^+ offer likely explanations for the therapeutic and possibly adverse effects (Figure 12-9). The first is the inhibitory effect of the ion on phosphomonoesterases involved in inositol signaling pathways. Li^+ inhibits phosphoinositide metabolism by inhibiting inositol monophosphatase, the enzyme responsible for converting inositol monophosphate to inositol. Li^+ also inhibits inositol polyphosphate-l-phosphatase, which catalyzes the l-dephosphorylation of certain inositol bisphosphates and polyphosphates. Li^+ might inhibit the effect of neurotransmitters that use signaling pathways involving inositol trisphosphate. The effect of inhibiting this pathway could be the depletion of inositol, which would deplete phosphatidylinositol bisphosphate. This effect would reduce signaling through receptors whose signaling involves the use of phosphatidylinositol bisphosphate as a substrate for the formation of inositol trisphosphate and diacylglycerol.

A second effect that may play an important role in the action of Li^+ is inhibition of glycogen synthase kinase-3β

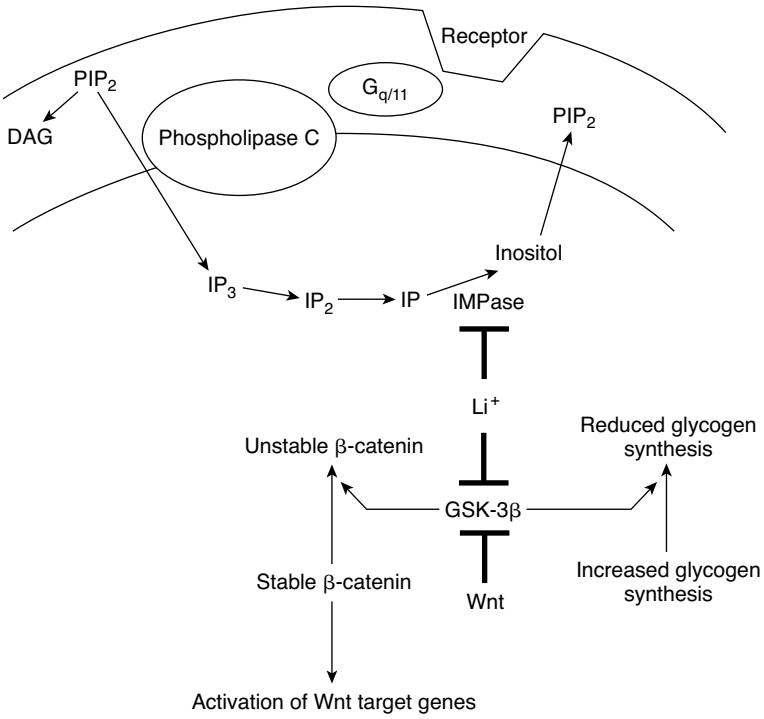

FIGURE **12-9** Two mechanisms by which Li^+ may mediate its pharmacologic effects. Li^+ inhibits inositol monophosphatase *(IMPase)* and glycogen synthase kinase-3β *(GSK-3β)*. By the first mechanism, Li^+ inhibits signaling through the inositol pathway by depleting phosphatidylinositol bisphosphate *(PIP_2)*. The result of this depletion is the inability to produce sufficient inositol-1,4,5 trisphosphate *(IP_3)*. By the second mechanism, Li^+ stabilizes β-catenin, leading to changes in neuronal function, such as receptor signaling and remodeling. In addition, glycogen synthesis is promoted by Li^+. *DAG*, Diacylglycerol; *IP*, inositol monophosphate; *IP_2*, inositol bisphosphate; *Wnt*, glycoprotein that inhibits GSK-3β.

(GSK-3β). This inhibition can affect at least two intracellular signaling cascades: activation of β-catenin and increased glycogen synthesis.[1,31] By inhibiting GSK-3β, Li^+ acts like the endogenous inhibitor of GSK-3β, which stimulates cell receptors linked to GSK-3β (see Figure 12-9). This stimulation results in changes in cell-cell interaction, axonal remodeling, and signaling in neurons. By inhibiting GSK-3β, Li^+ also acts like insulin, which stimulates glycogen synthesis (GSK-3β inhibits glycogen synthase).[31]

Clinically, Li^+ alleviates the manifestations of mania over 1 to 2 weeks. Sleep and appetite disturbances abate, and mood swings are prevented. Li^+ has little effect on mood in patients who do not have mania. Li^+ may provide a prophylactic action against future manic attacks. Patients who stop taking Li^+ may not respond as well to subsequent Li^+ treatment trials, possibly because of progression of the neurodegenerative process. Li^+ does not have anticonvulsant actions. When Li^+ is given in combination with pilocarpine, a severe form of continuous seizures can occur.[21]

Absorption, fate, and excretion

Li^+ is readily absorbed from the gastrointestinal tract. The cation eventually equilibrates throughout the total body water; no particular affinity for the brain or a specific organ has been detected. Excretion of Li^+ is primarily through the kidney, and reduced kidney function is associated with greater Li^+ toxicity if blood concentrations are not carefully monitored.

Adverse effects

Some of the most common side effects of Li^+ (e.g., gastrointestinal irritation, fine hand tremor, muscular weakness, polyuria, thirst, sleepiness, a sluggish feeling) are often associated with initial therapy and usually fade within 1 to 2 weeks. Thirst, polyuria, and hand tremor occasionally may continue for several months or years. Severe intoxication results in vomiting, diarrhea, unconsciousness, and convulsions. Most adverse effects of Li^+ have been found to correlate very closely with serum Li^+ concentrations. The therapeutic index for Li^+ is low, and plasma titers of Li^+ must be carefully monitored to ensure therapeutic effectiveness and avoid toxicity.

Li^+ inhibits the renal response to antidiuretic hormone and may cause nephrogenic diabetes insipidus. This is the basis for the thirst and polyuria associated with the drug. Renal effects are usually moderate and reversible. Thiazides and other diuretics reduce renal excretion of Li^+. Dosages of Li^+ may need to be reduced during concurrent therapy with a diuretic. Na^+ depletion leads to reduced excretion of Li^+ and a higher risk of toxicity. Any situation, such as a sodium-restricted diet or sweating, that tends to reduce the Na^+ load may increase Li^+ toxicity. Patients must be warned not to begin a sodium-restricted diet without medical surveillance. Cardiovascular disease, renal disease, or severe dehydration can also increase the risk of toxicity from Li^+.

Li^+ may cause hypotension and cardiac arrhythmias. If Li^+ produces electrocardiogram changes, the changes are not usually significant if concentrations remain in the therapeutic range. Li^+ can also induce hypothyroidism in 20% to 40% of patients.[28] Hypothyroidism can be managed with thyroid replacement therapy. In some cases of Li^+-resistant mania, increasing thyroxine concentrations to 150% of normal may overcome the resistance. With continued Li^+ therapy, approximately 4% of patients develop diffuse, nontoxic goiters. Patients may have elevated plasma Ca^{++}, which may be related to increased renal Ca^{++} reabsorption. Li^+ inhibits the effect of parathyroid hormone on osteoclasts, however, and parathyroid hormone levels may increase. Li^+ may cause numerous dermatologic side effects and alopecia. Teratogenic effects, such as cleft palate and deformities of the ear and eye, and cardiac defects are associated with Li^+ administration during the first trimester of pregnancy.

Simple and convenient methods for measuring Li^+ have been sought that do not involve taking blood samples. One such method has been the use of salivary measurements to predict serum concentrations. Li^+ concentrations in saliva are higher than plasma concentrations because the ion is actively

secreted into saliva. Although the saliva/plasma Li^+ ratio varies considerably from patient to patient, within a single patient its variability is low. There is some promise that saliva sampling may be beneficial in Li^+ monitoring.

General therapeutic uses

Li^+ is used for the treatment of mania and as long-term treatment of manic-depressive illness. Initial high (therapeutic) doses are often adjusted downward to maintenance levels, which may partially explain the initial feelings of tiredness. Even so, the delay of onset is such that 7 to 10 days are required before the antimanic effects are noted, and a short course of antipsychotic medication is normally required in cases of fully developed mania. Frequent measurements of Li^+ are required to maintain proper plasma concentrations and are particularly important as a guard against toxicity.

Implications for dentistry

Patients with bipolar disease may have substantial dental pathology. These patients have a greater risk for poor oral hygiene, accumulations of supragingival and subgingival calculus, extensive dental caries, and numerous missing teeth.[16] Some of the dental problems may be related to patient characteristics other than treatment, such as age or financial situation. Hyposalivation from the disease is common (approximately 71%), which may be associated with dental caries.

Nonsteroidal anti-inflammatory analgesics may decrease the renal excretion of Li^+ and lead to toxic plasma concentrations after several days of combined therapy. Although drugs such as piroxicam and indomethacin most readily cause this drug interaction, it is most likely to occur with formulations of ibuprofen, naproxen, and related drugs that are available over-the-counter and likely to be taken without professional supervision. Aspirin can increase the excretion of Li^+. The combination of Li^+ and pilocarpine must be avoided because of the risk of seizures.

Patients taking Li^+ frequently have a metallic taste that can alter the palatability of food. Most patients taking Li^+ have salivary gland dysfunction and a resultant decrease in salivary flow.[34] Polydipsia is common because of Li^+-induced diuresis and xerostomia. In early phases of Li^+ therapy, facial spasm and transient facial paralysis, especially of the lower jaw, have occurred. Facial pains associated with cluster headaches may respond to treatment with Li^+.

Other Antimania Drugs

Approximately 50% of patients who have mania do not respond to Li^+. Characteristics common to many Li^+-refractory patients include severe mania mixed with either psychotic episodes or anxiety and a history of rapid cycling. Antipsychotic agents are frequently used to help control the florid excitation and delusions early in treatment, and more recently the atypical antipsychotic olanzapine has been approved for this use. Aripiprazole is also being investigated for this use. Carbamazepine, an anticonvulsant discussed in Chapter 14, may be effective in some refractory cases. Carbamazepine has been reserved for patients who do not respond to conventional therapy. Patients who seem to respond most favorably to carbamazepine have severe forms of the disease. A Li^+/carbamazepine combination is sometimes effective in patients who are refractory to either drug alone. Carbamazepine may also be effective as a prophylactic agent. Valproic acid is another anticonvulsant that has clinical usefulness for the treatment of mania refractory to Li^+ and carbamazepine.

Newer anticonvulsant medications, such as lamotrigine, gabapentin, and topiramate, are being evaluated as adjuncts and have been called mood stabilizers when used in this context. The benzodiazepines clonazepam and lorazepam, when used in combination with haloperidol, are helpful in calming severely manic patients until Li^+ administration achieves a therapeutic concentration. This combination often permits adequate control without excessive doses of either the antipsychotic or the benzodiazepine. Ca^{++} channel blockers such as verapamil have proved helpful in some cases of Li^+-refractory mania, but more studies are required to assess their overall usefulness. Similar to Li^+, verapamil is not a depressant and is of little use for the initial treatment of severely manic patients. Omega-3 fatty acid treatment of bipolar disorder is under study but has not shown consistent efficacy.[33]

ANTIPSYCHOTIC AND ANTIDEPRESSANT DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Phenothiazines	
Acetophenazine*	Tindal
Chlorpromazine	Thorazine
Fluphenazine	Prolixin
Mesoridazine	Serentil

ANTIDEPRESSANT DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Tricyclics	
Amitriptyline	Elavil, Endep
Clomipramine	Anafranil
Desipramine	Norpramin
Doxepin	Adapin, Sinequan
Dothiepin*	Prothiaden
Imipramine	Tofranil
Nortriptyline	Aventyl, Pamelor
Protriptyline	Vivactil
Trimipramine	Surmontil
Monoamine oxidase (MAO) inhibitors	
Phenelzine	Nardil
Isocarboxazid	Marplan
Tranylcypromine	Parnate
Second-generation and third-generation agents	
Amoxapine†	Asendin
Duloxetine	Cymbalta
Maprotiline	Ludiomil
Trazodone	Desyrel
Nefazodone	Serzone
Bupropion	Wellbutrin, Zyban
Mirtazapine	Remeron
Reboxetine*	Vestra
Selective serotonin reuptake inhibitors (SSRIs)	
Fluoxetine	Prozac
Fluvoxamine	Luvox
Paroxetine	Paxil
Sertraline	Zoloft
Citalopram	Celexa
Escitalopram	Lexapro
Venlafaxine‡	Effexor
Antimanics	
Carbamazepine	Tegretol
Lithium carbonate	Eskalith, Lithobid
Lithium citrate	Cibalith-S
Valproic acid (and derivatives)	Depakene, Depakote

*Not currently available in the United States.
†Amoxapine is listed separately from the other tricyclics because it is a second-generation or atypical antidepressant.
‡Not classified as an SSRI, but is selective for 5-hydroxytryptamine transport at therapeutic doses.

CHAPTER 13

*Sedative-Hypnotics, Antianxiety Drugs, and Centrally Acting Muscle Relaxants**

JOSEPH A. GIOVANNITTI, JR., AND PAUL A. MOORE

The drugs discussed in this chapter have the common pharmacologic characteristic of being central nervous system (CNS) depressants, and they are capable of inducing various clinical responses, including relief of anxiety, sedative-hypnotic effects, and centrally acting muscle relaxation. Although all such drugs induce CNS impairment, drugs in certain categories have some degree of selectivity that determines their therapeutic indications in medical and dental practice. The ability of these agents to induce sedation, hypnosis, anxiolysis, or muscle relaxation selectively is limited, however, and significant overlap in the clinical indications for these drugs occurs. Pharmacokinetic differences and differences in mechanisms of action often distinguish these agents. The multiple actions and uses of these agents are also discussed in other chapters addressing anticonvulsants (see Chapter 14), general anesthetic agents (see Chapter 18), and antihistamines (see Chapter 22).

The drugs discussed in this chapter can be viewed as having dose-dependent, CNS-depressing effects progressing through anxiolysis, sedation, hypnosis, anesthesia, and ultimately death if the dose is sufficiently high. As anxiolytics, these drugs reduce the anxiety response; as sedatives, they produce relaxation, calmness, and decreased motor activity without loss of consciousness. As hypnotics, they induce drowsiness and a depressed state of consciousness that resembles natural sleep, with decreased motor activity and impaired sensory responsiveness. As anesthetics, these drugs cause a state of unconsciousness from which the patient cannot be aroused. Not all sedative-hypnotics are readily capable of inducing anesthesia, and not all CNS depressants can be used as sedative-hypnotics. General anesthetic agents easily induce unconsciousness and are unsuitable as sedative-hypnotics on an outpatient basis.

Insomnia is the salient feature of the nearly 90 different forms of sleep disorders.[11] Epidemiologic studies report that insomnia is widespread, affecting one third of the population. Insomnia is more prevalent among women than men and is more common in elderly individuals than in younger individuals. Nearly half of all Americans older than 65 years experience sleep disorders.[41]

Barbiturates were the most commonly prescribed sedative-hypnotics 50 years ago. Today they have been almost entirely replaced by benzodiazepine receptor agonists. One advantage of the benzodiazepines and related drugs over barbiturates is their wider margin of safety. Additional advantages include a slower development of tolerance and physical dependence, minimal induction of hepatic enzyme activity, and generally fewer drug interactions.

*The author wishes to recognize Dr. Leslie Felpel for his past contributions to this chapter.

Anxiety is one of the most common psychiatric disorders. In the United States, approximately 8% of the population have an anxiety disorder during any given 6-month period. Although most individuals have certain periods and degrees of anxiety, pharmacotherapy is indicated only when anxiety begins to interfere with daily life. Similarly, pharmacotherapy should be considered when situational anxiety, such as might be experienced by a patient in anticipation of an operative or diagnostic procedure, is judged to be sufficient to compromise clinical care.

According to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV),[10] the anxiety disorders comprise various acute and chronic anxiety and phobic states. Specific anxiety disorders include panic disorder with or without agoraphobia, agoraphobia without panic disorder, generalized anxiety disorder, obsessive-compulsive disorder, acute stress disorder, post-traumatic stress disorder, social phobia, specific (simple) phobia, substance-induced anxiety disorder, and anxiety resulting from a general medical condition. The major emphasis in this chapter is on drugs effective against anxiety as a symptom rather than as a specific disorder. Although antianxiety drugs have applications for treatment of anxiety disorders in general, other drugs, including tricyclic antidepressants, monoamine oxidase inhibitors, and selective serotonin reuptake inhibitors, are used in the pharmacotherapy of panic disorders, phobic disorders, and obsessive-compulsive disorders. These latter agents are discussed in detail in Chapter 12.

Nearly all CNS depressants, including ethanol, chloral hydrate, opioids, and barbiturates, can be used as antianxiety agents, but nonselective CNS sedation accounts for their antianxiety effect. The first drug that seemed to have some selectivity as an antianxiety agent was meprobamate. Originally developed and marketed as a skeletal muscle relaxant in the early 1950s, meprobamate soon became more widely used as an antianxiety agent. The popularity of meprobamate declined rapidly with the introduction of the benzodiazepines in the 1960s. The benzodiazepines became extremely popular drugs because they were found to have anxiolytic selectivity and to be relatively safe even after overt overdose. Nonetheless, sedation is a prominent side effect of the benzodiazepines, and additive CNS depression occurs if other CNS depressants are used concurrently. Their anxiolytic selectivity is best described in relative rather than absolute terms. The possibility that antianxiety and CNS depressant properties are pharmacologically distinguishable has been raised again with the introduction of buspirone, an azapirone derivative, which is an effective antianxiety agent with little or no sedative properties that causes very little additional depression when used with CNS depressants.

The usefulness and effectiveness of any given antianxiety agent varies depending on the patient, the clinical surround-

ings, the "chairside" manner of the dentist, the route of administration, and the properties of the chosen drug. Knowledge of the pharmacologic characteristics of the various antianxiety agents is crucial for selecting the proper drug, avoiding drug interactions, and obtaining the desired therapeutic response with minimal adverse side effects.

BENZODIAZEPINES

Benzodiazepines are among the most widely used drug classes in the history of medicine because of their selectivity and margin of safety. Literally thousands of benzodiazepine derivatives have been synthesized, and more than 100 of these have been tested for clinical activity. Currently, several dozen benzodiazepines are marketed throughout the world.

Diazepam was the most frequently prescribed drug in the United States during the 1970s and remained among the 10 most frequently prescribed drugs for nearly two decades. Alprazolam is the most frequently prescribed benzodiazepine today. Surveys indicate that approximately 15% of adults in the United States take one of the benzodiazepines at least once a year. Members of the medical community and the lay press have suggested that the benzodiazepines are overused and that they frequently serve either as a substitute for the practitioner's time or as a placebo for a population increasingly unwilling to accept a mild state of unhappiness. In response to this problem, manufacturers' prescribing information warns practitioners that benzodiazepines should not be prescribed for longer than 4 months without a careful reassessment of the patient's status and that they should not be prescribed for the stress of everyday life.

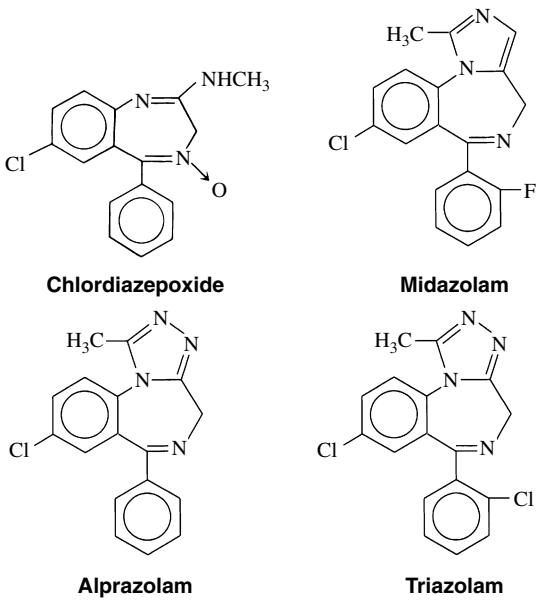

FIGURE **13-1** Structural formulas of chlordiazepoxide, the first benzodiazepine used clinically; midazolam, an imidazobenzodiazepine; and the triazolobenzodiazepines alprazolam and triazolam. Triazolam is derived from alprazolam by the addition of a chlorine atom on the ortho position of the phenyl group. Estazolam is formed from alprazolam by removal of the methyl group of the triazolo ring (not shown).

Chemistry and Structure-Activity Relationships

The structures of the pharmacologically active 1,4-benzodiazepines are shown in Figure 13-1 and Table 13-1. All benzodiazepines currently available in the United States are derived from the basic molecule shown in Table 13-1, to which are added various substituent groups. Slight modifications of the basic structure have produced triazolobenzodiazepines (e.g., alprazolam, triazolam) and imidazobenzodiazepines (e.g., midazolam).

All benzodiazepines with psychopharmacologic activity have an electronegative group at R_7. A chlorine atom seems to confer optimal activity, whereas bromo and nitro substitutions are only weakly anxiolytic. A nitro moiety at R_7 enhances antiseizure properties, however, as illustrated by clonazepam, which is used as an anticonvulsant. Hydrogen or methyl groups at R_7 significantly reduce pharmacologic activity. Substitution at position 5 with any group other than a phenyl ring also reduces activity. Halogenation at R_2' increases potency; larger alkyl substitutions decrease it. Substitution on the nitrogen at R_1 with a methyl group enhances activity, as do methyl or hydrogen groups at R_3. A biosynthetic pathway for the in vivo formation of diazepam-like benzodiazepines has been proposed.[7] Whether synthesis occurs naturally is unknown, but benzodiazepines are found in a variety of foods.[69]

Mechanism of Action

Perhaps the most exciting and significant advance in the understanding of anxiety and the mechanism of action of benzodiazepines occurred with the discovery of specific benzodiazepine binding sites in the brain and the understanding that these were in some way linked to the inhibitory neurotransmitter γ-aminobutyric acid (GABA). As shown schematically in Figure 13-2, when the GABA receptor is activated, the Cl^- channel opens, allowing Cl^- influx, membrane hyperpolarization, and neuronal inhibition. Benzodiazepines, by interacting at high-affinity benzodiazepine binding sites on the GABA receptor complex, facilitate GABA action. Although devoid of direct GABA-mimetic effects, benzodiazepines increase inhibitory neurotransmission resulting from GABA. Although the exact mechanism by which benzodiazepines accomplish their effect is not fully delineated, it is known that they increase the frequency at which Cl^- channels open in response to GABA.[60] GABA inhibition (chiefly postsynaptic inhibition) is enhanced by benzodiazepines, and any transmitter system modulated by this inhibitory drive is inhibited to a greater extent in the presence of benzodiazepines.

Benzodiazepine receptors are found in the brains of all mammalian species, birds, amphibians, reptiles, and higher fishes. Benzodiazepine receptors are linked to a specific GABA receptor subtype, the $GABA_A$ receptor (see Figure 13-2). Figure 13-3 provides further details on binding domains associated with the $GABA_A$ receptor. Historically, GABA receptors have been classified into two subtypes: the Cl^- channel–linked $GABA_A$ receptors and the G protein–linked $GABA_B$ receptors. Benzodiazepine-sensitive $GABA_A$ receptors are activated by GABA agonists, such as muscimol (a hallucinogen), and blocked by GABA antagonists, such as picrotoxin and bicuculline (convulsants).[72] $GABA_B$ receptors are benzodiazepine and bicuculline insensitive and are activated by baclofen, a centrally acting muscle relaxant.

The benzodiazepine receptor—along with the $GABA_A$ receptor, a barbiturate receptor, the Cl^- channel, and binding domains for other drugs—forms a single macromolecular complex. Similar to GABA receptors, benzodiazepine receptors are heterogeneous; there are at least three types: type 1 (BZ_1), type 2 (BZ_2), and the "peripheral type" benzodiazepine receptor. The presence of BZ_1 and BZ_2 receptor types is apparently determined by the subunit composition of the $GABA_A$ macromolecular complex. The BZ_1 receptor may be linked to sleep, whereas the BZ_2 receptor may be linked to cognition and motor function. High-affinity benzodiazepine binding sites are found on specific subunits of the $GABA_A$

TABLE **13-1**

Chemical Structures of Various Benzodiazepines

	SUBSTITUENT GROUPS

Triazolam	See Figure 13-1				

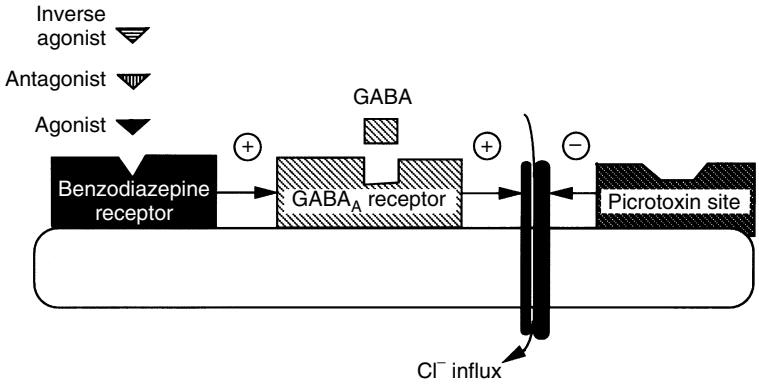

FIGURE **13-2** Schematic of the γ-aminobutyric acid $(GABA)_A$ receptor complex illustrating the sites of action of benzodiazepine agonists, antagonists, and GABA. The benzodiazepine receptor is coupled to the $GABA_A$ receptor so that its activation facilitates (denoted by the *plus sign*) the action of GABA on the Cl^- ionophore. Increased Cl^- influx leads to hyperpolarization (i.e., inhibition) of the neuron. Benzodiazepine antagonists inhibit the binding of benzodiazepines. Inverse agonists inhibit the constitutive activity of the benzodiazepine-$GABA_A$ receptor complex by binding to the benzodiazepine receptor. Also illustrated is the picrotoxin site, which, when acted on by picrotoxin, antagonizes *(minus sign)* the influx of Cl^- and can lead to convulsions. (Adapted from Dubovsky SL: Generalized anxiety disorder: new concepts and psychopharmacologic therapies, *J Clin Psychiatry* 51[suppl 1]:3-10, 1990.)

receptor complex, which, as shown in Figure 13-4, is a pentamer composed of several glycoprotein subunits (α, β, γ). This organization is analogous to the organization of the nicotinic receptor. As illustrated in Figure 13-4, which depicts the most common form of $GABA_A$ receptor complex in the rat brain, a γ subunit is necessary (but insufficient) for benzodiazepine binding and pharmacologic effects.[56] Cloning experiments have shown that there are multiple subtypes of α, β, and γ subunits,[33] which provide a basis for GABA receptor heterogeneity.[13,49]

The heterogeneity of receptor subunits may offer an explanation for the diverse pharmacologic effects (antianxi-

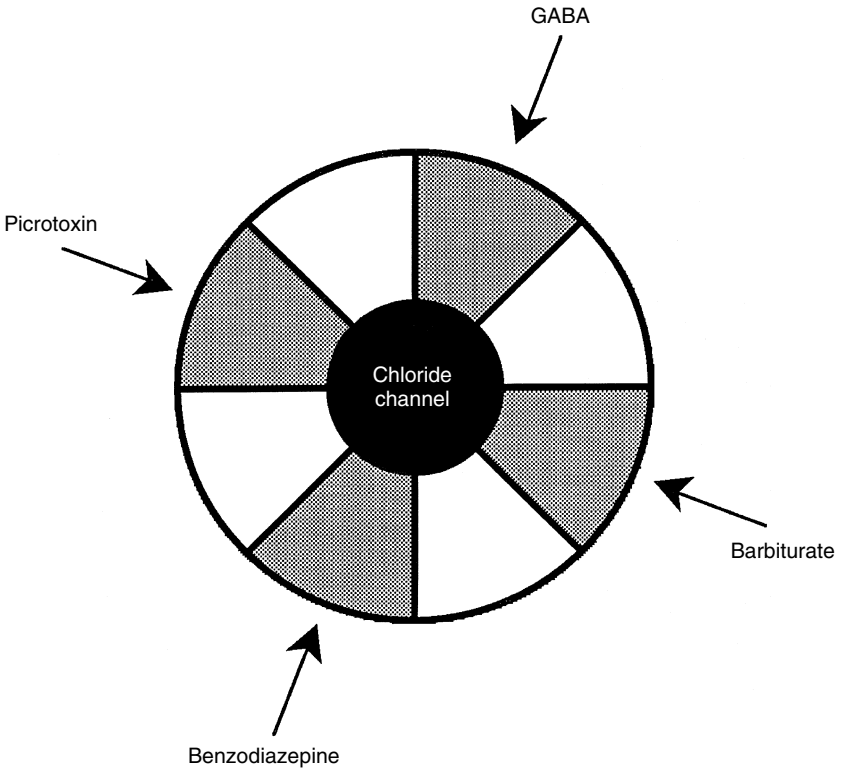

FIGURE **13-3** Arrangement of allosteric binding domains on the γ-aminobutyric acid *(GABA)*$_A$ receptor complex. The complex is composed of five unique subunits. Multiple receptor subtypes are possible on the basis of different combinations of the subunits. Binding sites for picrotoxin (a convulsant), barbiturates, GABA, and benzodiazepines are presented for illustrative purposes. In addition, distinct binding sites for other chemical agents have been identified (shown as blank areas). The figure does not identify which receptor subunits are involved in the binding of each drug. (Adapted from Sieghart W: $GABA_A$ receptors: ligand-gated Cl^- ion channels modulated by multiple drug-binding sites, *Trends Pharmacol Sci* 13:446-450, 1992.)

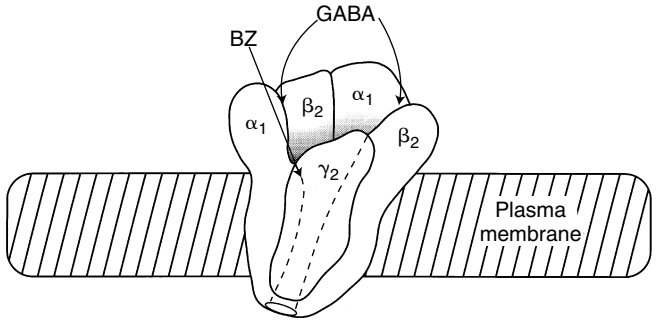

FIGURE **13-4** Structural model of the γ-aminobutyric acid *(GABA)*-benzodiazepine *(BZ)* receptor complex. The arrangement of the subunits *(α, β, γ)* forms the Cl^- channel. GABA binding sites are illustrated at the two analogous interfaces between the α and β subunits. The BZ binding site is associated with the interface of the α and γ subunits. (Adapted from Zorumski CF, Isenberg KE: Insights into the structure and function of GABA-benzodiazepine receptors: ion channels and psychiatry, *Am J Psychiatry* 148:162-173, 1991.)

ety, anticonvulsant, sedative, and skeletal muscle relaxant) of benzodiazepines. Determination of the molecular basis of receptor heterogeneity may eventually facilitate the development of benzodiazepines with a greater degree of selectivity in producing each of these effects. At present, none of the clinically available antianxiety benzodiazepines shows selectivity for either BZ_1 or BZ_2 receptors, although the hypnotic benzodiazepine quazepam is likely selective for the BZ_1 receptor.[50] Zolpidem and zaleplon, two nonbenzodiazepines selective for the BZ_1 receptor, are discussed later in this chapter.

The heterogeneous nature of $GABA_A$ receptors may explain some of the differences in clinical profile between benzodiazepines and barbiturates. In contrast to benzodiazepines, barbiturates increase the duration (but not the frequency) of opening of Cl^- channels activated by GABA and in high concentrations promote Cl^- conductance even in the absence of GABA. Variations of $GABA_A$ receptor responses to benzodiazepines and barbiturates in specific CNS areas may be another factor contributing to their respective pharmacologic profiles.

The benzodiazepine-insensitive $GABA_B$ receptors coupled to G proteins are associated with a decrease in Ca^{++} conductance and an increase in K^+ conductance and could be expected to cause pharmacologic effects when stimulated or antagonized. $GABA_B$ receptors are less widely distributed than $GABA_A$ receptors but are found in high concentrations in the cerebral cortex and cerebellum. Subtypes of $GABA_B$ receptors may exist. $GABA_B$ receptors have not been studied as extensively as $GABA_A$ receptors, but they may participate in blood pressure regulation[61] in addition to muscle activity and offer a potential site for therapeutic drug action.

The existence of subclasses of benzodiazepine receptors suggests that some agents, with specific activity for individual receptor subtypes, may be more selective than others in terms of their pharmacologic profile. Whether this selectivity results in significant clinical differences is an open question.[14] Quazepam, a long-acting benzodiazepine hypnotic, produces sedation, but seems to have little ataxic effect and may cause less tolerance than other benzodiazepines. Autoradiographic studies have shown selective binding of quazepam to BZ_1 receptors,[31] which may account for sedation with minimal muscle relaxant effects. Of all currently available benzodiazepines, only quazepam, one of its active metabolites (1-oxoquazepam), and possibly the antianxiety agent halaz-

epam have selectivity for the BZ_1 receptor subtype. These benzodiazepines differ chemically from other benzodiazepines by having a trifluoroethyl substituent (see Table 13-1), which may be responsible for BZ_1 selectivity. Selective activity at the BZ_1 receptor has not been associated with any special clinical benefit of quazepam, however, compared with other benzodiazepines for treating insomnia.

Another potential effect of benzodiazepines is on the "peripheral-type" benzodiazepine receptor, now known as the mitochondrial translocator protein. These peripheral benzodiazepine binding sites, which can be pharmacologically differentiated from central BZ_1 and BZ_2 receptors, have been found not only in the periphery (kidney, lung), but also in the brain. In the CNS, they are most prevalent on glial cells. Their functions include cholesterol transport into mitochondria with the resulting increase in steroid synthesis. The activity of this transporter seems to have important effects in certain brain disorders.

Although the pharmacologic actions of benzodiazepines are closely tied to GABA receptors, numerous other neurotransmitters, including glycine, norepinephrine, and 5-hydroxytryptamine (5-HT), have been suggested to play a role in their action. An interaction between GABA and 5-HT has been shown experimentally with diazepam and tryptaminergic anxiolytics.[36] This finding is interesting in light of the mechanism of action of the nonsedating antianxiety agent buspirone (see later), a $5\text{-}HT_{1A}$ partial agonist.

Pharmacologic Effects

Benzodiazepines have clinically useful antianxiety, sedative-hypnotic, amnestic, anticonvulsant, and skeletal muscle relaxant properties. Benzodiazepines previously were thought to differ pharmacologically only in terms of their pharmacokinetics. Although differences in pharmacokinetic properties explain many of their clinical differences, certain benzodiazepines seem to have unique properties.[17] Alprazolam has documented antidepressant and antipanic properties, and diazepam may be more selective as a skeletal muscle relaxant than other benzodiazepines. Diazepam is the only benzodiazepine approved for the treatment of skeletal muscle spasm and spasticity of CNS origin.

Central nervous system

Many of the gross CNS effects of benzodiazepines are similar to the effects of older sedative-hypnotics such as the barbiturates. All benzodiazepines produce a dose-dependent depression of the CNS. Drowsiness and sedation are common manifestations of this central depressant action and may be considered a side effect in some instances and therapeutically useful in others. Some benzodiazepines, such as flurazepam and temazepam, are marketed specifically as hypnotic agents. Although hypnotic benzodiazepines are probably no more specific in promoting sleep than antianxiety benzodiazepines, differences in their pharmacokinetics may make a given benzodiazepine more suitable as either a hypnotic or an antianxiety agent.

Although it is difficult clinically to differentiate the CNS effects of benzodiazepines from the effects of other sedative-hypnotics, certain experimental animal models indicate benzodiazepines have selective antianxiety properties. Normally vicious macaque monkeys and rats made highly irritable by lesions placed in the septal area of the brain are tamed and calmed by benzodiazepines. The doses required to produce these effects are one tenth of those that cause ataxia and somnolence. Barbiturates also tame these animals, but the doses required invariably produce incoordination and drowsiness.

Certain benzodiazepines in clinical doses can induce anterograde amnesia, which means that memory of events occurring for a time after drug administration is not retained.[12] This effect is useful therapeutically in intravenous sedation or monitored anesthesia care. Muscle relaxation and antiseizure activity are additional CNS effects of benzodiazepines. These effects are discussed later in this chapter (muscle relaxation) and in Chapter 14 (antiseizure activity).

Cardiovascular system

In a healthy adult, normal therapeutic doses of benzodiazepines cause few alterations in cardiac output or blood pressure. Greater than normal doses decrease blood pressure, cardiac output, and stroke volume in normal subjects and patients with cardiac disease, but these effects are usually not clinically significant. Benzodiazepines are often prescribed for cardiac patients in whom anxiety contributes to their symptoms.

Respiratory system

As is true of any sedative drug, benzodiazepines are respiratory depressants. In normal doses, benzodiazepines have little effect on respiration in healthy individuals. There have been reports, however, of benzodiazepine-induced respiratory failure in patients with pulmonary disease. Benzodiazepines may cause additive respiratory depressant effects with other CNS depressant drugs. Poor suckling, hypothermia, and a need for ventilatory assistance have been reported in neonates of mothers who received intravenous lorazepam shortly before delivery. Midazolam, used primarily for intravenous sedation and for the induction of anesthesia, can cause respiratory depression and apnea. Clinically significant respiratory depression may occur if an opioid is used in combination with midazolam.[12]

Absorption, Fate, and Excretion

The pharmacokinetics of individual benzodiazepines differ, and there is a wide range in speed of onset and duration of action among these compounds. Benzodiazepines frequently are classified according to their elimination half-life, as illustrated in Table 13-2; however, the elimination half-life of a given drug is only one factor affecting its clinical profile. The rates of drug absorption and tissue distribution and redistribution are often important factors in determining onset and duration of clinical effects after short-term administration. Additionally, there is a wide variation in drug half-lives among patients.

After oral administration, most benzodiazepines are rapidly absorbed and highly bound to plasma protein. Lorazepam, oxazepam, prazepam, and temazepam are more slowly absorbed. Peak blood concentrations are generally obtained in 1 to 3 hours. The lipid solubility of these compounds differs significantly, however, so that a highly lipid-soluble drug such as diazepam exerts its effect more rapidly, whereas lorazepam, which is less lipid-soluble, has a slower onset of action even after systemic absorption. Diazepam also accumulates in body fat because of its lipophilic properties, and it is slowly eliminated from these stores. This characteristic partially accounts for the prolonged half-life of diazepam, which can range from 1 to 4 days.

Many benzodiazepines are converted to pharmacologically active metabolites that have long half-lives (Figure 13-5). Clorazepate and prazepam are nearly completely converted (in the stomach and liver) to the long-acting metabolite desmethyldiazepam (nordazepam) before they enter the systemic circulation. Desmethyldiazepam is a metabolite of many other benzodiazepines, including chlordiazepoxide, diazepam, and halazepam. Flurazepam is also converted to active metabolites in its first pass through the liver. Generally, the products of phase I metabolism are eventually conjugated with glucuronic acid and inactivated and excreted in the urine

TABLE **13-2**

Classification of Benzodiazepines on the Basis of Elimination Half-Life after Oral Administration

DRUG	TIME TO PEAK PLASMA CONCENTRATION (hr)	ELIMINATION HALF-LIFE (hr)	MAJOR ACTIVE METABOLITES
Short-Acting to Intermediate-Acting			
Alprazolam	1-2	12-15	α-Hydroxyalprazolam
Estazolam	2	10-24	None
Lorazepam	1-6	10-18	None
Midazolam	0.2-1	2-5	α-Hydroxymidazolam
Oxazepam	1-4	5-15	None
Temazepam	2-3	10-20	None
Triazolam	1-2	1.5-5	α-Hydroxytriazolam
Long-Acting			
Chlordiazepoxide	1-4	5-30	Desmethylchlordiazepoxide Demoxepam Desmethyldiazepam
Clorazepate*	1-2	30-100	Desmethyldiazepam
Diazepam	1-2	30-60	Desmethyldiazepam
Flurazepam*	0.5-1	50-100	N-Desalkylflurazepam
Halazepam	1-3	14	Desmethyldiazepam
Prazepam*	2.5-6	30-100	Desmethyldiazepam
Quazepam	2	40	2-Oxo-quazepam N-Desalkylflurazepam

*Does not reach the circulation as the parent drug in clinically significant amounts. Values reflect the primary metabolite.

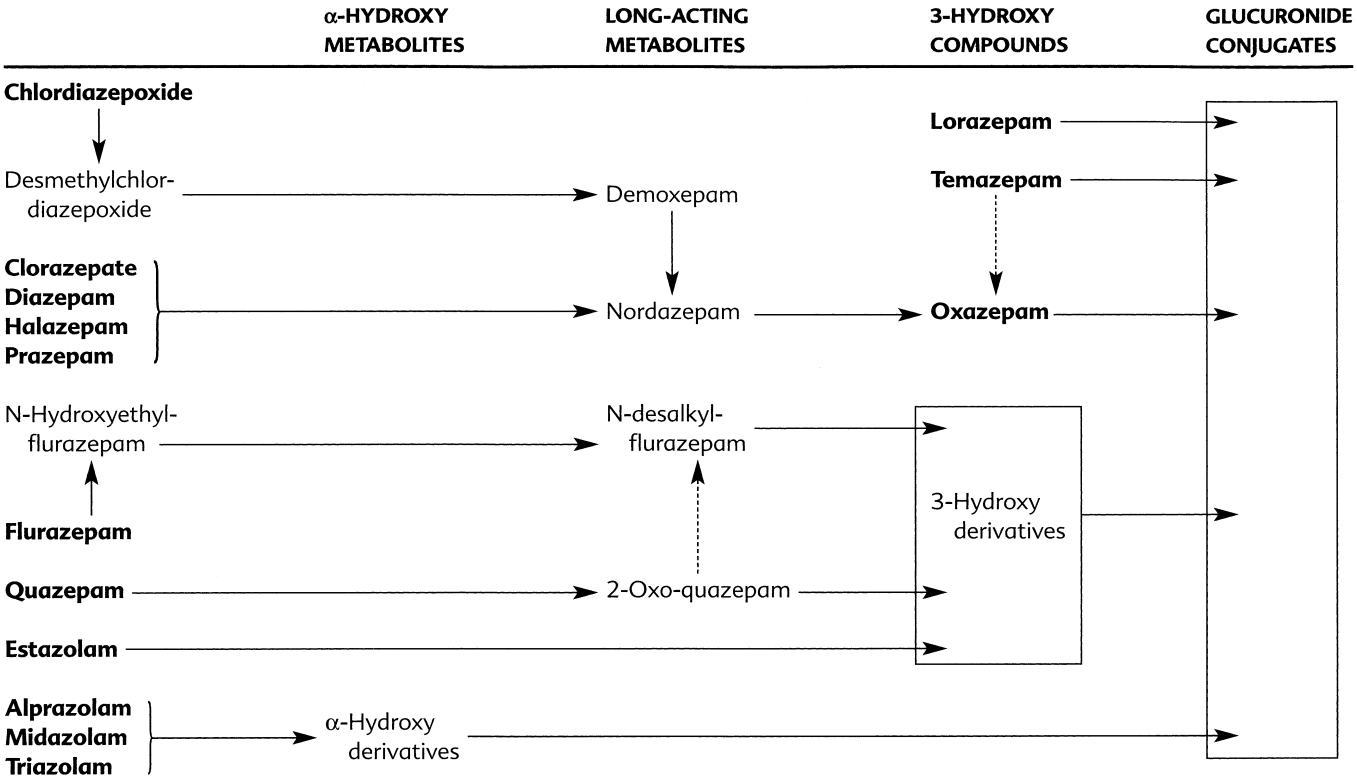

FIGURE **13-5** Metabolism of benzodiazepines. Drugs available for clinical use appear in **bold type**. With the exception of the prodrugs clorazepate and prazepam, only the glucuronide conjugates are inactive.

and feces. Because the half-lives of the different active metabolites vary considerably, the overall duration of the pharmacologic effect of benzodiazepines also varies considerably. Oxazepam and lorazepam are not converted to active metabolites but are directly conjugated and excreted. These drugs are eliminated rapidly and may be especially useful in patients who have a deficiency in hepatic microsomal enzymes resulting from liver disease or other reasons.

Alprazolam and triazolam, containing a fused triazolo ring, undergo α-hydroxylation on the methyl group of the ring. This reaction is mediated through hepatic CYP3A4 isoenzymes, and the subsequent conversion to the glucuronide

occurs rapidly in the case of triazolam and accounts for the short duration of action of the drug. Alprazolam and triazolam also undergo 4-hydroxylation of the benzodiazepine ring and then conjugation to the glucuronide. Midazolam, which contains a fused imidazo ring, is quickly metabolized in a similar manner. Midazolam has a rapid onset of action, a high metabolic clearance, a rapid rate of elimination, and a short duration of action. Termination of CNS activity is a result of peripheral redistribution and metabolic transformation. It is converted into several metabolites that have little pharmacologic activity; however, because of extensive first-pass metabolism, the α-hydroxy metabolite may contribute to the sedative effect when midazolam is given orally to children.

The poor oral bioavailability of triazolam, alprazolam, and midazolam of approximately 50% is believed to be due to CYP3A4 metabolism in the gut wall and hepatic first-pass metabolism. Triazolam's availability is improved when administered sublinqually.[32] Inhibition of CYP3A4 metabolism by coadministration of itraconazole, erythromycin, or grapefruit juice can significantly increase maximum blood concentrations and the area under the curves of these short-acting benzodiazepines.[27]

Many benzodiazepines are biotransformed to long-acting metabolites. These metabolites, which accumulate with repeated administration, are the cause of lingering residual effects. An active metabolite of flurazepam and quazepam, N-desalkylflurazepam, which accounts for some of the activity of quazepam and nearly all the activity of flurazepam, has an elimination half-life of 50 to 100 hours. In sleep laboratory studies, it has been shown that flurazepam does not reach full effectiveness until the second or third consecutive night of intake. Quazepam decreases sleep latency and facilitates sleep maintenance after a single dose.

Temazepam has a half-life of about 13 hours, and only a very small amount of oxazepam is formed as a metabolite; estazolam has a similar half-life and forms a short-lived active metabolite. Triazolam, with a mean half-life of 2.9 hours, is converted to metabolites that, although active, are rapidly eliminated. Because of their short durations of action, temazepam and triazolam do not generally accumulate even with repeated nightly use. Triazolam is indicated for patients who have difficulty falling asleep but who stay asleep when sleep ensues.

Adverse Effects and Drug Interactions

Drowsiness is the most common side effect of benzodiazepines. The drowsiness may not be an unwanted reaction, but rather a therapeutic benefit in anxiety states that cause insomnia. Other signs and symptoms of dose-dependent CNS depression include ataxia, incoordination, dysarthria, confusion, apathy, muscle weakness, dizziness, and somnolence. Elderly individuals (>65 years old) seem to be particularly susceptible and individuals with a history of alcohol or barbiturate abuse seem to be particularly resistant to the gross CNS depressant properties of benzodiazepines.

Elderly and young patients occasionally respond to benzodiazepines with excitement rather than depression. Excitatory CNS effects may include an increased incidence of nightmares, hyperactivity, insomnia, irritability, agitation, and rage and hostility. Because these responses differ from what would be expected of a CNS depressant, they have been termed *paradoxic reactions*. A paradoxic decrease in seizure threshold, particularly in patients with grand mal epilepsy, has also been observed, even though diazepam is used in acute treatment of status epilepticus. These unusual occurrences of what seems to be a CNS excitatory action may be a disinhibitory effect similar to that observed with alcohol.

Benzodiazepines cause changes in normal sleep patterns. Patients seem to adapt quickly to the nonspecific CNS depression of benzodiazepines. Nonetheless, daytime sedation after a nighttime dose, referred to as "hangover," is a common side effect, especially of long-acting benzodiazepines. This residual effect may be beneficial in some cases, but undesirable in others.

Adverse effects of benzodiazepines other than those referable to the CNS depressant actions are usually more irritating than life-threatening. Allergic reactions to benzodiazepines usually manifest as minor skin rashes. Because injectable formulations of diazepam contain propylene glycol and ethyl alcohol solvents, intramuscular and intravenous administration can cause local pain, phlebitis, and thrombosis. Phlebitis is more likely to occur if a vein in the hand or wrist is used and may be more common after repeated injections, especially in heavy smokers, elderly individuals, and women taking oral contraceptives. With the introduction of the water-soluble benzodiazepine midazolam, the occurrence of venous complications and pain at the injection site has diminished.

Tolerance and psychological dependence develop frequently with benzodiazepines, but true physical dependence is less common. Nevertheless, the abuse potential of benzodiazepines should not be ignored.[51] Tolerance to the sedative-hypnotic effects of benzodiazepines is slower to develop with longer acting agents. In cases of physical dependence, the severity of withdrawal depends on the dose of the drug being used and the drug's half-life. Rapid discontinuation of benzodiazepines, especially short-acting compounds, can lead to symptoms of withdrawal. Often these symptoms are nearly identical to the symptoms for which treatment was initiated, including anxiety, irritability, insomnia, and fatigue. The symptoms become more severe with high doses and prolonged treatment. Withdrawal can be minimized by reducing the dosage very gradually (≤10% per day over 10 to 14 days) or by the use of longer acting compounds. Withdrawal from lower doses is usually not life-threatening, and symptoms last no longer than 2 weeks. Withdrawal from high doses may be life-threatening because of accompanying convulsions.

Mechanisms involved in the development of tolerance are unknown, but the long-term administration of benzodiazepines to animals causes downregulation of benzodiazepine receptors,[40] which could be a contributing factor. Diazepam has been particularly popular as a drug of abuse. Because of the strong binding of diazepam to tissue constituents, it is not rapidly removed by dialysis or diuresis in patients with acute overdose. Flumazenil, a benzodiazepine antagonist (described later), can reverse benzodiazepine overdose. Flumazenil can precipitate withdrawal in benzodiazepine-dependent patients, however.

Some short-acting benzodiazepines are especially amnestic; triazolam also causes confusional states and delusions. Because of the prominence of these adverse CNS effects, the United States and several European countries have removed the 0.5 mg tablet form of triazolam from the market. The U.S. Food and Drug Administration (FDA) also approved labeling for triazolam that recommended use only for short-term (7 to 10 days) treatment of insomnia, emphasized the need to monitor patients for bizarre behavioral side effects, and set new limits on the maximum dosage. Triazolam is abused more frequently than either temazepam or flurazepam, probably because of its more rapid absorption.

Despite these problems, one of the major advantages of benzodiazepines compared with other sedatives is their high margin of safety. Death is rare in cases of overdose and is usually the result of a combination of drugs (especially alcohol) with benzodiazepines. The few deaths associated with the use of a benzodiazepine alone have primarily involved elderly patients, very young children, massive iatrogenic overdosing, or suicides.

Benzodiazepines cross the placental barrier. During the first trimester, long-term use of these drugs has been associated with increased fetal malformations, including cleft lip

TABLE **13-3**

Adverse Drug Interactions: Anxiolytics and Sedative-Hypnotics

ADVERSE DRUG INTERACTION (SPECIFIC EXAMPLES)	CLINICAL IMPLICATIONS
Anxiolytics and Sedative-Hypnotics with:	
Other anxiolytics and sedative-hypnotics, alcohol, opioids, antipsychotics, antidepressants, centrally acting muscle relaxants, local and general anesthetics, and other CNS depressants	In combination, CNS depression summates with anxiolytics and sedatives; loss of consciousness, respiratory depression, and death are possible complications
Benzodiazepines with:	
Carbamazepine, rifampin	Increased rate of metabolism reduces bioavailability of several benzodiazepines
Cimetidine, diltiazem, verapamil, erythromycin, clarithromycin, protease inhibitors (indinavir, nelfinavir, ritonavir), some azole antimycotics (itraconazole, ketoconazole), and some antidepressants (fluoxetine, fluvoxamine, trazodone)	Decreased rate of metabolism increases bioavailability of some benzodiazepines and significantly augments and prolongs their effects
Chloral Hydrate with:	
Alcohol	Each drug limits metabolism of the other; depression is greater than additive
Warfarin	Competition for plasma protein binding causes temporary increase in anticoagulant effect
Furosemide	Rare reports of diaphoresis, tachycardia, and hypertension
Epinephrine	Myocardial sensitization and cardiac dysrhythmias
Barbiturates with:	
Valproic acid and phenobarbital	Elimination of barbiturates is decreased; prolonged and enhanced sedation is reported
Warfarin	Bleeding risk increases when long-term barbiturate therapy is discontinued Anticoagulant effect of warfarin is reduced with concurrent therapy with phenobarbital

CNS, Central nervous system.

and cleft palate in humans. There is no clear estimate of the risk after single-dose use. All benzodiazepines are classified as pregnancy category D except triazolam, which is pregnancy category X. It is generally agreed that these drugs should be avoided during pregnancy.[43] The frequent use of benzodiazepines during late pregnancy may lead to withdrawal in the neonate. Large doses of benzodiazepines given to mothers during labor and delivery may result in respiratory depression, hypotonia, and hypothermia in neonates.

Drug interactions associated with anxiolytic and sedative drugs used in dentistry are listed in Table 13-3. The therapeutic index for benzodiazepines is normally so large that wide ranges of dosing recommendations and blood concentrations do not significantly affect their safety and efficacy. Plasma concentrations after a given dose may normally vary such that a minor shift in elimination from drug interactions is unlikely to result in an overdose. In healthy subjects taking no other medications, plasma concentrations 3 hours after a single 15 mg dose of diazepam have been reported to range from 20 μg/mL to 260 μg/mL.[38] A drug interaction that causes a 20% increase in diazepam plasma concentrations is unlikely to have significant toxicity. Most healthy patients can tolerate small variations in a drug's absorption or metabolism that are caused by coadministration of another drug. Combining sedatives is problematic. The combination of ethanol with a benzodiazepine is an important source of serious toxicity.[63]

Rifampin induces metabolic enzymes in the gut and liver responsible for the metabolism of diazepam, midazolam, and triazolam. A 96% reduction in the bioavailability of midazolam has been reported.[2] Triazolam is so rapidly and effectively metabolized in the gut that peak plasma concentrations are only 12% of normal.[68] This interaction is one of the most pronounced alterations in drug kinetics ever reported. The almost complete loss of triazolam bioavailability and subsequent efficacy is quite significant and warrants use of an alternative anxiolytic, such as oral oxazepam, nitrous oxide inhalation, or an intravenous agent. The anticonvulsant carbamazepine can also induce hepatic enzymes for the oxidative metabolism of benzodiazepines such as alprazolam, triazolam, and midazolam.[3] Decreased benzodiazepine plasma concentrations and greatly reduced sedative effects after oral administration of these agents may occur. This interaction may be important in medicine because of loss of seizure control. A loss of sedative efficacy in dentistry may also occur. Benzodiazepines that are metabolized solely through glucuronidation, such as oxazepam, are suitable alternative agents for sedation in these situations.

The Ca^{++} channel blockers verapamil and diltiazem have been shown to inhibit the CYP3A isozymes required for the metabolism of triazolam and midazolam. In controlled clinical trials, a 2-day regimen of these drugs decreased the metabolism and increased the bioavailability of midazolam and triazolam administered orally. Peak blood concentrations were increased twofold to threefold and were associated with increased sedation and performance deficits.[1] Avoidance of this combination is recommended, particularly in elderly patients known to be sensitive to benzodiazepines.

Cimetidine also inhibits the oxidative metabolism of certain benzodiazepines, such as triazolam and alprazolam. Half-life increases of 30% to 63% have been reported.[18] Metabolism of diazepam may also be delayed. An increased and prolonged level of sedation after oral administration may occur because of the decreased first-pass metabolism.[52] Benzodiazepines that are metabolized directly to the glucuronide

conjugate (e.g., oxazepam) are not affected. Similarly, the antimicrobials erythromycin and clarithromycin and the azole antifungals ketoconazole and itraconazole are potential inhibitors of the hepatic isozymes required for oxidative metabolism of these benzodiazepines. By decreasing the first-pass effect and improving bioavailability, triazolam blood concentrations may increase threefold.[67] The antiviral agents indinavir, nelfinavir, and ritonavir inhibit hepatic oxidative enzymes required for metabolism of many benzodiazepines. These significant pharmacokinetic drug interactions could potentially cause oversedation and respiratory depression.

Antagonists

Benzodiazepine antagonists are important therapeutic compounds that have the potential to reverse the effects of benzodiazepines. They have no intrinsic activity of their own but do not reverse constitutive benzodiazepine receptor activity. Flumazenil (Figure 13-6) is currently the only benzodiazepine receptor antagonist approved by the FDA.

Flumazenil has clinical application in managing benzodiazepine overdose and in hastening recovery from benzodiazepine sedation or anesthesia after diagnostic procedures or minor surgery. Although certain precautions must be observed, flumazenil may allow for a shorter monitoring period after surgery and earlier discharge of the patient.[20] Flumazenil has been used successfully in reversing benzodiazepine-induced coma, but whether it should be given routinely to comatose patients when the cause of the coma is unknown is unclear. The routine use of flumazenil is not recommended in cases of mixed drug overdose, airway obstruction, or seizure disorders. Flumazenil may increase the risk of cardiac arrhythmias and seizures in patients who have overdosed with tricyclic antidepressants.[22] Ventricular arrhythmias have also been precipitated by flumazenil in patients with chloral hydrate overdose.[55]

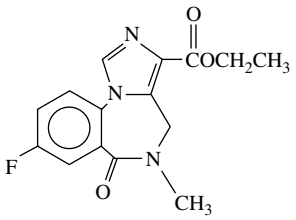

FIGURE **13-6** Structural formula of flumazenil.

Flumazenil administered intravenously can generally reverse benzodiazepine-induced sedation in 1 to 2 minutes. Reversal of benzodiazepine sedation by flumazenil may last for several hours. In a study in which patients were sedated with midazolam before dental extraction, flumazenil significantly improved patient assessment regarding state of alertness compared with placebo controls (Figure 13-7) only for the first 30 minutes.[8] The duration of action of flumazenil (elimination half-life of 45 to 75 minutes) is likely to be shorter than that of a benzodiazepine agonist. Other studies have also noted that the duration of action of flumazenil is shorter than that of midazolam and that sedation and respiratory depression may recur.[20] Flumazenil is not a substitute for careful postoperative monitoring.

Another cautionary note is the possibility of flumazenil precipitating withdrawal in patients who are dependent on the benzodiazepines. Signs of benzodiazepine withdrawal include flushes, agitation, tremor, and seizures. Resedation with a benzodiazepine or barbiturate may be required in these circumstances. Although some studies suggest the amnesia from benzodiazepines is reversed by flumazenil, this is not consistently observed.[9]

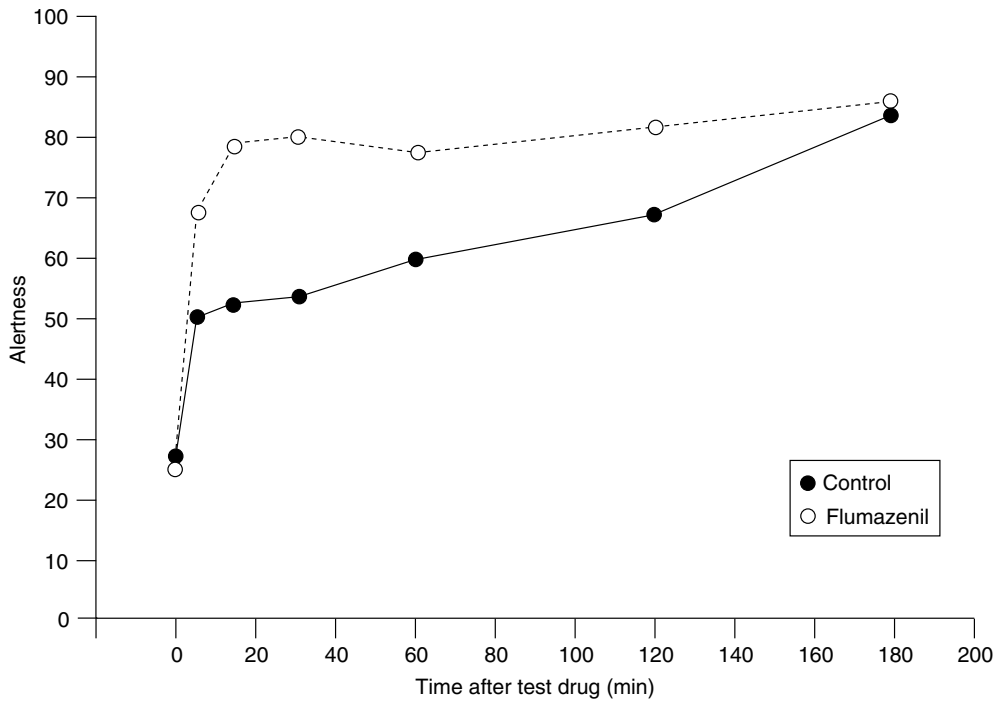

FIGURE **13-7** Reversal of midazolam sedation by flumazenil in patients undergoing a surgical dental extraction. Flumazenil or placebo was administered after intravenous midazolam and dental extraction. Differences between flumazenil and control groups were significant at the $P < .05$ level for the 5-, 15-, and 30-minute time periods. The *dashed line* represents the flumazenil group; the *solid line* represents the midazolam alone. (Adapted from Clark MS, Lindenmuth JE, Jafek BW, et al: Reversal of central benzodiazepine effects by intravenous flumazenil, *Anesth Prog* 38:12-16, 1991.)

General Therapeutic Uses

Not everyone requires pharmacotherapy for anxiety, fear, and apprehension; anxious states are often brought on by a series of events that eventually pass, allowing the anxiety to subside. Pharmacotherapy is indicated only when anxiety becomes chronic, or when it interferes with the individual's functioning. Benzodiazepines and other antianxiety agents are not curative; they merely treat the symptoms of anxiety. The patient then copes more effectively with the situation or responds more favorably to psychotherapy or other pharmacotherapy.

Approximately 35% of patients with a generalized anxiety disorder show marked improvement with benzodiazepines, 40% are moderately improved, and 25% remain unresponsive.[15] These antianxiety agents are useful in the treatment of acute anxiety resulting from transient stress that is environmental, physical, or psychological in origin. For the treatment of long-standing anxiety, benzodiazepines ideally should be used only with appropriate psychotherapy. Sometimes benzodiazepines are prescribed inappropriately and with too little supervision. Despite concerns about the abuse potential of benzodiazepines, patients who have no prior history of drug abuse are unlikely to be at risk. Table 13-4 lists benzodiazepines and other drugs used for the management of acute anxiety.

Although capable of selectively relieving anxiety, benzodiazepines are also CNS depressants capable of producing sedation and hypnosis. Some benzodiazepines—flurazepam, temazepam, triazolam, estazolam, and quazepam—are promoted specifically as hypnotics rather than as antianxiety agents. Whether a benzodiazepine is used primarily as an antianxiety agent or a hypnotic depends on a subtle interplay of the drug's pharmacodynamic properties, its pharmacokinetic characteristics, and the drug formulation.

During natural sleep, humans cycle through several stages of sleep ranging from the deepest stage, categorized as stage IV, to the most active form, known as rapid eye movement (REM) sleep. Benzodiazepines used as hypnotics increase stage II sleep at the expense of stages I, III, and IV and REM sleep. The significance of these changes is unknown, but a goal of the pharmacotherapy of insomnia is to achieve a normal sleep pattern. Sedative-hypnotic benzodiazepines may have an advantage over barbiturates with regard to REM sleep. Low doses of temazepam and flurazepam may leave REM sleep unaffected, and triazolam has such a short duration of effect that an early loss of REM cycles may be made up later in the same sleep period. Slow-wave sleep (as in stage IV) is now recognized as the most important restorative phase of sleep, and benzodiazepine suppression of slow-wave sleep may be equally problematic with long-term administration as the effects of barbiturates on REM sleep.

Because hypnotics are most commonly used for the treatment of patients who have difficulty falling asleep, rapid absorption is essential. Most hypnotic benzodiazepines are rapidly absorbed after oral administration, and various dosage forms have been formulated to hasten absorption.

Discontinuation of a benzodiazepine after long-term administration can lead to a pronounced withdrawal phenomenon and rebound insomnia in which the duration of sleep is reduced, and its quality is affected.[54] Because this temporary effect can cause patients to assume that the drug is still needed for satisfactory sleep, they should be made aware of the possibility of rebound insomnia if therapy is abruptly terminated. Rebound insomnia need not be an automatic consequence of drug abstinence. Withdrawal symptoms and rebound insomnia can be minimized with longer acting benzodiazepines because of the gradual decline of their active metabolites over time.[31]

TABLE 13-4

Preparations for Treatment of Anxiety

DRUG	USUAL DOSE* (mg)	ROUTE OF ADMINISTRATION
Alprazolam	0.75-4.0 (adult)	Oral
	0.5-0.75 (elderly)	Oral
Clorazepate	15-60 (adult)	Oral
	7.5-15 (elderly)	Oral
Chlordiazepoxide	15-100 (adult)	Oral
	50-100 (adult)	IM, IV
	10-20 (elderly)	Oral
Diazepam	4-40 (adult)	Oral
	2-20 (adult)	IM, IV
	2-5 (elderly)	Oral
	0.3-0.6 mg/kg (children)	Oral
Halazepam	60-160 (adult)	Oral
	20-40 (elderly)	Oral
Lorazepam	1.5-10 (adult)	Oral
	1-2 (elderly)	Oral
	2-4 (adult)	IM, IV
Midazolam	2-10 (adult)	IM, IV
	0.25-1 mg/kg up to 20 mg (children)	Oral
Oxazepam	30-120 (adult)	Oral
	30-60 (elderly)	Oral
Prazepam	20-60 (adult)	Oral
	10-15 (elderly)	Oral
Triazolam	0.25-0.5 (adult)	Oral
	0.125 (elderly)	Oral
Hydroxyzine (hydrochloride and pamoate salts)†	200-600 (adult)	Oral
	25-100 (adult)	IM
	0.5-0.7 mg/kg (children)	Oral
	12.5-50 (children >6 yr)	Oral
	0.6-1.1 mg/kg (children)	IM
Meprobamate	1200-2400 (adult)	Oral
	100-200 (children 6-12 yr)	Oral

*Oral adult and elderly doses represent daily amounts given in divided doses (except triazolam). Parenteral, children, and triazolam doses reflect single administration.

†The pamoate salt is reported to be converted to the hydrochloride salt in the stomach, with a resultant prolonged effect, but there is no experimental evidence to support this claim.

IM, Intramuscular; *IV,* intravenous.

In addition to relief of anxiety and insomnia, benzodiazepines are useful for many other conditions. They are generally accepted as major drugs for the treatment of alcohol withdrawal. Clonazepam has been approved as an anticonvulsant for several types of epilepsy, and diazepam, midazolam, and lorazepam are major drugs for the control of status epilepticus (see Chapter 14). Intravenous diazepam and midazolam are also used to control seizures caused by local anesthetics. The skeletal muscle relaxant properties of diazepam have led to its successful use in the treatment of tetanus and for the relief of the spasticity associated with cerebral palsy. Diazepam has been used as an adjunct in general anesthesia, but midazolam is now more popular (see Chapter 18). Benzodiazepines (especially alprazolam) are useful in the

treatment of depression because of their rapid onset, their antianxiety properties (which are often desirable in depression), and their low potential for lethal overdose. Generally, the benzodiazepines are more useful for reactive or neurotic depression, in which anxiety and insomnia are major components, than for severe depression.

BENZODIAZEPINE-LIKE SEDATIVE-HYPNOTICS

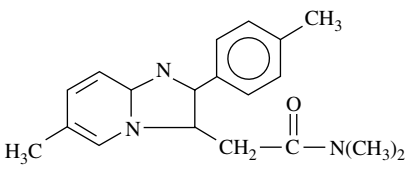
The drugs belonging to the classification of benzodiazepine-like sedative-hypnotics—zolpidem, zaleplon, zopiclone, and eszopiclone—are chemically unrelated to the benzodiazepines, but share a similar pharmacology. These drugs are selective GABA receptor agonists at the α_1-subunit of the Cl^- channel (BZ_1 receptor). This selectivity may dictate why they produce sedation but less memory and cognitive impairment than benzodiazepines and exert little skeletal muscle relaxation or anticonvulsant activity.[71] Biotransformation is by several CYP enzymes in addition to CYP3A4. CYP3A4 inhibitors and inducers have less impact on the clinical effectiveness of this drug class. The drugs are particularly interesting because they establish that the benzodiazepine structure is not an absolute requirement for a compound to act as a benzodiazepine receptor agonist.

Zopiclone and eszopiclone, marketed in Europe and the United States, are newer entries into the rapidly expanding sleep-aid market. Eszopiclone, the S conformation of zopiclone, is similar in its pharmacology to zopiclone. They are rapidly absorbed after oral administration. Their half-lives of approximately 6 hours likely accounts for their ability to improve sleep latency and sleep maintenance. Eszopiclone has been approved in the United States for administration for 6 months for the treatment of insomnia. The drugs undergo extensive metabolism in the liver. Adverse effects of eszopiclone include altered taste and dry mouth.

Zolpidem is a novel short-acting hypnotic having an imidazopyridine structure (Figure 13-8). Zaleplon is a pharmacologically similar drug that belongs to the pyrazolopyridine class of compounds. It has little effect on REM sleep and seems to induce a physiologic pattern of slow-wave sleep. Rebound insomnia at recommended doses, if it occurs, is mild.

Zolpidem and zaleplon have the advantage of being very rapidly absorbed after oral administration, with clinically demonstrable effects occurring in 15 to 20 minutes. Zolpidem has a half-life of approximately 2.5 hours and is metabolized in the liver to inactive metabolites. Zaleplon is similar except its half-life is about 1 hour, and zopiclone and eszopiclone have half-lives of 3.5 to 6.5 hours. Adverse effects include dizziness, drowsiness, and gastrointestinal symptoms.

Increases in hepatic enzymes in the plasma suggest that these drugs may be unsuitable for patients with liver disease. Zolpidem is a sedative-hypnotic of choice for pregnant women (FDA pregnancy category B), whereas zaleplon, zopiclone, and eszopiclone are pregnancy category C. Also in contrast to benzodiazepines, zolpidem, zaleplon, and eszopiclone are not contraindicated in patients with a history of narrow-angle glaucoma. Because of their similarities with benzodiazepines, zolpidem and zaleplon show utility as enteral sedation agents for dentistry. Zaleplon has compared favorably with triazolam as a sedative during oral surgery.[21] Flumazenil effectively reverses the CNS depression produced by the selective BZ_1 receptor agonists. These properties collectively help explain why these two drugs are now the most commonly prescribed sedative-hypnotics in the United States.



Zolpidem

FIGURE **13-8** Structural formula of zolpidem.

MELATONIN RECEPTOR AGONISTS

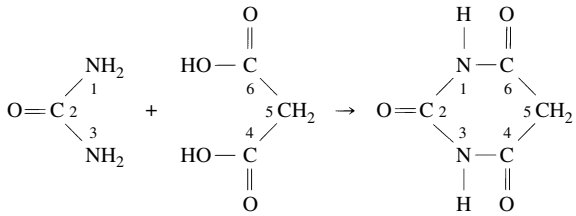
Melatonin is naturally secreted by the pineal gland at night according to the light/dark cycle and plays a major role in the maintenance of circadian rhythms and in the regulation of the sleep/wake cycle. Activation of the MT_1 and MT_2 melatonin receptors promotes sleep, regulates reproduction and immunoresponsiveness, and inhibits aging and cancer growth. Agomelatine and ramelteon are melatonin receptor agonists with clinical promise. Ramelteon is the first melatonin receptor agonist approved by the FDA for the treatment of insomnia. It has no appreciable affinity for the GABA receptor complex, and has no anterograde amnestic qualities and cannot be reversed by flumazenil.

Clinical uses for ramelteon include treatment of jet lag, treatment of insomnia, treatment of sleep disturbances associated with depression, tapering of patients from hypnotics (i.e., long-term benzodiazepine use), cancer treatment, and preoperative sedation or anxiolysis. Regarding preoperative sedation or anxiolysis, further comparative evaluation of ramelteon with benzodiazepines is warranted for its potential as a pretreatment anxiolytic before anesthesia or as a sole therapeutic sedative agent. Ramelteon is metabolized by various CYP enzymes and is susceptible to drug interactions involving inhibition or activation of these enzymes. Inhibitory agents such as fluvoxamine, fluconazole, and ketoconazole may increase the risk of ramelteon-related side effects. Conversely, rifampin may decrease the bioavailability of ramelteon, leading to lack of efficacy.

BARBITURATES

Chemistry and Structure-Activity Relationships

The basic chemical structure of all barbiturates is barbiturate acid (Figure 13-9). Barbituric acid, formed by the condensation of urea and malonic acid, lacks CNS depressant activity. To obtain barbiturates that have CNS depressant properties, both hydrogens at C_5 must be replaced by organic groups. Depending on the substituents added, three types of barbiturates are formed (Table 13-5). In the first group, substitutions are made only at C_5, yielding a large variety of drugs. The addition of a phenyl group at C_5 results in a drug with antiepileptic activity. If the side chain on C_5 reaches eight carbon atoms, the drug becomes more toxic and assumes convulsant properties. When alkyl groups are substituted at N_3, the

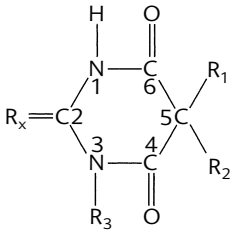


Urea **Malonic acid** **Barbituric acid**

FIGURE **13-9** Chemical formulation of barbituric acid.

TABLE **13-5**

General Barbiturate Ring Structure with Examples of Chemical Formulas of the Three Types of Barbiturates



GENERIC NAME	TYPE	R_1	R_2	R_3	R_X
Pentobarbital	Oxybarbiturate	Ethyl	1-Methylbutyl	H	O
Mephobarbital	N-alkylbarbiturate	Ethyl	Phenyl	CH_3	O
Thiopental	Thiobarbiturate	Ethyl	1-Methylbutyl	H	S

N-alkylbarbiturates are formed. The only N-alkylbarbiturates used clinically are the N-methyl derivatives (mephobarbital and methohexital).

A third class of barbiturates is formed when the oxygen at C_2 of the barbiturate nucleus is replaced with a sulfur atom. Technically, sulfur-substituted drugs are not true barbiturates because, by definition, barbiturates require oxygen at C_2. Sulfur-substituted barbiturates are commonly referred to as thiobarbiturates, whereas true barbiturates are sometimes called oxybarbiturates. Thiopental and thiamylal are examples of thiobarbiturates.

The clinical properties of barbiturates vary considerably depending on the lipid/aqueous partition coefficient. As lipid solubility of the barbiturate increases, hypnotic activity increases, the onset time decreases, and the duration of action decreases. With their extreme lipid solubility, thiopental and thiamylal have an extremely short duration of action and are sometimes used as intravenous anesthetics (see Chapters 18 and 48).

Mechanism of Action

The mechanism by which the barbiturates exert their CNS depressant effect is not completely established, but many pharmacologic effects bear striking similarities to the effects of benzodiazepines. Barbiturates enhance GABA binding and increase the duration of GABA-activated Cl^- channel opening by acting at specific barbiturate binding sites on the $GABA_A$ receptor complex (see Figure 13-3), leading to hyperpolarization and decreased neuronal firing.[37,54] Barbiturates modulate GABA receptor function to prolong presynaptic and postsynaptic inhibition. Although benzodiazepines increase the frequency (as opposed to increasing the duration) of Cl^- channel opening, the end result (increased inhibition) is similar for the two groups of compounds. Their similar therapeutic and pharmacologic properties are not surprising. At high concentrations, barbiturates also act directly on the Cl^- channel, not requiring the presence of GABA. A third action of barbiturates is inhibition of a specific subset of glutamate receptors. These latter two actions are not shared by benzodiazepines and may help explain the lower margin of safety and steeper dose-response relationship for barbiturates compared with benzodiazepines.

Pharmacologic Effects

The primary pharmacologic effects of barbiturates involve the brain and spinal cord, the cardiovascular system, and the respiratory system.

Central nervous system

As with all sedative-hypnotics, barbiturates depress the CNS to varying degrees, ranging from mild sedation to respiratory arrest and death. Many factors contribute to the level of depression attained, including the specific drug, dose, and route of administration; the patient's initial behavioral state; and the environmental surroundings at the time of administration. It has long been known that the physical environment and the psychological state of the patient influence the effectiveness of sedatives and hypnotics. A barbiturate taken at home before retiring for the evening is more likely to produce the desired sedative or hypnotic effect than the same drug taken at a rock concert.

The behavioral effects of barbiturates indicative of general CNS depression include diminished psychological performance and responsiveness to external stimuli. Subjectively, the patient experiences relaxation, a feeling of well-being, and drowsiness. Coincident with these subjective feelings, the electroencephalogram displays an increase in fast activity (25 Hz to 35 Hz) referred to as *barbiturate activation*. As the dose increases and the patient goes to sleep, an increase in high-amplitude slow waves (2 Hz to 8 Hz) similar to those observed during natural sleep occurs. These high-amplitude slow waves frequently occur in bursts termed *spindles*. Occasional periods of electrical silence occur as toxic doses are approached.

The electroencephalogram patterns recorded after the administration of barbiturates are similar to the patterns observed during natural sleep, but there are important differences. Barbiturates decrease the time spent in REM sleep. REM sleep is the period in which vivid dreaming occurs; it is also believed to be involved in the consolidation of learning. A person deprived of REM sleep "makes up" the loss by increasing the time spent in REM sleep at a subsequent time. A typical pattern would be an increase in the frequency and duration of REM sleep subsequent to the cessation of barbiturate therapy, leading to "restless sleep." The individual may find it difficult to have a good night's sleep for several nights without readministration of a sedative-hypnotic. A vicious cycle may be started. With the exception of moderate doses of certain benzodiazepine receptor agonists, all sedative-hypnotics significantly reduce REM sleep.

Although the barbiturates seem to depress all levels of the CNS, the reticular formation—a complex network of neurons, nuclei, and neural pathways that extends throughout the brainstem—is particularly sensitive to the depressant action of some barbiturates. The reticular formation and its rostral

thalamocortical projections are referred to collectively as the ascending reticular activating system. The importance of the ascending reticular activating system in the modulation of sleep and wakefulness has long been known. Stimulation of appropriate areas of the reticular formation in a sleeping animal causes behavioral arousal and converts the electroencephalogram from a characteristic sleep pattern to that of an awake animal. If the appropriate area of the ascending reticular activating system is experimentally destroyed, the electroencephalogram pattern becomes that of a drowsy or sleeping animal.

Cardiovascular system

At sedative doses, barbiturates do not affect the cardiovascular system. At hypnotic doses, they produce mild hypotension and a decrease in heart rate. Progressive depression of the cardiovascular system develops as the dose of barbiturates is increased beyond the hypnotic range.

Respiratory system

Sedative doses of barbiturates have little effect on respiration, but as doses are increased, the barbiturates become progressive respiratory depressants. Medullary respiratory centers are depressed by toxic concentrations of barbiturates, and eventually even the carotid arch and aortic body receptors are depressed. These depressant effects are most apparent with multiple drug regimens used for intravenous sedation and anesthesia.[12,42] Barbiturates increase respiratory reflex activity, such as cough, hiccough, sneezes, and laryngospasm, which complicates their use in anesthesia.

Absorption, Fate, and Excretion

Barbiturates are generally available as Na^+ salts, which are completely absorbed from the gastrointestinal tract and distributed to nearly all tissues of the body. One of the most important factors determining barbiturate distribution to the brain is lipid solubility. Thiopental, which is highly lipid-soluble, readily crosses the blood-brain barrier and, when administered intravenously, attains high concentrations in the CNS in seconds. The high blood flow to the brain also contributes significantly to the entry of thiopental. The placental barrier is equally permeable to the barbiturates, and severe respiratory depression can occur in the fetus if a barbiturate is used during delivery.

Barbiturates such as phenobarbital that are relatively lipid-insoluble penetrate the blood-brain barrier slowly. Phenobarbital, even if it is administered intravenously, may require 15 minutes to produce maximal CNS depression. With oral administration of phenobarbital, sedative effects begin after approximately 1 hour.

Phenobarbital is metabolized by the liver, but 25% to 50% is eliminated unchanged in the urine. Most other barbiturates are transformed completely by the liver to inactive metabolites, which are excreted by the kidney. The primary mechanism by which the CNS effects of the barbiturates are terminated after a single administration is redistribution from the brain to muscle and other body tissues. Subsequent storage of barbiturates occurs primarily in body fat. From this depot, the drugs are slowly released, metabolized, and excreted; this slow turnover of drug accounts for the prolonged depressant effect, or hangover, after general anesthesia with thiopental and after sedation with pentobarbital or phenobarbital. On repeated administration, redistribution becomes increasingly less important, and eventually the duration of effect is determined by the elimination half-life.

Long-term use of barbiturates causes an increase in liver microsomal enzyme activity that results from increased synthesis of enzyme. Increased enzyme activity facilitates the rate of metabolism of many drugs, including the barbiturates themselves, and gives rise to numerous drug interactions (see Table 13-3).

TABLE **13-6**

Classification of Barbiturates According to Duration of Action

	ONSET OF EFFECT	DURATION OF EFFECT
Long-acting: phenobarbital	1-3 hr*	10 hr
Short-acting to intermediate-acting: pentobarbital, secobarbital	30-60 min*	3-8 hr
Ultrashort-acting: thiopental	Immediate†	15-30 min‡

*Oral administration.
†Intravenous administration.
‡After single intravenous dose.

The duration of action of barbiturates serves as a useful criterion for classification, as illustrated in Table 13-6. As mentioned previously, the onset and duration of action of barbiturates are inversely related to the agents' respective lipid solubilities.

Adverse Effects and Drug Interactions

The principal toxic reactions associated with the use of the barbiturates result from their effects on the CNS (particularly when combined with other CNS depressants), their abuse potential (see Chapter 51), and their ability to induce hepatic microsomal enzymes. Because barbiturates are CNS depressants, at high doses they can depress respiration and should not be administered to patients whose respiration is already compromised. Additionally, intravenously administered anesthetic barbiturates increase the incidence of respiratory complications such as laryngospasm, coughing, sneezing, and hiccough. Confusion, somnolence, and impaired psychomotor performance are other possible undesired consequences of CNS depression. As is the case with benzodiazepines, many unusual behavioral reactions have been attributed to the barbiturates. Such reactions include attitudinal depression, agitated toxic psychosis, manic behavior, increased anxiety, hostility, and rage. Careful evaluation reveals that the incidence of these paradoxic responses is very small. In many cases, the response may be predictable if the patient has a history of poor impulse control or aggressive and destructive behavior.

Combining two or more CNS depressant drugs is known to produce increased levels of CNS depression. This summation reaction is the basis for some useful drug combinations in dental therapeutics, such as multidrug intravenous sedation in adults and oral sedation in children.[12,45,46,59] Nevertheless, the risk for adverse effects increases as more CNS depressants are used together. The popularity of "balanced anesthesia" used for general anesthesia is based on the appreciation that CNS depressants have additive effects, and premedication with an opioid such as morphine and the addition of nitrous oxide permit a significant reduction in the concentration of the primary anesthetic gas required for surgical procedures. The use of combinations of CNS drugs also increases the risk of unexpected oversedation and respiratory depression, particularly if opioids are included in the regimen.[12,45]

Because of the possible severe consequences that may occur with the combination of CNS depressants, dentists routinely inform patients to restrict alcohol consumption after general anesthesia or sedation. This drug interaction has been shown in healthy young adults after general anesthesia

with thiopental.[34] When 0.7 g/kg of alcohol was administered to these subjects 4 hours after thiopental administration, performance on psychomotor tests was impaired more than when alcohol alone had been used. This summation reaction has also been demonstrated for oral diazepam[35] and sedative antihistamines such as diphenhydramine and promethazine. Alcohol consumption after sedation therapy can cause severe drowsiness and significantly impair psychomotor performance, including driving skills, and must be restricted.

Some medically compromised patients may have reduced activities of drug-metabolizing enzymes because of hepatic disease, age (very young and very old), or genetic factors, and an exaggerated depressant response to a given regimen of sedative-hypnotics may be anticipated. Some drugs, such as valproic acid, reduce the hepatic clearance of the barbiturates, leading to an enhanced response (see Table 13-3). Numerous drug interactions with the barbiturates arise from the ability of these agents to induce hepatic microsomal enzyme activity. Because the dentist administers sedative-hypnotics to patients as single doses or for short regimens, this reaction should not be a problem unless the patient is taking the drugs long-term. If hepatic microsomal enzyme activity has been elevated, the effectiveness of warfarin and other drugs metabolized by this enzyme system is decreased. Many potentially dangerous drug interactions may be prevented simply by obtaining an accurate medical history, keeping a continuous record of drugs (prescribed and self-administered) taken by the patient, and consulting with the patient's physician when the patient's clinical status or drug history is uncertain.[42]

Barbiturates augment porphyrin synthesis and are strictly contraindicated in patients with acute intermittent porphyria, hereditary coproporphyria, or porphyria variegata. Barbiturates increase the concentration of δ-aminolevulinic acid synthase, the initial enzyme in the synthesis of porphyrin rings found in hemoglobin and other proteins. Because these forms of porphyria are caused by defective enzymes involved in heme synthesis, blockade of the synthetic pathway downstream from δ-aminolevulinic acid causes porphyrin precursors to build up, leading to an acute exacerbation of the disease.

General Therapeutic Uses

The indications for barbiturates reflect their durations of action and selective effects of some drugs. The long-acting agent phenobarbital is used to manage tonic-clonic seizures and other types of convulsive disorders. Short-acting to intermediate-acting drugs can be prescribed for sedative-hypnotic purposes, although they are much less commonly used since the advent of the benzodiazepines. Short-acting and ultrashort-acting barbiturates are administered as intravenous sedatives and anesthetics, although their use has declined particularly because of the increased use of propofol (see Chapter 18).

CHLORAL HYDRATE AND OTHER SEDATIVE-HYPNOTICS

Various drugs of diverse chemical structure, including chloral hydrate, paraldehyde, ethchlorvynol, glutethimide, and methyprylon, have sedative-hypnotic properties. Except for chloral hydrate, these agents have few clinical indications in dentistry.

Pharmacologic Effects

Chloral hydrate, one of the oldest nonbarbiturate sedative-hypnotics, continues to have dental applications. It is available in a liquid preparation that is convenient for the sedation of uncooperative children. Chloral hydrate is a commonly used sedative in children for painless technical procedures such as diagnostic imaging. Similarly, chloral hydrate is a popular sedative-hypnotic in pediatric dentistry. Although its overall safety record is considered acceptable, the therapeutic index of the drug is actually very small. In addition, severe laryngospasm with cardiorespiratory arrest after aspiration of orally administered chloral hydrate in liquid form has been reported.[24]

FIGURE **13-10** Structural formulas of chloral hydrate and its active metabolite trichloroethanol.

Chloral hydrate is commonly used in combination with other drugs, such as nitrous oxide, hydroxyzine, and promethazine. These agents are useful in augmenting the sedative effect of chloral hydrate and, in the case of promethazine, in relieving the nausea and vomiting produced by chloral hydrate.[28] Because of the drug's low therapeutic index, it is imperative that dose calculations be based on weight when it is used for pediatric sedation.[44] Chloral hydrate has minimal effects on REM sleep, although depression may occur with higher doses. The drug has been successfully used for the treatment of alcohol withdrawal, but benzodiazepines are now preferred.

Absorption, Fate, and Excretion

Chloral hydrate is well absorbed after oral or rectal administration and is rapidly converted by the liver to trichloroethanol, which is responsible for the CNS depressant properties of the parent compound (Figure 13-10). Plasma concentrations of chloral hydrate are nearly undetectable after administration. Trichloroethanol is conjugated with glucuronic acid and excreted in the urine. Trichloroethanol has a half-life of 4 to 12 hours. A portion of chloral hydrate and trichloroethanol is metabolized to dichloroacetic acid and trichloroacetic acid. With long-term administration, chloral hydrate can induce liver enzyme activity and compete for plasma protein binding sites, giving rise to several drug interactions (see later).[42]

Adverse Effects and Drug Interactions

Chloral hydrate has only minor cardiovascular effects in conventional doses. As the dose is increased beyond the therapeutic range, however, cardiovascular depression may occur. Chloral hydrate can precipitate cardiac arrhythmias in the sensitized heart and in the apparently healthy heart, and it may have been responsible for the reported death of a patient undergoing third molar extractions.[30] Chloral hydrate and trichloroethanol have chemical structures (see Figure 13-10) that resemble halothane, an anesthetic known to sensitize the myocardium to adrenergic amines. Trichloroacetic acid may also be cardiotoxic. The respiratory effects of sedative doses of chloral hydrate and the other nonbarbiturates are minimal, but become more severe as the dose is increased.

Chloral hydrate has been implicated in various drug interactions (see Table 13-3). As one might expect, chloral hydrate produces increased CNS depression when administered with other sedatives. The therapeutic advantage of this drug interaction is that it allows practitioners to decrease the dose of both CNS depressants and limit the side effects of the individual drugs. The reduced dosage requirement for chloral hydrate when combined with the sedative antiemetic promethazine has been shown to decrease appreciably the incidence of nausea and vomiting.[28] Similarly, the use of nitrous oxide in combination with chloral hydrate deepens the level of sedation. This therapeutic advantage may be lost when

nitrous oxide is used in combination with higher doses of chloral hydrate because the CNS depression may be increased to such an extent that the child's protective reflexes become compromised.[46]

Beyond the expected summation of CNS depressant effects, the combination of chloral hydrate with alcohol is thought to produce a potentiation drug interaction through an alteration of alcohol metabolism. Chloral hydrate and its primary metabolite, trichloroethanol, competitively inhibit alcohol-metabolizing dehydrogenases, elevating alcohol blood concentrations (see Table 13-3). This combination, known as a "Mickey Finn" or "knock-out drops," can induce severe alcohol intoxication with stupor, coma, or death. The interaction is significant because it induces greater than additive effects and may result in a potentially life-threatening CNS depression. The dental indications for chloral hydrate are almost exclusively in pediatric sedation, and alcohol is usually not a concomitantly administered drug.

Chloral hydrate has been implicated in modifying responses to the oral anticoagulants dicumarol and warfarin. Another metabolite of chloral hydrate, trichloroacetic acid, may increase free warfarin plasma concentrations by interfering with its protein binding (normally 98% to 99%). The possible result is a transient and usually small hypoprothrombinemia. Although caution is indicated, these interactions may be clinically insignificant, particularly with single-dose therapy of chloral hydrate.[42,66] Sedation with benzodiazepine regimens is a recommended alternative.

An unusual interaction characterized by transient diaphoresis, hot flashes, variable blood pressure, and tachycardia has been reported with chloral hydrate and the diuretic furosemide (see Table 13-3).[48] The mechanism is not well understood, but may relate to enhanced sensitivity to a chloral hydrate metabolite. Although rarely reported, this is a moderately severe reaction and can occur when furosemide is administered within a day of chloral hydrate.

Chloral hydrate and trichloroethanol can be detected in breast milk within 15 minutes and for 24 hours after administration. Peak concentrations in breast milk are sufficient to sedate the breastfeeding infant. A potential caution concerning the widespread use of chloral hydrate in infants and children is that chloral hydrate, trichloroethanol, and trichloroacetic acid all are metabolites of trichloroethylene,[57] an industrial solvent, environmental contaminant, and carcinogen. Chloral hydrate is also a mutagen and can cause chromosomal damage. Although no indication of human mutagenic or carcinogenic toxicity has been found with therapeutic uses of chloral hydrate, these concerns have decreased the popularity of chloral hydrate for use in pediatric dentistry.

ANTIHISTAMINES

A common side effect of the first-generation H_1 antihistamines is drowsiness and sedation. This response is caused by antagonism of histamine neurotransmitter receptors within the CNS. Antihistamines such as hydroxyzine, a piperazine derivative, and promethazine, a phenothiazine derivative, have proved to be useful adjuncts in sedation regimens (see Chapter 48). Part of their popularity relates to their ability to augment the sedative effects of other sedative-hypnotics and to reduce the incidence of nausea and vomiting. Similarly, the ethanolamine antihistamine diphenhydramine, although used primarily for the management of allergic reactions, is also marketed as an over-the-counter agent to treat motion sickness and insomnia.

The chemical structure of hydroxyzine, an antihistamine used for its sedative effects, is shown in Figure 13-11. Hydroxyzine's depression of CNS activity seems to be primarily subcortical. Bronchodilator, peripheral antihistaminic, antiemetic, and analgesic properties have also been clinically shown.

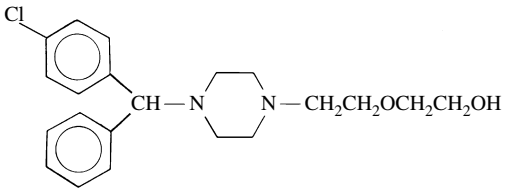


FIGURE **13-11** Structural formula of hydroxyzine.

Pharmacologic Effects

All the first-generation H_1 antihistamines produce mild CNS depression. These drugs also have prominent and sometimes beneficial anticholinergic, antihistaminic, and antiemetic properties. Side effects that may be of concern with these compounds at therapeutic doses are primarily drowsiness and dry mouth. Additive effects occur if these drugs are used in conjunction with other CNS depressants.

Hydroxyzine has a very slight depressant effect on the cardiovascular and respiratory systems. Similar to other antihistamines, hydroxyzine has antiarrhythmic properties and may cause bronchodilation. Hydroxyzine seems to have a slight analgesic effect and, when combined with morphine, produces greater analgesia than morphine alone. Hydroxyzine is helpful in diminishing the emetic effects of opioids, but the hydroxyzine-opioid combination produces significant drowsiness. When used as an adjunct to anesthesia, hydroxyzine has been reported to potentiate significantly the effects of barbiturates and opioids such as meperidine; reduction of total doses of these CNS depressant drugs is indicated.

Absorption, Fate, and Excretion

Hydroxyzine is rapidly absorbed from the gastrointestinal tract, and pharmacologic effects may begin within 15 to 30 minutes. Peak concentrations are achieved in 1 to 3 hours. The metabolic fate of hydroxyzine includes hepatic conversion to the lipid-soluble derivative norchlorcyclizine and the water-soluble hydroxyzine N-oxide. Hydroxyzine N-oxide is excreted rapidly, whereas norchlorcyclizine is excreted slowly and tends to accumulate in the body. The second-generation antihistamine cetirizine is an active carboxylated metabolite and contributes to the clinical effect. The terminal elimination half-life for hydroxyzine is approximately 1 day in adults but is considerably shorter in children. A syrup of hydroxyzine has a half-life of about 7 hours in children.

Adverse Effects and Drug Interactions

Hydroxyzine is generally considered to have low toxicity. The CNS depressant effect of hydroxyzine summates with that of other CNS depressants. There are indications that norchlorcyclizine may be dangerous to the fetus, but such an effect has been shown experimentally only at doses 50 to 100 times those considered to be therapeutic. Parenteral hydroxyzine is available for intramuscular injection only. Tissue necrosis is associated with subcutaneous or intra-arterial injections, and hemolysis may occur after intravenous administration.

GENERAL THERAPEUTIC USES OF SEDATIVE-HYPNOTICS

The use of barbiturate sedative-hypnotics to relieve fear and anxiety during dental procedures has been supplanted by use of benzodiazepine receptor agonists. Chloral hydrate and the antihistamine sedatives are still used in pediatric dentistry,[47]

although chloral hydrate poses more risk. Table 13-7 lists agents that are useful as sedative-hypnotics. Barbiturates, particularly ultrashort-acting agents, are useful in anesthesia and intravenous sedation to deepen CNS depression for brief periods. These therapeutic indications for sedative-hypnotic agents are discussed further in Chapters 18 and 48.

AZASPIRODECANEDIONES

Buspirone (Figure 13-12), an azaspirone (short for azaspirodecanedione) derivative structurally unrelated to the benzodiazepines, represents a unique class of antianxiety agents. Buspirone has antianxiety effects that are therapeutically equivalent to the effects of diazepam, but it lacks the more prominent CNS depressant effects and the anticonvulsant and muscle relaxant properties of the benzodiazepines. In addition, buspirone does not augment the sedative effect of ethyl alcohol or other sedatives, and it has little effect on psychomotor or cognitive function. Physical dependence does not occur, and withdrawal does not occur at abrupt cessation. This drug has a more anxiolytic-selective profile than benzodiazepines, representing a major advance in antianxiety therapy and a useful alternative to benzodiazepines.

Although the mechanism of antianxiety action of buspirone is unknown, it seems to diminish serotonergic tone. Buspirone is a partial 5-HT_{1A} agonist at both presynaptic 5-HT_{1A} autoregulatory receptors, which results in decreased 5-HT synthesis and release, and at postsynaptic 5-HT_{1A} receptors, which diminishes the effects of 5-HT.[70] Studies have shown dense labeling by radiolabeled buspirone of limbic

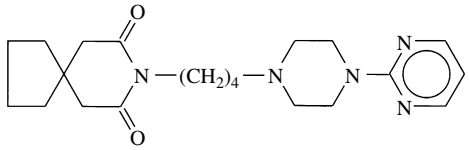

FIGURE **13-12** Structural formula of buspirone.

structures (amygdala, hippocampus, entorhinal cortex) that have high affinity for 5-HT_{1A} ligands. In animal studies, neurotoxins that selectively destroy tryptaminergic systems abolish the activity of buspirone.[16] There is good evidence for a tryptaminergic mechanism for the anxiolytic action of buspirone.[23] Although buspirone does not bind to the GABA-benzodiazepine receptor complex, the benzodiazepine antagonist flumazenil can block the antianxiety effect of ipsapirone,[36] a buspirone derivative, suggesting an interaction between benzodiazepine and tryptaminergic systems.

Peak plasma concentrations of buspirone are reached in less than 1 hour, but this may vary from patient to patient. Buspirone is extensively metabolized, with active and inactive metabolites excreted in the urine and feces. The elimination half-life is 2 to 8 hours.

Adverse effects of buspirone, such as headache, dizziness, nervousness, paresthesia, and gastrointestinal upset, are similar to the adverse effects of benzodiazepines but milder. Buspirone does not seem to produce additive sedative effects with the concomitant use of ethanol, a major advantage over benzodiazepines. Additionally, buspirone does not seem to produce significant CNS depression, which may offer a major clinical advantage for patients who, because of their employment, cannot afford an impairment in psychomotor skills. The abrupt withdrawal of buspirone is not associated with rebound anxiety or withdrawal symptoms. There have been reports that patients taking long-term diazepam who are quickly switched to buspirone may exhibit signs of increased anxiety and withdrawal because buspirone does not suppress benzodiazepine withdrawal or show cross-tolerance with benzodiazepines. Switching a patient who is currently on long-term benzodiazepine therapy to buspirone is accomplished by initiating low doses of buspirone and gradually tapering the dosage of benzodiazepine. Another problem associated with the use of buspirone is the long delay (1 to 3 weeks) to onset of clinical effects. This limits its usefulness in clinical dentistry.

CENTRALLY ACTING MUSCLE RELAXANTS

Propanediol and Glycerol Derivatives

The group of propanediol and glycerol derivatives includes several traditional agents, most of which are used as centrally acting muscle relaxants. They have, however, many effects in common with benzodiazepines. Meprobamate, a propanediol carbamate, was considered the agent of choice for the treatment of anxiety in the mid-1950s. With the discovery of the addictive properties of this compound and the introduction of benzodiazepines, its popularity declined rapidly. The pharmacologic profile of meprobamate differs little from barbiturates, although its antianxiety effects are demonstrable at doses that do not markedly diminish motor or intellectual performance. Meprobamate is rapidly absorbed from the gastrointestinal tract and reaches a peak plasma concentration in 2 to 3 hours. The half-life of a single dose of meprobamate is approximately 7 to 15 hours. Similar to barbiturates, meprobamate induces hepatic microsomal enzyme activity, but this induction seems to be more selective with meprobamate, and it may not induce its own metabolism. The half-life of meprobamate may be 48 hours with long-term therapy.

Mephenesin, chlorphenesin, methocarbamol, and carisoprodol are used primarily as centrally acting skeletal muscle relaxants. In 1945 the muscle relaxant effects of aryl-glycerol esters in experimental animals were observed; after evaluation of several analogues, mephenesin was introduced for clinical use in 1948. Mephenesin proved to be of limited usefulness because of its short duration of action. Methocarbamol and chlorphenesin have a more prolonged duration of action because of slow metabolic transformation and excretion. Mephenesin and similar drugs have also been shown to reduce polysynaptic spinal reflexes in experimental animals. In humans, these drugs act as mild sedatives and are used primarily to reduce abnormal muscle activity. Nevertheless, these and other centrally acting muscle relaxants are never used at doses that could cause flaccid paralysis of voluntary muscles.

Centrally acting muscle relaxants should be distinguished from several other classes of drugs that can reduce muscular activity through peripheral mechanisms. The neuromuscular blocking agents, such as tubocurarine and succinylcholine, act by blocking transmission at the neuromuscular junction. Dantrolene, a peripherally acting muscle relaxant, blocks excitation-contraction coupling in skeletal muscle. Curare-like drugs, succinylcholine, and dantrolene have very specific indications for their muscle relaxant properties (see Chapter 10).

Chemistry and structure-activity relationships

The chemical structures of meprobamate, mephenesin, and carisoprodol are shown in Figure 13-13. Meprobamate and carisoprodol are dicarbamate esters of propanediol, which have additional substituents to increase their potency and absorption.

Pharmacologic effects

Table 13-8 compares pharmacologic characteristics of various classes of drugs discussed in this chapter. Qualitatively, centrally acting muscle relaxants, sedative-hypnotics, and antianxiety drugs are similar pharmacologically, whereas antihistamines produce sedation that is qualitatively different.

Centrally acting muscle relaxants, of which mephenesin can be taken as the prototype, cause relaxation of voluntary muscle through depression of the CNS. These depressant effects have not been associated with an action on any specific transmitter system or neurologic circuit. Rather, alteration of the excitability of neural membranes in general may be involved. Although early investigations emphasized depression of spinal interneurons as the mechanism of action, these agents generally reduce neural activity in various brain structures, including the brainstem, thalamus, and basal ganglia. Certain agents that do not produce muscle relaxation also show some preferential depression of polysynaptic reflexes; depression of interneurons is not an identifying characteristic of this class. At progressively larger doses, sedation, hypnosis, unconsciousness, and death occur. Elevation of the convulsant threshold can be shown. The drugs are used orally.

The cardiovascular effects of sedative doses of centrally acting muscle relaxants of the mephenesin type are minimal. Adequate cardiovascular performance is usually maintained at doses higher than the doses that produce respiratory depression. The problems of shock and renal failure can complicate recovery from toxic doses of the agents, however.

Miscellaneous Drugs Affecting Skeletal Muscle

Significantly different from the glycerol and propanediol derivatives, orphenadrine (see Figure 13-13) is an analogue of the antihistamine diphenhydramine. The pharmacologic profile of orphenadrine, an antihistamine, differs from that of compounds similar to mephenesin. Conventional antihistamines, in addition to blocking histamine receptors, are frequently anticholinergic and produce drowsiness and sedation. This sedation is of a different character from the sedation produced by mephenesin-like drugs; increasing the dose of an

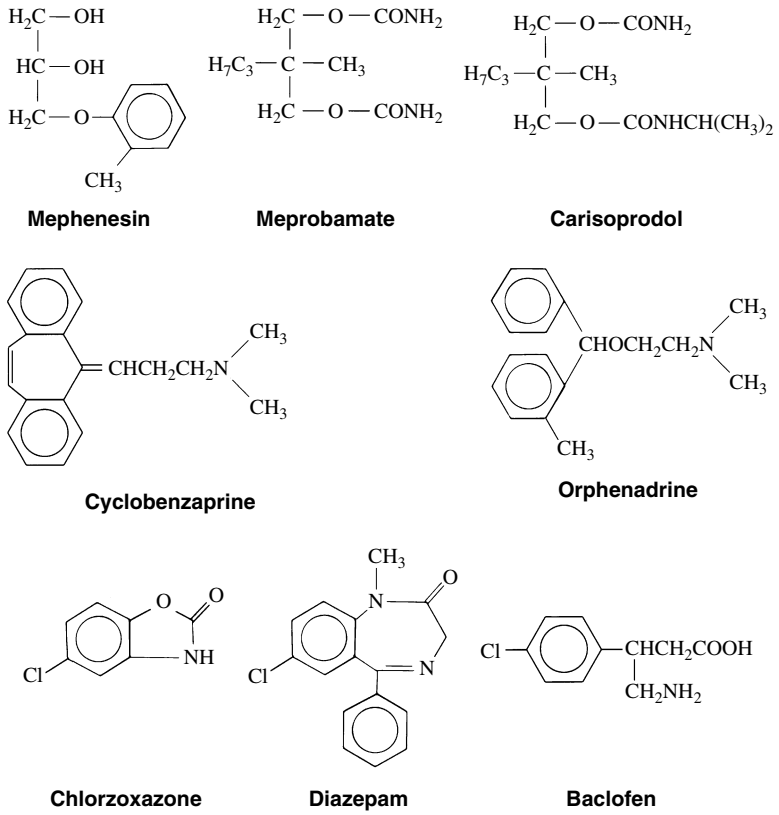

FIGURE **13-13** Structural formulas of some centrally acting muscle relaxants.

TABLE **13-8**

Pharmacologic Comparison of Centrally Acting Muscle Relaxants, Sedative-Hypnotics, Antianxiety Drugs, and Antihistamines

PHARMACOLOGIC PROPERTIES	CENTRALLY ACTING MUSCLE RELAXANTS (PROTOTYPE MEPHENESIN)	SEDATIVE-HYPNOTICS (PROTOTYPE PHENOBARBITAL)	ANTIANXIETY DRUGS (PROTOTYPE DIAZEPAM)	ANTIHISTAMINES (PROTOTYPE DIPHENHYDRAMINE)

Convulsant threshold	Raised	Raised	Raised	Lowered
Dependence liability	Yes, but usually mild	Yes	Yes, but usually mild	No

antihistamine leads to hallucinations, delusions, and convulsions. Nevertheless, because the dose-response curve for antihistamines is flat, these drugs have been considered safe and have been widely used in over-the-counter sleep aids for this reason. Likelihood of physical dependence is also minimal. Orphenadrine has been used primarily as an adjunct in the treatment of Parkinson's disease. Compared with the mephenesin group of drugs, no special advantage has been shown for orphenadrine as a muscle relaxant.

Cyclobenzaprine (see Figure 13-13), a structural and pharmacologic analogue of tricyclic antidepressants, is used for the short-term (2 to 3 weeks) treatment of muscle spasm associated with acute painful musculoskeletal conditions. One hypothesis for its mechanism of action is that it increases brainstem norepinephrine-mediated inhibition of ventral motor neurons of the spinal cord. Its effectiveness is similar to that of diazepam, but it produces more xerostomia, drowsiness, tachycardia, and dizziness. Many tricyclic antidepressants have significant antihistaminic effects, and the general pharmacologic properties of cyclobenzaprine are similar to those shown in Table 13-8 for the antihistamines. Metaxalone and chlorzoxazone (see Figure 13-13) are heterocyclic carbamates that show muscle-relaxing properties.

Baclofen has been shown to stimulate $GABA_B$ receptors, which are $G_{i/o}$ protein–linked receptors and are not coupled to Cl^- channels in the nerve membrane.[6] These $GABA_B$ receptors may inhibit motor tone by reducing the release of excitatory amino acid transmitters, reducing Ca^{++} conductance and increasing K^+ conductance. Blocking the receptor sites for excitatory amino acid transmitters may be a mechanism of action applicable to other centrally acting muscle relaxants. Baclofen, the *p*-chlorophenyl analogue of GABA, is recommended in multiple sclerosis or traumatic spinal cord injury for the relief of spasticity. Baclofen is also used to treat trigeminal neuralgia.

Although many agents are available as centrally acting muscle relaxants, the most commonly used drug for many muscle spasms is diazepam or another long-acting benzodiazepine. Benzodiazepines are thought to act primarily within the CNS, where they increase the response to GABA at $GABA_A$ receptor sites. Benzodiazepines, although they tend to have more sedative properties than some of the drugs used almost exclusively as centrally acting muscle relaxants, have a favorable clinical profile compared with the latter agents because of their relatively strong muscle-relaxing properties and relatively low toxic and physical dependence liabilities.[54]

TABLE **13-9**

Comparison of Ataxic and Lethal Doses of Central Depressant Drugs in Mice

AGENT	LD_{50} (mg/kg)	ATAXIA ED_{50} (mg/kg)	THERAPEUTIC INDEX
Phenobarbital	242	120	2.0
Mephenesin	610	178	3.4
Meprobamate	800	235	3.4
Carisoprodol	980	165	5.9
Chlordiazepoxide	720	100	7.2
Diazepam	620	30	20.7

ED_{50}, Median effective dose; *LD_{50}*, median lethal dose.

Adverse Effects

Muscle relaxants are generally used at sedative doses, and these drugs have limited effectiveness in the treatment of muscle spasms. Data obtained from experimental animals compare the relative safety of some commonly prescribed muscle relaxants (Table 13-9). The therapeutic index for muscle relaxation and other effects is many times greater for benzodiazepines than for barbiturates. The other clinically useful muscle relaxants have therapeutic indexes between these extremes.

Tolerance and physical dependence develop with the long-term administration of muscle relaxants, but generally withdrawal is mild although qualitatively similar to that seen with other CNS depressant drugs. Side effects associated with centrally acting muscle relaxants are primarily related to effects on the CNS and include drowsiness, dizziness, headache, blurred vision, ataxia, lethargy, paradoxic excitement, and nystagmus. Gastrointestinal symptoms such as vomiting, heartburn, nausea, anorexia, and abdominal distress have been reported. Allergic reactions may also occur and include skin rash, pruritus, and fever. Cyclobenzaprine has some additional side effects that stem from its actions on the autonomic nervous system. Because it has substantial anticholinergic properties, its use should be especially avoided in certain conditions (e.g., narrow-angle glaucoma, prostatic hypertrophy). Because of its effect on norepinephrine reuptake, cyclobenzaprine may also be contraindicated in patients for whom increased sympathetic activity is to be avoided (e.g., in patients

with hyperthyroidism or recovering from a myocardial infarction). A report of a manic episode after cyclobenzaprine use in a patient with a history of psychosis suggests that cyclobenzaprine should also be avoided in such patients.[4]

Baclofen can cause drowsiness, ataxia, and confusion, which may be especially troublesome in elderly individuals. Acute toxicity may lead to respiratory depression and seizures. Sudden withdrawal from therapeutic doses is associated with a high risk of hallucinations and tachycardia. Cessation of therapy should involve tapering the doses over several days.

Drug interactions with the centrally acting muscle relaxants are of several kinds. First, these drugs augment the depressant actions of each other and of the opioids, other sedatives (including ethanol),[63] antianxiety drugs, antihistamines, and antidepressants.[42] Second, drug interactions can occur when these agents induce drug-metabolizing and hormone-metabolizing enzymes of the liver. Although the degree of enzyme induction varies substantially among the various sedatives, caution should be used in patients taking anticoagulants and in patients with porphyria. Third, increased skeletal muscle relaxation should be expected when centrally acting muscle relaxants are given with drugs whose primary pharmacologic activity is neuromuscular blockade (e.g., succinylcholine) or with drugs that have such an activity as a side effect (e.g., aminoglycosides or volatile general anesthetics). Fourth, cyclobenzaprine should not be given to patients taking monoamine oxidase inhibitors or guanethidine and related drugs. (Barbiturates, benzodiazepines, and other sedatives should be used with considerable caution with monoamine oxidase inhibitors.) Fifth, because the muscle relaxant actions of diazepam are partially reversed by aminophylline,[65] patients being treated with diazepam should avoid the use of xanthine-containing foods.

General Therapeutic Uses

Centrally acting muscle relaxants are used medically as adjuncts to rest, physical therapy, and other measures for the relief of discomfort associated with acute, painful musculoskeletal conditions. They have been promoted for use in skeletal muscle spasms of local origin, multiple sclerosis, cerebral palsy, sprains, strains, fibrositis, rheumatoid spondylitis, bursitis, the urethral syndrome, and arthritis. Drugs such as salicylates and adrenocorticosteroids may be used concomitantly. Longer acting nonsteroidal anti-inflammatory agents are perceived as having an advantage in many of these disorders.

Certain conditions of skeletal muscle, such as muscle spasm or trismus, are believed to be the result of dysfunctional output patterns from the motor areas of the CNS to skeletal muscle. Drugs that could prevent or lessen these neurotropic influences on voluntary muscle would be helpful in physical medicine and dentistry. Centrally acting muscle relaxants, which overlap pharmacologically with antianxiety drugs, represent a diverse group of drugs whose pharmacologic effects include diminished output of nerve impulses to voluntary muscle. Benzodiazepines are sometimes used to alleviate abnormal muscle contractions by depressing polysynaptic CNS pathways, including polysynaptic spinal reflexes. Some newer benzodiazepine partial agonists have a minimal amount of muscle relaxant activity.[17] Full agonist agents such as diazepam should be used if muscle relaxation is desired.

β-ADRENERGIC RECEPTOR-BLOCKING DRUGS

The β-adrenergic receptor–blocking agent propranolol is not approved for the treatment of anxiety, but it is effective in decreasing the peripheral autonomic symptoms of anxiety (e.g., tremor, tachycardia, palpitation). Propranolol may be used for healthy patients who have disabling situational anxiety, or it may be combined with a benzodiazepine in patients who have the somatic manifestations of anxiety. Propranolol has gained some popularity with performing actors and musicians in preventing "stage fright." It is neither appropriate nor effective for the treatment of chronic anxiety.

α_2-ADRENERGIC RECEPTOR AGONIST DRUGS

The α_2-adrenergic receptor agonist drugs guanabenz, guanfacine, clonidine, tizanidine, medetomidine, and dexmedetomidine exert their action at central and peripheral α_2 receptors. Centrally, α_2 receptors are located in the brain (locus coeruleus) and the spinal cord. Stimulation of these receptors diminishes sympathetic outflow, which results in sedation, hypnosis, anxiolysis, analgesia, and reduced systemic blood pressure. Peripherally, α_2 receptors are located primarily at the prejunctional site of the sympathetic nerve terminal. Stimulation of these receptors impairs adrenergic transmission and results in reductions of heart rate and blood pressure.

Clonidine was first used as a nasal decongestant that coincidentally was discovered to reduce systemic blood pressure through central brainstem adrenergic stimulation. Clonidine is rapidly and almost completely absorbed after oral administration and may exhibit transient increases in blood pressure after initial dosing because of mild stimulation of peripheral postjunctional α_1 receptors. Sudden withdrawal of clonidine after long-term administration has been associated with rebound hypertension that may occur 20 hours after cessation of the drug. Clinically, clonidine is used as an antihypertensive agent (see Chapter 28). More recently, it has been used as an oral premedicant in patients with significant pretreatment anxiety.[25] Its anxiolytic and cardiovascular effects make it useful in the perioperative management of these difficult patients because it has been shown to decrease anesthetic requirements by 40% to 60% and to reduce postoperative analgesic dose requirements. Clonidine is also useful in the treatment of opiate, cocaine, food, and tobacco withdrawal.

The α_2-adrenergic receptor agonist tizanidine is a centrally acting muscle relaxant used for spasticity states, especially multiple sclerosis and spasticity arising from spinal cord injury. Within the spinal cord, the medullary locus coeruleus, and the substantia nigra, α_2 receptors have been shown to contribute to its action.[62,64] Other centrally acting muscle relaxants—midazolam and baclofen—also depress spinal reflexes when applied directly to the substantia nigra.[64]

Dexmedetomidine is a highly selective (7.3 times that of clonidine) α_2-adrenergic receptor agonist with sedative, hypnotic, and analgesic properties. It exhibits a biphasic blood pressure response in a dose-dependent fashion. Intravenous infusion of low doses results in a reduction of mean arterial pressure owing to selectivity for central and peripheral α_2 receptors. The resultant decreases in heart rate and systemic vascular resistance lead to decreases in cardiac output and systolic blood pressure. Intravenous infusion of high doses or rapid intravenous bolus administration may result in systemic hypertension because of activation of peripheral postjunctional α_2-adrenergic receptors. Dexmedetomidine has minimal, if any, effect on the respiratory system, and similar to clonidine, it significantly reduces analgesic and anesthetic requirements.

Currently, dexmedetomidine has three main clinical applications. Its primary use is as a sedative agent for critically ill patients requiring prolonged sedation and mechanical ventilatory support in a critical care setting. Dexmedetomidine

possesses all of the characteristics of an ideal sedative for intensive care. It lacks respiratory depression, is analgesic and anxiolytic, has a rapid onset and is titratable, and produces sedation with hemodynamic stability. In pediatric patients, dexmedetomidine is very useful in obtunding the emergence delirium sometimes seen after general anesthesia. It produces profound calming without respiratory depression. This is a major advantage over other sedatives and opioids that have commonly been used in this situation. Finally, dexmedetomidine is used as an adjunctive sedative agent for monitored anesthesia care. It can be used with agents such as opioids, benzodiazepines, and propofol to enhance sedation and promote and maintain hemodynamic stability. Because it does not produce respiratory depression, it is very useful in patients for whom this would be a concern. Its rapid distribution half-life (6 minutes) results in fast recovery and allows for faster patient discharge.

There are specific antagonists to α_2 receptor agonist drugs. One such agent, atipamezole, is effective in reversing the clinical effects of these drugs. With the increasing use of dexmedetomidine as a sedative agent in critical care and outpatient anesthesia, further research into the safety and efficacy of this reversal agent is warranted.

IMPLICATIONS FOR DENTISTRY

Drugs Used as Sedative-Hypnotics

Whether used by the dentist or physician, the common desired therapeutic response to these drugs is sedation or hypnosis. Additional therapeutic applications for sedative-hypnotics are discussed in detail in Chapters 14 (anticonvulsant drugs), 18 (general anesthetics), and 48 (management of fear and anxiety).

As a class, benzodiazepines are very safe and highly effective agents for producing sedation and sleep. Zolpidem and zaleplon seem to offer advantages similar to the advantages described for benzodiazepines: they are well tolerated, have a high margin of safety, and have a shallow dose-response profile. In addition, their rapid onset of action makes it possible for the patient to take the drugs immediately before bedtime.

Despite the declining use of barbiturates, they can occasionally be helpful in dentistry. Barbiturates are effective and relatively inexpensive. A wide range in duration of effect can be attained depending on the drug and the dose prescribed. The problems frequently associated with long-term use of barbiturates, such as tolerance and drug interactions, do not generally apply to their short-term use. The barbiturates are contraindicated, however, in pregnancy and latent porphyria (as described previously).

With the exception of benzodiazepines and the pharmacologically related benzodiazepine receptor agonists, nonbarbiturate sedative-hypnotics offer little advantage over barbiturates. Although antihistamines are not considered to cause physical dependence, most nonbarbiturate, nonbenzodiazepine sedative-hypnotics have abuse potential, cause dependence, depress the CNS, and may be more troublesome than barbiturates in overdose. Because of these limitations, few nonbarbiturate, nonbenzodiazepine sedative-hypnotics are used in dentistry. The primary exceptions are chloral hydrate, which is still used for sedation in young children, and the antihistamines hydroxyzine, diphenhydramine, and promethazine.

The use of nonbarbiturate sedatives other than those already described is not warranted for dental practice because they offer no significant advantages. The clinician is best advised to recognize the names of nonbarbiturate sedative-hypnotics and to be aware of the potential for drug interactions with other CNS depressants. In addition, the use of any of the hypnotic drugs for insomnia should be limited to short-term treatment at the lowest effective dose. An ongoing FDA program encourages physicians and dentists to restrict the prescribing of hypnotics and advises that the underlying cause of insomnia be sought and treated by nonpharmacologic means, if possible. The warning also includes the risk of sedative-induced complex sleep disorders, such as sleep-driving. Preparations and doses for clinically useful sedative-hypnotics are listed in Table 13-7. These doses should be used only as guidelines because each patient has different requirements, and dosages should be individualized. Eszopiclone seems to have a greater tendency than most other sedatives to cause unpleasant taste.

Many of the problems associated with the sedative-hypnotics, such as tolerance to sedative effects, addiction, abuse, rebound sleep disturbances, and the induction of hepatic microsomal enzyme activity, result from long-term use. Sedative-hypnotic drugs are indicated only for short-term use in dentistry; many of the usual factors limiting their use are not pertinent. This assertion is not to imply that problems do not arise with the administration of sedative-hypnotics in dental practice, but only that they are minimized. Although overdose with sedative-hypnotics would be unlikely with the amount of drug required for most dental situations, a potential problem exists if the patient combines the prescribed sedative-hypnotic with other CNS depressants, such as alcohol. It is the clinician's responsibility to ensure that the patient is made cognizant of the danger of combining other CNS depressants, particularly alcohol, with these drugs.

Certain patients require special precautions. Elderly patients are at special risk for impaired cognitive and motor function after the administration of a sedative-hypnotic. Patients with impaired liver function also fall into this category. Patients with sleep apnea, which is more common among obese and elderly individuals (especially men), should be treated cautiously because any hypnotic may exacerbate this condition. A complete medical history, including input from a spouse, might alert the practitioner to the possibility of such complications. The use of sedative-hypnotics is generally contraindicated in pregnant patients, especially during the first trimester. Because patients with a history of drug abuse are at a higher risk of becoming dependent on sedative-hypnotics, the minimally effective dose should be prescribed and only when absolutely necessary.

Although barbiturates produce significant depression of the CNS, to the point of unconsciousness, they are not analgesics. A patient receiving sedative doses may exhibit increased responsiveness to painful stimuli. When pain is present or evoked, the patient may become aroused, agitated, and delirious. If pain is a contributing factor to either anxiety or insomnia, an analgesic is required to obtain sedation or hypnosis.

Drugs Used to Treat Anxiety

Antianxiety agents are important in dentistry for the premedication of apprehensive adult patients, patients exhibiting mild neurosis, and uncooperative children. Antianxiety agents, particularly intravenous midazolam and diazepam, are used as adjuncts to local anesthesia. The effectiveness of intravenous diazepam in the relief of intraoperative anxiety in a patient population undergoing surgical removal of impacted third molars is illustrated in Figure 13-14. Although intravenous sedation with diazepam usually lasts approximately 45 minutes, the duration of anxiety relief may be 3 hours.[26] Midazolam and diazepam cause anterograde amnesia so that patients often cannot recall the procedures performed. Both drugs also depress the gag reflex and are major drugs for the treatment of seizures induced by local anesthetic overdose.

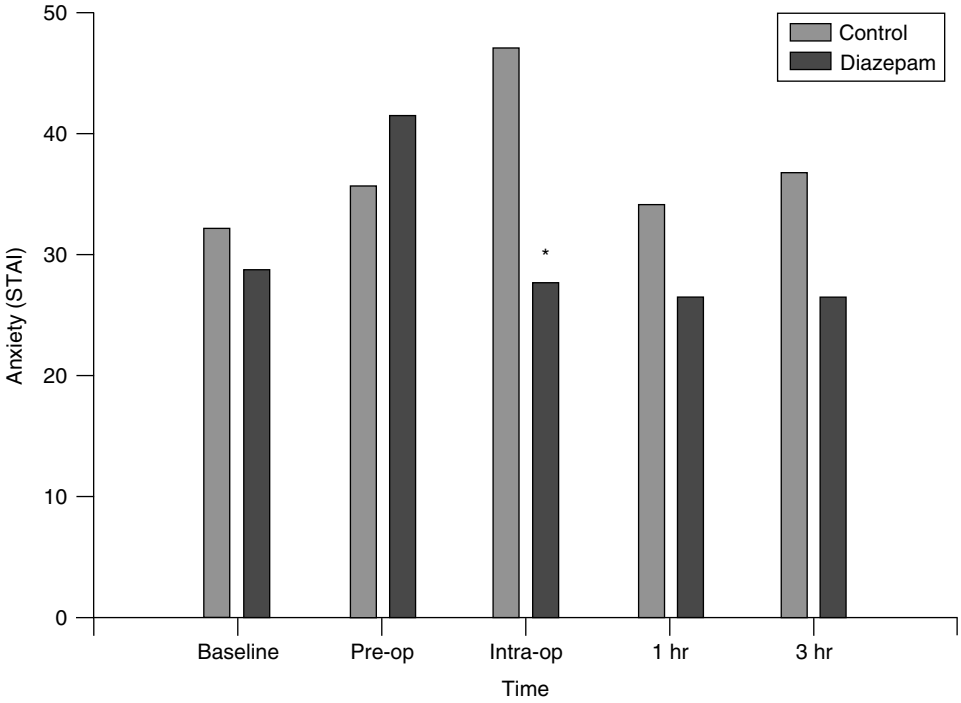

FIGURE **13-14** Effects of placebo and diazepam on reported anxiety with a state-trait anxiety index *(STAI)* in patients undergoing surgical removal of impacted third molars. Patients were treated with placebo solution or diazepam (0.3 mg/kg) 5 minutes before surgery. All patients also received standard local anesthesia with 2% lidocaine containing 1:100,000 epinephrine. Anxiety was assessed before ingestion and before, during, and after surgery. *Significantly different from control ($P < .01$). (Adapted from Hargreaves KM, Dionne RA, Mueller GP, et al: Naloxone, fentanyl, and diazepam modify plasma beta-endorphin levels during surgery, *Clin Pharmacol Ther* 40:165-171, 1986.)

Midazolam is popular as a preoperative sedative because it is prepared in a water-soluble form and produces little irritation on injection. In contrast to diazepam, residual CNS depression and anxiety relief extending beyond the period of clinical recovery are not commonly observed when midazolam is administered as a single agent. Careful observation of the patient is mandatory in attempting to reverse benzodiazepine-induced sedation with flumazenil. Careful attention must be paid to the manufacturer's recommended dose, time interval of administration, and prolonged patient monitoring time.

One of the more perplexing questions for the practicing dentist is which oral benzodiazepine to choose from the ever-expanding list. There is little doubt of the clinical effectiveness of these drugs in various dental procedures,[19,59] but there are no unusual characteristics associated with any one benzodiazepine that would make it clearly superior to the others. Essentially, any benzodiazepine is suitable as an antianxiety agent if the pharmacokinetics of that drug are kept in mind. The major decision to be made in the treatment of the anxious patient is which drug possesses the best pharmacokinetic profile for a given use. Although there is no simple rule of thumb, the pharmacokinetic characteristics of individual compounds to a large extent dictate the optimal dose schedule. Oxazepam and lorazepam are potentially useful drugs in patients with liver disease because they are converted to inactive glucuronides, and the conjugation reaction is often affected less by hepatic disease than other steps in drug metabolism. Although buspirone offers many advantages for the treatment of anxiety, its usefulness in dentistry is limited by its delayed onset of effect. Other azaspirones currently undergoing clinical trials may offer anxiety relief with a short onset time.

Because of its short half-life and rapid onset, triazolam has been recently recommended as a safe and effective enteral preoperative sedative in the United States. Given the large number of patients who avoid dental care because of fear and anxiety, general dentists, with minimal advanced anesthesia training, have found enteral triazolam to fulfill the need for a safe sedation protocol.[29] The typical adult dose is 0.125 mg to 0.250 mg administered orally or sublingually 30 to 45 minutes before the dental procedures. Its efficacy in reducing anxiety before venipuncture and in reducing the doses of agents used for intravenous sedation has been shown.[59] Clinical research suggests that the sublingual route for triazolam administration may be slightly more efficacious secondary to slightly higher plasma concentrations compared with the oral route.[5] Indications and contraindications for administering oral or sublingual triazolam to anxious dental patients are discussed in Chapter 48.[52]

The primary concern of the dentist in using an antianxiety agent should be excessive CNS depression. CNS depression may result from the antianxiety agent alone or its combination with other CNS depressants that the dentist may plan to give or that the patient may already have taken. The antianxiety agents summate with anesthetics, antipsychotics, antidepressants, opioid analgesics, and sedative-hypnotics. Alcohol may markedly increase the CNS depressant effects of benzodiazepines. If CNS depressant drugs are used for deep sedation and general anesthesia in the dental clinic, suction and monitoring equipment, emergency drugs, and a means to deliver oxygen under positive pressure must be readily available. The practitioner should have appropriate advanced training in anesthesia techniques. The benzodiazepine antagonist flumazenil offers the opportunity to reverse benzodiazepine-induced sedation after dental procedures,[9,19,20] hastening postoperative patient recovery. Flumazenil is also a rapidly acting antidote for benzodiazepine intoxication. The possibil-

ity of resedation and recurrence of respiratory depression because of its short half-life has been described. The best practice in the use of benzodiazepines is to limit their administration so that an emergency antidote is never required.

The patient should be reminded that antihistamines, even the small amounts contained in over-the-counter preparations promoted as cold remedies or for insomnia, may add to the CNS depressant effect of antianxiety agents. Because of benzodiazepine-induced psychomotor impairment, the dentist should caution patients on the hazards of driving an automobile or operating potentially dangerous machinery for 24 hours after drug administration.

Chloral hydrate has been implicated in serious adverse effects when used as a sedative in dentistry. There is a risk of overdose. In addition, a prolonged recovery may occur. Chloral hydrate also increases the risk for cardiac arrhythmias. These adverse effects require special caution in its use.

Numerous factors influence the choice of an antianxiety drug. This chapter has covered some of the more important ones that the dentist should consider when making a selection. The therapeutic use of drugs for anxiety relief in dentistry is reviewed further in Chapter 48. In practice, the dentist should become familiar and comfortable with a few antianxiety drugs and select from these according to the drugs' pharmacokinetics, the particular treatment to be rendered, and the needs of the patient. The potential for the development of more specific antianxiety agents should serve as a stimulus for the practicing dentist to stay current in the field of antianxiety medication. Knowledge of the pharmacologic profile of the existing drugs may also prevent the dentist from being misled by dubious claims of specificity for newly introduced agents.

Table 13-4 lists preparations and doses recommended for anxiety control. The doses indicated should be viewed only as guidelines; each patient requires individualized treatment. The minimum effective dose should be administered.

Drugs Used as Centrally Acting Muscle Relaxants

Although the indications are limited, centrally acting muscle relaxants may be valuable therapeutic agents for some dental procedures.[58] Diazepam is generally preferred because of its good muscle-relaxing properties, prolonged action, and safety. Diazepam administered for 1 week may be useful in reducing postprocedural trismus and may be effective as an adjunct for treating muscle spasms of the head and neck, as in temporomandibular disorders. The causes of temporomandibular pain are complex, however, involving multiple interacting factors, such as patient anxiety, muscle spasms, occlusal problems, and joint dysfunction. The effectiveness of therapy with centrally acting muscle relaxants is greater if anxiety or muscle spasm primarily causes the dysfunction. Because the relationship between CNS activity and peripheral muscle tone is complex, it is unlikely that the centrally acting muscle relaxants would produce either consistent or predictable results. There are still few double-blind studies that show the benefit of such treatment; what is clear from such studies is that the incidence of improvement from placebos is high. The use of centrally acting muscle relaxants should be monitored carefully, and long-term therapy beyond a few weeks is generally not indicated.

Although combinations of centrally acting muscle relaxants and peripherally analgesic drugs may be valuable, fixed-dose combinations often provide suboptimal doses of the analgesic drug (see Chapter 47). Prescribing full therapeutic doses of each agent is warranted if the use of a combination is indicated. In addition, better results have been obtained from longer acting agents on a once-daily or twice-daily dosing schedule. The interaction between sensory and motor systems suggests that a multiple drug treatment approach could be useful. The idea that hyperalgesia produces a significant increase of noxious sensory afferent input from injured muscle has been documented.[39] The decrease in peripheral sensory thresholds produced by hyperalgesia is the result of many different inflammatory compounds, which implies that anti-inflammatory drugs of some kind may be useful by reducing the inflammation.

The concept of extensive convergence of afferents from skin, muscle, joints, and other tissues onto brain sensory nuclei, which can result in decreased sensory thresholds and increased referred pain, has also been documented.[53] The use of analgesics to reduce peripheral and spinal (or trigeminal) hyperalgesia and centrally acting muscle relaxants to reduce brain excitation may help to reduce muscle spasm; this may explain why analgesics combined with muscle relaxants can sometimes produce a better effect than either one given alone. Centrally acting muscle relaxants generally are not the primary treatment for every type of facial pain. Trigeminal neuralgia (tic douloureux) requires specific therapies (see Chapter 23).

DRUGS USED AS ANTIANXIETY AGENTS

Nonproprietary (generic) name	*Proprietary (trade) name*
Benzodiazepines	
Alprazolam	Xanax
Chlordiazepoxide	Librium
Clorazepate	Tranxene
Diazepam	Valium
Halazepam*	Paxipam
Lorazepam	Ativan
Midazolam	Versed
Oxazepam	Serax
Prazepam*	Centrax
Triazolam	Halcion
Azaspirodecanediones	
Buspirone	BuSpar
Propanediol carbamates	
Meprobamate	Miltown, Equanil
Chlormezanone*	Trancopal

*Not currently available in the United States.

DRUGS USED AS SEDATIVE-HYPNOTICS

Nonproprietary (generic) name	*Proprietary (trade) name*
Barbiturates	
Amobarbital	Amytal
Aprobarbital*	Alurate
Butabarbital	Butisol
Butalbital	in Fiorinal
Mephobarbital	Mebaral
Pentobarbital	Nembutal
Phenobarbital	Luminal
Secobarbital	Seconal
Benzodiazepines	
Estazolam	ProSom
Flurazepam	Dalmane
Quazepam	Doral

Continued

DRUGS USED AS SEDATIVE-HYPNOTICS—cont'd

Nonproprietary (generic) name	*Proprietary (trade) name*
Temazepam	Restoril
Triazolam	Halcion
Antihistamines	
Hydroxyzine hydrochloride	Atarax
Hydroxyzine pamoate	Vistaril
Promethazine	Phenergan
Diphenhydramine	Benadryl, Nytol
Others	
Acetylcarbromal	Paxarel
Chloral hydrate	Aquachloral Supprettes
Dexmedetomadine	Precedex
Eszopiclone	Lunesta
Ethchlorvynol*	Placidyl
Glutethimide*	Doriden
Methyprylon*	Noludar
Paraldehyde*	Paral
Ramelteon	Rozerem
Zaleplon	Sonata
Zolpidem	Ambien

*Not currently available in the United States.

DRUGS USED PRIMARILY AS MUSCLE RELAXANTS

Nonproprietary (generic) name	*Proprietary (trade) name*
Benzodiazepines	
Diazepam	Valium
Miscellaneous	
Baclofen	Lioresal
Carisoprodol	Soma
Chlorphenesin	Maolate
Chlorzoxazone	Paraflex
Cyclobenzaprine	Flexeril
Mephenesin*	—
Meprobamate	Miltonin, Equanil
Metaxalone	Skelaxin
Methocarbamol	Robaxin
Orphenadrine	Norflex
Tizanidine	Zanaflex

*Not currently available in the United States.

CHAPTER 14

*Anticonvulsants**

VAHN A. LEWIS

Epilepsy comprises a group of disorders characterized by the periodic and abnormal discharge of nervous tissue. Violent involuntary muscle contractions, or *convulsions*, are characteristic of most forms of epilepsy, and the epileptic attack, accompanied in most cases by convulsions, is called a *seizure*. The abnormal neuronal discharge causes electroencephalogram (EEG) disturbances and various changes in activity of tissues, receptors, or brain oxygenation that can be detected by a variety of tomographic methods (e.g., positron emission tomography [PET], single photon emission computed tomography, functional magnetic resonance imaging [MRI] and blood oxygen level dependent [BOLD] functional MRI, magnetoencephalography) Various epileptic syndromes exist, each defined by such factors as cause, seizure type, age of onset, and clinical manifestations. Seizures can have many causes and constitute evidence of an underlying neurologic disorder, not a disease per se. The signs and symptoms of these syndromes frequently overlap, and differential diagnosis of the form of epilepsy is sometimes difficult.

Anticonvulsants are being used for some nonseizure disorders, such as chronic neuropathic pain (including migraine) and bipolar disorder. When used to treat pain, these agents may be referred to "analgesics." Their actions and use are significantly different from opiates ornonsteroidal anti-inflammatory drugs. When used to treat bipolar disorder, anticonvulsants have been referred to as "mood stabilizers." Anticonvulsants have also been evaluated in some disorders of impulse control, such as impulsive aggressiveness.

CLASSIFICATION OF EPILEPTIC DISORDERS

The classification proposed in 1989 by the Commission on Classification and Terminology of the International League Against Epilepsy (ILAE) is complex because of the variable characteristics of many epileptic syndromes. A simplified approach more suited to this discussion limits consideration to the seizures themselves (Table 14-1). Seizure patterns are broadly divided into two major groups: (1) *partial seizures*, in which convulsions begin in a localized region of the brain, involve restricted areas of the body, are initially unilateral, and yield EEG recordings of rhythmic activity that is restricted at least initially to one hemisphere, and (2) *generalized seizures*, with convulsions often involving the entire body and EEG recordings having characteristic bilateral patterns. A modified ILAE classification scheme is under development to classify epilepsy based on Axis 1, descriptive terminology for ictal events; Axis 2, seizure description; Axis 3, syndromes and diseases; and Axis 4, life impairment.[10]

Generalized Seizures

The most common type of generalized seizure is *tonic-clonic* (grand mal), which has a sudden onset (sometimes preceded by an aura, a brain sensation recognized by the patient), beginning with the so-called epileptic cry caused by the forcing of air through the tonically contracted muscles of the larynx. This cry is followed by a loss of consciousness, loss of postural tone, and tonic-clonic contraction of skeletal muscles. Autonomic responses commonly include sweating, loss of sphincter control (often resulting in urination and defecation), pupillary dilation, and loss of light reflexes. The EEG pattern displays bilateral, synchronous high-voltage polyspike activity. Injury may occur as a result of the uncontrolled movements or loss of postural tone. Tongue biting and fracturing of teeth may result from the powerful contraction of the muscles of mastication. After the tonic-clonic contractions, the patient usually awakens, is confused and lethargic, and goes to sleep for approximately 30 minutes. On reawakening, the patient is again lethargic, confused, and disoriented and often has headache and muscle ache. Grand mal epilepsy is often responsive to pharmacotherapy.

A second common form of generalized seizure is *absence* seizure, which characteristically occurs in childhood. There are several varieties of absence seizures. The most common form (petit mal) is characterized by an abrupt but very short (5 to 10 seconds) loss of consciousness, often with minor muscular twitching (commonly restricted to the eyelids and face), and a 3-Hz spike-and-wave EEG pattern but no loss of postural control. Severe cases may involve hundreds of seizures per day. The term *absence* is appropriate because of the brief loss of consciousness and the vacant stare of the patient during a seizure. Similar to tonic-clonic seizures, absence seizures are often responsive to pharmacotherapy.

Uncommon types of generalized seizures include (1) *myoclonic*, characterized by sudden, brief, and violent spasms of one or more muscles or muscle groups, and (2) *atonic*, characterized by a sudden, brief loss of muscle tone. These varieties are usually associated with diffuse and severe progressive diseases of the brain and are often refractory to drug treatment. Rarely seizures are precipitated by triggers, such as catamenial seizures (associated with menstruation) or reflex seizures, which can be triggered by tones, visual stimulation (e.g., video games, flashing lights), or touching.

Generalized seizures occurring in the form of repeated or continuous attacks are referred to as *status epilepticus*. Tonic-clonic status epilepticus is rare but life-threatening. Status

*The author wishes to recognize Dr. Leslie Felpel for his past contributions to this chapter.

TABLE **14-1**

Classification of Epileptic Seizures

CLASSIFICATION	CLINICAL ASPECTS
I. Partial (focal, local) seizures	Involves one side of brain at onset
A. Simple partial seizures (e.g., Jacksonian)	Consciousness not impaired; specific or localized motor, sensory
B. Complex partial seizures (e.g., psychomotor, temporal lobe)	Consciousness impaired, automatisms, autonomic or psychological signs or symptoms; patients may report aura beforehand
C. Partial seizures evolving to generalized seizures	See generalized seizures; patients may report aura beforehand
II. Generalized seizures	Involve both sides of brain at onset
A. Tonic-clonic seizures (grand mal)	Consciousness is lost; bilateral sharp tonic contraction of muscles, generalized from onset, followed by clonic contractions; patient may report aura before seizure
B. Absence seizures (e.g., petit mal)	Consciousness impaired, postural muscles not impaired, EEG spike and slow wave complexes at approximately 3 Hz
C. Myoclonic seizures	Sudden, brief contractions of individual muscles or groups producing shocklike spasms in muscles of face, trunk, and extremities
D. Clonic seizures	Repetitive clonic jerking (alternating contractions of opposing muscles)
E. Tonic seizures	Violent muscular contraction (simultaneous contraction of flexors and extensors) with limbs in strained position
F. Atonic seizures (astatic)	Sudden loss of muscle tone, consciousness sometimes lost, patients sustain fall injuries
III. Unclassified seizures	Cannot be classified because of insufficient data or atypical pattern of seizure

Adapted from Commission on Classification and Terminology of the International League Against Epilepsy, *Epilepsia* 22:489—501, 1981.
EEG, Electroencephalogram.

epilepticus may develop in patients with convulsive disorders, with acute disease affecting the brain (meningitis, encephalitis, toxemia of pregnancy, uremia, acute electrolyte imbalances), after abrupt withdrawal of depressant or anticonvulsant medication (barbiturates, benzodiazepines, opioids), or rarely after local anesthetic administration. Status epilepticus can occur in the absence of a prior history of seizures. The drugs most widely used to treat status epilepticus are intravenous benzodiazepines (lorazepam, diazepam, and midazolam), phenytoin, fosphenytoin, phenobarbital, and valproic acid.[17,35,48] In refractory status epilepticus, the patient may have to undergo general anesthesia (e.g., midazolam, propofol, thiopental, and pentobarbital). An anesthetic dose of pentobarbital or propofol is effective and has a more rapid onset than phenobarbital. Because large doses of these drugs are usually required, there is the danger of respiratory depression and respiratory arrest, especially with barbiturates or propofol. Grand mal status epilepticus is best treated in a hospital setting.

Partial Seizures

The partial epilepsy syndromes are divided into three broad categories. The first type, called *simple partial seizure*, is characterized by seizures limited to certain muscles or involving specific sensory changes, psychic symptoms, or autonomic activity. The seizure may remain localized, or it may spread to contiguous brain tissue, causing progressive symptoms as the wave of depolarization "marches" along the cerebral cortex. This latter seizure type is referred to as *jacksonian epilepsy*, after John Hughlings Jackson, who first described the phenomenon. The motor version begins with contraction of an isolated muscle, followed by the gradual involvement of other muscles. Jacksonian sensory epilepsy gives rise to sensations from various areas of the body. By definition, the affected individual remains conscious.

A second type of partial seizure, known as *complex partial seizure*, usually originates in the temporal or frontal lobe but spreads to broader areas, frequently in a bilateral pattern. Consciousness is impaired, flashbacks or psychotic-like behavior may occur, and autonomic dysregulation and automatisms (involuntary, repetitive, and coordinated movements) are common.

A third type of partial seizure is one that progresses to a generalized attack. The initial inciting seizure may be simple or complex. The final clinical result depends on the type of generalized seizure that is triggered. Partial seizures are more refractory to drugs than common generalized seizures.

Secondary Seizures

Seizures may be caused by a fundamental disorder in the ability of the brain to regulate excitation because of genetic causes or abnormal development. Seizures may also occur, however, as a symptom of another medical condition. Seizures in an otherwise normal individual may be precipitated by inhibition of the respiratory chain (e.g., anoxia, metabolic poisons), hyperbaric oxygen, intoxication, fever, cerebral infection or inflammation, traumatic brain injury, repeated electrical brain stimulation, drug use, systemic administration of local anesthetics, overdose of stimulant or antidepressant drugs, or withdrawal of depressant drugs (e.g., alcohol, barbiturates, opioids). These seizures may resolve after resolution of the underlying cause or may continue if the insult or seizures have resulted in brain injury.

PATHOPHYSIOLOGY

The pathophysiologic characteristics of epilepsies are not well understood. Idiopathic epilepsy has a primary genetic basis, with some influence of environmental factors.[26] The various types of epilepsies share many features but also differ in many respects. The fact that many anticonvulsant drugs are selective for specific seizure types[12] suggests that the origin and progression of all seizures are not identical. Several hypotheses have been proposed to explain why seizures occur. These hypotheses focus on defects in (1) ionic conductance of the neuronal membrane, including Na^+, Ca^{++}, K^+, Cl^-, and H^+; (2) inhibitory neuronal circuits, especially those involving the inhibitory neurotransmitter γ-aminobutyric acid (GABA); (3)

excitatory mechanisms, especially those involving the excitatory neurotransmitter glutamate; (4) altered synaptic function; (5) depressed energy metabolism; and (6) other processes supporting presynaptic or postsynaptic function, such as other neurotransmitters with modulatory roles, peptides, hormones, growth factors, second messengers, nuclear changes, glial function, and gap junctional function.

Different brain structures may participate as seizure sources. The cortex is often involved. In complex partial epilepsy, unusual activity in the temporal lobe and limbic structures is found. A more recent gene chip study identified abnormal release of glutamate from astrocytes as a significant change in temporal lobe epileptic foci.[28] For absence seizures, changes in the thalamus, basal ganglia, and substantia nigra pars reticulata may be involved.[50] Audiogenic seizures seem to involve the mesencephalon and basal ganglia.

Diagnostic imaging is being used to help localize the sites of abnormal brain function in epilepsy. Positron labeled 2-[^{18}F]fluoro-2-deoxy-D-glucose has been approved as an aid for diagnosis of epilepsy by PET. Generally, epileptic zones show hypometabolism in the intraictal state. Another PET imaging technique involves the use of the benzodiazepine antagonist flumazenil, which visualizes generally decreased binding in epileptic tissues.[40] Additional tracers and imaging techniques are being developed.

In otherwise normal brains, seizures can sometimes be initiated by repeated electrical stimulations, a phenomenon called *kindling*. Epilepsy may result when a genetic predisposition or environmental factor triggers a seizure, which is followed by additional processes such as seizure-induced neuronal death and abnormal postseizure tissue repair. Repeated seizures can produce cumulative damage. By studying patients, animal models of epilepsy, and the mechanism of action of the anticonvulsant drugs, new ideas for therapy are developed. Individual anticonvulsants often have more than one possible pharmacologic action that may explain their anticonvulsant effect.

ANTICONVULSANT THERAPY

Anticonvulsants control, but do not cure epilepsy. They may play a neuroprotective role, however, by limiting cumulative pathology resulting from the seizures. The primary objective of anticonvulsant therapy is to suppress seizures while causing minimal impairment of central nervous system (CNS) function or other deleterious side effects. With the currently available anticonvulsants, significant seizure control can be obtained in 70% to 80% of cases. Many patients with epilepsy have to take medication for life to ensure control of seizures.

Phenobarbital, introduced in 1912, was the first drug used extensively to treat seizures. Between 1938 and 1960, numerous anticonvulsant agents were introduced, including the hydantoins, succinimides, and primidone. Between 1960 and 1992, several novel anticonvulsants were introduced (e.g., carbamazepine, valproic acid, clonazepam, clorazepate). With the passages of the Expedited Drug Approval Act and Prescription Drug User Fee Act in 1992, the approval process was facilitated, and 10 agents have since been introduced (with several more currently in clinical trials). Many of these drugs have been approved as adjunctive agents for use with earlier drugs in the treatment of "partial onset seizures"; these indications have broadened with increased experience in their use. In some cases the newer agents are referred to as second-generation and third-generation agents, and in several cases newer agents are related to older agents, such as phenytoin and fosphenytoin; carbamazepine and oxcarbazine; and meprobamate, felbamate, and fluorofelbamate (the last mentioned in premarketing trials).[34]

Drugs are described as having characteristic spectra for treating the various forms of seizures (Figure 14-1). Prescribing antiepileptic drugs for conditions outside their spectra may lead to problems beyond simple therapeutic failure. In particular, absence seizures can be exacerbated by many of

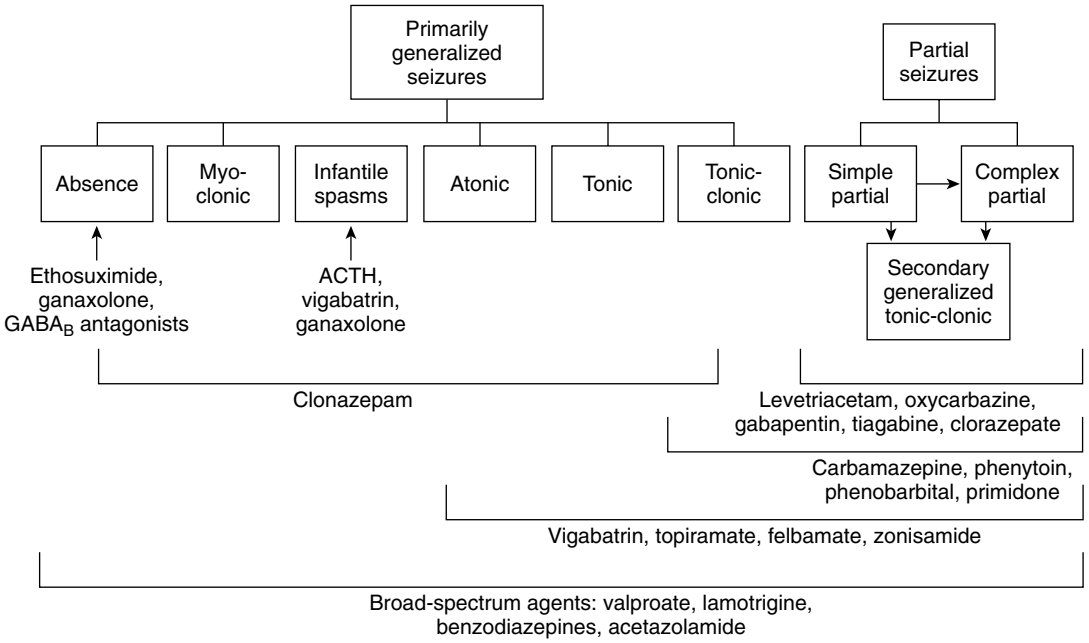

FIGURE **14-1** Therapeutic spectra of anticonvulsant drugs. Anticonvulsant agents need to be matched to the convulsive disorder being treated. Phenytoin, phenobarbital, carbamazepine, oxycarbazine, vigabatrin, gabapentin, and tiagabine are ineffective in, but can aggravate, absence and myoclonic seizures. Benzodiazepines and acetazolamide have broad spectra, but tolerance develops to their actions, so they cannot be used for maintenance therapy. *ACTH*, Adrenocorticotropic hormone; *GABA$_B$*, γ-aminobutyric acid$_B$ receptor.

the drugs used to treat tonic-clonic seizures. Some children "outgrow" absence epilepsy but have a tendency to develop other forms of epilepsy in later years. The discovery of valproic acid, which can control many forms of epilepsy, was a major breakthrough for patients in whom absence seizures convert to tonic-clonic seizures. The careful withdrawal of anticonvulsant therapy in children with a history of tonic-clonic epilepsy, but who have been seizure-free for several years, is sometimes successful. Finally, adults whose seizures were few in number before initiation of treatment and are well controlled with a single anticonvulsant may be weaned after 2 years of therapy with a reasonable expectation (>50%) of avoiding relapse.

Different anticonvulsant drugs can be used for different aspects of seizure disorders. *Anticonvulsant* is a term that has used for agents that terminate seizures or status epilepticus events.[17] Antiepileptogenic agents are used to prevent the development of epilepsy after a seizure-triggering event. The term *anti-ictogenic* refers to drugs that prevent the reoccurrence of seizures in an individual with a diagnosis of epilepsy. In this context, benzodiazepines are used as anticonvulsants for the emergency treatment of seizures in the dental office, although their use as anti-ictogenic drugs is limited by the development of tolerance to their anticonvulsant actions.

Typically about 50% of patients respond to traditional agents, and between 20% and 40% of the remainder respond to the addition of a supplemental agent. The drugs used to treat epilepsy and their proposed mechanisms of action and current indications are summarized in Table 14-2.

Because anticonvulsants are often taken for prolonged periods, the likelihood of detecting and documenting side effects and adverse reactions is greater than for agents used for shorter periods. Anticonvulsants may have long lists of potential adverse reactions, but the incidence of many of these reactions is low. Adverse reactions can result from the direct action of the drug, such as dizziness, drowsiness, and ataxia. These dose-related reactions are common but not usually dangerous. Reported adverse reactions may also include withdrawal phenomena, which make the reactions seem paradoxic. Some reactions reflect manifestations of allergic reactions, which may range from a rash to life-threatening Stevens-Johnson syndrome. Other adverse reactions are detected by standard blood tests; these range from benign elevation of liver enzymes to serious hepatic failure.

Several antiepileptic drugs can alter liver enzyme function. A cluster of adverse reactions and drug interactions can result from induction of hepatic enzymes, which may alter the metabolism of (1) the inducing anticonvulsant agent; (2) other drugs, altering their half-lives or toxicity; (3) vitamins (folate, vitamins D or K), which can produce vitamin deficiency disorders such as megaloblastic anemia, decreased bone density, fetal toxicity, or bleeding disorders; and (4) hormones (thyroid hormone or birth control pills). Drug effects on liver microsomal enzyme activity are summarized in Box 14-1. Carbamazepine, phenobarbital, phenytoin, and primidone are well-documented induction agents for the oxidative cytochrome P450 pathway and for phase II synthetic or conjugation elimination pathways (including uridine diphosphate glucuronosyltransferase [UGT]) and in some cases for P-glycoprotein or multidrug resistance proteins (MDR), which may play a role in multiple anticonvulsant drug resistance and poor seizure control. Phenobarbital, phenytoin, carbamazepine, felbamate, lamotrigine, gabapentin, and topiramate bind to P-glycoproteins that seem to facilitate their elimination from the brain. Lamotrigine selectively inhibits UGT. Valproate and topiramate may inhibit oxidative enzymes, prolonging the actions of other drugs. Oxcarbazepine and phenytoin may also inhibit some liver enzymes, as shown in Box 14-1.

BOX 14-1

Adverse Effect of Antiepileptic Drugs on Liver Microsomal Enzymes

Drugs That Can Induce Liver Microsomal Enzymes

Phenytoin†

*Induces to a lesser degree than carbamazepine.
†Inhibition and induction have been reported. This is possible because different cytochrome P450 enzyme classes are involved in each effect.

Additional adverse reactions associated with anticonvulsant drugs include gingival overgrowth, aplastic anemia, hepatotoxicity, renal stones, visual disturbances, and fevers. These may represent pharmacogenomic processes or poorly understood aspects of their pharmacologic features in susceptible patients. Sometimes the reaction is manifested as teratogenicity or cancer; these delayed toxicities are dose independent, but host dependent. More recent studies have found new evidence that anticonvulsant drug use contributes to an increased incidence of birth defects.[19] Behavioral, neurologic, and psychiatric reactions are common and can occur with several of the anticonvulsants. Drugs that facilitate GABA or inhibit glutamate pathways may be more likely to induce amnesia.

Anticonvulsant drugs can paradoxically promote seizure activity or precipitate new seizure types. Carbamazepine can increase absence and other seizures. Other anticonvulsants that may exacerbate seizures include phenytoin, phenobarbital, vigabatrin, oxycarbazine, lamotrigine, gabapentin, felbamate, and tiagabine.[12] Increased seizure frequency is more likely in patients with severe seizure disorders.

Newer agents are expected to have more favorable safety profiles based on their different mechanisms of action and their lessened interaction with the microsomal drug metabolizing system. A full understanding of the clinical toxicology of drugs can take years to develop, however. In the case of vigabatrin, early reports about the drug can be found in the 1970s, but the first report of patients commonly (≥30%) developing irreversible visual field defects was published in 1997.[15] Gabapentin was found to have a low side-effect profile in evaluation trials but is now being used at doses that are many times greater than were typically studied. Experts have noted that much of what is known about the new anticonvulsant drugs has been derived from manufacturer-sponsored trials. Differences in studied patient populations, dosages used, and the end points reported make clinically meaningful comparisons problematic; larger comparison studies by independent groups are still needed.[9]

CHEMISTRY AND STRUCTURE-ACTIVITY RELATIONSHIPS

Figure 14-2 shows the common structure present in all the clinically effective anticonvulsants developed before 1960. Substitution at position 1 of the ring results in the various classes of anticonvulsants indicated in Table 14-3.

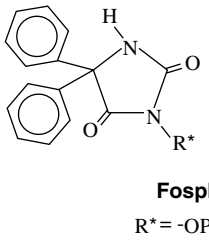
Carbamazepine **Oxcarbazepine**

FIGURE **14-4** Structural formulas of carbamazepine and oxcarbazepine.

A phenyl ring at R_1 or R_2, such as appears in phenytoin, is a highly desirable, although not crucial substituent for protection against tonic-clonic epilepsy. An alkyl substituent at R_1 or R_2, such as appears in ethosuximide, is desirable (but not crucial) for control of absence seizures. A great deal of detailed structure activity information was obtained to identify opportunities for developing improved agents. More recent discoveries have included several agents with unrelated structures, however. Valproic acid is n-dipropylacetic acid (Figure 14-3), a simple branched-chain carboxylic acid, and carbamazepine (Figure 14-4) is chemically related to the tricyclic antidepressants and is used in the treatment of certain affective disorders (see Chapter 12).

HYDANTOINS

Phenytoin (diphenylhydantoin) is one of the first drugs to be discovered through an organized scientific search for a therapeutically effective compound. Introduced in 1938, phenytoin was immediately recognized as a breakthrough in anticonvulsant therapy because it suppressed seizures without causing as much sedative effect as phenobarbital. Phenytoin is an effective anticonvulsant against tonic-clonic and partial seizures and an important pharmacologic tool that has increased understanding of the underlying mechanisms responsible for epileptic syndromes. Mephenytoin and ethotoin are hydantoins related to phenytoin but are now rarely used. Fosphenytoin, the newest hydantoin, is a phosphorylated prodrug that is rapidly converted to phenytoin by endogenous phosphatase enzymes. It is water soluble and is better tolerated by parenteral administration. The structures of phenytoin and fosphenytoin are shown in Figure 14-5.



Phenytoin **Fosphenytoin**

R* = H R* = $-OPO_3^{--} + 2\,Na^+$

FIGURE **14-5** Structural formulas of phenytoin and fosphenytoin.

Pharmacologic Effects

Although the mechanism of action responsible for the anticonvulsant effect of phenytoin is not established, many of its known pharmacologic properties may contribute to it. In neurophysiologic studies, phenytoin prevents the spread of abnormal neuronal depolarization from the epileptic focus to surrounding normal neuronal populations, but spontaneous discharge at the focus is not depressed. Additionally, phenytoin suppresses the duration of neuronal afterdischarge. Phenytoin may reduce the spread of neuronal activity and afterdischarge by blocking post-tetanic potentiation, a phenomenon in which synaptic transmission is enhanced as a result of repetitive presynaptic activation (as would occur at an abnormally firing epileptic focus).

The major site of action of phenytoin seems to be at the Na^+ channel, and various actions have been shown at this site. The only mechanism evident at concentrations equivalent to therapeutic plasma concentrations (10 μg/mL to 20 μg/mL) is a reduction, however, in sustained high-frequency neuronal firing caused by phenytoin binding reversibly to inactivated Na^+ channels.[27] Phenytoin delays the neuronal recovery process whereby Na^+ channels cycle from the refractory, inactivated state to the responsive, closed configuration, which is required before an action potential can be generated again. Phenytoin binding to inactivated Na^+ channels is frequency and voltage dependent so that it becomes greater as neuronal depolarization and firing frequency increase. These properties are ideally suited for anticonvulsant activity because high-frequency neuronal discharge is characteristic of the epileptic disorders.

High extracellular K^+, typically found during seizures, also increases the effectiveness of phenytoin. Normal (slower) neuronal activity is unaffected by phenytoin, which may explain its minimal sedative effects. At slightly greater than therapeutic concentrations, phenytoin interferes with Ca^{++} channels and the interaction of Ca^{++} and calmodulin, which disrupts Ca^{++}-dependent phosphorylation of proteins necessary for neurotransmitter release from presynaptic nerve terminals. There are also some reports of phenytoin facilitating GABA or inhibiting glutamate processes.[8] Phenytoin has also

been found to alter the metabolism of some growth factors, which could play a role in neuroprotective actions of the drug (see later).

Although many mechanisms have been shown for phenytoin, prolonging Na^+ channel inactivation is the most compelling explanation for its anticonvulsant effect. This action is one of the few that occur at therapeutic concentrations, and the characteristics of this mechanism are ideally suited for anticonvulsant activity.

Absorption, Fate, and Excretion

Phenytoin is absorbed slowly from the gastrointestinal tract. The absorption rate varies with the individual, but differences in formulation of the dosage unit account for much of this fluctuation. The U.S. Food and Drug Administration (FDA) requires that phenytoin capsules be labeled as "extended" or "prompt" depending on their absorption rate. An extended-action capsule has slow absorption, with peak blood concentrations obtained in 4 to 12 hours. A prompt-action capsule has rapid absorption, with peak concentrations occurring in 1.5 to 3 hours. Because noncompliance is a major problem in anticonvulsant therapy, it is sometimes advisable to administer the total daily dose of phenytoin at one time. Once-a-day administration is inappropriate for suspensions of phenytoin (commonly used for children) because plasma concentrations may reach toxic values. Changing from one dosage form or manufacturer to another has led to suboptimal plasma concentrations from differences in bioavailability.

Phenytoin given by intravenous injection can produce thrombophlebitis, arrhythmia, and hypotension. These side effects are largely caused by the vehicle needed to solubilize phenytoin for injection. Intramuscular injection of phenytoin may precipitate in the muscle, cause pain, and be poorly absorbed. Fosphenytoin is a water-soluble analogue that may be given intravenously or intramuscularly. After intramuscular administration, it produces much less pain and is absorbed rapidly.[35]

Phenytoin is highly protein bound (90%), which may play a role in interactions with drugs that compete for plasma protein binding sites. Phenytoin is inactivated in the liver to its primary metabolite, the parahydroxyphenyl derivative. Phenytoin can induce drug metabolizing enzymes, including CYP3A4 and UGT. After conjugation with glucuronic acid, phenytoin and its metabolites are eliminated in the urine. Phenytoin removal from the brain may be facilitated by P-glycoproteins and MDR proteins, which may be induced in epileptic tissue. Phenytoin is also excreted by the salivary glands, which may be a contributing factor in producing gingival overgrowth (hyperplasia) (see later). With peak concentrations seen at 3 to 12 hours, the elimination half-life of phenytoin (and fosphenytoin) generally ranges from 6 to 24 hours. Near the effective dose, phenytoin often exhibits capacity-limited metabolism because the enzymes responsible for its metabolism are readily saturated. The drug's half-life can become longer, and, if blood concentrations are increased beyond the saturation threshold, rapid drug accumulation may increase the likelihood of adverse reactions.

Adverse Effects

Ataxia, nystagmus, incoordination, and unsteadiness occur with phenytoin overdose. These sequelae may result from phenytoin-induced changes on Purkinje cells of the cerebellum (such changes may also be caused by repeated seizures). Drowsiness, lethargy, diplopia, confusion, and (rarely) hallucinations are other manifestations of phenytoin toxicity. Phenytoin in usual doses has little detrimental effect on the cardiovascular system; however, it can cause cardiovascular collapse, irreversible coma, and death if administered in massive intravenous doses.

Phenytoin promotes gingival overgrowth in approximately 10% to 30% of all patients. Gingival overgrowth is usually more severe in children, for whom its incidence may be 50%. The primary mechanism responsible for this side effect is unknown. Several hypotheses have been proposed involving inflammation, bacterial plaque, the presence of teeth or dental implants, gingival fibroblast phenotype, epithelial growth factor, collagenase activation, folic acid deficiency, Na^+/Ca^{++} flux, and perhaps salivary delivery of phenytoin into the mouth.[2] It has been observed more recently that phenytoin increases platelet-derived growth factor B and its mRNA from macrophages that are thought to induce gingival fibroblast proliferation and local angiogenesis.[20] The transforming growth factor-β pathway involving Grb1, SOS-RAS-ERK1/2, AP1, and Ca^{++} signaling pathways has been implicated in hereditary gingival overgrowth and may play a role in drug-induced gingival overgrowth.[13] The result is an increase in fibroblast cell growth with increased interstitial ground substance.[38] Other drugs that induce gingival overgrowth include the immunosuppressant cyclosporine and the dihydropyridine Ca^{++} channel blocking drugs. A more recent investigation has found that all of these drugs have the ability to reduce apoptosis (programmed cell death), suggesting that reduced cell loss rates could also play a role in gingival overgrowth.[24] Figure 14-6 represents a possible model of gingival overgrowth.

Phenytoin may also cause numerous other side effects as summarized in Table 14-4. Phenytoin interferes with the metabolic activation of vitamins D and K, and the absorption of Ca^{++}. Although the resultant effect on bone metabolism is usually subclinical, overt cases of rickets and osteomalacia have been observed.[33] Vitamin D or K supplements may prevent these conditions.[19,33] Vitamin K modulates the synthesis of osteocalcin and matrix G1a proteins, which influence Ca^{++} metabolism in bone. Children born to mothers who have received phenytoin (often in combination with phenobarbital, carbamazepine, or valproic acid) throughout their pregnancy are at increased risk of congenital malformation.[18] The most common anomalies are cleft lip, cleft palate, and congenital heart disease. These developmental defects, a delay in psychomotor development, prenatal and postnatal growth deficiencies, impaired intellectual performance, and genitourinary and skeletal deformations are collectively referred to as the *fetal hydantoin syndrome*. Although none of the well-studied anticonvulsants is completely devoid of teratogenic potential, animal data suggest that, of the older drugs, carbamazepine and phenobarbital may be safer anticonvulsants to use in pregnancy.[45]

BARBITURATES

Phenobarbital is one of the oldest, least expensive, least toxic, and most effective anticonvulsants available. Because of its sedative effect and the introduction of newer drugs, the use of phenobarbital for treating epileptic disorders has waned. Phenobarbital offers an appreciable spectrum of anticonvulsant activity because of its effectiveness against many tonic-clonic and partial seizures.

Barbiturates other than phenobarbital are occasionally used for the treatment of epilepsy. Mephobarbital is less sedating than phenobarbital, although its anticonvulsant properties result largely from its metabolic conversion to phenobarbital. Primidone, a deoxybarbiturate relative of phenobarbital, is used for generalized and partial seizures, particularly seizures refractory to other drugs. The use of primidone is limited because of its marked sedative properties immediately after administration.

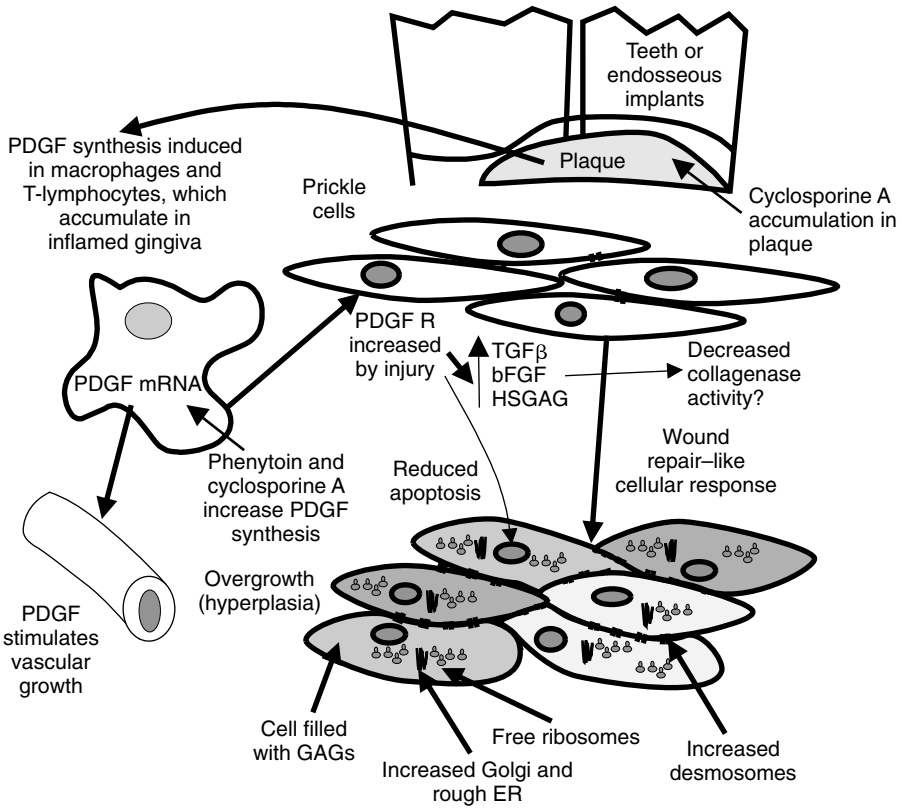


FIGURE **14-6** Effect of phenytoin and cyclosporine on gingival overgrowth. Predisposing factors include the presence of teeth or implants, inflammation, and overgrowth-inducing drugs. Phenytoin increases by sixfold platelet-derived growth factor *(PDGF)* mRNA in reparative/proliferative macrophages.[38] PDGF is thought to increase angiogenesis and wound repair. Increases in fibroblastic growth factors, such as transforming growth factor-β *(TGFβ)* and basic fibroblast growth factor *(bFGF)*, and production of heparin sulfate glycosaminoglycan *(HSGAG)* are induced by PDGF acting on its receptor *(R)*. Prickle cells in the gingiva become filled with glycosaminoglycans *(GAGs)*, rough endoplasmic reticulum *(ER)*, and ribosomes, and their connective desmosomes proliferate *(bottom)*.

TABLE **14-4**

Adverse Reactions Reported for Anticonvulsant Drugs

DRUG	ADVERSE REACTIONS
Phenytoin and fosphenytoin	Gingival hyperplasia, hirsutism, megaloblastic anemia, osteomalacia, sedation, ataxia, gastrointestinal disturbances, behavioral changes
Carbamazepine and oxcarbazepine	Sedation, weakness, ataxia, diplopia, gastrointestinal disturbances, skin rash, behavioral changes, aplastic anemia (rare)
Phenobarbital	Sedation, weakness, ataxia, reduced cognition, respiratory depression, blood dyscrasias, megaloblastic anemia, osteomalacia, drug dependence
Valproic acid	Sedation, weakness, ataxia, gastrointestinal disturbances, weight gain, hepatotoxicity (especially in children <2 years old), spina bifida if given during pregnancy, visual disturbances, pancreatitis, hyperammonemia
Ethosuximide	Sedation, weakness, gastrointestinal disturbances, ataxia, behavioral changes, lupus erythematosus (rare)
Diazepam	Sedation, weakness, nystagmus, ataxia, drug dependence, drug tolerance
Lorazepam	Same as diazepam
Midazolam	Same as diazepam
Chlorazepate	Same as diazepam
Clonazepam	Same as diazepam
Gabapentin	Sedation, weakness, ataxia, rash, tremor
Lamotrigine	Sedation, weakness, ataxia, diplopia, rash, headache, gastrointestinal disturbances, Stevens-Johnson syndrome (1% of children)
Topiramate	Sedation, weakness, ataxia, visual disturbances, paresthesias, kidney stones, breast pain
Tiagabine	Sedation, weakness, ataxia, gastrointestinal disturbances, tremor
Vigabatrin	Sedation, weakness, ataxia, psychotic reactions, visual disturbances, blood dyscrasias
Zonisamide	Sedation, weakness, ataxia, gastrointestinal disturbances, skin rashes, Stevens-Johnson syndrome, renal tubule acidosis, renal stones
Levetiracetam	Sedation, weakness, ataxia, exacerbation of behavioral problems, withdrawal reactions

Pharmacologic Effects

The barbiturates are CNS depressants and exert a marked inhibitory effect on repetitive neuronal activity in CNS pathways. Similar to phenytoin, phenobarbital limits the spread of seizure discharge, but it also raises the threshold for activation of epileptic foci. As discussed in Chapter 13 (which also addresses the general pharmacology of these drugs), the barbiturates enhance the binding of GABA to postsynaptic $GABA_A$ receptors and increase the time that GABA-activated Cl^- channels are open. They also activate Cl^- channels inde-

pendently of GABA. Inhibition of the excitatory effects of glutamate (possibly kinate and α-amino-3-hydroxy-5-methyl-4-isoxazole propionate [AMPA] receptor types) may also be a major antiepileptic mechanism. Other mechanisms seem to play lesser roles. Barbiturates block the transcellular transport of Na^+ and K^+, which could explain their membrane-stabilizing properties. Similar to phenytoin, barbiturates interfere with Ca^{++} channels and inhibit Ca^{++} entry into presynaptic nerve terminals.

Absorption, Fate, and Excretion

Phenobarbital is completely but slowly absorbed from the gastrointestinal tract. About half of the drug is bound to plasma protein. Approximately 30% of phenobarbital is excreted unchanged in the urine, and the rest is inactivated by the liver. Phenobarbital is a substrate for several cytochrome P450 isozymes. As discussed in Chapter 2, phenobarbital can also induce CYP2A, CYP2B, CYP2C, CYP3A, and CYP6A isoforms; reduced nicotinamide adenine dinucleotide cytochrome P450 reductase; UGT[44]; P-glycoproteins; and MDR proteins (see Chapter 2). The plasma half-life of phenobarbital ranges between 50 and 140 hours. Because of its long half-life, very small fluctuations in plasma concentrations occur over a 24-hour period. Primidone is metabolized to phenobarbital, which can be detected in the plasma in approximately 24 to 48 hours, and phenylethylmalonamide, which also has anticonvulsant properties and is measurable in plasma within 1 to 2 hours and has a 10- to 18-hour half-life.

Adverse Effects

The major adverse effects of phenobarbital are discussed in Chapter 13. The most common initial effect of phenobarbital and the other barbiturates is sedation. (A paradoxic excitatory reaction may sometimes occur in children and elderly patients.) Tolerance usually develops to the sedative effect. Similar to phenytoin, phenobarbital can cause megaloblastic anemia and osteomalacia, which have been successfully treated with folic acid and vitamins D and K. Phenobarbital seems to be free of teratogenic effects, but when phenobarbital is given with phenytoin (a commonly used combination), teratogenicity seems to increase.

The most common side effects of primidone are primarily a result of its CNS depressant properties. Complications include sedation, dizziness, ataxia, and nystagmus. Various blood dyscrasias and rashes similar to conditions described for phenytoin can occur.

CARBAMAZEPINE

Carbamazepine is an iminostilbene derivative (see Figure 14-4) closely related chemically to the tricyclic antidepressants. It differs from the tricyclic antidepressant imipramine by the presence of a double bond in the central ring and a shorter side chain. Carbamazepine is a major anticonvulsant drug and is highly effective against tonic-clonic and partial seizures. It also lacks dysmorphic side effects (e.g., gingival hypertrophy, acne, hirsutism) common to phenytoin. Similar to phenytoin, carbamazepine is indicated for the treatment of trigeminal neuralgia; carbamazepine has been the most commonly used drug for this disorder. Carbamazepine is also effective for other neuropathic pains, such as glossopharyngeal neuralgia, postherpetic neuralgia, diabetic neuropathy, causalgia, and hemifacial spasm, but it is not a typical analgesic because it is ineffective for other types of pain. As discussed in Chapter 12, carbamazepine is sometimes effective in the treatment or prophylaxis of affective disorders.

A keto analogue, oxcarbazepine, has a therapeutic profile similar to carbamazepine. It may have fewer side effects than carbamazepine and is well tolerated. Oxcarbazepine is a prodrug, requiring metabolic reduction to the 10-hydroxy metabolite before it becomes active. Oxcarbazepine has been approved as monotherapy for partial seizures in patients older than 4 years and adjunctive therapy for children between 2 and 4 years old.

Pharmacologic Effects

Similar to phenytoin, carbamazepine reduces experimentally induced sustained high-frequency neuronal firing at doses that produce clinically relevant plasma concentrations.[31] This effect, similar to that of phenytoin, seems to result from carbamazepine binding to inactivated Na^+ channels, slowing neuronal recovery after activation. This action has been confirmed by using neurophysiologic techniques, such as cell membrane voltage clamping. Carbamazepine also reduces Ca^{++} and Na^+ flux across the neuronal membrane. As with other anticonvulsants, various mechanisms may contribute to its anticonvulsant effect. Nevertheless, limitation of sustained repetitive neuronal firing offers the most likely explanation for the drug's antiepileptic properties. Because of its structural similarity to antidepressants, effects on monamine reuptake function might be expected, but these effects, if any, seem to be minor.

Absorption, Fate, and Excretion

Carbamazepine is absorbed slowly, reaching peak plasma concentrations in 4 to 8 hours. It is distributed throughout the body; highest concentrations occur in the liver, kidneys, and brain. The drug is transported out of the brain by P-glycoproteins and MDR proteins. Carbamazepine is metabolized by cytochrome P450 3A4 and can induce CYP3A4 and UGT, leading to drug interactions and a significant reduction in its own half-life, which is 25 to 65 hours initially and 12 to 17 hours after long-term administration. CYP3A4 inhibitors (e.g., erythromycin) can increase the duration of action of carbamazepine. At least one metabolite of carbamazepine, carbamazepine-10,11-epoxide, has anticonvulsant properties and is stable. Carbamazepine is inactivated by further oxidation and conjugation before being excreted in the urine.

The carbamazepine analogue oxcarbazepine (see Figure 14-4) is rapidly converted to the 10-hydroxy metabolite, which exerts peak activity from 3 to 13 hours and has a 9-hour half-life. Oxcarbazepine is a mild CYP3A4 inducer and, similar to but to a lesser degree than carbamazepine, can accelerate the metabolism of several drugs, including oral contraceptives.

Adverse Effects

The most common signs and symptoms of overdose with carbamazepine are dizziness, diplopia, drowsiness, headache, ataxia, and slurred speech. Convulsions may be precipitated by acute intoxication with carbamazepine, and it exacerbates absence and myoclonic seizures. Various types of involuntary motor activity in elderly patients have been reported, and hallucinations have occurred. Skin rashes have been reported. Certain Asian populations seem to have an increased risk for Stevens-Johnson syndrome. If leukopenia occurs, it is usually mild. Other hematologic reactions to carbamazepine are rare but sometimes life-threatening. Aplastic anemia is of particular concern, and agranulocytosis has also occurred.

VALPROIC ACID

Valproic acid (dipropylacetic acid), approved by the FDA in 1978, is a broad-spectrum anticonvulsant particularly effective against absence seizures but also useful for other general-

ized forms of epilepsy (e.g., tonic-clonic, myoclonic) and partial seizures. Interest has focused on valproic acid because it has a simple chemical structure (see Figure 14-3) unrelated to that of traditional anticonvulsant drugs and was the first drug effective against absence and tonic-clonic seizures. It has also been approved for treatment of mania in bipolar disorder and for migraine pain.

Pharmacologic Effects

Similar to phenytoin and carbamazepine, valproic acid reduces sustained high-frequency neuronal firing at therapeutic doses.[27] Valproic acid apparently binds to a different site on the Na^+ channel than phenytoin, but the final result is similar. As discussed for phenytoin, inhibition of Na^+ channels represents a plausible action because the drug effect is frequency and voltage dependent, becoming more prominent at increasing rates of neuronal depolarization.

Experimental studies have shown that supertherapeutic doses of valproic acid increase brain GABA concentrations by interfering with enzymes involved with GABA. Valproic acid is a weak inhibitor of GABA transaminase, the first enzyme in the catabolic pathway, and a more potent inhibitor of succinic semialdehyde dehydrogenase, the next enzyme in the pathway. Valproic acid may also increase brain GABA by stimulating glutamic acid decarboxylase, the major synthetic enzyme for GABA. Other research has found an association between valproate anticonvulsant activity and reductions of the excitatory neurotransmitter aspartate in the brain.[27]

The salutary effect of valproic acid on absence seizures is most likely associated with the drug's ability to inhibit Ca^{++} influx through T-type Ca^{++} channels. This mechanism is discussed later in the section on the succinimides. In addition to seizures, valproic acid is approved for the treatment of bipolar disorder, and its divalproex extended-release form is approved for the prevention of migraine headaches.

Absorption, Fate, and Excretion

Valproic acid is completely absorbed from the gastrointestinal tract and is highly bound to plasma proteins. The absorption rate depends on the formulation (capsules, tablets, or syrup); food may delay absorption. Divalproex sodium, a combination of valproic acid and its Na^+ salt, is supplied in capsules that are designed to be opened and sprinkled on soft food. This product is a convenient dosage form for children and elderly patients.

Valproic acid crosses membrane barriers and is found in the fetus, milk, liver, kidney, and brain. It also accumulates in growing bone. Valproic acid is thought to enter the brain through a saturable process, and brain concentrations can be increased by blocking the MDR protein with probenecid. Valproic acid undergoes complex oxidation and conjugation before excretion in the urine with 10 or more metabolites. It inhibits its own metabolism and that of other drugs, such as phenobarbital. This effect can contribute to drug accumulation and drug interactions. Valproic acid inhibits the metabolism of some substrates metabolized by CYP2C9 and UGT. Experimental data suggest that valproic acid can induce CYP3A4 and MDR glycoproteins; however, this has not been widely acknowledged.[4] The half-life of valproic acid is approximately 5 to 20 hours, with peak blood concentrations at 1 to 4 hours.

Adverse Effects

The most common manifestations of valproic acid toxicity are appetite disturbances, indigestion, heartburn, nausea, and weight change. The gastrointestinal reactions are usually temporary. Tremor is also a common adverse effect, especially at higher doses. Valproic acid can cause fatal hepatic dysfunction, and children are particularly susceptible. The likelihood of this apparently idiosyncratic effect decreases with age, being most common in children younger than 2 years and uncommon after age 10 years. Irreversible hepatotoxicity seems to be caused by a toxic metabolite (2-n-propyl-4-pentenoic acid). Because its production is known to be increased by enzyme-inducing anticonvulsants, combined therapy of valproic acid and such anticonvulsants puts the patient at increased risk of liver damage. More commonly, valproic acid may cause a reversible hepatotoxicity that is dose dependent.

Another serious toxicity associated with valproate is life-threatening pancreatitis. Pancreatitis can occur in children or adults and may follow a rapid course. This reaction may occur any time when taking the medication. Presenting signs include abdominal pain, nausea, vomiting, or anorexia. If pancreatitis is diagnosed, the drug should be stopped. Other serious side effects, such as neurologic and hematologic toxicity, are rare. High doses of valproic acid may cause platelet disorders, leading to bruising of the skin and, occasionally, gingival bleeding. Platelet dysfunction usually is not severe, however, and the patient is asymptomatic. Valproic acid is associated with neural tube defects, and its use during pregnancy results in a significantly higher risk of spina bifida. Surveys have found the teratogenic risk may be higher than that for other anticonvulsants.[47]

SUCCINIMIDES

Ethosuximide is a major drug for the treatment of absence seizures. The use of related succinimides (methsuximide, phensuximide) is restricted to patients refractory to ethosuximide because these agents are less effective or more toxic, or both. Another agent, the oxazolidinedione trimethadione, has also been used in absence seizures but is rarely used today because of its toxicity.

Pharmacologic Effects

Ethosuximide prevents absence seizures in approximately 50% of patients and reduces their frequency in another 40% to 45%. The mechanism of action of ethosuximide is not firmly established; however, its administration leads to a dose-dependent inhibition of low-threshold Ca^{++} currents carried by T-type Ca^{++} channels.[7] Low-threshold Ca^{++} currents are an important factor in oscillatory behavior of thalamic neurons, and the thalamus is known to play an important role in generating the 3-Hz spike-and-wave rhythms that characterize petit mal epilepsy. This effect occurs at clinical concentrations and is the best explanation yet proposed for the mechanism of action of drugs effective against absence seizures.

Absorption, Fate, and Excretion

The succinimides are absorbed from the gastrointestinal tract, metabolized in the liver (by CYP3A4), and excreted as metabolites in the urine. The plasma half-life of ethosuximide is approximately 30 hours in children and 45 to 60 hours in adults. Ethosuximide passes membrane barriers rapidly and appears in cerebrospinal fluid, milk, saliva, and fetal tissues. Salivary titers accurately reflect plasma concentrations and may be useful to monitor blood levels.

Adverse Effects

The succinimides commonly cause gastrointestinal distress, headache, dizziness, and skin rash. More serious reactions have been reported but are rare, especially with ethosuximide. Nevertheless, blood counts are recommended at no greater than monthly intervals because potentially fatal bone marrow depression may occur. Patients with hematopoietic toxicity may exhibit fever, sore throat, and coagulopathy, as indicated

by oral and cutaneous petechiae. Ethosuximide is less teratogenic than valproate, of the two, and is preferred in pregnancy.[45]

DRUGS AFFECTING γ-AMINOBUTYRIC ACID TRANSMISSION

GABAergic mechanisms seem to contribute to seizure susceptibility in numerous animal models of epilepsy. Impaired GABAergic function can be shown in rats, mice, gerbils, and baboons genetically prone to epilepsy. Although faulty GABAergic mechanisms have not been convincingly shown in humans, cerebrospinal fluid concentrations of GABA are reduced in epileptic patients, and surgically removed epileptic brain tissue exhibits decreased GABAergic activity. Drugs that are antagonists at $GABA_A$ receptors (bicuculline, picrotoxin) are potent convulsants, whereas drugs that facilitate GABAergic mechanisms (benzodiazepines) are anticonvulsants. Flumazenil, a benzodiazepine receptor antagonist, has been reported to precipitate seizures in patients who have an elevated seizure risk or are taking anticonvulsant benzodiazepines or tricyclic antidepressants,[41] or received midazolam to treat local anesthetic toxicity.[53] Abnormal flumazenil binding, imaged with PET, is used to target abnormal epileptogenic tissue for surgical removal.[23] Inverse agonists at the benzodiazepine receptors can also act as convulsants because they reduce the contribution of constitutively active (active without agonist) benzodiazepine receptors. This effect leads to decreased Cl^- channel conductance, resulting in depolarization.

Similar to other neurotransmitter pathways, the $GABA_A$ receptor system has multiple sites that may lend themselves to pharmacologic control (Figure 14-7).[5] Presynaptically, neurotransmitter synthesis, storage, and release mechanisms may be targeted. Additionally, GABA reuptake transporters, autoreceptors, and catabolic enzymes are found presynaptically. Some GABAergic neurons contain cotransmitters, such as enkephalin or substance P. Postsynaptically, multiple forms of $GABA_A$ receptors (ligand-gated ion channels) are found. The ligand-gated ion channel can be composed of various component isoforms. At this time six α, four β, three γ, three ρ, and individual δ, ε, π, and θ subunit isoforms have been identified. Each ion channel is a mixture of five of these subunits, with the most predominant isoform being two α_1, two β_2, and one γ_2. Some changes in ion channel composition have been seen in epileptic brain.[6] A postsynaptic machinery for controlling the numbers and types of receptors has been described, and there are postsynaptic second messenger processes and receptor phosphorylation.[29]

Cooperative relationships may exist between GABA receptors and other receptor types that produce adaptive changes.[5] These processes may include the basis for developing tolerance to the actions of some antiepileptic drugs. In addition, GABA uptake proteins and metabolic enzymes may be found in glial cells and some perineural structures.[5] GABA also acts through $GABA_B$ receptors (metabotropic receptors; see Chapter 13).

Benzodiazepines

Most benzodiazepine agonists have anticonvulsant properties. The pharmacologic profiles of these drugs and the mechanisms by which they facilitate GABAergic transmission are discussed in detail in Chapter 13. Diazepam, clonazepam, clorazepate, midazolam, and lorazepam are the principal benzodiazepines used clinically in the United States as anticonvulsants. Midazolam, clonazepam, and lorazepam have higher affinities for the benzodiazepine receptor and may be more effective anticonvulsants.[37] Diazepam is effective in terminating the life-threatening continual convulsion of status epilepticus and for the treatment of local anesthetic–induced seizures. Intravenous lorazepam (0.1 mg/kg) was found to be more effective than phenytoin alone (18 mg/kg) for the treatment of generalized status epilepticus[48] and successfully treated a greater percentage of patients than diazepam. The actions of lorazepam can be slow to develop but are longer lasting than diazepam. Intravenous midazolam has also been found to be effective in the treatment of status epilepticus and local anesthetic excitotoxicity. Buccal midazolam is also effective and can be administered more quickly and conveniently than rectal diazepam emulsion, and its actions are seen more quickly.[1,52] Clonazepam is generally effective for absence seizures and childhood myoclonic epilepsy and is sometimes

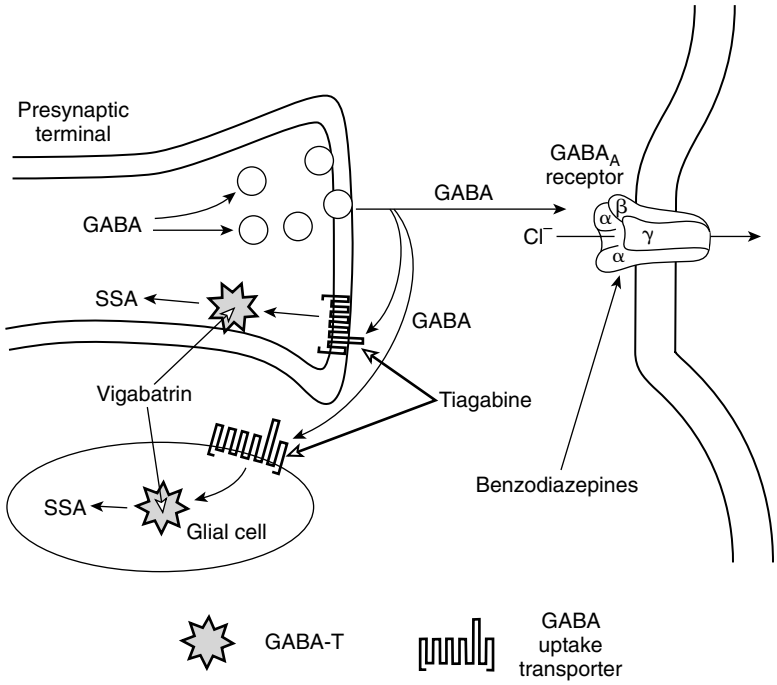

FIGURE **14-7** Proposed sites of actions for drugs acting at the γ-aminobutyric acid *(GABA)* synapse. GABA inhibits the postsynaptic neuron by acting on a receptor *($GABA_A$)* on the Cl^- channel. Benzodiazepines act to facilitate the action of GABA postsynaptically by interacting with a separate site on the Cl^- channel. The action of GABA can be terminated by reuptake or catabolism. GABA is taken back into the presynaptic nerve terminals and glial cells by a Na^+-driven symporter protein. Tiagabine blocks this GABA transporter. GABA α-oxoglutarate transaminase *(GABA-T)* terminates the action of GABA by converting it to succinic semialdehyde *(SSA)*. Vigabatrin inhibits GABA-T.

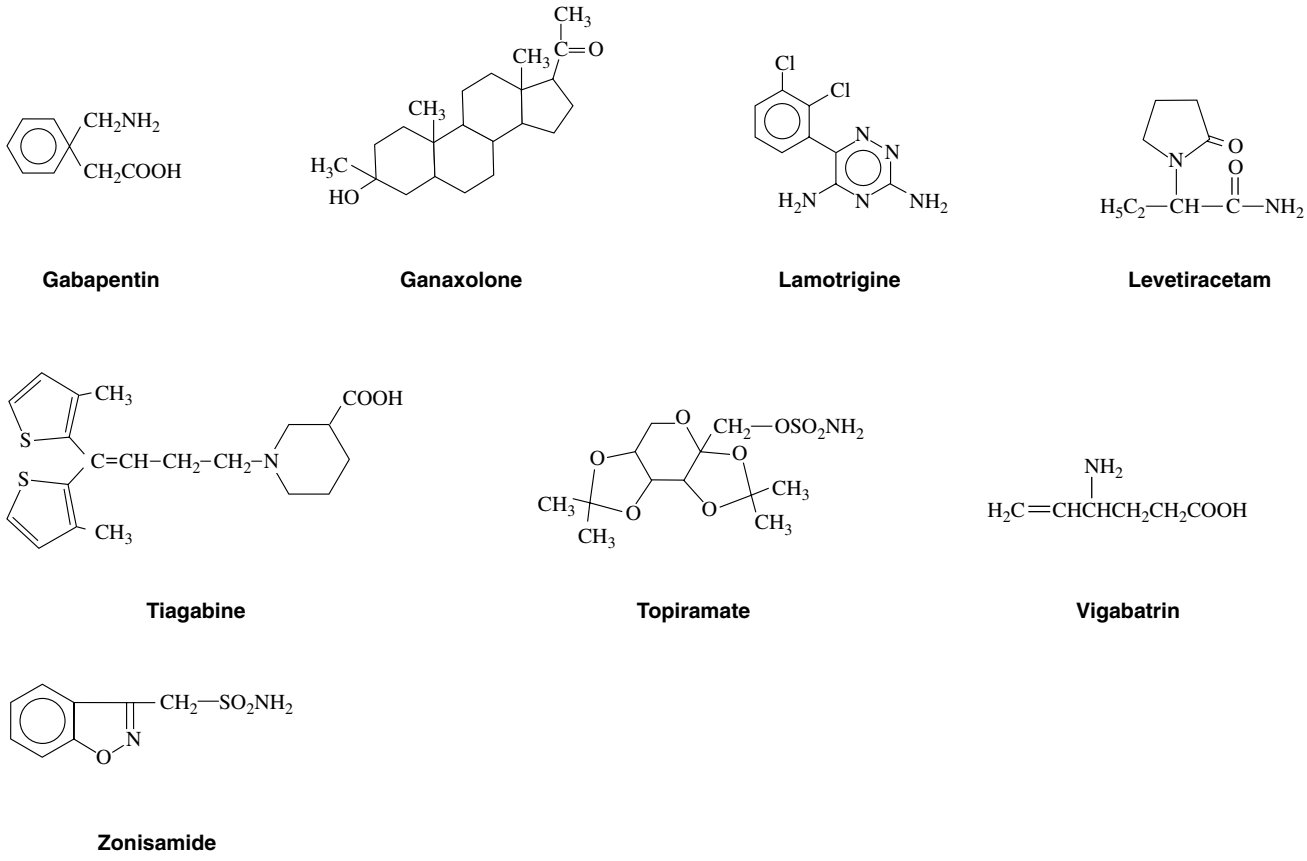

FIGURE **14-8** Structural formulas of newer antiepileptic drugs.

effective for complex partial seizures and reflex epilepsies (photosensitive epilepsy). Clorazepate is indicated as adjunctive therapy in the management of partial seizures.

Similar to phenytoin, benzodiazepines prevent the spread of the seizure discharge but have little effect on neuronal firing at the seizure focus. The anticonvulsant effect of benzodiazepines is thought to be exerted through modification of GABA-mediated systems, as is the case for their antianxiety effect. Different $GABA_A$ receptor subtypes might be involved, however. $GABA_A$ and $GABA_B$ mechanisms are believed to be involved in absence seizures.[42]

The absorption, fate, and excretion of benzodiazepines are discussed in Chapter 13. There are no differences in these properties when these drugs are used as anticonvulsants compared with when they are used as antianxiety agents. Desmethyldiazepam, the major metabolite of clorazepate and diazepam, has anticonvulsant properties. Although the benzodiazepines are useful adjuncts to the conventional anticonvulsants for seizure prophylaxis, patients seem to develop tolerance to their antiseizure effect quickly. The benzodiazepines may have greatest clinical usefulness in short-term therapy, such as when anticonvulsant medication is being changed or for emergency treatment.

The predictable adverse effects of drowsiness, dizziness, ataxia, nystagmus, dysarthria, and hypotonia occur with all benzodiazepines. Respiratory depression can be an issue when intravenous agents are used. Serious side effects are very rare. The administration of clonazepam occasionally precipitates a different variety of seizure from the one being treated. The teratogenic potential of the benzodiazepines is discussed in Chapter 13. There is little evidence that clonazepam is teratogenic, but it is recommended that use of the compound during pregnancy be limited to cases in which the clinical situation warrants the risk.

Nitrazepam, used primarily as a hypnotic, is prescribed in some countries as an anticonvulsant, particularly for the treatment of infantile spasms (see neurosteroids later). Nitrazepam is not available in the United States. The 1,5-benzodiazepines, including clobazam, also are unavailable in the United States. They have anticonvulsant properties and adverse effects similar to the 1,4-benzodiazepines.

Vigabatrin

The inhibitory effect of GABA may be increased by mechanisms other than facilitating its action, as occurs with the benzodiazepines. Inhibition of enzymes responsible for the catabolism of GABA results in increased brain concentrations of GABA.[49] Vigabatrin (γ-vinyl GABA) (Figure 14-8) is an irreversible inhibitor of the enzyme GABA transaminase. Vigabatrin is considered an adjunctive anticonvulsant and is effective for drug-refractory epilepsy. It is more effective for simple and complex partial seizures than for generalized seizures. The drug is rapidly absorbed by the oral route, reaching peak blood concentrations in 0.75 to 2 hours. It does not bind appreciably to plasma protein. Vigabatrin has no active metabolites and is excreted by the kidneys. Its plasma half-life is 4 to 7 hours, but irreversible inhibition of GABA transaminase lasts for several days after the drug is cleared, prolonging the antiepileptic effect. Adverse effects of vigabatrin include sedation, fatigue, weight gain, amnesia, and visual field defects, which include hemi-field or concentric field contractions and may be related to retinal damage produced by edema. The defects may be more common in men and seem to be related to

the total drug exposure.[15] They persist after drug withdrawal. Psychosis may occur infrequently.

Tiagabine

Tiagabine (see Figure 14-8), approved in 1996 as an adjunct for refractory complex epilepsy, is a nipecotic acid derivative that inhibits GABA uptake. Tiagabine is readily absorbed, with a peak blood concentration reached in 45 minutes. This drug is metabolized in the liver by CYP3A4 and possibly CYP1A2, 2C19, and 2D6 to inactive 5-oxo metabolites and is also glucuronidated. Tiagabine has a half life of 7 to 9 hours. Side effects include dizziness, fatigue, sleepiness, nausea, tremor, and difficulty concentrating.

Neurosteroids

In addition to its receptor for benzodiazepines, the $GABA_A$ receptor complex has a separate binding site for steroid molecules. Steroid hormones generally are thought to act through steroid nuclear binding proteins that modify DNA translation in the cell nucleus. Some steroids, such as allopregnenolone, also act on these cell surface receptors to facilitate the action of GABA on the $GABA_A$ receptor of the Cl^- ion channel.

Infantile spasm with a "chaotic" EEG is a serious epileptic condition of early life that is refractory to most anticonvulsants and has a poor prognosis. Historically, it has been effectively treated with adrenocorticotropic hormone. More recent studies have shown that vigabatrin and the neurosteroid ganaxolone[25] are also effective for this condition. Ganaxolone (see Figure 14-8) is a pregnenolone derivative without progestational hormonal activity. It exerts anticonvulsant activity against complex partial seizures, has an anticonvulsant spectrum that suggests usefulness in absence seizures, and is anticonvulsant in an animal model of catamenial epilepsy.[36] It is thought to act on selective $GABA_A$ component isoforms. Other, newer anticonvulsant drugs that are being evaluated for treatment of infantile spasms include topiramate, lamotrigine, and zonisamide.[54]

MISCELLANEOUS ANTICONVULSANTS

Gabapentin and Related Drugs

Gabapentin (see Figure 14-8) is a GABA analogue specifically designed to cross the blood-brain barrier. It is effective as an adjunct for patients with refractory partial seizures. Gabapentin does not interact with GABA receptors, uptake, or metabolism. It may influence synthesis or release of GABA, and it increases GABA concentrations in certain regions of the brain. Gabapentin also binds to an L-type Ca^{++} channel subunit, α2δ. It inhibits depolarizing high voltage–activating Ca^{++} channel currents at therapeutic concentrations.[43] Analogues that bind more tightly to the α2δ subunit seem to be more potent anticonvulsants for partial seizures. Gabapentin is ineffective in the treatment of absence seizure, but has proved useful in the treatment of chronic pain conditions, such as postherpetic neuralgia, diabetic neuropathy, trigeminal neuralgia, and pain associated with multiple sclerosis. The Ca^{++} channel α2δ subunit is upregulated in peripheral nerves with chronic nerve injury.[30] The drug is used orally and has saturable absorption. Elevations of the dose do not produce equivalent increases in blood concentration. It is not bound to plasma protein, is excreted almost entirely by the kidneys, and has a plasma half-life of 4 to 7 hours. The drug is generally well tolerated. Adverse effects include fatigue, dizziness, headache, nausea, and ataxia.

Pregabalin is similar to gabapentin; however, pregabalin has greater affinity for the α2δ subunit of the calcium ion channels and may have greater efficacy for treating neuropathic pain where these subunits are upregulated. It has been approved for the treatment of postherpetic pain, diabetic neuropathy, adjunctive treatment of partial onset seizures, and fibromyalgia. It has been studied as a treatment of oral surgery pain[16] and was found to produce some pain relief. It has also been studied as a treatment for general anxiety disorder.

GABAmimetic Agents

Drugs that successfully mimic GABA in the CNS include progabide, a GABA agonist available in Europe. Progabide is effective in rodent models and some human forms of epilepsy, but it can cause serious adverse effects. Despite its toxicity, progabide has been used to treat simple and complex partial and generalized tonic-clonic, atonic, and myoclonic seizures in patients refractory to other anticonvulsants. GABA agonists generally have a lack of specificity and theoretically could result in GABA receptor downregulation.

Felbamate

In 1993 the FDA approved felbamate, a meprobamate derivative, for use in refractory partial seizures and as adjunctive therapy in children for seizures associated with Lennox-Gastaut syndrome, a disease resistant to most antiepileptic drugs. Shortly thereafter, felbamate was linked to aplastic anemia and acute hepatic failure, and an advisory by the FDA recommended against its use except in cases in which withdrawal or avoidance of the drug represented a serious risk for the patient.

Lamotrigine

Lamotrigine (see Figure 14-8) is a phenyltriazine derivative that inhibits Na^+ influx in rapidly firing neurons. The drug has also been shown to inhibit the release of glutamate from the cortex of rat brain.[49] Lamotrigine exerts anticonvulsant effects in several experimental models of epilepsy and in patients with partial and generalized tonic-clonic seizures. The drug has also been approved for the treatment of mania in bipolar disorder. The drug is used orally and is well absorbed from the gastrointestinal tract. The plasma half-life is approximately 24 hours, but induction of liver microsomal enzymes by such drugs as phenobarbital, phenytoin, and carbamazepine may decrease the half-life to approximately 12 hours. Conversely, valproic acid may increase the half-life of lamotrigine up to 60 hours by inhibiting its metabolism. Lamotrigine usually has mild side effects, including ataxia, dizziness, diplopia, and rash. Stevens-Johnson syndrome has been reported in 0.8% to 2% of young children using the drug.[9] The drug is approved for treatment of Lennox-Gastaut syndrome in children older than 2 years. Lamotrigine binds to melanin and may accumulate in the eyes and other tissues containing melanin. No adverse consequences of this binding have been reported.

Carbonic Anhydrase Inhibitors

Acetazolamide and other carbonic anhydrase inhibitors are primarily effective against absence seizures but are also useful for the control of seizures that have a tendency to recur at a specific time of the menstrual cycle (catamenial epilepsy). Tolerance develops rapidly, however, so the carbonic anhydrase inhibitors are primarily used as adjunctive agents. The diuretic and natriuretic effects of acetazolamide are well known. By inhibiting carbonic anhydrase (located in glial cells), carbon dioxide is allowed to accumulate in the brain, which can decrease intracellular Na^+ and increase intracellular K^+. This ionic shift results in neuronal hyperpolarization and decreased excitability, which is thought to block the spread of seizure discharge.

Topiramate

Topiramate (see Figure 14-8) is a broad-spectrum anticonvulsant currently approved for partial onset seizures, monotherapy of tonic-clonic seizures, treatment of Lennox-Gastaut syndrome, and prophylaxis of migraine headaches. The drug exerts multiple actions, including frequency-dependent blockade of Na^+ channels, benzodiazepine-like potentiation of GABA activity, and inhibition of kainate receptors for glutamate. Absorption after oral ingestion is rapid; an elimination half-life of approximately 20 hours permits twice-daily dosing. It may specifically inhibit CYP2C19.[11] Topiramate is reported to be more effective than several newer anticonvulsants; however, it also produces more side effects; this may reflect the dosages used to evaluate the drug rather than minimally effective doses. CNS depression is the most common side effect. Topiramate can compromise short-term memory function.

Zonisamide

Zonisamide (see Figure 14-8) was developed in Japan and is now available in the United States. Zonisamide is structurally related to the sulfonamides. It is completely absorbed, with peak concentrations occurring in 4 to 6 hours. Primarily metabolized by CYP3A4, blood concentrations may vary if inducing antiepileptic drugs are used concurrently. Zonisamide may act by multiple mechanisms, including blocking of Na^+ and T-type Ca^+ channels; the drug binds to the $GABA_A$ channel but does not alter Cl^- currents. Zonisamide facilitates dopaminergic and serotonergic transmission. The drug also is a weak carbonic anhydrase inhibitor. Zonisamide was studied as adjunctive therapy for the treatment of partial onset seizures and found to improve therapy. Because it is a sulfonamide, it can produce numerous allergic reactions in patients who are sensitive to sulfonamides. These reactions include skin rashes (Stevens-Johnson syndrome), epidermal necrolysis, and agranulocytosis. The incidence of these events is very low. Other unusual side effects include a propensity to produce renal acidification[21] and renal stones and, rarely, dehydration and hyperthermia in children during hot weather.

Levetiracetam

Levetiracetam (see Figure 14-8) is a pyrrolidine derivative that is rapidly absorbed (1 hour to peak) after oral administration and is less than 10% bound to plasma proteins. Steady state is reached in 2 days with twice-daily dosing. The half-life is approximately 7 hours, and the drug is metabolized by a non–cytochrome P450 route and is eliminated by renal excretion. The drug has a unique anticonvulsant profile; it is effective in some common tests predictive of efficacy in partial seizures but not in other tests. Its mechanism is unknown, but in the brain it binds stereoselectively to a functionally important synaptic plasma membrane protein (SV2). Levetiracetam was evaluated as adjunct therapy for adult partial onset seizures and found to reduce seizures in a dose-dependent manner. It has also been approved for the treatment of myoclonic epilepsy. Typical side effects included somnolence and fatigue, coordination difficulties, and exacerbation of behavioral problems. Most of the side effects were reported in the first month of therapy. This drug should be terminated gradually to avoid withdrawal reactions. Drug interactions with this agent seem to be minimal.

Magnesium Salts

Although not used in treating epilepsy, magnesium sulfate is used to prevent or control convulsions of eclampsia and severe preeclampsia of pregnancy. The drug acts on the CNS to decrease excitability and acts to reduce activity at the neuromuscular junction. Its mechanism of action is not well defined. In addition, magnesium reduces cardiac and smooth muscle activity and reduces blood pressure, which is beneficial in eclampsia and preeclampsia.

Experimental Drugs

Although many seizures can be controlled with anticonvulsant medication, approximately 20% remain resistant to treatment. Recognizing this need, the Epilepsy Branch of the National Institute of Neurological Disorders and Stroke began clinical trials in 1968 of numerous drugs, including drugs already approved for other uses in the United States. Carbamazepine, clonazepam, valproic acid, and clorazepate were made available between 1974and 1981 as a result of these efforts. Further government, industrial, and academic support for anticonvulsant drug research resulted in the creation of a formal government program, the National Anticonvulsant Drug Development Program and Antiepileptic Screening Project, which has introduced a series of potential anticonvulsant drugs. Significant advances in understanding the synthesis and regulation of receptors, ion channels, drug elimination mechanisms, and other components of cells have revealed many new opportunities for intervention.

One approach involves excitatory neuronal mechanisms. Abnormal distribution patterns of excitatory amino acid receptors have been shown in the hippocampus and parahippocampal gyrus of humans with temporal lobe epilepsy. A novel anticonvulsant strategy is to decrease excitatory neurotransmitter drive. Evidence exists that classic anticonvulsants may have this ability. Phenytoin, carbamazepine, benzodiazepines, and lamotrigine may decrease the synaptic release of excitatory amino acids.

Several excitatory amino acid antagonists exist. Their variety is due to not only the fact that competitive and noncompetitive antagonists exist, but also that metabotropic glutamate receptors (which modulate intracellular second messengers) and three major classes of glutamate-gated ion-channel receptors (N-methyl-D-aspartate [NMDA], kainate, and AMPA) exist. These receptors all are stimulated by glutamate but can be distinguished according to their preferred agonists and antagonists. The phosphonic acid derivatives 2-amino-5-phosphonovaleric acid (AP5) and 2-amino-7-phosphonoheptanoic acid (AP7) are competitive NMDA antagonists that are potent anticonvulsants in experimental epilepsy models. Because AP5 and AP7 are restricted by the blood-brain barrier, derivatives of AP5 and AP7 have been developed to enter the CNS more effectively. Side effects (impairment of learning and memory, behavioral changes) may limit the use of these compounds. Noncompetitive NMDA antagonists (e.g., phencyclidine) are effective anticonvulsants, but side effects (hallucinations, ataxia, altered sensory perception, interference with memory, and behavioral disturbances) are prominent.

Despite their problems, NMDA antagonists are effective in preventing the development of seizure kindling. The excitotoxic effect of glutamate is well known, and data suggest that nitric oxide, a highly reactive local hormone, may be the agent responsible for glutamate-induced cell death. An excitotoxic effect may play a role in epilepsy. Selective antagonists of AMPA are under study (Talampanel and NS1209) that may be useful as anticonvulsant or antielectrogenic agents; however, sedation may prevent their use as anti-ictogenic drugs. (Barbiturates also have significant sedative action.) Other unique approaches include retigabine, a facilitator of the opening of inhibitory potassium channels; antiepilepsirine, which increases extracellular serotonin; and harkoseride, a blocker of the strychnine-insensitive glycine site on the NMDA receptor complex.

Novel approaches to anticonvulsant therapy may include other endogenous compounds. Adenosine, inosine, hypoxan-

thine, β-endorphin and other endogenous opioids, somatostatin, cholecystokinin, neuropeptide Y, and prostaglandins have been investigated. Additional approaches may be suggested by gene array studies, which have found changes in glial function that may become targets in the future.

NONPHARMACOLOGIC TREATMENTS

Surgical treatment of seizure disorders is possible when the focus is localized and located in nonessential brain tissue. Removal of poorly healed and abnormally functioning brain tissue can produce "cures." This procedure is performed with growing success because of the availability of improved diagnostic imaging techniques, such as 2-[^{18}F]fluoro-2-deoxy-D-glucose and [^{11}C]-flumazenil coupled with EEG.

A nonpharmacologic approach to the treatment of seizures has resulted from studies showing that stimulation (by implanted pulse generators) of the vagus nerve blocks experimentally induced seizures, and this technique is now commercially available.[51] Vagal stimulation has obvious implications regarding cholinergic drugs.

Another approach for the treatment of childhood epilepsy is a ketogenic diet. A ketogenic diet is high in fats and low in carbohydrates and proteins. These diets must be carefully controlled but have been found effective in some patients. Genetic mapping studies suggest that ketogenic diets may bolster mitochondria and energy metabolism.[3]

GENERAL THERAPEUTIC USE

The goal of anticonvulsant therapy is to obtain complete control of epileptic seizures with the fewest drugs and at the least toxic and lowest possible dose. Approximately 80% of all patients can be seizure-free if drug plasma concentrations are properly monitored, and the appropriate dose adjustments are made. Initial anticonvulsant therapy sometimes necessitates frequent alterations in dose and a trial-and-error approach until the seizure responds to a specific anticonvulsant. Even after seizures are initially controlled, the continued administration of anticonvulsant drugs may lead to the development of tolerance. The addition of other anticonvulsants necessitates dosage adjustments. Anticonvulsant therapy is not static, routine, and completely predictable, but rather subject to a variety of ever-changing factors.

Febrile seizures, induced by high fevers, are the most frequent seizures in children. Propensity for these seizures may have a genetic basis, be related to particular diseases (influenza), or be caused by immaturity of CNS excitation control. Children with febrile seizures rarely develop other seizure disorders or continue to have seizures. Short-term treatment with diazepam, phenobarbital, or intranasal midazolam has been used. In some patients in whom febrile seizures are recurrent, prophylactic phenobarbital or diazepam may be prescribed to prevent seizures in future fevers. Rarely, patients may need longer term continuous phenobarbital or valproic acid treatment.

Although anticonvulsant medications have substantial toxic potential, uncontrolled seizures also carry important risks. Repeated seizures can result in loss of memory and mental function. For several of the newer anticonvulsants that facilitate GABA or inhibit excitatory amino acid function, there is the potential for additional drug-induced compromise of memory function.

Anticonvulsants can be valuable in treating patients with various chronic pain problems. Neuropathic pain results from abnormalities in nerve fiber conduction, such as neuralgia, causalgia, and phantom pain. Beneficial actions of anticonvulsants may be related to blockade of Na^+ and Ca^{++} channels, activation of GABAergic transmission, and inhibition of NMDA and other glutamate receptors. Agents that have proved effective in these conditions include carbamazepine, phenytoin, sodium valproate, gabapentin, and clonazepam.[9]

Traditional anticonvulsants (carbamazepine and valproic acid) and "mood stabilizers" (a synonym used in psychiatry for some newer anticonvulsants) are sometimes valuable adjuncts in treating the manic phase of bipolar disorder. Other anticonvulsant drugs may also be useful; however, in one study adjunctive gabapentin was no more effective than placebo.[32]

IMPLICATIONS FOR DENTISTRY

Dentists should expect to be confronted at some time by a seizing patient in the dental office. It is extremely helpful if an emergency plan has been previously developed and practiced before having to deal with convulsions clinically. One of the best ways to manage seizures is to prevent them. Appointments should be planned for times when an epileptic patient has high blood concentrations of anticonvulsant medication. The dentist should verify that the patient has taken his or her medications before the appointment. Careful attention to local anesthetic doses and avoiding accidental intravascular injections by practicing aspiration before administration are important. If the patient's seizure is of the reflexive type, avoiding the triggering stimuli is important. The dentist should ask the patient before treatment if he or she is aware of any triggering stimuli. Finally, attention to the patient's fear and apprehension can limit the risk of inciting an attack.

Some patients sense the onset of seizure activity in the form of auras. If a patient reports an aura, the dentist should prepare for a seizure by removing all instruments from the patient's mouth and pulling back trays or other objects from which the patient might sustain injury. The patient should be placed in the supine position. If no seizure occurs, the patient can determine when to proceed. If the patient does have a seizure, the dentist must protect the patient from injury and falls. No attempt should be made to open the patient's mouth during a tonic-clonic seizure because this can induce additional injuries. Seizures generally end in 2 to 5 minutes, after which the patient is disoriented or falls asleep for 30 or more minutes. If the patient is snoring or seems to have an obstructed airway, the head, neck, and jaw should be positioned to ensure a clear airway.

If a second seizure occurs, it may indicate status epilepticus. Seizures induced by local anesthetic overdoses tend to be prolonged and may require anticonvulsant treatment. Animal experiments suggest that benzodiazepines and phenobarbital are highly effective for treating local anesthetic–induced seizures, whereas carbamazepine, phenytoin, and valproate may increase seizure activity.[39] Emergency medical services should be called if the seizure recurs or is prolonged or if respiration is compromised. Patients may need supportive care after a seizure, which would include treatment of any wounds that may have occurred and dealing with incontinence.

In most cases, seizures are brief and self-limiting. Occasionally pharmacotherapy may be required, however. Part of the dentist's emergency plan should include a properly stocked emergency cart and staff trained in the use of the medications. Anticonvulsant medications should ideally be administered by the intravenous route; however, this is not always possible in the dental office. New products have improved this situation. A rectal gel dosage form of diazepam (Diastat) is available that can produce anticonvulsant blood concentrations in approximately 15 minutes. This product has been formulated

for use by laypeople for the emergency treatment of seizures at home and simplifies emergency treatment if an intravenous line is unavailable. The disadvantage of this approach is that many individuals are uncomfortable with the route of administration. Midazolam has been tried and found effective in the treatment of status seizures and can be administered intravenously, intramuscularly, intranasally, or intrabuccally.[52] Seizure control is almost immediate with intravenous administration. The buccal route would be natural in the dental office.

Because diazepam and midazolam have relatively short durations of action, the use of a longer acting agent, such as lorazepam, phenytoin, or phenobarbital, may be needed in the hospital to provide prolonged seizure control. Fosphenytoin may have some advantages over traditional agents. Fosphenytoin at 15 mg/kg to 20 mg/kg phenytoin equivalents is tolerated better and can be effective 10 to 60 minutes after intramuscular injection into the gluteus maximus.[35] The volume of fosphenytoin to achieve this dose ranges from 20 mL to 40 mL, which should be divided into smaller volumes and then administered bilaterally. Care should be taken to avoid injections into the sciatic nerve or inferior gluteal vessels.

As described in this chapter, patients receiving anticonvulsants are subject to various adverse effects. Common or significant adverse effects that are pertinent for the everyday practice of dentistry should be noted. Most anticonvulsant drugs produce some degree of CNS depression. The clinician should be aware of the additive effect of other CNS depressants, such as local and general anesthetics, antianxiety agents, antidepressants, and opioid analgesics. Some newer agents may also interfere with memory. Patients should receive written treatment instructions, which should also be provided to appropriate guardians. Blood dyscrasias are rare but serious side effects seen with most anticonvulsant agents; they may increase the patient's susceptibility to infection. Aplastic anemia may manifest as increased gingival bleeding, whereas agranulocytosis may be identified by pharyngitis or oral mucosal lesions. The fact that some anticonvulsants alter mineral metabolism should be considered when confronted with anomalies in tooth development or advanced bone loss. Several anticonvulsants can produce teratogenic effects. The defects produced can involve the facial and oral structures. Practitioners should be alert for new drug-related adverse effects and report them to the FDA Medwatch program.

Several side effects specific to individual anticonvulsant agents are clinically relevant to dentistry. Phenytoin-induced gingival overgrowth is a well-known example. Overgrowth most commonly occurs in the anterior mandibular region, especially in the case of "mouth breathers," and develops to the greatest extent in the interdental papillae between the incisors. Edentulous areas of the alveolar mucosa do not undergo hypertrophy or do so to a lesser extent than other areas. Phenytoin-induced overgrowth may totally or partially obscure the crowns of teeth, which hampers mastication and oral hygiene, is aesthetically unpleasant, and necessitates periodic resection. Because of the angiogenesis induced, the gingival tissue is quite vascular; surgery by cautery or laser is often preferred. The rate of development of gingival overgrowth can be diminished by proper oral hygiene.

Considerable evidence exists that the use of phenytoin to enhance wound healing holds promise.[46] There is interest in applying modern knowledge of growth factors to aid in the healing of periodontitis and other oral wounds. Because phenytoin is widely available and inexpensive, it might be helpful in some cases. Research in this area is clearly needed.

Anticonvulsants may increase hepatic microsomal enzyme activity, which can reduce the blood concentration of other drugs metabolized by the same enzyme system. Of relevance to dentistry is the effect of enzyme induction on antibiotics (e.g., tetracycline) and other agents (midazolam, triazolam) used in clinical practice. Drugs that inhibit CYP3A4 (e.g., erythromycin) can lead to unexpected elevations of anticonvulsant drugs and potential toxicity. The microsomal enzyme-inducing anticonvulsants can reduce the effectiveness of oral contraceptives. Valproic acid can inhibit CYP3A4 drug metabolism. It can also inhibit platelet aggregation, so increased monitoring of patient use of aspirin or nonsteroidal anti-inflammatory drugs may be warranted.

Some short-term effects directly involve the mouth. Carbamazepine-induced taste disorders have been reported, but these apparently subside with time.[14] Xerostomia has also been reported. Primidone is known to cause the unusual side effect of localized gingival pain. This response has led patients and dentists to assume erroneously that the pain is of pathologic rather than pharmacologic origin. Clonazepam has been reported to produce hypersalivation in some patients. A complete medical history is essential for proper dental treatment.

It is often recommended that a patient with epilepsy be treated cautiously to reduce emotional upset and help prevent the precipitation of a seizure. Except when seizures are not well controlled, individuals with epilepsy need not be handled differently from other patients. Because of the lingering stigma associated with epilepsy, these patients may be reluctant to reveal their disease. A seizure disorder may be ascertained only by a clinician who is alert to subtle clues offered by anticonvulsant-induced side effects and by careful questioning of the patient.

Anticonvulsants may be used in the treatment of chronic orofacial pain problems, such as trigeminal neuralgia or burning mouth syndrome. Carbamazepine has been the first-choice drug for the treatment of trigeminal neuralgia. Some patients also respond to other anticonvulsants. Burning mouth syndrome is currently a treatment challenge and may involve pathologic and psychological components. Current treatments include clonazepam, capsaicin, and antidepressant therapy.

Finally, saliva offers a readily available and potentially useful tool for monitoring concentrations of several antiepileptic drugs. Saliva/plasma correlations have been described for carbamazepine, phenobarbital, phenytoin, and ethosuximide. Stability of the samples for some drugs is high and allows the samples to be mailed to a laboratory for analysis, potentially making drug monitoring faster and less expensive.[22]

ANTICONVULSANTS

Nonproprietary (generic) name	*Proprietary (trade) name*
Hydantoins	
Ethotoin	Peganone
Fosphenytoin	Cerebyx
Mephenytoin*	Mesantoin
Phenytoin	Dilantin
Barbiturates	
Mephobarbital	Mebaral
Phenobarbital	Luminal
Primidone†	Mysoline
Succinimides	
Ethosuximide	Zarontin
Methsuximide	Celontin
Phensuximide*	Milontin

Continued

ANTICONVULSANTS—cont'd

Nonproprietary (generic) name	*Proprietary (trade) name*
Oxazolidinediones	
Paramethadione*	Paradione
Trimethadione*	Tridione
Benzodiazepines	
Clobazam*	Frisium
Clonazepam	Klonopin
Clorazepate	Tranxene, Gen-Xene
Diazepam	Valium, Diastat
Midazolam	Versed
Nitrazepam*	Mogadon
Lorazepam	Ativan
Others	
Acetazolamide	Diamox
Carbamazepine	Tegretol
Felbamate‡	Felbatol
Gabapentin	Neurontin
Pregabalin	Lyrica
Lamotrigine	Lamictal
Levetiracetam	Keppra
Oxcarbazepine	Trileptal
Tiagabine	Gabitril
Topiramate	Topamax
Valproic acid	Depakene, Depakote§
Vigabatrin*	Sabril
Zonisamide	Zonegran
Phenacemide*	Phenurone

*Not currently available in the United States.
†Not a true barbiturate.
‡Restricted use.
§Divalproex, a stable compound of valproic acid, and sodium valproate.

CHAPTER 15

*Anti-Parkinson Drugs**

VAHN A. LEWIS

Parkinson's disease, first clearly described in 1817 by James Parkinson, is a chronic, progressive, degenerative disease of the central nervous system (CNS). The disease rarely occurs before age 40 years but affects approximately 1% of the population older than 50 years. Parkinson's disease has an insidious onset, beginning with mild signs such as slight unilateral weakness of the hand, mild tremor, and subtle changes in speech and writing. The essential signs of clinical parkinsonism are resting tremor, rigidity, bradykinesia, and postural instability. Because of the bradykinesia and postural instability, patients may develop a "shuffling gait" to reduce the likelihood of falling. Patients with Parkinson's disease appear to have reduced tone in their facial muscles and have been said to have a "masklike" facial appearance. Some patients also exhibit a tremor of the hands that is reminiscent of the way pharmacists once made "pills," called a "pill-rolling tremor." The motion of the arms and neck may become stiff, and such movement is in a stepwise fashion, referred to as "cogwheel rigidity." Control of respiratory muscles and the larynx is impaired, so that breathing capacity is reduced, and the voice develops a monotonous quality.

Prodromal symptoms such as orthostatic hypotension, urinary retention, constipation, incontinence, excessive sweating, and pain are harbingers of possible Parkinson's disease development. Loss of olfaction for particular odors (e.g., gasoline, banana, pineapple, smoke, cinnamon)[19] appears before any motor abnormality develops. Disorders of the autonomic nervous system are common. Subtle changes in motor function may occur, such as changes in speech, handwriting changes, or reduced arm swinging during walking. The patient may have various ill-defined sensory symptoms consisting of numbness, tingling, abnormal temperature sensation, and visual disturbances.[8] Higher rates of anxiety disorder (40%) are reported in Parkinson patients (e.g., panic disorder, generalized anxiety, and social phobia), and the anxiety issues may precede the motor symptoms.[57] Pain and chronic pain are common in Parkinson's disease, primarily related to dyskinesias[66] but may also represent diseased central sensorimotor interactions.[59] Sleep disturbances, including increased daytime sleepiness, abnormal rapid eye movement (REM) sleep, and increased motor activity during REM sleep (e.g., restless legs syndrome [RLS]), have been identified. Drooling commonly occurs and is mainly caused by difficulty in swallowing (dysphagia) rather than excessive salivation. Dysphagia may be severe and can result in death by asphyxia, aspiration, or pneumonia.

Although Parkinson indicated that the senses and intellect were "uninjured" in parkinsonism, the disease is associated with mental slowing that can be reversed with treatment. In addition, the incidence of dementia is approximately three times greater in patients with Parkinson's disease than in age-matched control subjects. Symptoms of depression may develop.[8] Approximately 30% of patients report hallucinations or delusions.

Parkinson's disease may be primary, secondary, or Parkinson's plus. The primary or idiopathic form is the typical elderly-onset disorder with motor signs and primary damage to the dopamine cells in the basal ganglia. Idiopathic Parkinson's disease has been associated in patients older than 50 years, and the incidence increases with increasing age. The degenerative progression of idiopathic Parkinson's disease proceeds at irregular rates, and a subclinical form of the disorder may exist for years before the patient has the motor signs associated with Parkinson's disease. Higher incidences are seen in certain occupations, such as physicians, dentists, teachers, technicians, and agricultural workers.[34] Some cases of primary Parkinson's disease may have a genetic contribution and are usually seen in patients younger than 50 years. Candidate loci have been identified on chromosomes 1, 2, 4, 6, and 12.[7] Secondary Parkinson's disease is preceded by cerebral infections (syphilis, influenza), toxic chemicals (e.g., carbon monoxide, manganese, pesticides), cerebral hypoxia (vascular defects), traumatic brain injury,[33] or antipsychotic drugs. The best-documented infectious source was the influenza epidemic of the late 1910s, which contributed to a delayed epidemic of cases as the patients aged.

Parkinson's plus disorders are a group of maladies in which the signs and symptoms of Parkinson's disease contribute to a larger disorder (e.g., multiple system atrophy) that often involves more extensive brain damage in the brainstem and cerebral cortex. In many cases, the exact cause of the parkinsonism is unknown. Certain activities and chemicals may reduce the risk of Parkinson's disease, including physical exercise, statin anticholesterol drugs, low-fat diets, smoking,[22,64] caffeine (coffee, tea),[38] and moderate alcohol consumption.

NEUROBIOLOGY AND PATHOPHYSIOLOGY

Although the actual cause of Parkinson's disease remains undetermined, advances have been made in understanding of the neuropathology of parkinsonism, the central control of movement, and the role of neurotransmitters in motor control and extrapyramidal function. The classic motor signs of Parkinson's disease occur when there is a 60% to 80% loss

*The author wishes to recognize Dr. Leslie Felpel for his past contributions to this chapter.

of dopamine in the basal ganglia. The cause of the loss can vary with the patient, however.

Lewy bodies are neuron inclusion bodies found in the brains of patients with idiopathic Parkinson's disease and some other neurologic disorders. These inclusion bodies contain α-synuclein, ubiquitin, and in some cyclin-dependent kinase 5 (cdk5) and leucine-rich repeat kinase 2 (LRRK2).[7] The role of α-synuclein has been associated with synapses and nuclei ("sy" + "nuclei" + "n"), cell membrane, mitochondrial membranes, and possibly reuptake transporters.[2] Excess formation of α-synuclein is termed a *synucleinopathy*. Ubiquitin is associated with the ubiquitin-proteasome catabolic system involved with removal of damaged or misfolded proteins (e.g., synuclein). The cdk5 enzyme has a role in regulating microtubular structural proteins that mediate neuronal function. The accumulation of cdk5 also may contribute to inflammatory changes in the brain.[17] LRRK2 has been found in some genetic Parkinson's disease cases in Asia. Lewy bodies decrease neuron survival of the affected cells, which may trigger increased microglial mediated inflammation and cell destructive activity.[52]

By studying the pattern of α-synuclein inclusions, it has been observed that the common sporadic form of Parkinson's disease starts in the brainstem and olfactory tract before motor symptoms appear. The most sensitive neurons apparently are small neurons with long axons, typical of catecholamine and other autonomic neurons. Early damage occurs in the dorsal motor nucleus of the vagus, spinal cord,[11] and olfactory neurons. Prodromal autonomic and olfactory symptoms coincide with the development and spread of α-synuclein accumulations. As the disorder progresses, the lesions ascend to involve brainstem, thalamus, basal ganglia, limbic, and finally cortical structures.[10] When sufficient damage to dopamine cells occurs, clinical motor signs become evident. The overt symptoms generally progress over 10 to 20 years and may terminate in severe invalidism. Life expectancy is reduced because of the usual complications associated with long-term invalidism. There is growing interest in developing neuroprotective treatments that might be useful before these debilitating changes occur.

Hereditary Parkinson's diseases are familial disorders usually seen in patients younger than 50 years old. Most of the known genetic differences that predispose to Parkinson's disease are associated with changes in α-synuclein, ubiquitin-proteosome, or mitochondrial function; the number of possibilities continues to increase with further research (Table 15-1). Autosomal dominant loci tend to induce the disease, whereas recessive factors often contribute to expression but may not act alone. Mutations that affect the function of dopamine neurons can cause Parkinson's symptoms directly, whereas in other cases Lewy bodies are conspicuous and may lead to subsequent damage of the dopamine cells.

Environmentally induced Parkinson's disease is a result of a toxic agent from the environment or brain trauma that damages the basal ganglia. A dramatic upsurge of interest in environmental factors as a cause for Parkinson's disease occurred when several young drug abusers developed severe parkinsonian symptoms after self-administering a drug that they thought was a heroin analogue. The compound, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), was a by-product of a faulty synthesis of the opiate analgesic alphaprodine. Later work established that the chemical causing the toxicity was actually 1-methyl-4-phenylpyridinium (MPP+), a metabolite of MPTP. MPP+ toxicity stems from its transportation into cells by catecholamine reuptake transporters and subsequent interference with mitochondrial energy production. Acute MPP+ selectively destroys dopamine neurons in the substantia nigra, and this replicates many of the motor disorders of Parkinson's disease, although not the synucleinopathy.[4] In some models, chronic or continuous MPTP administration can compromise the ubiquitin-proteasome system and can lead to the accumulation of α-synuclein.[24] MPTP-induced damage is reduced in α-synuclein knockout mice, suggesting that these inclusions may potentiate the toxin's damage.[40]

Various environmental agents may contribute to the development of Parkinson's disease, and various pyridines are present in the environment in insecticides, herbicides, and contaminants. The insecticides rotenone and paraquat (structurally related to MPP+) have been found to produce a Parkinson-like syndrome in rats.[51] Antipsychotic drugs often produce reversible Parkinson-like signs. The antipsychotic agent haloperidol is metabolized to a pyridinium metabolite that increases oxidative damage in experimental animals,[39] raising the possibility of irreversible damage. Mitochondrial respiratory complexes may be compromised by MPP+, and mitochondrial complex 1 has been found to be prone to functional compromise. It is unclear whether mitochondrial disorders are a feature of idiopathic Parkinson's disease, however.[36] Another important environmental toxin is the metal manganese, and miners and users of some manganese products may develop secondary Parkinson's disease.

Changes in Brain Function in Parkinson's Disease

Motor function in the spinal cord and trigeminal nucleus is directly controlled by motor regions of the cerebral cortex. A

TABLE **15-1**

Inheritance of Parkinson's Disease

LOCUS	GENE	INHERITANCE	AFFECTED SYSTEM	AGE OF ONSET	LEWY BODIES
Park 1	*SNCA*	D	α-Synuclein	40s	Diffuse
Park 2	*Parkin*	R	Ubiquitin-E3-ligase	20-40	Few or none
Park 3	*Chr2p13*	D	Ubiquitin	60	Tangles and plaques
Park 4	*SCNA*	D	α-Synuclein—multiple copies	30	Fulminant
Park 5	*UCHL-1*	D	Ubiquitin, proteosome	50	?
Park 6	*PINK*	R	Mitochondria	30-40	?
Park 7	*DJ-1*	R	Oncogene localized to the cytoplasm and mitochondria	30-40	?
Park 8	*LRRK2*	D	Mitochondria	60	No
Park 13	*HTRA2*	D	Mitochondria	Late	
	NURR1	D	Orphan steroid/retinoic acid receptor	Late	Yes

D, Dominant; *R,* recessive.

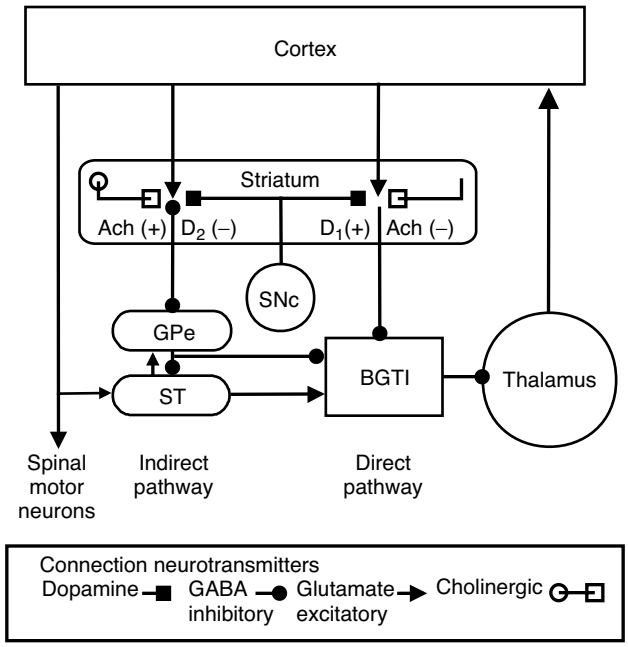

FIGURE **15-1** Movement controlled by the cortex under the influence of the thalamus and basal ganglia. The thalamus relays excitatory input to the cortex. Glutamatergic cortical fibers project to the striatum, activating GABAergic neurons. The GABAergic output from the basal ganglia is funneled through the basal ganglia thalamic inhibitor *(BGTI)*, which exerts an inhibitory action on the thalamus. By the direct pathway, cortical input inhibits the BGTI and disinhibits the thalamus output. The indirect pathway, involving the globus pallidus externus *(GPe)* and the subthalamic nucleus *(ST)*, is complex but generally leads to an increase in inhibitory output from the BGTI. Excitatory D_1 dopamine receptors are believed to modulate the output of the direct pathway, whereas inhibitory D_2 receptors modulate the output of the indirect pathway. Dopamine neuron cell bodies are located in the substantia nigra pars compacta *(SNc)*. Acetylcholine *(ACh)* is found in large interneurons within the striatum and opposes the effects of dopamine. *GABA*, γ-Aminobutyric acid.

model of basal ganglia function is shown in Figure 15-1. Motor activity in the cerebral cortex is stimulated by thalamocortical input, which is modulated by many factors, including sensory feedback, memory readout, and emotional response. The basal ganglia modulate the thalamocortical processing through a γ-aminobutyric acid (GABA)–mediated inhibitory input derived from the substantia nigra pars reticulata and the internal part of the globus pallidus, nuclei whose functions seem to be similar and for this discussion are referred to as the *basal ganglia thalamic inhibitor* (BGTI). The output of the BGTI is influenced by two pathways within the basal ganglia, the direct and indirect. The direct pathway generally inhibits the BGTI and disinhibits the thalamic drive and increases motor activity. The indirect pathway, involving excitatory input from the subthalamic nucleus, inhibits movement by facilitating BGTI outflow.

Dopamine from the substantia nigra pars compacta (SNc) innervates the direct and indirect pathways in the striatum.[4] In the direct pathway, it acts on D_1 receptors, which increase GABA inhibition of the BGTI. In the indirect pathway, dopamine acts on D_2 receptors, which inhibit GABA outflow to the indirect pathway. In the case of Parkinson's disease, a loss of dopamine neurons from the SNc leads to dysregulation of the indirect pathway by the subthalamic nucleus, producing activation of the BGTI and inhibition of movement (bradykinesia or akinesia). Damage anywhere in these loops may result in localized motor abnormalities such as dystonias. Parallel cortico–basal ganglia–thalamic circuits are proposed that subserve aspects of executive and emotional thinking, which may help explain some of the psychiatric symptoms (e.g., depression, hallucinations) observed in some patients with Parkinson's disease.[47,54]

The tremor associated with Parkinson's disease has been more difficult to explain. Research has suggested that the interaction between the subthalamic nucleus and the external segment of the globus pallidus may be one source of tremor. Other studies suggest a role for the thalamus in tremor generation. Tremors may also represent a dysregulation of the communication between the cerebellum and basal ganglia and other parts of the brain. Other research has found a relationship between acetylcholine, norepinephrine, or serotonin[18,25] levels and tremors.

Parkinson's tremors predominate when the patient is resting, whereas cerebellar loop damage tremors predominate during movements. Cortical-striatal-thalamic loops, impaired in Parkinson's disease, are associated with deficits in internally guided motor activity—difficulty with volitional behavior. A second motor control circuit, the cerebellar-thalamic-cortical loop, is thought to be more important for reacting to externally guided behavior. Evidence has accumulated more recently that these systems communicate at many levels—cortical,[46] thalamic,[37] and midbrain.[3]

Hints for a role of the cerebellum in Parkinson's disease include the observation that patients can sometimes initiate blocked motor behaviors when presented with externally applied cues, such as an external target to guide a foot to initiate walking. In addition, patients with Parkinson's disease freeze in conjunction with certain external stimuli, such as passing through a doorway. Functional brain imaging suggests that the cerebellum is hyperactive in patients with Parkinson's disease and possibly trying to compensate for the basal ganglia deficiency.[20,42]

Although Parkinson's disease is primarily associated with movement problems, there may be additional changes. Responses to sensory stimuli, measured in the basal ganglia, tend to have large receptive fields. This tendency suggests that the basal ganglia may participate in poorly localized sensations such as pain.[60] As noted earlier, changes in olfaction and pain are early signs of the disorder. Pain sensation may be altered in Parkinson's disease, including reductions in discriminative, affective, and cognitive dimensions.[14] Patients differ on the direction of the sensory changes. In some cases, pain responding may be reduced, whereas in others diffuse and annoying spontaneous pains may be present, often associated with muscle pain. The basal ganglia may participate in the actions of opiates because the globus pallidus is rich in opiate receptors.[6]

Neuroprotection

Neuroprotective strategies for the treatment of Parkinson's disease have evolved from theories regarding the cause of the disease. The free radical hypothesis is based on the concept that free radicals (generated from oxidative reactions) react with membrane lipids and cause lipid peroxidation, cell injury, and subsequent cell death. Mitochondrial damage and inhibition of oxidative phosphorylation also occur as a result of free radical attack.[9] Figure 15-2 illustrates the relationship between dopamine metabolism and the generation of reactive oxygen species. In addition, the damaged neurons may lose resistance to the toxic effects of the afferent excitatory neurotransmitter glutamate (afferents from the cortex, pedunculopontine nucleus, and subthalamic nucleus), whose toxicity is mediated by excessive Ca^{++} flux and nitric oxide synthesis (Figure 15-3). In the most severe case, these reactions can lead to apoptosis and cell death.

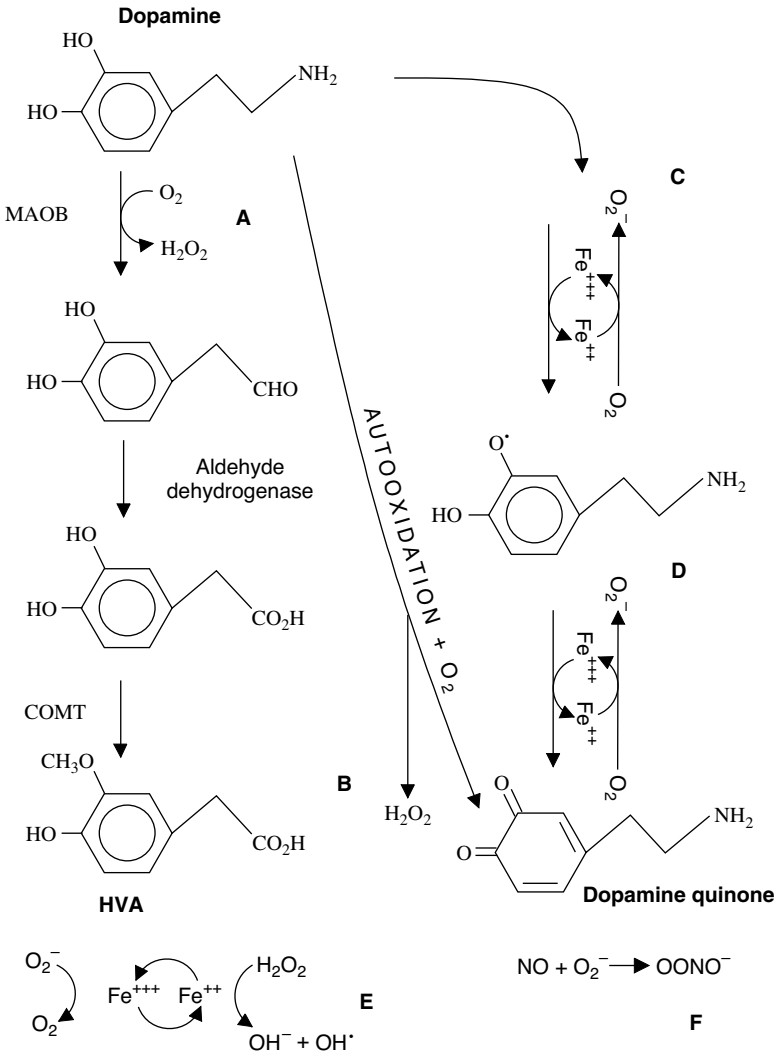

FIGURE **15-2** Dopamine metabolism and the oxidative challenge to the substantia nigra pars compacta. Metabolism of dopamine can generate hydrogen peroxide *(H_2O_2)* at steps *A* and *B*. In the presence of Fe^{++} (pathologically elevated in the substantia nigra of patients with Parkinson's disease), increased generation of reactive hydroxy ions *(OH^-)*, superoxide species *(O_2^-)*, and free radicals occurs (steps *C*, *D*, and *E*). Finally, additional reactions may occur between these active oxygen species and nitric oxide to generate toxic peroxynitrite free radicals *($OONO^-$)* (step *F*). Dysregulation of these reactions may lead to oxidative damage in dopaminergic nerves. *COMT*, Catechol-O-methyltransferase; *HVA*, homovanillic acid; *MAO-B*, monoamine oxidase B.

The brain is usually protected from damage caused by free radicals because it contains protective substances (e.g., glutathione, ascorbic acid, melatonin, vitamin E) and enzymes (e.g., glutathione peroxidase, superoxide dismutase) that prevent free radical buildup. The SNc of patients with Parkinson's disease has reduced concentrations of glutathione and glutathione peroxidase. This decrease occurs early in the disorder and can by itself decrease mitochondrial complex 1 function.

Free radical scavenger drugs such as vitamin E have been administered experimentally, albeit so far without much success. The monoamine oxidase (MAO) B inhibitor selegiline offers a potential, but as yet unproved, neuroprotective action by inhibiting the breakdown of dopamine. The pituitary hormone melatonin has antioxidant and proglutathione actions and has been found to be protective in the MPP+ model. Other vitamins may influence neuroprotective processes. Vitamin A and D receptors (RXR and VDR) are concentrated in the substantia nigra, and deficiencies may contribute to Parkinson symptoms. The NURR1 genetic defect affects the RXR receptor. Inadequate levels of vitamins A and D may potentiate the degree of Parkinson symptoms in addition to increasing the risks of bone fractures associated with falls.[49,63]

Late-stage Parkinson's disease is quite resistant to treatment; drugs become ineffective, and tissue grafts and implants lose efficacy. Examples of irreversible neural degenerative cascades[45] may provide a framework for understanding why Parkinson's disease continues to progress (pathologic remodeling, gliosis, or vascular problems) despite attempts to replace dopamine. Earlier interventions that could prevent such irreversible changes are needed.

Tomographic Imaging in Parkinson's Patients

Tomographic imaging techniques are useful for investigations into causes, disturbed brain processing, and diagnostic information about Parkinson's disease.[41] Systems used to image brain changes in patients with Parkinson's disease include positron emission tomography; single photon emission computed tomography, which can assess ligand binding within the brain; and functional magnetic resonance imaging (fMRI) and the related blood oxygen level–dependent (BOLD) fMRI. These all are indirect measures of brain tissue function.[16] Transcranial ultrasound has been useful for finding changes in substantia nigra iron levels. Table 15-2 summarizes several imaging ligands and how they are used to assess the function of the basal ganglia and other related brain regions. In particular, β-CIT has been used to visualize dopamine uptake transporters in the basal ganglia. These images distinctly outline the caudate-putamen region of the brain and show that in Parkinson's disease the labeling in the basal ganglia is reduced either unilaterally or bilaterally.

Unified Parkinson's Disease Rating Scale

Parkinson's disease signs and symptoms can be semiquantitatively estimated with the Unified Parkinson's Disease Rating

TABLE **15-2**

Imaging Techniques Used to Evaluate Parkinson's Disease

NAME	USES
^{18}Fluoro-DOPA	Labels levodopa-to-dopamine conversion and presynaptic dopamine
Beta-CIT, (2 beta-carbomethoxy-3 beta-(4-iodophenyl)tropane)	Selectively labels DAT
SCH 39166 and NNC 756	Selective D_1 receptor binding
Raclopride	Selectively binds to dopamine D_2 receptors
d-Methylphenidate	Sensitive to dopamine system loss in basal ganglia
WAY100635	Labeling 5-HT_{1A}, shown to be inversely related to Parkinson's tremor
Fluorodeoxyglucose	Labels glucose (energy) use for differential diagnosis between Parkinson's disease and MSA
^{15}Oxygen	PET oxygen use technique for assessment of Parkinson's disease and MSA
PK11195	PET marker of PBBS, which are selectively expressed by activated microglia associated with brain inflammation
fMRI and BOLD fMRI	Indirect activity measure based on blood desaturation in brain active regions. Used to assess relative activity in different brain regions. May be useful to assess MSA
Transcranial ultrasound	Used to identify iron accumulation in substantia nigra in pre—Parkinson's disease or early Parkinson's disease

Data from references 16, 18, 26, and 29.
5-HT_{1A}, 5-Hydroxytryptamine type 1A; *BOLD*, blood oxygen level–dependent; DAT, dopamine transporter; *fMRI*, functional magnetic resonance imaging; *MSA*, multiple system atrophy; *PBBS*, peripheral benzodiazepine sites; *PET*, positron emission tomography.
Positron emitters include ^{123}I, ^{18}F, or ^{11}C.

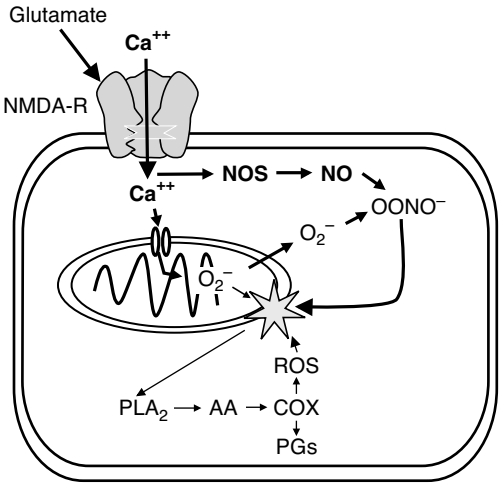

FIGURE **15-3** Ca^{++}-mediated oxidative stress in nerves with glutamate (or glutamatergic) receptors. Activation of N-methyl-D-aspartate (NMDA) receptors *(NMDA-R)*, one type of glutamate receptor permits Ca^{++} currents to enter the cell. Intracellular Ca^{++} is normally reduced by sequestration in mitochondria and endoplasmic reticulum (not shown). Excess Ca^{++} stimulates nitric oxide synthase *(NOS)*, which catalyzes the synthesis of nitric oxide *(NO)*. Excessive Ca^{++} currents are thought to compromise the function of mitochondria and permit the generation of free radicals and superoxide *(O_2^-)*, which can react with NO to produce the toxic peroxynitrite radical *($OONO^-$)*, which can damage the mitochondria and cell membranes. Damaged membranes can be metabolized further by phospholipase A_2 *(PLA_2)*, producing arachidonic acid *(AA)*, a substrate for cyclooxygenase *(COX)*. Additional reactive oxygen species *(ROS)* are generated in the synthesis of prostaglandins (*PGs*) from AA. These reactions may contribute to the sensitivity of the substantia nigra pars compacta neurons to premature cell death.

Scale (UPDRS). This scale evaluates four separate dimensions of the disorder: I, Mentation, Behavior, and Mood (4 items); II, Activities of Daily Living (13 items); III, Motor Examination (14 items); and IV, Complications of Therapy (A, Dyskinesias; B, Clinical Fluctuations ["on" or "off"; see below], and C, Other). This scale, or parts of it, has been used to estimate the impact of treatments on patients with Parkinson's disease.

Using only Part III, Motor Examination, an individual without Parkinson's disease would score 0 or a low value. For a Parkinson's patient whose symptoms have been reduced with treatments and who feels "on" (i.e., able to move freely), the score is less than 8. Patients feel "off" when the score is greater than 20.[13] One sample of Parkinson's patients[65] averaged around 41 in the untreated state and around 22 in the group with levodopa treatment. Some of these patients also received subthalamic nucleus deep brain stimulation, and their scores also decreased about 20 points on deep brain stimulation alone. There is considerable variation in responding, such that one patient may improve from 56 to less than 8, whereas another patient may show no improvement or worsening. Some patients respond to placebo with improvement of motor function.[32] Over time without treatment, a typical patient's score increases about 6 points per year as the disease progresses.[23] Published UPDRS scores for several Parkinson's disease treatments are summarized in Table 15-3.

DOPAMINE REPLACEMENT AS A BASIS FOR THERAPY

In the 1960s, investigators discovered high concentrations of dopamine in two areas of the extrapyramidal system: the striatum and the SNc. Patients with Parkinson's disease were found to have low concentrations of dopamine in these areas, which can now be shown in living patients using appropriate tomographic imaging. The drug reserpine was known to reduce catecholamines and produce characteristic Parkinson's disease–like effects (extrapyramidal signs). Levodopa (L-3,4-dihydroxyphenylalanine, the precursor of dopamine) was shown to reverse reserpine-induced bradykinesia, and a link between dopamine and extrapyramidal motor function was established.

The clinical effectiveness of intravenously administered levodopa on Parkinson's disease was soon discovered, but its oral effectiveness was limited. Much of the drug (97% to 99%) is metabolized to dopamine before gaining access to the CNS, which led to adverse side effects such as nausea, vomiting, and cardiovascular problems.

Carbidopa, a dopa-decarboxylase inhibitor, prevents much of the peripheral metabolism of levodopa (Figure 15-4). Carbidopa does not cross the blood-brain barrier, so it does

FIGURE **15-4** Levodopa (L-dopa) metabolism alone and with a dopa-decarboxylase inhibitor. L-Dopa can be eliminated by several mechanisms before it reaches the brain. Substantial elimination occurs in the gastrointestinal *(GI)* tract and peripheral tissues. Carbidopa reduces L-dopa metabolism outside the brain. A higher percentage (10% versus 1% to 3%) of the dose of L-dopa gets to the brain when administered with carbidopa. To reduce metabolism of dopamine further, catechol-O-methyltransferase *(COMT)* inhibitors may be added; these drugs also reduce 3-O-methyldopa competition for levodopa transport into the brain. *MAO*, Monoamine oxidase.

not inhibit the CNS synthesis of dopamine from levodopa. Systemically administered levodopa is transported into the brain through the blood-brain barrier by a saturable amino acid transporter. Combining levodopa with carbidopa permits the use of lower doses of levodopa with greater effectiveness in parkinsonism compared with levodopa alone. It has been found that catechol-O-methyltransferase (COMT) may become upregulated in patients taking carbidopa. This discovery prompted the development of COMT inhibitors to inhibit further the peripheral metabolism of levodopa. Another enzyme important in catecholamine metabolism is MAO. MAO-B inhibitors may also help reduce the amount of levodopa required to reduce Parkinson's symptoms.

The classic dopaminergic/cholinergic imbalance concept of Parkinson's disease explains various clinical and pharmacologic responses, but clinical parkinsonism is more complicated than an imbalance between two neurotransmitters. There are many other neurotransmitters in the basal ganglia, including norepinephrine, 5-hydroxytryptamine (5-HT), GABA, adenosine, and glutamate. Peptides such as enkephalins (indirect pathway) and substance P (direct pathway) coexist with GABA in some striatal efferent neurons. Although the role of these substances in Parkinson's disease is unknown, they offer possible pharmacologic approaches for therapy. There are occasional reports of parkinsonism being exacerbated or improved by agents acting on these other receptor systems.

Dopamine is a neurotransmitter in numerous areas of the brain, and the side effects of its supplementation can be understood in the context of it actions. Dopamine can act to amplify the effects of stimulation and can modulate functions of numerous cortical and subcortical structures. Dopamine in the basal ganglia is crucial for regulating motor tone, and its loss is associated with motor stiffness. Dopamine modulates learning and memory. The mesolimbic dopamine and basal ganglia seem to be associated with drive, salience, and reward. Drugs that increase the actions of dopamine can cause dependence.

Increased dopamine release in the basal ganglia is produced by such behaviors as eating food, listening to music,[46] and sexual activity. In fear-mediating brain regions (e.g., amygdala), dopamine may act to make fearful stimuli more salient.[2] Dopamine cells fire more during waking than sleep, suggesting a role in sleep-wake cycles. This relationship is complicated by the multiple dopamine receptors, some of which seem to promote sleepiness.[48] Dopamine may modulate appetite, but again the relationship is not simple. Dopamine neurons inhibit the release of prolactin by an action on the hypothalamus. Dopamine is associated with the chemoreceptor trigger zone where it produces an emetic action. Dopamine neurons are also found in the eye and olfactory tract. Dopamine is also a precursor for the neurotransmitter norepinephrine and so may alter blood pressure or cardiovascular function. Dopamine has a vasodilatory action in the kidney. Similar to many neurotransmitters, dopamine has many and varied actions.

There are several types of dopamine receptors, $D_{1\text{-}5}$ with two important variants: a D_2 short version associated with a presynaptic autoreceptor that decreases dopamine release, and a D_2 long version that acts as a postsynaptic receptor. D_5 is thought to be similar to D_1 in function, and D_3 and D_4 are similar to D_2. Dopamine D_2 type receptors are thought to be more important than D_1 and D_5 receptors for anti-Parkinson effectiveness, but stimulation of both groups of receptors seems to be involved in the therapeutic efficacy of levodopa.

DRUG THERAPY FOR PARKINSON'S DISEASE

Table 15-4 presents an overview of the drugs used in the treatment of Parkinson's disease. Dopamine replacement with levodopa is the principal treatment. Patients do not always respond uniformly to levodopa, however, and adjunct agents can be beneficial. The relative effectiveness of selected therapies is shown in Table 15-3. Dopamine agonists gradually lose

TABLE **15-4**

Overview of Drugs and Procedures Used in the Treatment of Parkinson's Disease

DRUG OR PROCEDURE	PURPOSE	COMMENTS
Levodopa	Transported into brain then converted to dopamine	Natural precursor to dopamine; side effects include nausea, vomiting, dystonias, and postural hypotension
Carbidopa (with levodopa)	Blocks metabolism of levodopa in peripheral circulation	Reduces dose of levodopa and its peripheral side effects
Tolcapone, entacapone	Nitrocatechol COMT inhibitors; help spare levodopa from peripheral metabolism and from competition for brain amino acid transporters	Tolcapone may induce hepatic failure; possible drug interactions between COMT inhibitors and dental drugs
Selegiline (also called deprenyl) and rasagiline	Blocks MAO-B irreversibly; modest improvement of symptoms; may reduce synthesis of active oxygen metabolites; may slow progression of disease	Possible drug interaction with opiates, antidepressants, foods, and other drugs
Dopamine Receptor Agonists		
Bromocriptine, pergolide, lisuride, apomorphine, pramipexole (D_2, D_3), ropinirole (D_2, D_3), rotigotine (D_1, D_2, D_3)	Act directly on dopaminergic receptors; newer agents used to initiate therapy; also used in "off" cycles; used when loss of presynaptic dopaminergic neurons is great	Use limited by postural hypotension, nausea, sedation; may contribute to confusion, sleep disorders, wake disorder, hallucinations, psychosis, impulsiveness
Anticholinergics (Antimuscarinic)		
Trihexyphenidyl, benztropine, biperiden, procyclidine, diphenhydramine	Balance CNS dopamine/acetylcholine ratios	Can cause dry mouth, constipation, urinary retention, triggering of acute-angle glaucoma, impaired memory, and hallucinations
Other		
Amantadine	Increases release of dopamine; blocks dopamine reuptake and NMDA receptors	Also used as an antiviral agent
Antidepressants		
Tricyclic antidepressants, SSRIs, other antidepressants	Used to treat depression associated with disease; may be useful in treating levodopa-induced depression	Antidepressants may worsen Parkinson's symptoms in some patients
Procedures		
Brain stimulation	Used to relieve essential tremor	Commercial stimulator unit has been marketed
Surgical lesions for Parkinson's disease	Unilateral stereotaxic lesions are introduced to control levodopa dystonias and parkinsonism tremor, rigidity, or bradykinesia	Some risk of stroke, paralysis, and visual field defects
Fetal transplants, stem cells, special cell culture implants	Used to replace dopamine cells	More effective in younger patients

CNS, Central nervous system; *COMT,* catechol-O-methyltransferase; *MAO-B,* monoamine oxidase B; *NMDA,* N-methyl-D-aspartate; *SSRIs,* selective serotonin reuptake inhibitors.

efficacy, and dementia may follow, which is not reversible with dopamine agonists.

Levodopa

Levodopa (Figure 15-5) is a neutral amino acid formed from L-tyrosine, and it is a precursor of the endogenous catecholamines, including dopamine and norepinephrine. The major metabolic fate of levodopa is decarboxylation to dopamine by aromatic L-amino acid decarboxylase, commonly referred to as dopa decarboxylase. COMT is an enzyme that can methylate levodopa and reduce its transport into the brain. COMT inhibitors have been developed to reduce this problem.

Pharmacologic effects

The CNS and peripheral nervous system actions of levodopa are indirect and thought to result from its conversion to dopamine. In practice, levodopa is almost always given with a decarboxylase inhibitor to increase the percentage of levodopa delivered to the CNS and to reduce peripheral toxicity from levodopa. Stalevo is a fixed combination of levodopa, a decarboxylase inhibitor, and a COMT inhibitor (levodopa/carbidopa/entacapone).

Central nervous system. Because Parkinson's disease is characterized by a dopamine deficiency, the obvious therapeutic strategy would be to restore dopamine concentrations to normal. Dopamine does not cross the blood-brain barrier, however, and is ineffective when administered systemically. The immediate amino acid precursor of dopamine, levodopa, is readily transported into the brain and is decarboxylated to dopamine in nigrostriatal neurons. The newly synthesized dopamine is sequestered in vesicles in the neuron terminals in the striatum, where it is available for release. Despite this seemingly physiologic approach, levodopa is not curative.

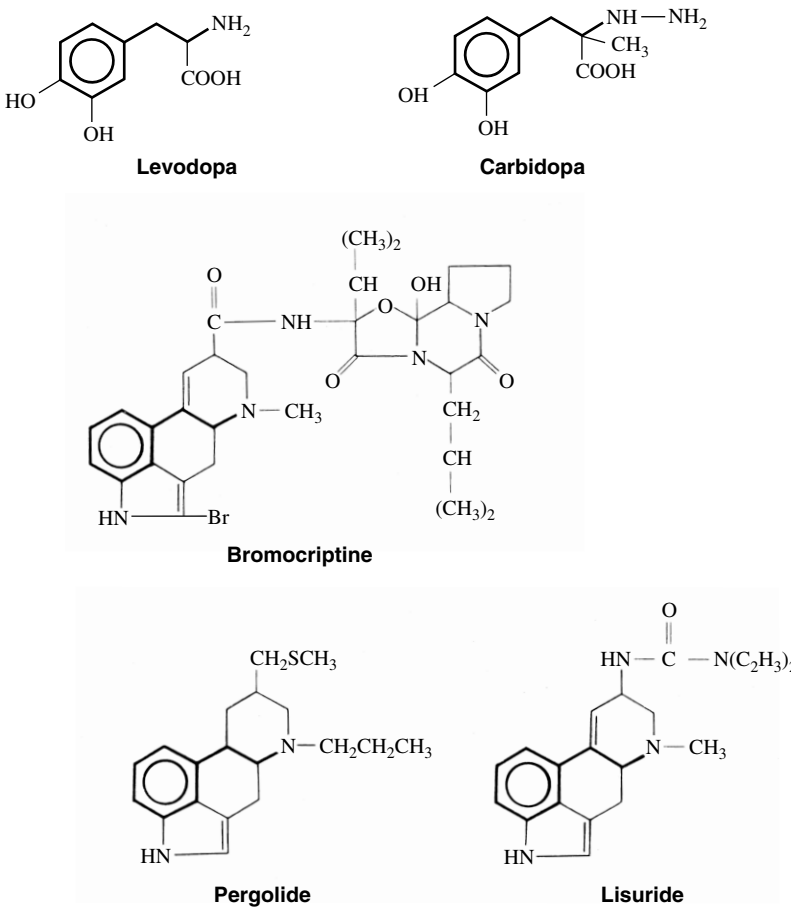

FIGURE **15-5** Structural formulas of some dopamine-related drugs used in the treatment of Parkinson's disease. The dopamine backbone contained within these structures is emphasized.

Postmortem examinations of the brains of Parkinson's patients indicate that morphologic changes in the CNS are similar regardless of whether patients are treated with levodopa.

A beneficial response to levodopa is obtained in approximately 75% of patients. Signs of parkinsonism, including bradykinesia, rigidity, and to a lesser extent tremor, are typically controlled, but the clinical efficacy decreases with time.

Patients receiving long-term levodopa therapy commonly experience a "wearing-off" effect, which refers to an apparent decrease in the length of time that a given dose of levodopa exerts its therapeutic effect. Another complication of long-term levodopa therapy is the "on-off" phenomenon. The patient has periods in which the levodopa is effective in reducing parkinsonian symptoms, but in which abnormal involuntary movements (AIMs) occur as levodopa side effects. AIMs may take the form of dyskinesias, which may correlate with the maximum plasma concentration of levodopa (peak-dose dyskinesia), or of dystonias, which are not strictly related to plasma concentrations of levodopa. This "on" state alternates with an "off" state in which there is a lack of therapeutic response to the drug, characterized by rigidity and akinesia. Oscillations in performance are so disabling and troublesome that, in an attempt to control them, patients may increase their total dose of levodopa to the point of abuse and dependence, leading to the consequences of severe AIMs.

The mechanisms responsible for these unusual responses are unknown, but may relate to variations in drug absorption or receptor changes. Loss of dopaminergic input (denervation) to the striatum produces some increased sensitivity of postsynaptic dopamine receptors (denervation supersensitivity) to dopamine. D_1 receptor and stimulated adenylyl cyclase activity is increased by denervation and by long-term levodopa.[12] D_2 receptors are increased in early Parkinson's disease,[67] but neither D_1 nor D_2 receptors are increased in the postmortem brain tissue of these individuals. Receptor desensitization may play a role in the diminishing response to levodopa and in the "on-off" effect. Support for this concept is provided by the observation that withdrawal of levodopa for 2 to 3 weeks (drug holiday) may permit its reinstitution at a greatly reduced dose and with less therapeutic fluctuation.[15]

Levodopa-induced dyskinesias are a common problem, and various factors may be involved in their generation. Current efforts to minimize abnormal movements are focusing on variables such as dose, dosing schedules, prolonged-release dose forms, and the degree of D_1 and D_2 receptor activation caused by dopaminergic agents.

Although levodopa initially improves the mental status of a patient with Parkinson's disease, a progressive dementia may still occur. A concern that levodopa might generate toxic metabolites has not been confirmed in studies. Patients started on levodopa therapy show an immediate benefit, and there is no evidence for any acceleration of neural damage.[23] More recent reports suggest that direct dopamine agonists may protect β-CIT binding better than levodopa before overt parkinsonian symptoms, but further study is needed to verify such results.

Levodopa-induced behavioral changes are dose dependent and subside with dose reduction, but parkinsonian symptoms then worsen. The atypical antipsychotic agent clozapine may be useful for treating levodopa-induced psychosis because of a reduced potential for parkinsonian side effects.[68] Newer atypical antipsychotic drugs may also be useful and are not associated with the serious hematologic effects linked to the use of clozapine (see Chapter 12). Paradoxically, centrally

acting acetylcholinesterase inhibitor drugs may be helpful in some cases of levodopa-induced psychosis.[1] Ondansetron, a 5-HT_3 receptor antagonist (used as an antiemetic agent), has been found to diminish levodopa-induced visual hallucinations and psychotic symptoms.

Cardiovascular system. A moderate degree of tachycardia and hypotension may occur with levodopa therapy. These effects are caused by dopamine formed by the metabolism of levodopa outside the CNS. Dopamine may also be responsible for the increased incidence of arrhythmia and hypertension reported with levodopa therapy, but age-related coronary heart disease is also likely to contribute. The incidence of levodopa-induced sinus tachycardia and atrial and ventricular extrasystoles is low and can be reduced further with the addition of a peripherally acting decarboxylase inhibitor (carbidopa) or COMT inhibitors. Severe hypertension from levodopa is more likely to result from a drug interaction with one of the nonselective MAO inhibitors.

Gastrointestinal tract. Levodopa is rapidly converted to dopamine in the gastrointestinal tract and elsewhere. Dopamine causes significant nausea, which can be reduced by the coadministration of systemic levodopa metabolism inhibitors.

Absorption, fate, and excretion

Levodopa is absorbed from the gastrointestinal tract, but approximately 95% of the drug is converted to dopamine in the small intestine and liver. Individuals with reduced gastric acidity may have reduced absorption.[50] Only 1% of orally administered levodopa reaches the brain. When the drug is combined with a peripherally acting decarboxylase inhibitor, the dose of levodopa can be reduced by 80%. The enzymes MAO and COMT found in the nervous system and various tissues metabolize dopamine further, and inactive metabolites are excreted in the urine. Agents that block these enzymes are available. A diminished response to levodopa may occur when it is taken with a meal high in protein, perhaps related to competition for saturable amino acid carrier transport systems in the CNS. Protein-restricted diets are sometimes advocated.[62]

Adverse effects

Initially, most patients treated with levodopa experience nausea, vomiting, and orthostatic hypotension. Tolerance develops to these side effects, reducing the need for therapeutic intervention. These symptoms are greatly reduced if a decarboxylase inhibitor is given concurrently. The most perplexing and perhaps most disabling toxic effect of levodopa is the appearance of AIMs. AIMs are often restricted initially to the orofacial muscles and include abnormal mouth movements, protrusion and retraction of the tongue, chewing motions, facial grimacing, and abnormal movements of the head. The limb and trunk musculature may be involved with continued treatment. AIMs often occur at dosages of levodopa that are just at the threshold for control of the parkinsonian symptoms. Although they are relieved by a reduction in levodopa dose, this strategy results in increased parkinsonian symptoms.

On initial therapy, levodopa often produces anxiety, insomnia, nightmares, and nervousness. More serious psychiatric side effects occur in a few patients and can result in delirium, depression, and psychotic states.

Levodopa Combined with Decarboxylase Inhibitors

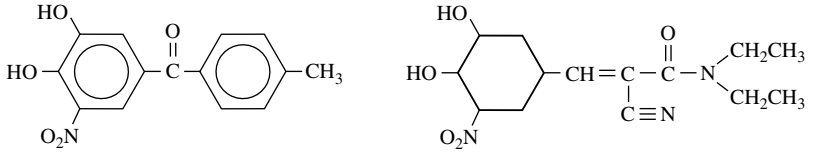
Aromatic L-amino acid decarboxylase is responsible for the enzymatic decarboxylation of levodopa to dopamine. Carbidopa is a commonly used decarboxylase inhibitor. The decarboxylase inhibitors do not penetrate the blood-brain barrier and inhibit only the peripheral conversion of levodopa to dopamine, including the conversion that occurs in the intestinal lumen (see Figure 15-4). Carbidopa allows an 80% decrease in the dosage of levodopa necessary to control parkinsonian symptoms. AIMs, particularly movements of the orofacial muscles, are not significantly diminished by the administration of carbidopa with levodopa, and there are indications that AIMs become more frequent and start earlier. There also seems to be little difference between the mental disturbances produced by levodopa alone and those produced by this drug combination. Carbidopa is relatively nontoxic but is inactive as an anti-Parkinson drug in the absence of levodopa.

The levodopa-carbidopa combination is not recommended in pregnancy or in patients younger than 18 years. Carbidopa is available as a single agent or formulated with levodopa in a fixed ratio of 10 mg/100 mg, 25 mg/100 mg, and 25 mg/250 mg (carbidopa/levodopa) and controlled-release preparations with fixed ratios of 25 mg/100 mg and 50 mg/200 mg (carbidopa/levodopa). Packaged alone (but used in combination with levodopa), carbidopa is useful for patients who require either greater or lesser amounts of the drug than provided in the standard ratios.

Catechol-O-Methyltransferase Inhibitors

COMT and MAO are two major catabolic enzymes for catecholamines. Therapeutic blockade of dopamine decarboxylase with carbidopa can induce an increased metabolism of levodopa by COMT to 3-O-methyldopa. This loss of levodopa and greater competition by 3-O-methyldopa for levodopa transporters reduces the effectiveness of levodopa treatment. The nitrocatechols tolcapone and entacapone (Figure 15-6) reversibly inhibit COMT and enhance or extend the effect of levodopa in patients who have advanced or fluctuating Parkinson's disease. Typically, the levodopa dose can be reduced by approximately 30% when a COMT inhibitor is added.

Tolcapone is administered three times a day and inhibits peripheral and central COMT. It is absorbed in 2 hours, is highly protein bound, and is extensively glucuronidated to an inactive metabolite. Tolcapone has been occasionally associated with severe hepatotoxicity and death. Patients using this agent need to be carefully selected and need to have their hepatic function monitored. Entacapone is a peripherally



Tolcapone **Entacapone**

FIGURE **15-6** Structural formulas of the nitrocatechol catechol-O-methyltransferase (COMT) inhibitors tolcapone and entacapone.

acting drug and is administered in conjunction with the levodopa-carbidopa combination. Entacapone is approximately 35% absorbed and extensively protein bound (98%). Entacapone is isomerized and glucuronidated and eliminated in the bile (90%). Its half-life (1 to 2 hours) is similar to that of levodopa.

The main adverse effects of the COMT inhibitors are related to increased dopaminergic effects, such as dyskinesia, hallucinations, orthostatic hypotension, sleep disorders, and gastrointestinal side effects (e.g., nausea, vomiting). Reduction of the levodopa dose may be required to minimize these side effects. Drug interactions of concern with COMT inhibitors include the catecholamines (e.g., epinephrine), drugs that interfere with biliary excretion (including ampicillin and erythromycin), drugs with sedative actions (anxiolytics, sedative antihistamines, barbiturates, opioid agonists, antipsychotics, and many tricyclic antidepressants), and nonselective MAO inhibitors.

Monoamine Oxidase Type B Inhibitors

Selegiline and rasagiline are "selective" irreversible inhibitors of MAO-B, the major MAO enzyme in the striatum.[69] Because MAO-A is not inhibited, peripheral catecholamine metabolism is less affected. The rationale for using a selective MAO-B inhibitor is to elevate brain dopamine concentrations, while causing little or no effect on norepinephrine or 5-HT.

Selegiline is used as adjunct therapy to levodopa-carbidopa in an attempt to slow the progression of parkinsonian symptoms. It has been evaluated more recently as monotherapy in early-stage Parkinson's disease, and it improves motor function and reduces freezing.[30] Selegiline is metabolized to amphetamine and methamphetamine in the brain and liver. Very often patients report that they feel better after selegiline therapy, possibly because of an amphetamine-like action. More recent studies seem to confirm selegiline's efficacy; however, its benefits are modest and decline as the disease progresses. There may be small protective effect (9%) on β-CIT binding (see Table 15-2).

Rasagiline is an MAO-B inhibitor that is not metabolized to toxic amphetamine metabolites and is severalfold more potent than selegiline. Rasagiline is metabolized by hepatic metabolism to glucuronides and by cytochrome P450 CYP1A2. To reduce first-pass metabolism, this agent is available in orally disintegrating tablets for buccal administration.

Adverse effects of selegiline and rasagiline include nausea, dry mouth, confusion, occasional visual hallucinations, dizziness, headache, and insomnia, especially at higher doses. The combined use of these agents at high doses and levodopa results in an increased incidence of dyskinesia and psychoses. For selegiline, the effect may result from the formation of toxic quantities of an amphetamine metabolite. Although MAO-B inhibitors are thought to have fewer drug interactions than MAO-A inhibitors, clinical data have found that when the dose is increased, typical MAO A drug interactions, such as the "cheese effect," may be seen. The U.S. Food and Drug Administration (FDA) labels warn against combining with most foods that contain elevated tyramine. They are contraindicated with meperidine, methadone, propoxyphene, and dextromethorphan and caution is urged with any other opiates. MAO-B inhibitors are contraindicated with most antidepressants. Caution is advised with any sympathomimetic amines.

Direct Dopamine Receptor Agonists

The discovery of dopamine receptor subtypes, recognition of the limits of levodopa therapy, and advances in knowledge of the neurochemistry of normal and parkinsonism-altered nerve pathways have stimulated the search for dopamine agonists for the treatment of Parkinson's disease. Because these agents act directly on postsynaptic dopamine receptors, they complement levodopa. These drugs offer several advantages over levodopa: (1) They do not require metabolic conversion to an active compound, (2) they do not require the presence of nigrostriatal neurons or nerve impulses for their activity, (3) they have longer durations of action than levodopa with fewer "on-off" changes, (4) they are more selective than levodopa on specific subpopulations of dopamine receptors, and (5) they are less likely to generate damaging free radicals. The UPDRS benefit from the direct dopamine receptor agonists is less than that for levodopa or brain stimulation (see Tables 15-3 and 15-4 to compare the relative benefit of various Parkinson's treatment agents). Direct dopamine agonist dosing is often limited by side effects, such as nausea and vomiting.

Bromocriptine, pergolide, and lisuride are amine ergot derivatives that share a common dopamine-like substructure, as shown in Figure 15-5. These agents may be used alone or in combination with levodopa-carbidopa. Efficacy tends to decline as the disease progresses. Bromocriptine is the oldest and best studied of this group of drugs. It is a potent D_2 receptor agonist and a weak D_1 antagonist. When combined with levodopa therapy, it may alleviate the "on-off" phenomenon, and it can be useful in patients who are unresponsive to levodopa-carbidopa. Patients placed on bromocriptine cannot stop taking levodopa-carbidopa because a dramatic increase in parkinsonian symptoms would otherwise occur.

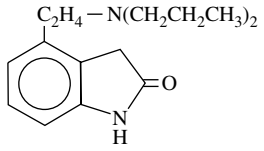
Pergolide is a potent D_1, D_2, and D_3 receptor agonist. As a result of its prolonged action, pergolide may decrease levodopa-induced dyskinesias and increase the "on" time after the patient begins "on-off" fluctuations. A third ergot derivative, lisuride, is more potent than bromocriptine. Lisuride is primarily a D_2 receptor agonist, but it is a 5-HT receptor agonist as well; it is unavailable in the United States.

Adverse effects of these amine ergot agents are similar and include AIMs, mental changes (confusion and psychosis), and orthostatic hypotension. Oral side effects include xerostomia, sialadenitis, dysgeusia, stomatitis, gingivitis, glossitis, periodontal abscesses, dysphagia, and jaw pain. Rare side effects include pleural or retropleural fibrosis (associated with 5-HT_{2A} or 5-HT_{2B} agonist activity[35]) and livedo reticularis, a reddish skin eruption of the lower extremities. The adverse effects are generally reversible on withdrawal of the drug. In some patients, pergolide may cause hallucinations, cardiac arrhythmias, hepatotoxicity, worsened dyskinesias, and sudden episodes of "freezing" and somnolence. Lisuride seems also to cause somnolence and greater psychiatric changes than bromocriptine, which may result from its tryptaminergic properties.

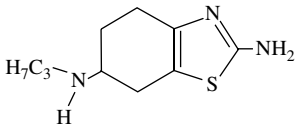
Pramipexole, ropinirole, and rotigotine are non–ergot-derived dopamine receptor agonists (Figure 15-7). Their antiparkinsonian effect is thought to be caused by activity at the D_2 or D_3 receptor, but may also include a neuroprotective component. These agents can be used as initial monotherapy (reduced risk of dyskinesia compared with levodopa) or as an adjunct to levodopa therapy to smooth out its fluctuating propensity ("on-off" phenomena). Rotigotine is thought to stimulate D_1 dopamine receptors as well.

Pramipexole is cleared primarily by renal excretion (96%), whereas ropinirole is metabolized mainly by the CYP1A2 isoform. Ciprofloxacin can inhibit CYP1A2 and significantly increase ropinirole blood concentrations. Rotigotine has been marketed as a time-release patch to reduce blood level fluctuations and may be helpful when compliance or inability to use an oral dosage form is an issue. It is eliminated primarily by conjugation and renal excretion, but also to a certain extent by oxidative dealkylation.

Pramipexole and ropinirole have also been approved for the treatment of RLS. RLS is a sensorimotor disorder associated with strong urges to move the legs, usually in men at night. There is an elevated incidence of RLS in patients on



Ropinirole



Pramipexole

FIGURE **15-7** Structural formulas of ropinirole and pramipexole.

kidney dialysis, but it may also be seen before the development of Parkinson's disease and in other disorders, including bipolar disease. Dopamine agonists have a limited effect in RLS, prompting some to question whether their use is justified in light of side effects such as sudden sleep onset or increases in compulsive or aggressive behaviors. Previous treatments for RLS have included levodopa, opioids, benzodiazepines, clonidine, and baclofen. Anticonvulsants such as lamotrigine may also be useful in some patients. Aripiprazole is commonly used for RLS.

Several side effects have been noted with direct dopamine receptor agonists. Postural hypotension and peripheral edema can occur. Asthenia (weakness), fatigue, and somnolence are reported.

Some patients, usually older patients with more severe disease, have daytime sleepiness and have fallen asleep during daytime activities, including driving.[68] An explanation for this problem is that agonists at D_1 receptors seem to produce a waking effect, whereas D_2 (short form) presynaptic dopamine autoreceptors increase sleepiness, and postsynaptic D_2 (long form) receptors mediate waking. D_3 receptor stimulation is also thought to produce sleepiness. Low doses of D_2 receptor agonists are thought to stimulate predominantly the presynaptic D_2 short receptors.[48]

Insomnia, hallucinations, and panic attacks have also been reported. Motor side effects include dyskinesias and extrapyramidal reactions. Some patients have experienced increased behavioral drive and have difficulty controlling gambling, sexual activity, and appetite.[55] Gastrointestinal side effects of nausea, constipation, xerostomia, sialorrhea, and dysgeusia have been reported. Rotigotine has a higher incidence of skin reactions associated with the patch adhesives and the drug.

Direct-acting dopamine agonists alone may begin to lose their clinical effectiveness after 1 or 2 years. Switching to a different dopamine agonist, when one begins to fail, sometimes restores clinical efficacy. Dopamine agonists have typically been used as adjuncts in anti-Parkinson therapy. In combination with levodopa-carbidopa, they allow reduction in the levodopa dose, which may diminish "on-off" responses and other side effects. Most clinical trials with dopamine agonists have been conducted on patients who are taking other anti-Parkinson drugs or whose conditions are refractory to conventional treatments. The fact that any of these patients respond to the dopamine agonists at all is encouraging.

Apomorphine has been recognized as a direct dopamine agonist since 1951. It has been rarely used clinically, however, because of nausea. It has been "rediscovered" and approved by the FDA as an agent to reverse "off" periods; subcutaneous injection may be more efficacious than oral therapy for this indication.

Drugs with Antimuscarinic Activity

Before the discovery of levodopa, the standard drugs for the treatment of Parkinson's disease were the antimuscarinic agents. Antimuscarinic drugs act to restore the dopaminergic/cholinergic balance by antagonizing the action of acetylcholine; they may also inhibit dopamine uptake. The antimuscarinic drugs are not highly effective antiparkinson agents, but tremor often responds better to these drugs than to levodopa-carbidopa.

The antimuscarinic drugs produce sedation and, in high doses, can elicit visual hallucinations and changes in mood. Trihexyphenidyl has been reported to have abuse potential, and Parkinson's patients may "fake" parkinsonian signs to obtain the drug. Toxic doses of antimuscarinic drugs can cause severe mental disturbances, including excitement, confusion, hallucinations, delirium, depression, coma, and medullary paralysis. Because of muscarinic receptor blockade, these drugs may produce xerostomia; increase intraocular pressure in closed-angle glaucoma; and cause tachycardia, palpitations, arrhythmias, urinary retention, constipation, and tachypnea.

Muscarinic and nicotinic acetylcholine receptors are found in the striatum. Although nicotinic treatments are not generally used, cigarette smoking, which might be considered an inhalation drug delivery system for nicotine, is reported to be Parkinson's disease protective.[63] This is paradoxic because many of the components of smoke are known to be damaging (e.g., carbon monoxide) or to produce inflammation.[5]

Miscellaneous Drugs

Amantadine

The anti-Parkinson effects of amantadine, an antiviral agent, were discovered when the drug was used to treat a viral infection in a patient who had Parkinson's disease. The mechanism of action of amantadine is unknown. It has been proposed that the drug (1) prevents dopamine reuptake and facilitates the release of dopamine; (2) has weak anticholinergic properties; and (3) blocks the glutamate N-methyl-D-aspartate (NMDA) receptor, which could contribute to reducing excitation-induced neurotoxicity and dyskinesias. Other amantadine analogues (e.g., memantine) are being tested for anti-Parkinson activity. Blockade of glutamatergic transmission with excitatory amino acid antagonists is a new approach to anti-Parkinson therapy. A glutamate-dopamine balance may exist in the basal ganglia, which can be improved with glutamate antagonists. These agents may also be neuroprotective. Glutamate antagonists can adversely affect memory formation, however.

Amantadine is usually prescribed in combination with levodopa-carbidopa because an additive effect has been shown when these drugs are used together. When given alone, its efficacy diminishes after several weeks. Amantadine is probably best used (1) alone at the early stages of Parkinson's disease, when symptoms are troublesome but not severe; (2) alone for the management of patients who do not respond well to levodopa; or (3) in combination with levodopa-carbidopa when a more beneficial response is required.

Approximately 80% to 90% of amantadine is excreted unchanged in the urine, and accumulation occurs in patients with impaired renal function. This accumulation may lead to the toxic manifestations of confusion, hallucinations, toxic psychosis, convulsions, and coma. Similar to the direct-acting dopamine agonists, amantadine may cause livedo reticularis of the lower extremities. More common side effects include anorexia, insomnia, nausea, vomiting, dizziness, AIMs, lightheadedness, edema, and sweating. These side effects are not severe and are limited further by the development of tolerance. Riluzole is approved for the treatment of amyotropic lateral sclerosis; it has NMDA glutamate antagonist properties and some blocking of Na^+ and Ca^{++} channels. These are properties that are thought to be valuable in reducing neurodegenerative processes that may play a role in Parkinson's disease. Although animal studies seem promising, studies in humans have not yet shown clinical advantages.[31,43]

Antioxidants
Selegiline (also known as deprenyl) and tocopherol formed the basis of the DATATOP (Deprenyl and Tocopherol Antioxidant Therapy of Parkinsonism) study,[53] a large clinical project designed to test the effectiveness of selegiline and antioxidants in Parkinson's disease. The results of studies with tocopherol have shown no significant benefit either alone or with selegiline.

β-Adrenergic receptor blockers
Propranolol and nadolol have been found to be useful in the treatment of parkinsonian tremor. The fact that nadolol is excluded from entry into the brain suggests that peripheral β-adrenergic receptors have a role in parkinsonian tremor. Because brain norepinephrine release may also be decreased in parkinsonism, L-threo-3,4-dihydroxyphenylserine, a norepinephrine precursor transported into the brain, has been used successfully to reduce depression in the Parkinson's plus, or multiple system atrophy disorder.

Benzodiazepines
The benzodiazepine clonazepam may be effective in treating some aspects of Parkinson's disease, presumably because of its GABAergic activity. Although baclofen and other $GABA_B$ agonists have not been effective in Parkinson's disease, the known and prominent GABAergic pathways of the basal ganglia suggest that manipulation of GABAergic transmission might be a valid approach to the treatment of this disease.

Antidepressants
Antidepressants may be useful in parkinsonian patients who may exhibit depression. Older agents can also contribute antimuscarinic actions, which may reduce tremors. Newer selective agents can be used when increased anticholinergic actions are not wanted.

Antipsychotic drugs
As noted earlier, patients with Parkinson's disease may experience psychotic-like signs either from the disease or from the drugs used to treat the disease. Atypical antipsychotic drugs have been found to be helpful because of their minimal extrapyramidal effects.

General Therapeutic Uses

There can be little doubt that the combination of levodopa and carbidopa is the most effective antiparkinson treatment available to date. Because of the serious side effects associated with levodopa therapy and its limited period of effectiveness, however, other drugs and drug combinations are commonly used. Some physicians initiate therapy with selegiline, a dopamine agonist, amantadine, or antimuscarinic agents. When the disease is judged to be moderate, levodopa-carbidopa and a COMT inhibitor can be added, although there is no objective evidence to delay treatment with levodopa until the disease has progressed. There is still a strong interest in drugs that may provide a neuroprotective effect and reduce progression of the disease. Finally, the continual use of levodopa often results in unresponsiveness to the drug. At this stage, drug holidays are attempted, and adjunctive agents are added.[15]

SURGICAL THERAPY

Advances in brain imaging techniques have resulted in improvements of surgical approaches to the treatment of Parkinson's disease. Ablation of the globus pallidus or thalamus or stimulation of the thalamus, globus pallidus, pedunculopontine, and subthalamic nucleus (subthalamic nucleus–deep brain stimulation) can reduce motor disturbances in Parkinson's patients. Before surgery, it is not always predictable whether ablation or stimulation will be effective. The presumed effect of surgery is to reduce excessive excitatory neuronal activity or to increase inhibitory tone by stimulation. The efficacy seems to be similar to levodopa, and the benefits apparently are related to dopamine function.[65] Efferent pathways of the subthalamic nucleus seem to be excitatory and mediated by glutamate, as are corticosubthalamic pathways. Brain stimulation in the globus pallidus or subthalamic nucleus can reduce tremor associated with parkinsonism. Deep brain electrodes must be surgically placed, and the patient has a battery-powered neurostimulator implanted near the collarbone.

Another approach to the treatment of Parkinson's disease involves the grafting of small pieces of brain tissue or the patient's own adrenal medullary tissue (chromaffin autograft) into the caudate nucleus or putamen.[21] These tissues release catecholamines, primarily epinephrine and norepinephrine, but in the absence of adrenocortical influences, the synthesis of epinephrine slows, and the dopamine/norepinephrine ratio increases. A suggested advantage of such grafts is that they could also release growth factors, which may be deficient in patients with Parkinson's disease. These patients show initial improvement, but long-term results have not been overwhelmingly positive. Some patients continue to improve for 5 years. There is also interest in developing dopamine-releasing cells using stem cell culturing techniques.

DRUGS USED FOR OTHER MOVEMENT DISORDERS

Several disorders less common than Parkinson's disease also cause movement disabilities. These diseases include Huntington's disease (Huntington's chorea), Gilles de la Tourette's syndrome (Tourette's syndrome), Wilson's disease, and dystonic syndromes. Although these movement disorders are more refractory to pharmacotherapy than Parkinson's disease, some drugs are beneficial, and they have furthered our understanding of the role of the basal ganglia in motor control.

Huntington's disease, probably the best known of these disorders, is characterized by choreic hyperkinesias and dementia. Huntington's disease is caused by a genetic error in the huntingtin gene and subsequent abnormal synthesis of a huntingtin protein that contains excess polyglutamine repeats. The pathologic change in Huntington's disease is degeneration of GABAergic neurons in the striatum and the expression of choreas: a reduced ability to stop unwanted "motor programs" expressed as uncontrolled movements of large muscle groups (shoulder or head), leading to awkward and unwanted movements. The strategy followed in parkinsonism of "replacing" the missing neurotransmitter has not proved effective in Huntington's disease because GABA receptor agonists and various inhibitors of GABA catabolism have been clinically disappointing. Adjusting the dopamine/acetylcholine balance by antagonizing dopamine is more effective. The antipsychotic drugs, which are potent dopamine antagonists, may be useful for certain chorea symptoms. A dopamine-depleting drug, tetrabenazine, has also been useful in Huntington's disease. In advanced stages of the disease, pharmacotherapy is ineffective.

Tourette's syndrome is characterized by phonic and motor tics and complex mannerisms. The pathophysiology of Tourette's syndrome is not well understood; however, it may share properties with obsessive-compulsive disease that has been associated with orbital frontal cortex disorders and basal ganglia disorder associated with motor program regulation.[1] Symptoms of Tourette's syndrome are responsive to antipsychotic medication (e.g., haloperidol, fluphenazine, and pimozide). The effectiveness of these compounds is short-lived,

however. Many novel approaches are being investigated, including various atypical antipsychotic agents. Paradoxically, the dopamine receptor agonist pergolide has been found to be effective and well tolerated (but with some risk of cardiac valve damage). In addition, some beneficial results have been reported with clonidine, an α_2-adrenergic receptor agonist.[56]

Wilson's disease, an inherited disorder of copper metabolism, is characterized by damage to the liver; a characteristic brown stain at the edge of the cornea; and various motor disorders, including akinesia, rigidity, and dystonia. Wilson's disease can generally be managed by chelating excess copper with penicillamine. If treatment is begun late in the course of the disease, however, penicillamine may not control the neurologic symptoms. At this point, levodopa and the anticholinergic antiparkinson drugs are useful.

Many common dystonic syndromes, such as torsion dystonia and spasmodic torticollis, are largely refractory to pharmacotherapy. Low doses of levodopa and high doses of bromocriptine and lisuride have mild beneficial effects, especially in young patients. Because of the effectiveness of antimuscarinic agents and drugs that interrupt cholinergic transmission, it has been suggested that cholinergic hyperactivity might be responsible for the dystonias, but the underlying pathology and cause of these syndromes remain unknown. High doses of antimuscarinic antiparkinson agents are also helpful in young patients, probably because these patients can tolerate the side effects better. Botulinum toxin A, which inhibits the release of acetylcholine from cholinergic neurons, may be useful in treating certain dystonias. Antimuscarinic drugs may also be useful for treating focal dystonias.[44]

IMPLICATIONS FOR DENTISTRY

Parkinson's Disease

Patients with untreated Parkinson's disease face many potential challenges to maintaining adequate oral health. Orofacial motor impairments of Parkinson's disease include disorders of mastication, swallowing, and speech, and may be different from motor impairments in the extremities and may not respond to pharmacotherapy in the same manner. Jaw muscle function is altered with reduced voluntary and rhythmic activity. The rate of movement and strength of jaw muscles are improved with treatment.[58] Parkinson's patients have difficulty in sustaining repetitive motions, such as those used for tooth brushing or flossing. Electric toothbrushes can help circumvent some of the problem, although a patient with motor freezing may still have difficulty and need assistance. Oral tremor or dyskinesias can also make oral health care challenging for the dentist, and prosthetic restoration may pose additional challenges because of the presence of uncontrolled oral movements.

Oral dyskinesias are possibly exacerbated by dental disorders, and some investigators have reported improvements by dental treatment or improved denture function.[44] Assessment of the value of these treatments should be tempered by realization that the course of Parkinson's disease can be episodic and to some extent influenced by placebo treatments.[32]

Patients with Parkinson's disease may have a xerostomia or less often sialorrhea and experience nausea and vomiting more frequently than other patients, with possible adverse effects on oral health. Reduced gastric acid in elderly patients may prompt caregivers to administer levodopa with acidic juices, with potential impact on enamel and dentin. Patients with Parkinson's disease who can perform regular dental hygiene procedures do not have an elevated risk for dental disorders.[27]

Parkinson's patients report higher levels of anxiety, which may be associated with the disease and possibly some of the treatments. Parkinsonian patients may react slowly to pain and not provide rapid feedback about progressive tissue damage. They have difficulty maintaining postural stability and normal walking gait and may be more prone to falling; assistance entering and leaving the office should be considered. In addition to motor freezing, these patients may have difficulty comprehending or remembering prolonged instructions; written or taped treatment plans and medication instructions should be provided to the patient and responsible accompanying parties. Orthostatic hypotension can be present, so patients should be allowed to change position slowly and stabilize their blood pressure. During a procedure, consideration should be given to the patient's difficulty with swallowing. Aggressive saliva control and not tipping the patient too far back in the dental chair can be helpful.

Parkinson's disease is a motor function disorder, and so caution should be used with agents that could compromise motor function further. Various agents used in dentistry should be carefully considered and dosed. Drugs that may depress respiratory function need to have their doses adjusted appropriately for the weight, age, and physical condition of the patient. Opiates, barbiturates, skeletal muscle relaxant agents (peripherally and centrally acting), and some antibiotics (clindamycin[61] and aminoglycosides) should be used with caution.

Levodopa

It has been recommended that patients be scheduled for treatment within 60 to 90 minutes of the patient's levodopa dosage to reduce their disability during treatment. For some patients this timing may lead to a higher incidence of dyskinesias during the visit because of pulsatile exposure of the brain to elevated dopamine at the peak of the absorption curve. Facial movements induced by levodopa may cause numerous dental problems, including inflammation, damage to oral structures, protrusion of anterior teeth (because of tongue thrusting), and difficulty in wearing and retaining dentures. Dyskinesias can become so severe that they interfere with swallowing, speech, and respiration.

Levodopa and other antiparkinsonian agents can cause dysgeusia, or alteration in the sensation of taste, possibly explained by the loss of olfaction. This reaction is not seen when levodopa is combined with a decarboxylase inhibitor.

Tolerance usually develops to levodopa-induced orthostatic hypotension. Nonetheless, the patient may still have episodes of hypotension, perhaps more frequently after dosage adjustments. Orthostatic hypotension can be a particular problem for the dentist because of the reclining position of the patient during dental care. If orthostatic hypotension persists, reducing the levodopa dosage may be required to control it.

Many drug interactions involving levodopa are of potential concern to the dentist. It is believed by some investigators that levodopa sensitizes the heart to epinephrine-induced arrhythmias. The mechanism responsible for this effect is unknown, but the excitatory action of levodopa on the heart may result from an action of dopamine on cardiac β_1-adrenergic receptors. Although some practitioners believe that this interaction provides a valid contraindication for the use of local anesthetics with vasoconstrictors in patients taking levodopa, the clinical significance of these interactions is not established. The use of phenothiazines (including promethazine), hydroxyzine, and metoclopramide as antinauseants should be discouraged for patients undergoing levodopa therapy. Such agents can exacerbate the motor irregularities of Parkinson's disease because of their dopamine receptor–blocking properties. A peripheral dopamine receptor antagonist, domperidone, is a useful antinauseant, but it is currently unavailable in the United States. Analgesics may be used with levodopa, but if

general anesthesia is required, consultation with the patient's physician is recommended. Pyridoxine (vitamin B_6), which is present in over-the-counter multivitamin preparations, antagonizes the anti-Parkinson effect of levodopa because it enhances levodopa's conversion to dopamine in the periphery. This antagonism does not occur when a peripheral decarboxylase inhibitor is coadministered with levodopa.

Levodopa and anticholinergic drugs can induce hallucinations. Addition of adjunctive agents such as carbidopa elevate dopamine in the CNS and contribute to this adverse effect.

Dopaminergic Agonists, Amantadine, and Selegiline

Side effects of dopaminergic agonists, amantadine, and selegiline are generally related to their effect of stimulating (directly or indirectly) dopaminergic receptors. If a patient has recently been started on any of these medications, transient nausea and vomiting may occur. A patient scheduled for dental work at this time is more susceptible to gagging, nausea, and vomiting. Because of hypotension on initial therapy, the same precautions described for levodopa apply. Dopamine agonists can cause oral dyskinesia similar to dyskinesias produced by levodopa. The new selective dopamine agonists may induce daytime sleepiness in some patients; caution should be used if sedative or opioid therapy is planned. In some cases, ergot-derived dopamine agonists may be used, which can produce possible cardiac valvular damage; this may lead to heart sounds of regurgitation. In some cases, antibiotic prophylactic coverage may be required. These issues are similarly seen in patients being treated for RLS.[25]

Although MAO-B inhibitors are thought to produce a selective MAO block, package warnings of possible drug interactions with meperidine, other opiates, antidepressants, and many foods suggest that careful screening for potential drug and food interactions is important. Some MAO-B inhibitors are available in buccally dissolving "oral disintegrating tablets." No adverse reports have been associated with this route of administration yet; however, dentists are in a position to evaluate adverse oral effects.

Catechol-O-Methyltransferase Inhibitors

COMT inhibitors have caused drug interactions such as tachycardia, an increase in blood pressure, or arrhythmias with vasoconstrictors (e.g., epinephrine), and increased sedative effects with antianxiety drugs, sedating antihistamines, opioid analgesics, and other drugs with CNS depressant properties. Several antibiotics (e.g., ampicillin, erythromycin) used by dentists can reduce the elimination of entacapone by interference with biliary excretion.

Anticholinergic Agents

A patient taking antimuscarinic agents may have typical antimuscarinic side effects. Xerostomia may increase the incidence of caries, impair swallowing, increase the likelihood of soft tissue disease in the oral cavity, and make speech difficult. Drugs with which the anti-Parkinson anticholinergics might summate include antihistamines, tricyclic antidepressants, and other drugs with antimuscarinic effects. Adverse reactions and drug interactions involving antimuscarinic drugs are discussed further in Chapter 9.

ANTI-PARKINSON DRUGS

Nonproprietary (generic) name	*Proprietary (trade) name*
Anticholinergics	
Benztropine	Cogentin
Biperiden	Akineton
Procyclidine	Kemadrin
Trihexyphenidyl	Artane, Trihexy-2
Other drugs with anticholinergic activity	
Diphenhydramine	Benadryl
Ethopropazine*	Parsidol
Dopamine precursor and decarboxylase inhibitors	
Carbidopa	Lodosyn
Levodopa	Dopar, Larodopa
Levodopa + benserazide*	Madopar
Levodopa + carbidopa	Sinemet
Levodopa + carbidopa + entacapone	Stalevo
Dopamine receptor agonists	
Apomorphine	Apokyn
Bromocriptine	Parlodel
Pergolide	Permax
Pramipexole	Mirapex
Ropinirole	Requip
Rotigotine	Neupro
Other anti-Parkinson drugs	
Amantadine	Symmetrel
Memantine	Namenda
Riluzole	Rilutek
Entacapone	Comtan
Rasagiline	Azilect
Selegiline (L-deprenyl)	Eldepryl
Tolcapone	Tasmar

*Not currently available in the United States.

SOME DRUGS FOR OTHER MOVEMENT DISORDERS

Nonproprietary (generic) name	*Proprietary (trade) name*
Clonidine	Catapres
Fluphenazine	Prolixin
Gabapentin	Neurontin
Haloperidol	Haldol
Nadolol	Corgard
Pimozide	Orap
Primidone	Mysoline
Propranolol	Inderal
Tetrabenazine	Xenazine

CHAPTER 16

Local Anesthetics

JOHN A. YAGIELA

Local anesthetics are agents that reversibly block nerve conduction when applied to a circumscribed area of the body. Although numerous substances of diverse chemical structure are capable of producing local anesthesia, most drugs of proven clinical usefulness (identified by the suffix *-caine*) share a fundamental configuration with the first true local anesthetic, cocaine. For centuries, natives of the Peruvian highlands have relied on the leaves of the coca bush to prevent hunger, relieve fatigue, and uplift the spirit. European interest in the psychotropic properties of *Erythroxylon coca* led to the isolation of cocaine by Niemann in 1859 and to a study of its pharmacology by von Anrep in 1880. Although Niemann and von Anrep reported on the local anesthetic action of cocaine, credit for its introduction into medicine belongs to Karl Koller, a Viennese physician. In 1884, Koller was familiarized with the physiologic effects of cocaine by Sigmund Freud. Koller recognized the drug's great clinical significance and demonstrated its pain-relieving action in several ophthalmologic procedures. The benefits of cocaine were widely appreciated; within 1 year, local anesthesia had been successfully administered for various medical and dental operations.

Knowledge of cocaine's potential for adverse reactions soon followed its general acceptance as a local anesthetic. Several deaths attributed to acute cocainization testified to the drug's low therapeutic index. The abuse liability of cocaine was dramatically illustrated by the self-addiction of William Halsted, a pioneer in regional nerve blockade. A chemical search for safer, nonaddicting local anesthetics was instituted by Einhorn and associates in 1892, culminating 13 years later in the synthesis of procaine. Since then, numerous improvements in the manufacture of local anesthetic solutions have been made, and many useful agents have been introduced into clinical practice. Because no drug is currently devoid of potentially serious toxicity, however, the search for new and better local anesthetic agents continues.

CHEMISTRY AND CLASSIFICATION

Certain physicochemical characteristics are required of a drug intended for clinical use as a local anesthetic. One prerequisite is that the agent must depress nerve conduction. Because an axon whose cytoplasmic contents have been completely removed can still transmit action potentials, a drug must be able to interact directly with the axolemma to exert local anesthetic activity. A second important consideration is that the agent must have lipophilic and hydrophilic properties to be effective by parenteral injection. Lipid solubility is essential for penetration of the various anatomic barriers existing between an administered drug and its site of action, including the nerve sheath. Water solubility ensures that, when injected in an effective concentration, a drug does not precipitate on exposure to interstitial fluid. These requirements have placed important structural limitations on the clinically useful local anesthetics.

Structure-Activity Relationships

The typical local anesthetic molecule can be divided into three parts: (1) an aromatic group, (2) an intermediate chain, and (3) a secondary or tertiary amino terminus (Figure 16-1). All three components are important determinants of a drug's local anesthetic activity. The aromatic residue confers lipophilic properties on the molecule, whereas the amino group furnishes water solubility. The intermediate portion is significant in two respects. First, it provides the necessary spatial separation between the lipophilic and hydrophilic ends of the local anesthetic. Second, the chemical link between the central hydrocarbon chain and the aromatic moiety serves as a suitable basis for classification of most local anesthetics into two groups, the esters (—COO—) and the amides (—NHCO—). This distinction is useful because there are marked differences in allergenicity and metabolism between the two drug categories.

Minor modifications of any portion of the local anesthetic molecule can significantly influence drug action. The addition of a chlorine atom to the ortho position on the benzene ring of procaine yields chloroprocaine, a more lipophilic local anesthetic four times as potent as the parent compound yet half as toxic when injected subcutaneously. Table 16-1 lists several important physicochemical properties of local anesthetics and how they correlate with clinical activity.

Influence of pH

By virtue of the substituted amino group, most local anesthetics are weak bases with a negative logarithm of the acid ionization constant (pK_a) ranging from 7.5 to 9.0. A local anesthetic intended for injection is usually prepared in salt form by the addition of hydrochloric acid. Not only is water solubility improved, but also stability in aqueous media is increased. When injected, the acidic local anesthetic solution is quickly neutralized by tissue fluid buffers, and a fraction of the cationic form is converted to the nonionized base. As determined by the Henderson-Hasselbalch equation (Figure 16-2), the percentage of drug converted depends primarily on the local anesthetic pK_a and the tissue pH. Because only the base form can diffuse rapidly into the nerve, drugs with a high pK_a tend to be slower in onset than similar agents with more favorable dissociation constants. Tissue acidity may also impede the development of local anesthesia. Products of inflammation can lower the pH of the affected tissue and limit formation

FIGURE **16-2** Distribution of a local anesthetic during nerve block. On injection of a local anesthetic solution, a portion of the cationic acid is converted to the free base. Calculated for lidocaine is the base-to-acid ratio in the extracellular fluid at equilibrium. *Dark arrows* depict the major pathway followed by a local anesthetic in reaching its site of action *(asterisk)* within the nerve membrane. Although the acid form is responsible for most of the blocking activity, the contribution of the nonionized base (*light arrows* within the axolemma) must not be overlooked.

of the free base. Ionic entrapment of the local anesthetic in the extracellular space delays the onset of local anesthesia and may render effective nerve blockade impossible.

Numerous attempts have been made to augment local anesthesia by capitalizing on the influence of pH. Theoretically, alkalization should increase local anesthetic activity by promoting tissue penetration and nerve uptake. Many topical agents are marketed in the base form to improve diffusion across epithelial barriers. Although it has been shown experimentally that alkalization of local anesthetic solutions just before use enhances nerve blockade, practical considerations have limited routine clinical application. Even so, extracellular fluid has in most instances sufficient buffering capacity to negate differences in local anesthetic pH soon after injection.

An alternative approach to modifying drug distribution is through the addition of carbon dioxide. Carbonation of a local anesthetic solution can increase the rate of onset and sometimes the depth of anesthesia. It has been suggested that the hydrocarbonate salt of the local anesthetic penetrates membranes more rapidly than the conventional formulation and that the injected carbon dioxide diffusing into the nerve trunk lowers the internal pH and concentrates local anesthetic molecules by ion trapping.[55] There is also evidence that carbon dioxide may potentiate local anesthetic activity by a direct effect on the nerve membrane.[15,19] Although promising, carbonated local anesthetic solutions are unavailable in the United States, and a study of carbonated lidocaine used for mandibular anesthesia failed to reveal any significant benefit compared with lidocaine hydrochloride.[22]

MECHANISM OF ACTION

Local anesthetics block the sensation of pain by interfering with the propagation of peripheral nerve impulses. The generation and the conduction of action potentials are inhibited. Electrophysiologic data indicate that local anesthetics do not significantly alter the normal resting potential of the nerve membrane; instead they impair certain dynamic responses to nerve stimulation.

Effects on Ionic Permeability

The quiescent nerve membrane is impermeable to Na^+. Excitation of the neuron by an appropriate stimulus temporarily increases Na^+ conductance and causes the nerve cell to become less electronegative regarding the outside. If the transmembrane potential is sufficiently depressed, a critical threshold is reached at which the depolarization becomes self-generating. Local electrotonic currents induce a rapid influx of Na^+ through activated Na^+-selective channels traversing the nerve membrane. The inward Na^+ current creates an action potential of approximately +40 mV, which is propagated down the nerve. The action potential is quite transient at any given segment of membrane; loss of Na^+ permeability (inactivation of the Na^+ channels) and an outward flow of K^+ (in nonmyelinated axons) quickly repolarize the membrane. These events are reviewed in Figure 16-3.

Local anesthetics interfere with nerve transmission by blocking the influence of stimulation on Na^+ conductance. A developing local anesthetic block is characterized by a progressive reduction in the rate and degree of depolarization and a

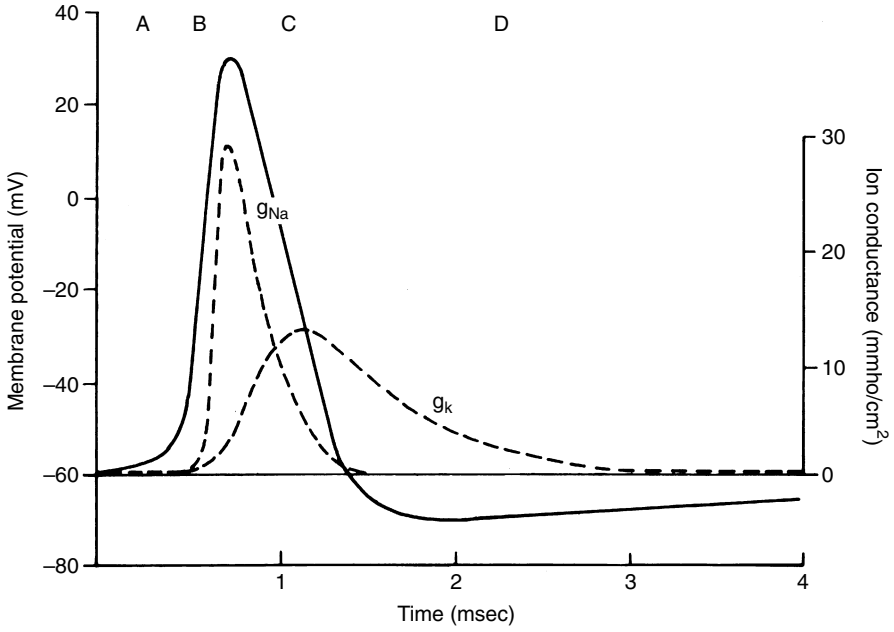

FIGURE **16-3** The action potential. Dashed lines indicate the Na^+ *(gNa)* and K^+ *(gK)* conductance changes responsible for membrane depolarization and recovery. *A*, Resting state; Na^+ channels are in the resting (closed) configuration. *B*, Depolarization phase; Na^+ channels open. C, Repolarization phase; Na^+ channels become inactivated, and the nerve becomes refractory to stimulation. *D*, Recovery phase; Na^+ channels convert from the inactivated to the resting state, and the nerve regains the ability to conduct action potentials.

slowing of conduction. When the depolarization is retarded sufficiently such that repolarization processes develop before the threshold potential can be reached, nerve conduction fails.[1]

Site of Action

Several sites exist within the nerve membrane where drugs could potentially interfere with Na^+ permeability. It was argued that local anesthetics could interact with membrane lipids to impair Na^+ channel function, just as had long been proposed for general anesthetics (see Chapter 17).[86] In recent years, evidence has accumulated that conventional local anesthetics interact directly with Na^+ channels to inhibit nerve conduction.[18,88] Each Na^+ channel is composed of several subunits. The α subunit is the largest component (260 kDa) and forms the actual channel,[20] whereas the smaller β subunits help to stabilize the channel complex within the membrane.[56] As depicted in Figure 16-4, the α subunit consists of four homologous domains (I to IV), each of which is composed of six structurally similar helical segments (S1 to S6) that traverse the plasma membrane. Collectively, the S4 segments of each domain constitute the voltage sensor of the "m" or "activation" gate, which opens in response to a depolarizing stimulus. Each S4 segment contains positively charged amino acid residues, specifically arginine and lysine, at every third position of the α helix. In the "helical screw model" of activation,[21] depolarization causes the outward conformational rotation of the S4 segments, which can be detected experimentally as the small gating currents that precede the action potential. Local anesthetic blockade of the Na^+ channel is characterized by a reduction in the peptide movements responsible for these gating currents.[63] Lidocaine tends to trap the S4 segment of domain III in the external, depolarized configuration and to retard movements of the S4 segment of domain IV.[77] As a consequence, the Na^+ channel remains in an inactivated configuration that precludes normal opening.

As the active site for local anesthetics resides within the Na^+ channel, access becomes an important issue. In this regard, studies with permanently charged local anesthetics have proved enlightening.[44] Conversion of the amino terminus of certain local anesthetics (e.g., lidocaine) to the quaternary form (e.g., QX-314) yields permanently charged cations largely incapable of crossing the nerve membrane. Although ineffective when applied externally to the axolemma, these experimental compounds show full blocking activity on internal administration. They gain access to the receptor by traveling up an aqueous route within the Na^+ channel, which must be fully open or at least partially activated to permit their entry from the cytoplasm. Lipophilic molecules, such as benzocaine or the uncharged form of lidocaine, can reach the channel and receptor site by traversing a hydrophobic route, which may include the membrane lipid and hydrophobic portions of the Na^+ channel.

Specific mutations of the S6 segment of domain IV of the Na^+ channel greatly alter local anesthetic blockade.[68] Replacement of the phenylalanine amino acid midway down the S6 helix with an alanine residue reduces by 99% the apparent binding affinity of the local anesthetic etidocaine to open and inactivated channels. A similar, although smaller, effect occurs when the tyrosine located 11 Å and two turns inward on the same side of the S6 helix is replaced with alanine. Because these aromatic amino acids can interact with local anesthetics through hydrophobic and van der Waals interactions, and their spatial separation conforms to the length of the typical local anesthetic molecule (10 Å to 15 Å), they are believed to be part of and to identify the local anesthetic receptor site. Mutation studies have also shown specific amino acid residues on the S6 segments of domains I and III that appear to form part of the receptor site (Figure 16-5).[94]

As previously mentioned, local anesthetics block nerve conduction by impeding the gating mechanisms that underlie cycling of the Na^+ channel. Other actions that could contribute to nerve blockade include a physical occlusion of the channel, an allosterically mediated change in channel conformation, and (at least with local anesthetic cations) a distortion of the local electrical field.[57] Some of these actions may be complementary, as binding of a cationic local anesthetic molecule to the putative receptor site places its positive charge adjacent to the most constricted portion of the channel and stabilizes the S4 domain III segment (and to a lesser degree the S4 domain IV segment) in the extruded position.[62] Figure 16-6 depicts the Na^+ channel as it cycles through its primary configurations in response to a depolarizing stimulus and postulated interactions with neutral and charged local anesthetic species.[5]

Similarities in molecular structure among voltage-gated ion channels provide the basis by which local anesthetics influence the movement of ions other than Na^+. Inhibition of specific K^+ and Ca^{++} currents may contribute to various local anesthetic effects, including the blockage of nociception.

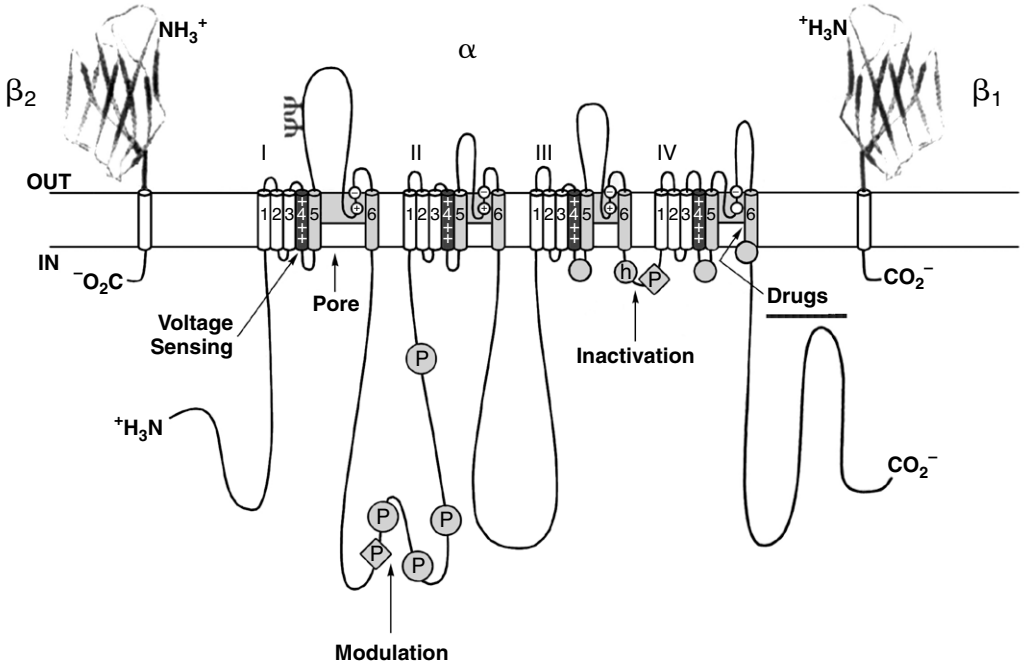

FIGURE **16-4** Functional structure of the Na^+ channel (linear representation). The four primary domains of the α subunit are indicated by Roman numerals, with the six helical segments (designated S1 through S6, *left to right*) of each domain shown spanning the membrane. A portion of each of the S5-S6 linkages lines the outer portion of the pore and confers ion selectivity to the channel. The inner portion is lined by the S6 and (to a lesser extent) S5 helices. Outward rotation of the positively charged S4 cylinders and coupled movements of the S6 segments open the pore. Concurrently, portions of the S4-S5 linkages of domains III and IV, which help form the inner mouth of the channel, and the S6 segment of domain IV create a receptor (*unlettered circles*) for a hydrophobic triad of amino acid residues (isoleucine-phenylalanine-methionine; IFM motif) in the intracellular loop between domains III and IV, which constitutes the inactivation, or *h*, gate *(h)*. Binding of the h gate to its receptor inactivates the channel within about 1 ms. Each *P* indicates a phosphorylation site for protein kinase A (*circles*) and protein kinase C (*diamonds*). Phosphorylation of the h gate slows inactivation; phosphorylation of other sites reduces channel activation. The *ψ* symbols indicate glycosylation sites. The β subunits (β_1 and β_2) modulate Na^+ channel electrophysiology and serve as cell adhesion molecules, stabilizing the α subunit in the nerve membrane by interacting with other β subunits and with contactin and ankyrin proteins. (Adapted from Catterall WA: From ionic currents to molecular mechanisms: the structure and function of voltage-gated sodium channels, *Neuron* 26:13-25, 2000.)

Use-Dependent Block

Conventional local anesthetics inhibit high-frequency trains of impulses more readily than they do single action potentials. This phenomenon, variously referred to as use-dependent or frequency-dependent conduction block, phasic or transitional block, or Wedensky inhibition, is an important pharmacologic attribute of local anesthetics and one vital to the elucidation of their interaction with the Na^+ channel.

It has been stated that quaternary derivatives of local anesthetics retain nerve-blocking activity when they are injected intra-axonally, but are ineffective by external administration. Because these drugs can reach their site of action within the Na^+ channel only when the channel is open to the cytoplasm, repetitive stimulation of the nerve should increase exposure of the receptor site to the anesthetic—and lead to increasing drug action—until a steady state is established between the bound drug within the channel and the free drug in the axoplasm. A similar, although less extensive use dependency could be anticipated for lidocaine and related drugs that are partially ionized at physiologic pH.

Numerous studies have proved that high-frequency stimulation increases the magnitude of channel blockade by local anesthetics. Within certain limits, the degree of axonal block is strongly and continuously dependent on the stimulus rate regardless of equilibration time. A concentration of lidocaine that reduces a compound action potential by 40% at a stimulation rate of 1 Hz causes a depression of 80% after 15 seconds at 40 Hz.[14] These results, as embodied in the modulated receptor hypothesis of local anesthesia, suggest that stimulation of the nerve membrane not only exposes the site of action to local anesthetic cations, but also increases temporarily the affinity of the channel receptor for them.

As originally proposed by Hille,[44] the modulated receptor hypothesis holds that both the charged and neutral forms of local anesthetics bind preferentially to open and inactivated Na^+ channels. The binding reciprocally tends to stabilize the channels in the inactivated state. If stimulations are sufficiently infrequent, time is available after each depolarization for the slower-than-normal transition from inactivated to resting channels to take place. This conversion reduces local anesthetic binding and permits a net diffusion of neutral anesthetic molecules out of the channels. The remaining anesthetic bound to closed channels provides a basal or tonic block. Conversely, repeated stimuli do not allow for full recovery between depolarizations; anesthetic binding remains enhanced, Na^+ channels in the inactive configuration accumulate, and use-dependent block ensues. Subsequent refinements to the modulated receptor hypothesis include discoveries that the increased affinity

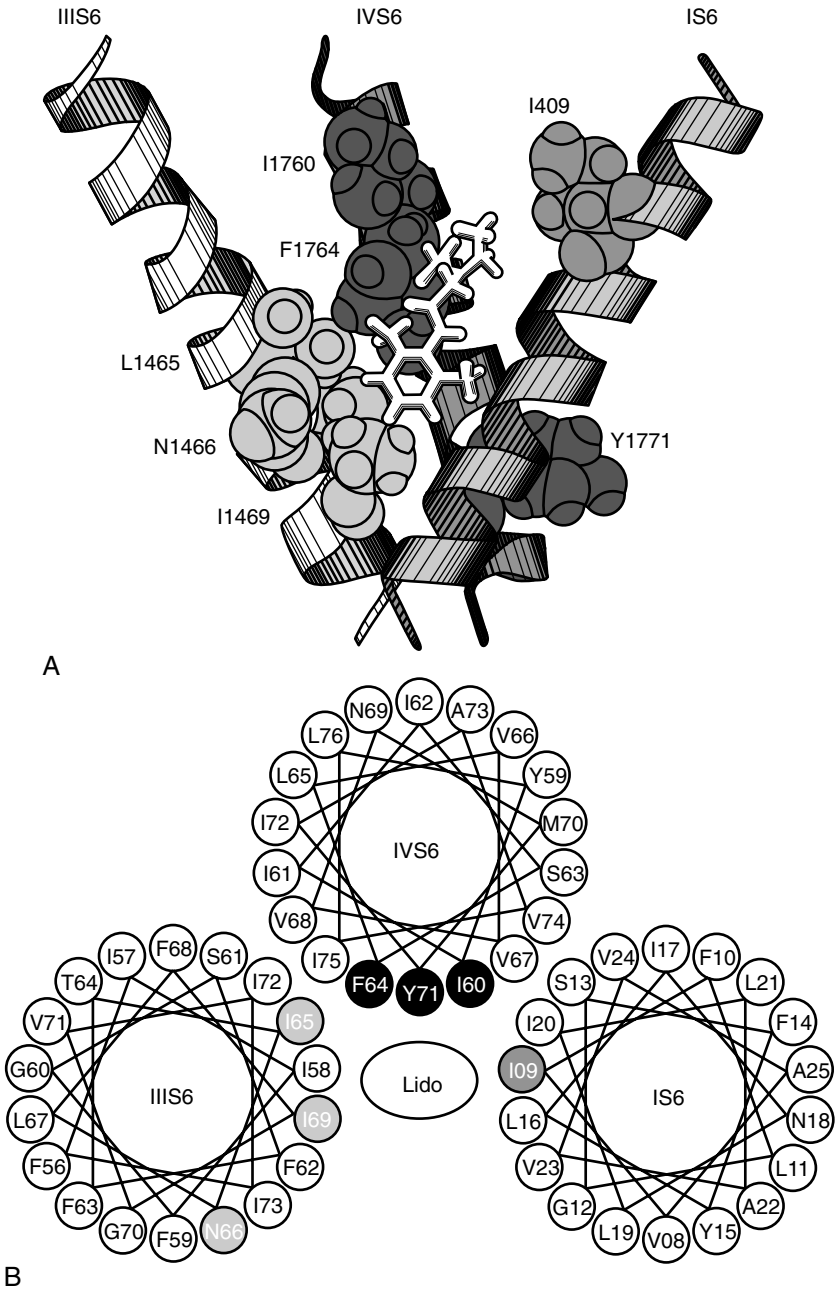

FIGURE **16-5** Proposed local anesthetic binding to the S6 transmembrane segments of domains I (*IS6*), III (*IIIS6*), and IV (*IVS6*). **A,** Three-dimensional model. The local anesthetic lidocaine is shown in stick representation; amino acid residues important to local anesthetic binding are shown in space-filling representation. For each amino acid illustrated, the letter identifies the amino acid present (*F,* phenylalanine; *I,* isoleucine; *L,* leucine; *N,* asparagine; *Y,* tyrosine), and the number indicates its position on the α-subunit polypeptide. One isoleucine (*I1760*) does not bind lidocaine per se but blocks its potential exit through a hydrophilic pathway. **B,** α-Helical representation showing the axial positions of the amino acids (*solid circles*) whose mutation causes reduction in the affinity of lidocaine (*Lido*) for the inactivated Na^+ channel. (Adapted from Yarov-Yarovoy V, McPhee JC, Idsvoog D, et al: Roles of amino acid residues in transmembrane segments IS6 and IIS6 of the Na^+ channel a subunit in voltage-dependent gating and drug block, *J Biol Chem* 277:35393-35401, 2002.)

state of the receptor caused by depolarization of the membrane is not synonymous with the classically defined open or inactivated forms of the channel but may include closed but partially activated channels and several "slow" inactivated configurations promoted by local anesthetic binding.

Marked differences in use dependency have been recorded for various local anesthetics.[24] Benzocaine and related nonionized compounds show little phasic block and then only at very high stimulus rates. Conventional local anesthetics exhibit an approximate 10-fold range in frequency dependence, with phasic block becoming clinically significant at 2.5 Hz for lidocaine and at 0.5 Hz for bupivacaine. Permanently charged local anesthetic derivatives develop use-dependent blocks with stimulus rates of 2.4 per minute (0.04 Hz). Basic knowledge gained by the study of use dependency is increasingly being applied to clinical questions involving local anesthetic efficacy and toxicity and to related classes of drugs, such as various antiarrhythmic and anticonvulsant agents that also exhibit phasic block. Ultimately, new drugs and modes of therapy are expected to arise from the pharmaceutical exploitation of this phenomenon.

Differential Nerve Block

Clinically, neurons vary according to fiber size and type in their susceptibility to local anesthetics. Autonomic functions subserved by preganglionic B and postganglionic C fibers are readily disrupted by local anesthetics, whereas motor control dependent on larger A fibers is not. Sensory neurons are quite heterogeneous in size and exhibit a wide range of sensitivity. Modalities listed in increasing order of resistance to conduction block include the sensations of pain, cold, warmth, touch, and deep pressure. Generally, the more susceptible a fiber is to a local anesthetic agent, the faster it is blocked, and the longer it takes to recover.

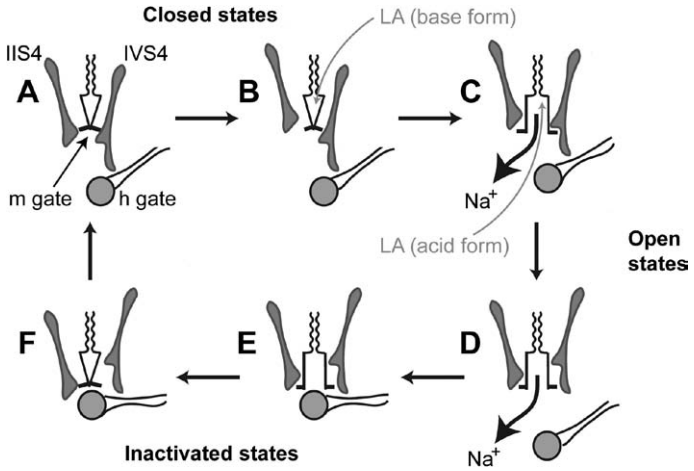

FIGURE **16-6** Normal Na^+ channel cycling and local anesthetic blockade. Shown for domains II and IV are the S4 segments (*IIS4* and *IVS4*) surrounding their respective S5-S6 linkages (*scalloped lines*) and S6 segments (helping to form the activation, or *m*, gate). **A,** In the basal resting state, the S4 segments of all domains are fully deactivated, forced inward by the negative resting polarity. The m gate is fully closed. **B,** With partial depolarization of the membrane, the S4 segments of domains I, II, and III rotate outward independently. The m gate remains closed. Noncharged local anesthetics can gain access to the channel at any stage of the channel cycle by traversing a hydrophobic pathway. **C,** Conduction begins when the S4 segment of domain IV moves part way out. The steric hindrance on the m gate is relieved, and the gate opens sufficiently for influx of Na^+. Charged local anesthetic molecules can reach the receptor only when the channel is in an open configuration. **D,** Subsequent movement of the S4 domain IV segment allows the channel to open fully. The immediate area assumes a positive polarity as Na^+ rushes inward. This movement also exposes the receptor site for the inactivation, or *h*, gate. **E,** Inactivation of the channel by docking of the h gate to its receptor automatically follows. The influx of Na^+ is terminated. **F,** As the local internal Na^+ concentration dissipates, and the membrane begins to repolarize, the S4 segments of domains I and II return to their resting configurations. At this point, the m and h gates are closed. Return to the normal resting state occurs as the S4 domain returns to its fully resting state, evicting the h gate from its binding site in the process. (Adapted from Armstrong CM: Na channel inactivation from open and closed states, *Proc Natl Acad Sci U S A* 103:17991-17996, 2006.)

Critical length

The clinical observations already described (and best seen after spinal or epidural anesthesia) should not be construed as proof that large myelinated axons are inherently more resistant to local anesthetics than smaller fibers. A careful study of individual axons by Franz and Perry[35] revealed that the minimum blocking concentration of procaine is not directly related to fiber diameter. A differential block, in which small C and A fibers were affected but larger A fibers were not, could be obtained but only when the length of compound nerve exposed to procaine was restricted in length. On the basis of these findings, the authors concluded that differential sensitivities of fibers of unequal diameter result from variations in the "critical length" that must be exposed to a local anesthetic for conduction to fail.

In myelinated nerves, action potentials are propagated from one node of Ranvier to the next in a saltatory fashion, with a safety factor sufficient to require at least three consecutive nodes to be completely blocked before impulse transmission is interrupted. Because internodal distance is directly related to fiber diameter, small neurons may seem to be more sensitive clinically than large fibers to conduction block. As a local anesthetic diffuses into the nerve trunk, it reaches an effective concentration over a length required to inhibit small axons (i.e., block three nodes) before it spreads sufficiently to block large fibers. Anatomic barriers to diffusion, nonuniform distribution of drug, or the use of a minimal amount of local anesthetic may preclude some large axons from ever being affected. As local anesthesia fades, small neurons are the last to recover because circumscribed areas of drug concentrations adequate for their inhibition remain along the nerve after the more substantial areas required for large axons have broken up.

When the concentration of local anesthetic is insufficient to block three adjacent nodes completely, anesthesia may still occur if a larger train of nodes is partially blocked.[34,69] As long as more than 70% of the Na^+ channels in a node are inhibited, the resulting action potential at that node is reduced in size. Progressive declines in the action potentials of partially blocked nodes along the axon ultimately result in failure of conduction if a sufficient length of nerve is exposed to the drug. As shown in Figure 16-7, smaller neurons are again more readily blocked because of the shorter length required for exposure of the requisite number of nodes.[69]

The critical length hypothesis may also be applied to unmyelinated axons as a group. Differences in modes of impulse transmission preclude direct comparisons based on fiber size between myelinated and unmyelinated axons. Smaller in diameter, C fibers nevertheless have approximately the same apparent critical length as small myelinated axons.

Use-dependent block

In addition to anatomic and physiologic variables, the pattern of impulse traffic normally carried in situ by the different nerve fibers may contribute greatly to a differential nerve block.[73] Noxious stimuli and sympathetic nervous system transmissions are encoded in rapid bursts of impulses, whereas motor function usually involves low-frequency discharges. Local anesthetics whose use-dependent characteristics fall within this frequency range tend to block pain sensations and autonomic responses preferentially.

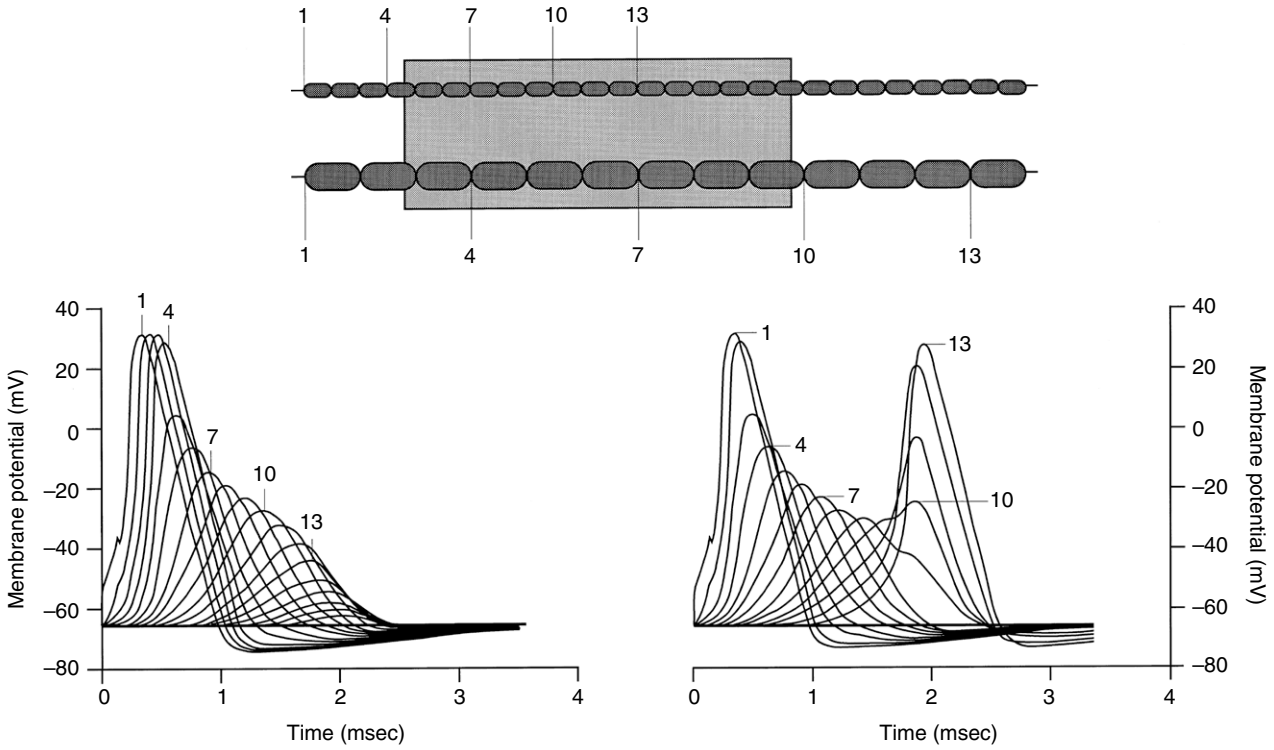

FIGURE **16-7** Differential nerve block. Two adjacent myelinated axons, differing in diameter and internodal distance by a factor of 2, are exposed to a local anesthetic (*gray zone*). Impulses arising from successive nodes of the small axon are plotted on the left. Exposure of 14 nodes to a specific concentration of local anesthetic causes conduction to fail. Identical exposure of the larger axon (*right*) results in seven nodes being affected, an insufficient number to prevent conduction at this local anesthetic concentration. (Adapted from Raymond SA, Thalhammer JG, Strichartz GR: Axonal excitability: endogenous and exogenous modulation. In Dimitrijevic, Wall PD, Lindblom U, editors: *Altered sensation and pain*, Basel, Switzerland, 1990, Karger.)

Peripheral nerve organization

The location of various axons within a nerve trunk has an important bearing on the rate and sometimes the depth of local anesthesia. In major nerve blocks, the epineurium and perineurium limit the spread of anesthetic solution by bulk flow, and the drug must rely more on diffusion to reach the axons within the nerve. Diffusion takes considerable time with nerves that are 1 mm in diameter or greater, and the net result is that the outer, or mantle, fibers are blocked well before the inner core fibers have been exposed to an effective concentration of drug. Removal of the agent by the bloodstream, particularly by intraneuronal blood vessels, may prevent anesthesia of core fibers altogether. Generally, the more proximal tissues supplied by a nerve are more readily affected by local anesthetics because the axons that serve them are located peripherally. The nonuniform distribution of various fiber types within a particular nerve may lead to differential blockade of sensory, motor, and autonomic axons innervating a given structure.

Local anesthetic selectivity

Local anesthetics vary in their relative inherent ability to block sensory versus motor fibers. A good example of this form of differential block involves bupivacaine and etidocaine. Both of these drugs are highly lipid-soluble agents capable of producing prolonged nerve blockade. Bupivacaine can elicit sensory anesthesia at one third the concentration required for motor blockade, whereas etidocaine shows no selectivity of effect.[79] Because maintenance of uterine muscle contractility is important in childbirth, bupivacaine is the preferred agent for epidural anesthesia during labor and delivery.

The mechanism behind such differential effects of local anesthetics has not been elucidated. One possibility relates to the drugs' relative tendency to block different K^+ channel subtypes. A local anesthetic (presumably etidocaine) with a strong ability to block voltage-gated K^+ channels important in reversing neuronal depolarization might be expected to work against itself in nonmyelinated axons subserving the perception of pain. In such nerves, inhibition of K^+ efflux would give Na^+ efflux a better chance of reaching threshold and propagating the action potential. A selective blockade of K^+ influx through K^+ channels that specifically control the resting membrane potential of small, nociceptive axons would result in partial membrane depolarization and a potentiation of Na^+ channel inactivation and local anesthetic blockade.[49]

Inflammation

The failure to obtain satisfactory clinical pain relief in inflamed tissues is a well-known and undesirable form of differential nerve block. Clinically, this phenomenon is encountered in a patient who exhibits profound local anesthetic effect except in the specific area requiring treatment. If inflammation lowers the pH at the injection site, diffusion of the drug into the axolemma would be impaired, as described previously. There is some evidence, however, that the buffering capacity of inflamed tissues is not always reduced[67] and that other reasons for local anesthetic failure must exist in these conditions.

Increased blood flow and decreased catecholamine effectiveness in inflamed tissues may speed removal of the local anesthetic from the injection site. Alteration of Na^+ channel number, function, or type may offset the ability of local anesthetics to block nerve conduction. Analogous changes in the expression or activity of other ion channels involved in

nociception may have a similar effect.[52] Neuromediators and other products released or synthesized during inflammation may increase responsiveness of nociceptors and/or enhance nerve conduction in response to painful stimuli. These include histamine, prostaglandin E_1, kinins, adenine nucleotides, and substance P.

PHARMACOLOGIC EFFECTS

Although primarily used to depress peripheral nerve conduction, local anesthetics are not selective and may interfere with impulse transmission in any excitable tissue. Most prominent of the systemic effects of local anesthetics are effects related to the cardiovascular system and the central nervous system (CNS), but virtually any organ with dependence on nervous or muscular activity may be affected. Local anesthetics may also influence various tissues through actions unrelated to specific disturbances in Na^+ conductance.

Central Nervous System

Local anesthetics readily pass from the peripheral circulation into the brain. Because CNS neurons are particularly sensitive to local anesthetics, blood concentrations incapable of altering peripheral nervous activity may profoundly influence CNS function.

Sensitive psychomotor tests and subjective reports of mild drowsiness indicate that systemic effects caused by local anesthetics can occur with plasma concentrations that are achieved in dental patients.[6] Analgesic and anticonvulsant effects also occur in subtoxic concentrations. Initial signs and symptoms of a toxic effect are often excitatory in nature and consist of a feeling of lightheadedness and dizziness, followed by visual and auditory disturbances, apprehension, disorientation, and localized involuntary muscular activity. Depressant responses, such as slurred speech, drowsiness, and unconsciousness, may also occur and are especially prominent with certain drugs (e.g., lidocaine). As higher blood concentrations of drug are attained, muscular fasciculations and tremors intensify and develop into generalized tonic-clonic convulsions. On termination, seizure activity is often succeeded by a state of CNS depression identical to general anesthesia. With excessively large doses, respiratory impairment becomes manifest; if untreated, death by asphyxiation may ensue.

The CNS excitation sometimes observed after local anesthesia is intriguing because the sole action ascribed to these agents is one of depression. Studies involving the topical application of local anesthetics to exposed cortical or spinal cord neurons document that the only direct effect of procaine and related drugs is to inhibit electrical activity.[26] The apparent stimulation observed clinically may be explained on the basis that inhibitory cortical neurons or synapses are highly susceptible to transmission block. Initial disruption of these pathways results in a disinhibition of excitatory neurons, manifested clinically as stimulation. Electroencephalographic studies indicate that local anesthetic seizures begin in the amygdala.[37,76] Disinhibition of this part of the limbic system allows high-voltage discharges to occur, which spread throughout the brain. A more recent finding that local anesthetics can block a family of K^+ channels (whose inhibition increases neuronal excitability) raises the possibility that CNS stimulation and cardiac arrhythmias may arise in part from direct neuronal excitation.[49]

Cardiovascular System

Local anesthetics can exert various effects on the cardiovascular system. Some influences are beneficial and serve as a basis for the use of selected agents in the treatment of cardiac arrhythmias; others are not helpful and merely serve to accentuate systemic toxicity. In almost all instances, however, the observed effects result from the interplay of direct actions of local anesthetics on the myocardium and peripheral vasculature as well as CNS actions indirectly mediated through the autonomic nervous system.

Myocardium

At nontoxic concentrations, local anesthetics differ in their electrophysiologic influences on the heart. Lidocaine shortens the action potential duration and the effective refractory period in Purkinje fibers, whereas procaine acts in the opposite direction. Both drugs increase the effective refractory period relative to the action potential duration, however, and decrease cardiac automaticity, especially in ectopic pacemakers.

Presumably because of their ability to block Ca^{++} channels and evoked Ca^{++} release from the sarcoplasmic reticulum and to reduce myofibrillar responsiveness to available Ca^{++}, local anesthetics depress myocardial contractility in a dose-dependent manner.[59] With conventional doses of lidocaine, this effect is minor and sympathetic reflexes and direct vascular effects produce a compensatory increase in peripheral resistance, which prevents a decrease in blood pressure. Through a centrally mediated disinhibition of sympathetic nervous activity, heart rate and arterial blood pressure may become elevated coincident with CNS excitation. Conversely, mepivacaine has been reported in moderate doses to decrease peripheral vascular resistance and increase cardiac output,[48] which suggests that local anesthetics may exert dissimilar patterns of direct and indirect effects on the heart at subtoxic blood concentrations.

Local anesthetics in doses toxic to the heart are qualitatively similar in action. Membrane excitability and conduction velocity are depressed throughout the heart. Sinus bradycardia and impairment of myocardial contractility contribute to a reduction in cardiac output. These effects are magnified by hypoxia, but even if respiration is supported artificially, circulatory collapse occurs after excessively large doses.

Reports in humans suggest and experiments in several other species confirm that bupivacaine and certain other highly lipophilic local anesthetics are cardiotoxic compared with less lipophilic congeners. Serious ventricular arrhythmias and cardiovascular collapse are more likely to occur, and resuscitation is more problematic. One explanation for these observations involves use-dependent blockade.[24] As indicated in Table 16-2, bupivacaine has a high molecular weight for a local anesthetic. That, coupled with its lipophilic tendency and perhaps its high pK_a, enables the drug to exert a strong phasic block at normal heart rates. Inhibition of K^+ and Ca^{++} channels may also contribute to the arrhythmogenic potential of bupivacaine in toxic concentrations. Finally, intracerebroventricular injection of bupivacaine can cause intractable arrhythmias in animals, indicating a CNS contribution to the drug's cardiac toxicity.[10]

Peripheral vasculature

The effects of local anesthetics on blood vessels are complex and dose dependent.[4,12] Dilute solutions enhance spontaneous myogenic contractions and peripheral resistance in certain vascular beds, presumably by increasing the cytoplasmic concentration of Ca^{++} within smooth muscle fibers. Coincidentally, local anesthetics reduce vascular tone related to autonomic function by diminishing neurotransmitter release and smooth muscle responsiveness. Subconvulsive doses of local anesthetics exert minor influences on the peripheral vasculature as a whole. Toxic blood concentrations may cause arteriolar dilation and profound hypotension.

The net effect on any vasculature bed depends on the local anesthetic, its concentration, and the existing sympathetic tone in the tissue. A therapeutically relevant estimate of local

Comparison of Local Anesthetics Used in Dentistry

PREPARATION CONTENTS	PROPRIETARY (TRADE) NAME	MAXIMUM DOSE* (mg/kg)	MAXIMUM DOSE* (mg)	DURATION OF ANESTHESIA (SOFT TISSUE) MAXILLARY INFILTRATION (min)	DURATION OF ANESTHESIA (SOFT TISSUE) INFERIOR ALVEOLAR BLOCK (min)
2% Lidocaine hydrochloride; 1:100,000 epinephrine	Xylocaine with epinephrine, 1:100,000	7	500	170	190
2% Lidocaine hydrochloride; 1:50,000 epinephrine	Xylocaine with epinephrine, 1:50,000	3.5†	250†	170	190
2% Lidocaine	Xylocaine	4.5	300	40‡	100‡
2% Mepivacaine hydrochloride; 1:20,000 levonordefrin	Carbocaine 2% with Neo-Cobefrin	6.6	400	150	190
3% Mepivacaine hydrochloride	Carbocaine	6.6	400	90	165
4% Prilocaine hydrochloride; 1:200,000 epinephrine	Citanest Forte	8	600	140	205
4% Prilocaine hydrochloride	Citanest	8	600	105	175
0.5% Bupivacaine hydrochloride; 1:200,000 epinephrine	Marcaine with epinephrine	—	90	340	440
4% Articaine hydrochloride; 1:100,000 epinephrine	Septocaine with epinephrine, 1:100,000	7	—	200	230
4% Articaine hydrochloride, 1:200,000 epinephrine	Septocaine with epinephrine, 1:200,000	7	—	180	200

*The maximum dose is the smaller of the two values (e.g., 7 mg/kg lidocaine up to a maximum dose of 500 mg).
†Lower doses than those approved by the U.S. Food and Drug Administration are recommended on the basis of the high epinephrine content.
‡Lidocaine without epinephrine produces unreliable pulpal anesthesia, especially of the maxilla.

anesthetics listed in decreasing order of vasodilatory potential includes procaine, bupivacaine, lidocaine, articaine, prilocaine, mepivacaine, ropivacaine, and cocaine. With the possible exception of ropivacaine, local anesthetics administered submucosally inhibit myogenic activity and autonomic tone clinically and cause vasodilation in the area of injection. Cocaine is unique in its ability to decrease local blood flow after topical application to mucosal surfaces. Cocaine potentiates the vasoconstrictive effect of catecholamines by inhibiting their transport into adrenergic nerve terminals.

Miscellaneous Effects

Aside from their influences on cardiovascular and CNS function, local anesthetics exert few systemic effects in concentrations compatible with life. Transmission at the neuromuscular junction and at autonomic ganglia may be affected, but intra-arterial administration is usually required for these effects to be observed in vivo. Various smooth muscle actions and antibacterial, antihistaminic, and antimuscarinic effects have also been reported.[27] Local anesthetics have been shown to influence the metabolism of arachidonic acid and to inhibit platelet aggregation.[16]

In tissue culture, local anesthetics can disrupt numerous cellular functions—locomotion, endocytosis, exocytosis, axonal transport, cell fusion, and maintenance of normal morphology. These effects have been ascribed to disturbances of the cytoskeleton (microtubules and microfilaments). Various Ca^{++}-dependent and calmodulin-dependent enzymatic activities and membrane transport systems are also susceptible to local anesthetic influences.[87] The toxicologic and therapeutic implications of these actions are mostly yet to be determined.

Vasoconstrictor Effects

Vasoconstrictors are often added to local anesthetic solutions to impede systemic absorption of the anesthetic agent (see Chapter 6). Epinephrine in concentrations of 5 μg/mL to 20 μg/mL (1:200,000 to 1:50,000) is most commonly used for this purpose, but other sympathomimetic amines, including levonordefrin, norepinephrine, and phenylephrine, are or have been used. Localization of the anesthetic solution in the area of injection by epinephrine is often highly beneficial. The duration of local anesthesia may be prolonged several times, and the success rate and intensity of nerve block may be improved. Systemic toxicity may be reduced because less drug may be needed, and anesthetic metabolism is more likely to keep pace with drug absorption. During surgery, hemostasis afforded by the infiltration of a local anesthetic solution containing epinephrine may also be advantageous.

Normally, sympathomimetic drugs included in anesthetic formulations produce no pharmacologic effects of clinical consequence other than localized arteriolar constriction. Low doses of epinephrine, such as those contained in one or two dental cartridges of lidocaine with 1:100,000 epinephrine (18 μg to 36 μg), decrease total peripheral resistance by 20% to 30%, but a commensurate increase in cardiac output supported by increases in stroke volume, heart rate, or both leaves the mean blood pressure unchanged. Injudicious dosage, accidental intravascular injection, or adverse drug interactions may promote clinically noticeable effects on the CNS and sympathetic nervous system. Heart rate and systolic blood pressure may be elevated by epinephrine, causing uncomfortable palpitation and pain in the chest. Restlessness and apprehension similar to the effects produced by local anesthetics in overdose may also occur. Phenylephrine, a relatively pure α-adrenergic agonist, avoids most of the direct cardiac stimulation associated with epinephrine, but it may significantly elevate systolic and diastolic pressures and reflexively slow the heart for an extended period. Other sympathomimetics, such as norepinephrine and levonordefrin, are intermediate in their systemic effects.

As a guideline for cardiac patients, the New York Heart Association recommended in 1955 that the amount of epinephrine administered during any one session not exceed 200 μg (equivalent to 20 mL of a 1:100,000 epinephrine solution).[81] Current evidence indicates that this amount is excessive for patients with compromised cardiovascular systems and that more restrictive guidelines should be followed (see Chapter 6). Several studies have shown that the intraoral injection of 20 μg of epinephrine effectively doubles the preoperative plasma concentration and that higher

doses produce proportionately greater elevations.[85] At doses approaching 200 μg, the resulting epinephrine titers can surpass titers associated with heavy exercise, surgery, and pheochromocytoma.[25,28] Increases in cardiac work become significant, and myocardial ischemia and cardiac arrhythmias are more likely to occur.

ABSORPTION, FATE, AND EXCRETION

Pharmacokinetic considerations regarding local anesthetics are vital because the balance between the uptake of a local anesthetic into the systemic circulation and its removal through redistribution, metabolism, and excretion in large measure determines the drug's toxic potential.

Absorption

The rate of absorption depends on several factors, including the dosage and pharmacologic profile of the drug used, the presence of a vasoconstrictor agent, and the nature of the administration site. The more drug that is injected, the higher its resultant blood concentration. Less obvious are the qualitative influences of the anesthetic solution and how these interact with the site of administration. Drugs with potent vasodilating properties, such as procaine and lidocaine, may significantly enhance their own uptake, particularly when injected into a highly vascular space. Inclusion of epinephrine or another vasoconstrictor is especially important in these instances. Drugs that are not strong vasodilators, such as mepivacaine and prilocaine, do not markedly accentuate their own absorption and do not require as much vasoconstrictor to limit uptake.

Absorption after topical application varies widely. Although intact skin and keratinized mucosa are relatively impermeable, local anesthetics are readily absorbed from most mucosal surfaces. Instillation of tetracaine into the piriform fossa results in a peak plasma concentration one third to one half that obtained after rapid intravenous infusion. By comparison, absorption of lidocaine from the tracheobronchial tree is much slower. Regardless of the site of application, sympathomimetic agents in standard doses are ineffective topically in delaying absorption. Uptake may be minimized, however, by using local anesthetics prepared in the form of an ointment or gel instead of an aqueous spray.

Distribution

On entering the circulation, a local anesthetic is partially (5% to 95%) bound by plasma proteins—α_1-acid glycoprotein in particular and albumin to a much lesser extent—and red blood cells. Plasma protein binding is directly correlated with the hydrophobicity of the local anesthetic.[84] Because the concentration of α_1-acid glycoprotein is influenced by many factors (see Chapter 2), the fractional binding of local anesthetics differs among individuals and within the same individual at different times. Factors that acutely depress binding include respiratory acidosis and possibly the coadministration of other basic drugs.

After distribution throughout the intravascular space, the unbound drug is free to diffuse into the various tissues of the body. So-called barriers to diffusion are ineffective against local anesthetics. In addition to entering the CNS, these drugs readily cross the placenta and occasionally may induce severe cardiac depression in the fetus.

Distribution to peripheral tissues is a major means for the removal of amide and slowly metabolized ester local anesthetics from the bloodstream and for keeping their plasma concentrations below the toxic range. By virtue of the pulmonary circulation, the lung plays a unique role in this process when a local anesthetic is injected intravenously.[47] Initially, 90% of the drug may be taken up by the lung. Although most of the agent diffuses back into the bloodstream within the first minute after injection, the evanescent buffering action of the lung can nevertheless reduce the peak arterial blood concentration by a factor of 3.

Metabolism and Excretion

The metabolic fate of a particular agent largely depends on the chemical linkage between the aromatic residue and the rest of the molecule. Ester drugs are inactivated by hydrolysis. Derivatives of *p*-aminobenzoic acid (e.g., procaine and tetracaine) are preferentially metabolized in the plasma by pseudocholinesterase; the ratio between plasma and tissue hydrolysis with other esters is variable. Products of hydrolytic cleavage may undergo further biotransformation in the liver before being eliminated in the urine. The half-life for the hydrolysis of procaine is normally less than 1 minute and less than 2% of the drug is excreted unchanged by the kidneys.

Metabolism of amide drugs primarily occurs in the liver. The initial reaction is usually N-dealkylation of the tertiary amino terminus, principally by CYP3A4 and CYP1A2.[64,89] The resultant secondary amine of most amides is susceptible to hydrolysis by hepatic amidase activity, but conjugation, hydroxylation, and further dealkylation may also occur. Hepatic blood flow seems to be the rate-limiting factor governing metabolism of lidocaine and some other amides; elimination half-lives range from 1.5 to 3.5 hours. Inactivation of prilocaine, a secondary amine, is unusual because dealkylation is not required before hydrolysis can take occur, which may explain why almost half of its metabolism is extrahepatic. Articaine is also atypical because it is inactivated in the blood and other tissues by hydrolysis of an ester side chain required for local anesthetic activity. With an initial plasma half-life of approximately 25 minutes, articaine is removed from the circulation faster than other injected amides. The rapid biotransformation of articaine to articainic acid (an essentially inactive metabolite) coupled with an unusually extensive tissue distribution significantly reduces the potential for cumulative toxicity after repeat dosing.[78]

Some local anesthetic metabolites retain significant pharmacologic activity and may contribute to drug toxicity. Much of the sedative effect of lidocaine has been attributed to its de-ethylated metabolites monoethylglycinexylidide and glycinexylidide.[82] As with the ester compounds, minimal amounts (1% to 20%) of administered amides appear in the urine as unmetabolized compounds.

Differences in biotransformation of the various local anesthetics are sometimes clinically relevant. Individuals with certain genetically based defects in pseudocholinesterase activity are unusually sensitive to procaine and other esters (but presumably not articaine); conventional doses of these drugs may occasionally lead to toxic reactions. Alternatively, severe hepatic disease or reduced hepatic blood flow may produce systemic intolerance to lidocaine and presumably other local anesthetics dependent on adequate liver function for their metabolism.

ADVERSE EFFECTS

Modern local anesthetic solutions are quite safe when used by competent personnel. Nevertheless, a substantial amount of literature describing various adverse reactions attests to the potential toxicity of these agents, particularly when they are used in a cavalier manner.

Systemic Toxicity

Most serious toxic effects are related to excessive blood concentrations caused by inadvertent intravascular injection or

the administration of large quantities of drug. Convulsions, respiratory arrest, and cardiovascular collapse represent the greatest hazards to health. Such reactions can usually be prevented by observing three precautions: (1) administer the smallest dose that provides effective anesthesia; (2) use proper injection techniques, including aspiration; and (3) use a vasoconstrictor-containing solution when not contraindicated by patient history or operative need. If an adverse response occurs despite these procedures, immediate therapy must be provided. The patient should be placed in the supine position and oxygen administered. This procedure is often all that is needed for mild toxic reactions, epinephrine responses, or syncopal attacks.

Convulsions are usually self-limiting and require no treatment other than supporting ventilation and protecting the patient from bodily harm. Pharmacologic intervention is necessary, however, when the seizures are so intense or prolonged that hypoxia threatens to ensue. The most satisfactory method of seizure control in the dental environment is the intravenous administration of a rapidly acting benzodiazepine.[61] Experimental evidence and clinical experience indicate that intravenous diazepam (0.1 mg/kg to 0.3 mg/kg) or midazolam (0.03 mg/kg to 0.1 mg/kg) can eliminate local anesthetic convulsions without producing significant adverse effects on ventilation or circulation. Small intravenous doses of a rapidly acting barbiturate (e.g., thiopental) may also terminate local anesthetic seizures, but they tend to potentiate the postconvulsive depressant phase of local anesthetic toxicity. Succinylcholine, a neuromuscular blocker without CNS depressant action, is sometimes used in refractory cases. Neuromuscular blockade treats only the outward manifestations of a convulsion; electrical disturbances within the CNS progress unimpeded. An immediate ability to institute artificial ventilation is a mandatory prerequisite for succinylcholine's use because the drug paralyzes the muscles of respiration.

Various agents have been administered prophylactically in attempts to prevent seizures. Most anticonvulsants examined have been disappointing in this regard, but diazepam has been shown in cats to double the median convulsant dose of lidocaine without causing undesirable CNS disturbances.[29] Midazolam seems to provide a similar benefit, and consequently either drug is a premedication of choice when the administration of a large quantity of local anesthetic is anticipated. Some drugs previously commonly used for preoperative sedation, including meperidine and promethazine, may increase the likelihood of local anesthetic convulsions.

Treatment of severe toxic reactions is largely symptomatic and consists of reversing respiratory and circulatory disruptions as they occur. Because most deaths attributed to local anesthetics are related to tissue anoxia, support of ventilation is of paramount importance. Arterial hypotension is controlled by the coadministration of intravenous fluids and sympathomimetic agents. Cardiopulmonary resuscitative techniques are necessary when cardiac function is disrupted.

Local Tissue Responses

Commercially available local anesthetics are relatively nonirritating to tissues. Many reactions described in the past were caused not by local anesthetics, but by metallic or alcoholic contaminants that gained access to the solutions during or after manufacture. Local anesthetic concentrations necessary to damage peripheral nerves usually far exceed the concentrations required for transmission blockade. Accidental intraneural injection may lead to nerve damage, however, from the combination of undiluted local anesthetic, strong hydrostatic pressure, and direct physical injury. High-concentration agents, such as 4% solutions of prilocaine or articaine, are significantly more likely to cause long-lasting or permanent nerve injury when administered for inferior alveolar nerve block.[40] Exposure of unsheathed neurons to these concentrations results in an irreversible increase in intracellular Ca^{++} and necrotic cell death.[46]

Conventional anesthetic preparations may induce focal necrosis in skeletal muscle tissue approximating the injection site.[93] The damage occurs rapidly after a single administration and is completely reversed in several weeks. In certain circumstances, local anesthetics may also impede cell motility, depress collagen synthesis, and delay wound healing.

Adverse tissue responses to injected local anesthetic preparations are usually caused or augmented by vasoconstrictor additives. Epinephrine creates tissue hypoxia by reducing local blood flow while increasing oxygen consumption. Although tissue injury may be induced by any of the sympathomimetics currently used, norepinephrine is particularly apt to cause ischemic necrosis. The injection of local anesthetic with a vasoconstrictor has been described historically as especially hazardous in areas supplied by terminal arteries (e.g., nose, digits, and penis). More recent research has shown, however, the safety of epinephrine used with local anesthetics in digital nerve blocks and for injections of the nose and ear.[42,60] In dentistry, tissue irritation may result in an increased incidence of postanesthetic pain at the injection site in patients receiving local anesthetic formulations containing vasoconstrictors.

Idiosyncratic Reactions

In rare instances, patients have had toxic reactions to small amounts of local anesthetic. Some of these reactions may represent an abnormal susceptibility to the local anesthetic. Most often, these responses are anxiety related, associated with the vasoconstrictor, or the result of inadvertent intravascular injection. Regarding the last possibility, it has been accidentally determined that the convulsant dose of lidocaine in humans is only 10 mg when the drug is injected into the vertebral artery.[50]

Amide local anesthetics were previously thought by some authorities to be causative agents for malignant hyperthermia (MH). This conclusion was based on a few anecdotal cases of supposed MH and on the ability of lidocaine-like drugs to potentiate contracture of skeletal muscle in various experimental situations. Subsequently, direct evidence indicated that no injectable local anesthetic is a triggering agent. Lidocaine has no effect on porcine MH, and it has not caused problems when used for local anesthesia in patients with a history of MH.[90] Amide local anesthetics are safe for routine dental use in patients susceptible to MH, and lidocaine may be used for the treatment of ventricular arrhythmias during an acute episode of MH.

Allergic Phenomena

Local anesthetics rarely cause allergic reactions; however, when one does occur, an ester derivative of *p*-aminobenzoic acid is usually involved. Methylparaben, a preservative used in certain local anesthetic preparations (but not in dental cartridges), may also occasionally serve as an antigenic stimulant. Historically, most documented cases of allergy—in the form of contact dermatitis—occurred in dentists and other health care professionals exposed to ester agents on a regular basis. Urticarial eruptions, erythematous rashes, and other dermatologic responses represent typical manifestations of local anesthetic allergy in patients and are regularly treated with antihistamines. Anaphylactic responses of a serious nature require epinephrine.

Since 1976, evidence has accumulated that certain individuals, mostly asthmatic patients, are intolerant of sulfites, including the bisulfite and metabisulfite preservatives used in local anesthetic solutions with vasoconstrictors. Although the original case report[66] seems to have had an immunologic basis, subsequent findings suggest that most affected individuals are

hyperreactive to sulfites that are inhaled or ingested but not injected. These reactions are more properly classified as idiosyncratic and do not contraindicate the use of sulfite-containing local anesthetics except perhaps in some patients with steroid-dependent asthma. Isolated case reports of bisulfite allergy occurring after the intraoral administration of local anesthesia constitute the rare absolute contraindication.[72]

Despite the low incidence of verifiable allergy to local anesthetic solutions in patients, a high percentage of individuals have medical histories of presumptive local anesthetic hypersensitivity. Many of these cases undoubtedly represent anxiety or toxic reactions misdiagnosed as immunologic in origin. Such mistakes are particularly apparent when amides are involved because most investigations have shown these compounds to be virtually nonallergenic.[7] When a single agent is involved, substitution with another local anesthetic is the simplest method of resolving the problem if consideration is given to the fact that esters may exhibit cross-allergenicity with each other and with methylparaben.

Drug selection becomes more difficult when a patient has a reported allergy to all conventional agents. Diphenhydramine (1% with 1:100,000 epinephrine) and other antihistamines have been used with some success in such instances, but their overall suitability as local anesthetics is limited. An alternative approach is to screen for drug allergy. Although sensitivity testing methods are generally unreliable and may be potentially dangerous, a regimen of intracutaneous injections graduating to full challenge tests in a supervised medical setting has proved useful in identifying local anesthetic formulations that can be administered safely.[30]

Use During Pregnancy

Local anesthetics are generally regarded as safe for use throughout pregnancy. Studies of women receiving local anesthesia for emergency procedures in the first trimester and/or routine dental procedures in the second trimester have supported this view.[54] Animal studies are also largely negative, although bupivacaine has been shown to cause fetal death at five times the maximum recommended human dose. The U.S. Food and Drug Administration (FDA) has classified lidocaine and prilocaine in pregnancy risk category B, and articaine, mepivacaine, and bupivacaine in category C (see Chapter 3).

The possibility has been raised that local anesthetics may affect behavioral development in offspring. Injection at midgestation of a single intramuscular dose of local anesthetic equivalent to the maximum recommended human dose was found to produce developmental delays and behavioral deficits in rats.[80] These results have not been verified in primates but are sobering in the face of an estimate that 23% of all children are exposed to local anesthetics sometime in utero.

DRUG INTERACTIONS

Because of their influences on excitable membranes, local anesthetics are potentially capable of interacting with a wide spectrum of therapeutic agents. The CNS depressant effects of local anesthetics summate with the effects of the general anesthetics, barbiturates, and opioid analgesics, yielding interactions with therapeutic and toxicologic significance. Lidocaine combined with another antiarrhythmic drug may generate profound disturbances in cardiac automaticity and conduction, far in excess of what either compound would have caused if given alone. Although feeble by itself, the neuromuscular blocking activity of local anesthetics has been used to advantage in preventing succinylcholine-induced fasciculations and in reducing the dose of succinylcholine required during surgery for adequate muscle relaxation. Elucidation of the role of CYP3A4 and CYP1A2 enzymes in the metabolism of amide local anesthetics has led to the discovery that inhibitors of these enzymes, such as erythromycin (CYP3A4) and fluvoxamine (CYP1A2), can modestly increase plasma concentrations of lidocaine and related agents.[64]

In coronary care units, where large doses of lidocaine may be infused intravenously to treat ventricular arrhythmias, the coadministration of cimetidine,[45,70] a histamine H_2-receptor blocker, or propranolol,[9] a β-adrenoceptor antagonist, has led to lidocaine toxicity. Both agents seem to inhibit the oxidation of lidocaine directly; propranolol also reduces hepatic blood flow and delivery of the local anesthetic to the liver.

A unique interaction may occur between certain esters and the sulfonamides. Procaine and several other local anesthetics (benzocaine, tetracaine) are metabolized to yield *p*-aminobenzoic acid. The antibacterial action of sulfonamides is competitively antagonized by this metabolite.

Although the potential for interactions involving local anesthetics is great, clinical manifestations appear infrequently outside the hospital and then only when very large doses are used or when unusual patient factors are present. Much more likely to occur are interactions between various drugs and the vasoconstrictors used during local anesthesia. Epinephrine may generate ventricular arrhythmias during general anesthesia. Similarly, catecholamines can induce undesirable changes in cardiac action and blood pressure in patients taking tricyclic antidepressants and related norepinephrine transporter inhibitors, cocaine, nonselective β-adrenergic blockers, digoxin, inhibitors of catechol-O-methyltransferase, or adrenergic neuron–blocking drugs (e.g., guanethidine). Compounds with prominent α-adrenoceptor–blocking activity, such as the phenothiazine and butyrophenone antipsychotics, may lead to hypotension if coadministered in large doses with epinephrine.

Despite statements to the contrary in local anesthetic product information approved by the FDA, local anesthetics containing epinephrine may be used without special reservation in patients taking monoamine oxidase (MAO) inhibitors. Exogenous catecholamines are mostly degraded by the enzyme catechol-O-methyltransferase; inhibition of MAO has little impact on their respective metabolic fates or cardiovascular actions.[13] Of the vasoconstrictors used with local anesthetics, only phenylephrine is contraindicated with concomitant MAO therapy.

The most important interaction featuring vasoconstrictors is the intended one: inhibition of local anesthetic uptake from the injection site. Animal data suggest, however, that this is not the only interaction that can occur involving the anesthetic agent and its vasoconstrictor partner. Acute lethality studies document that epinephrine potentiates the toxicity of several local anesthetics administered intravenously.[2,91] By protecting against local anesthetic depression of blood pressure, the vasoconstrictor allows a greater-than-normal fraction of anesthetic to reach the brain and spinal cord.[92] It is unknown if this interaction occurs in humans.

Largely because of the cardiovascular stimulation associated with the sympathomimetic amines, attention has been focused on noncatecholamine alternatives for vasoconstriction. Of these, several analogues of the antidiuretic hormone vasopressin have proved suitable, and one, felypressin (2-phenylalanine-8-lysine vasopressin), is used in Europe and elsewhere as a vasoconstrictor for local anesthesia. Although felypressin is not as effective as epinephrine and cannot be relied on for surgical hemostasis, it avoids the drug interaction problems of the catecholamines. Local toxicity is also reduced because felypressin does not stimulate tissue oxygen consumption. Local anesthetics with felypressin are unavailable in the United States.

GENERAL THERAPEUTIC USES

Local anesthetics are widely used for pain relief. By obviating the necessity of general anesthesia, these drugs have been instrumental in reducing the mortality and morbidity associated with various operative procedures. They also render valuable service by obtunding the pain of sunburn, toothache, and other ailments. In addition, local anesthetics are increasingly being used for purposes unrelated to pain control.

Techniques of Anesthesia

The onset, quality, extent, and duration of local anesthesia vary markedly with the technique of administration used. As might be expected, no single agent is capable of performing all the clinical duties local anesthetics are expected to fulfill.

Surface application

Local anesthetics are prepared for topical use in several different forms. Aqueous solutions and sprays are especially suited for coverage of large surfaces; anesthesia of small areas is often best accomplished with an ointment or viscous gel. Although penetration of the intact epidermis is insignificant, uptake by injured skin or by mucous membranes can be rapid. Topical activities are often not related to efficacies determined for other administration sites; tetracaine and lidocaine are useful topically as single agents, whereas mepivacaine, prilocaine, and procaine are not. Benzocaine, ineffective parenterally, is well adapted for surface anesthesia because of its slow systemic absorption and relative safety.

Infiltration, field block, and nerve block

Inhibition of transmission in circumscribed portions of the peripheral nervous system is accomplished by the techniques of infiltration, field block, and nerve block. Infiltration anesthesia is performed by injecting a local anesthetic into the area to be anesthetized. In this manner, the nerve endings exposed to the anesthetic solution are quickly made unresponsive. Field block refers to the subcutaneous or submucosal injection of anesthetic agents where the extent of anesthesia extends distal to the tissues infiltrated with drug. In dentistry, anesthesia of the tooth pulp after supraperiosteal injection is a form of field block because the local anesthetic does not gain access to the pulp but nevertheless renders it insensitive to stimulation. Nerve block is produced by depositing a local anesthetic solution close to the appropriate nerve trunk but proximal to the intended area of anesthesia. After a certain latency period required for penetration of the local anesthetic into the nerve interior, sensations are lost in all tissues innervated by the distal portion of the affected nerve. Although infiltrations, field blocks, and single nerve blocks usually anesthetize discrete areas, compound injections (e.g., brachial plexus or sciatic-femoral blocks) may affect large segments of the body, including whole limbs. All of the many local anesthetics suitable for infiltration are also useful for field and nerve blocks.

Spinal anesthesia

Deposition of a local anesthetic solution in the subarachnoid space can be used to produce surgical anesthesia in all structures of the body below the diaphragm. Injection is ordinarily made inferior to the first lumbar vertebra to avoid possible injury to the spinal cord. When introduced, the drug mixes with the cerebrospinal fluid and begins to spread throughout the subarachnoid space. The extent of cephalad diffusion of the local anesthetic, and the level of anesthesia obtained, is governed by several factors, including the dose, specific gravity (baricity), and volume of local anesthetic solution administered; the size and position of the spinal canal; and the degree of cerebrospinal fluid mixing imposed by the rate of injection and by movements of the patient. Tetracaine, lidocaine, and bupivacaine are most commonly used for spinal anesthesia in the United States, but numerous other agents are also used.

Epidural block

Local anesthetic infusion into the potential space between the dura mater and the connective tissue lining of the vertebral canal provides an effective alternative to subarachnoid anesthesia. Patient resistance to epidural injection is less of a problem, and the neurologic difficulties sometimes encountered after spinal block are avoided. Epidural anesthesia is comparatively slow in onset, however, and requires considerably more total drug than its subarachnoid counterpart. The level of anesthesia is also less predictable and more difficult to control. Bupivacaine, ropivacaine, and lidocaine are especially popular for epidural anesthesia, but virtually any local anesthetic available for nerve blockade may be used.

Intravascular injection

Local anesthetics are sometimes introduced directly into a blood vessel to effect short-term regional analgesia. One popular technique consists of injecting an anesthetic solution (e.g., 0.5% lidocaine) intravenously into a limb previously exsanguinated by elevation or with an Esmarch bandage. Isolation of the local anesthetic solution from the systemic circulation is accomplished by placing a pneumatic tourniquet proximal to the injection site. Egress of the local anesthetic from the vascular compartment to peripheral tissues is so rapid that releasing the tourniquet 5 minutes after injection does not result in toxic blood concentrations. Other techniques that use intravascular local anesthetics have also occasionally been practiced. Lidocaine may be mixed with drugs known to be irritating in an attempt to alleviate the pain associated with their intravascular injection.

Treatment of Cardiac Arrhythmias

Lidocaine, procainamide (the amide congener of procaine), and several local anesthetic–like drugs (e.g., flecainide and mexiletine) have established roles in the therapeutic management of cardiac arrhythmias, especially of ventricular origin. The antiarrhythmic properties of these agents are discussed in Chapter 24.

Other Uses

Local anesthetics are sometimes administered intravenously to produce or to supplement general anesthesia. As an adjunctive agent, lidocaine has been used to prevent postoperative muscle pain caused by succinylcholine and to depress airway reflexes and sympathetic nervous system responses during endotracheal intubation and extubation and other procedures affecting the bronchial tree. Local anesthetics have also been used, with mixed success, to treat protracted cough and laryngospasm and as intravenous analgesic and anticonvulsant medications. An adhesive patch containing 5% lidocaine is approved for relief of postherpetic neuralgia. Finally, the anti-inflammatory effect of lidocaine has been used to manage postoperative paralytic ileus.

USES IN DENTISTRY

It would be difficult to overstate the profound influence of local anesthesia on the practice of dentistry. Most of the complex restorative procedures routinely performed on conscious patients would be inconceivable without effective pain control. By eliminating nociceptive sensations associated with dental care, local anesthetics improve patient acceptance of dental treatment and thereby contribute significantly to oral

health. Because local anesthetics are so frequently used and, for many practitioners, represent the only drugs administered parenterally, the toxicity and efficacy of these agents is of particular interest and concern.

Safety in Dentistry

Without question, local anesthesia is often considerably safer in dentistry than in medicine. Dosages used for injection in the oral cavity are often less than one tenth the dosages used for compound nerve block or for epidural injection. Recipients of dental anesthesia are usually in better systemic health than some medical patients requiring surgery and usually undergo only minor operative stress. Nevertheless, reports occasionally appear describing instances of death from local anesthesia in dental practice.

Statistics related to local anesthetic toxicity in dentistry are meager and subject to error. Mortality figures range from 1 death in 1.4 million local anesthetic administrations[74] to 1 in 45 million.[75] These values are open to question. It is possible that some deaths from local anesthetics go unreported and that others are mistakenly identified as myocardial infarctions or cerebrovascular accidents. It is also quite likely that some deaths imputed to local anesthetics are caused by procedural stress or are merely accidents of time and place and are not causally related to drug administration at all. Tabulations of nonfatal adverse reactions directly attributable to local anesthetics in clinical practice are limited; however, Persson[65] recorded adverse effects in 2.5% of 2960 patients given one to two cartridges of various anesthetic agents. Because most of the complications observed—pallor, unrest, sweating, fatigue, palpitation, nausea, and fainting—are common manifestations of acute anxiety, it is evident that many adverse effects ascribed to local anesthesia are actually generated by the process of injection and not by the drugs themselves.

Most nonpsychogenic systemic reactions in adult patients probably arise from accidental intravascular injections. In view of the small amount of local anesthetic (e.g., <100 mg of lidocaine) routinely administered for most procedures, toxic overdosage seems unlikely; allergic responses are also considered rare, particularly with the amide drugs in current use. Aspiration tests indicate that the needle is placed inside a blood vessel in approximately 3% of all injections and much more frequently during blockade of the inferior alveolar and posterior superior alveolar nerves. Negative aspiration does not guarantee that the needle lumen is outside the vessel; using inadequate force or time for aspiration, or placing the lumen against a vessel's intimal lining, can prevent blood from entering the anesthetic cartridge.

In view of the fact that lidocaine is routinely given intravenously in quantities that exceed the amount in a dental cartridge without producing toxic manifestations in cardiac patients, it was proposed that local anesthetics injected intraarterially within the oral cavity may gain direct access to the CNS by passing regressively down the branches and trunk of the external carotid artery and into the internal carotid artery.[3] This hypothesis would seem to account for adverse reactions associated with small amounts of drug, but studies in rats have shown that internal carotid injections are less toxic than intravenous administrations.[91] The explanation for this finding is that the circle of Willis is not patent physiologically in the normal brain, precluding drug entry into the medulla where it can depress respiration. It is possible that toxic reactions in dentistry might occur only in patients with an abnormal cerebral circulation, but a more plausible explanation is that intravenous injection of even the small amounts of drug in a single dental cartridge can cause adverse responses in sensitive individuals, particularly if the drug is given rapidly, and a vasoconstrictor is present in the solution.

Notwithstanding the previous discussion, there are two situations in which the chances for toxic overdose are of concern: local anesthesia in small children and administration of large doses during deep sedation or light general anesthesia. Maximum dosage limits are quickly reached in young patients. The injection of two cartridges of 3% mepivacaine exceeds the maximum recommended dose for a 15-kg child, and inattention to such limits has needlessly resulted in fatalities.[11,43] The combination of CNS depression, possible respiratory acidosis, and a tendency to perform dental procedures in multiple quadrants increases the risk of systemic toxicity in adults and children receiving sedation or anesthesia. When overdoses of sedative, analgesic, and local anesthetic agents are given together, fatal outcomes may be expected.[38]

Drug Selection

Selection of a local anesthetic for dental application must include considerations of efficiency, safety, and individual patient and operative needs. That such factors are difficult to evaluate is illustrated by the diversity of results obtained in various clinical trials. One of the few areas of agreement is that the introduction of the amide lidocaine in 1948 marked a significant advance over the ester preparations then available. For routine use, 2% lidocaine hydrochloride with 1:100,000 epinephrine remains a standard dental anesthetic.

Besides lidocaine, four additional amides are available in dental cartridges that possess similar advantages in stability, nonallergenicity, and efficacy over the ester agents (see Table 16-2). Mepivacaine, introduced in 1957, is generally equivalent to lidocaine in its pharmacologic profile. Two distinctive features of mepivacaine are its topical ineffectiveness and its use as a 3% solution without a vasoconstrictor. Prilocaine, used clinically for the first time in 1960, is a less potent and less toxic alternative to lidocaine. Similar to mepivacaine, it is not used topically as a single agent but is effective for dental application without epinephrine.

Articaine, the only thiophene-based amide local anesthetic, was first tested in humans in 1970 and is now available for dental use in the United States, Canada, and Europe. An issue of current interest is whether the marketed formulations of 4% articaine with 1:100,000 or 1:200,000 epinephrine are equivalent or superior to other amide preparations. Although properly controlled clinical trials have not generally shown increased efficacy with standard injections, many dentists believe articaine increases the likelihood of obtaining adequate pain relief in cases in which other agents have failed.[39,54] More recently, several studies have indicated clinical superiority of articaine over lidocaine (both with epinephrine) when injected supraperiosteally for mandibular anesthesia.[41,71]

Bupivacaine was used initially in 1963 but not marketed in a dental cartridge until 1983. It exhibits a slightly slower onset time than the other amides but is similarly efficacious after nerve block and has a much longer duration of action, making it well suited for providing postoperative pain relief in oral surgery. The bupivacaine preparation intended for dental use is a 0.5% solution with 1:200,000 epinephrine.

One significant dissimilarity among the amide preparations concerns the presence or absence of a vasoconstrictor additive. Local anesthetic formulations without epinephrine-like drugs are particularly useful when sympathomimetic amines are contraindicated. Plain solutions are additionally promoted on the basis of a shorter duration of action. Although soft tissue anesthesia is comparatively brief after maxillary injection with 3% mepivacaine or 4% prilocaine (both without vasoconstrictor), differences in duration after mandibular nerve block are trivial (see Table 16-2). Because the period of pulpal anesthesia is often 20% to 25% that of soft tissue anesthesia, the limited maxillary duration of these agents is sometimes disadvantageous. For restorative procedures aver-

aging 25 minutes in length, 4% prilocaine, which compares favorably with 2% lidocaine with epinephrine in onset and depth of anesthesia, fails approximately one fifth of the time to provide adequate pain relief toward the end of the procedure.[17]

The use of local anesthetics without vasoconstrictors in pediatric dentistry warrants special comment. It is sometimes said that the shorter duration of soft tissue symptoms with plain local anesthetic solutions should reduce the incidence of self-inflicted tongue, cheek, and lip trauma. Such claims are dubious because blockade of the lingual, inferior alveolar, and buccal nerves that supply most of the tissues at risk is not significantly shortened by these preparations. No studies relating a reduction in traumatic cheilitis to the use of plain solutions have been reported. Consideration of systemic toxicity should limit the pediatric dental use of local anesthetics without vasoconstrictors.[23] Because the safety margin of local anesthetics is quite low in small children, it is advisable to use a preparation containing a vasoconstrictor if not doing so would result in more total drug being administered. Injection of phentolamine may be a superior alternative strategy to reducing the incidence of accidental soft tissue injury (see Chapter 7).

Other than amide compounds being advocated over esters, it is difficult to suggest a particular local anesthetic for routine dental application. If a proposed treatment requires a considerable volume of drug or necessitates a prolonged operation, formulations such as lidocaine with epinephrine are indicated. Small volumes of lidocaine with 1:50,000 epinephrine can be advantageous when surgical hemostasis is desired. Articaine with epinephrine may be considered for situations in which the drug's short plasma half-life and possible increased efficacy may prove advantageous. Bupivacaine with epinephrine would be a good choice for nerve block if a truly extended effect is desired. A plain local anesthetic solution might be more appropriate, however, for short procedures involving the maxillary arch.

When special patient factors or operative needs are not present, drug selection is best founded on the respective anesthetic efficacies and potential toxicities of the agents available. Because no local anesthetic preparation has emerged that is definitely superior to the rest in affording pain relief, use of any particular drug should be dictated largely by its relative likelihood of avoiding untoward responses. Estimates of systemic toxicity of local anesthetics as used in dentistry have not been published. Accepting that serious adverse reactions in most patients are caused by intravascular injections, one could predict by considering just the local anesthetic moieties involved that a 3% mepivacaine solution would be 50% more toxic than an equal volume of 2% mepivacaine with levonordefrin.[23] As described previously, however, some evidence suggests that sympathomimetic amines may potentiate the intravascular toxicity of concomitantly administered local anesthetics, making conclusions at this point impossible. Until definitive information about the intravascular toxic potentials of the various local anesthetic formulations becomes available, the recommendation of any single preparation for general use over all the others cannot be made.

PREPARATIONS AND DOSAGE

Agents for Parenteral Administration

Local anesthetics intended for injection within the oral cavity are supplied in 1.7-mL and 1.8-mL single-dose cartridges. (These differences largely relate to changed regulations by the FDA for reporting cartridge volume, not to true volume disparities. It is safest to assume a volume of 1.8 mL for dosage calculation purposes.) Pyrogen-free distilled water with sodium chloride added for osmotic balance serves as the local anesthetic vehicle. Local anesthetic solutions in cartridges range in pH from less than 3.0 to greater than 6.0; preparations with vasoconstrictors are adjusted to a lower pH than are plain formulations to enhance stability of the sympathomimetic amine constituents. Citric acid and sodium metabisulfite (or an equivalent antioxidant) are also included to help prevent vasoconstrictor breakdown. (Oxidation of the catecholamine compounds produces acids that tend to lower the pH over time.) Some local anesthetics contain methylparaben. Useful for its antimicrobial action in multidose vials, methylparaben serves no purpose in dental cartridges and has been omitted. Currently available local anesthetics marketed for dentistry in the United States and Canada are discussed next.

Lidocaine hydrochloride

Lidocaine is an aminoethylamide derivative of xylidine. It is several times more potent and toxic than procaine and provides local anesthesia that is by comparison more prompt, more extensive, and longer lasting. The administration of 2% lidocaine hydrochloride with 1:100,000 epinephrine is most suitable for routine dental use, but the drug is also available as a plain solution and with 1:50,000 epinephrine. Although 2% lidocaine with vasoconstrictor provides satisfactory dental anesthesia in normal circumstances, it has sometimes proved ineffective in rendering extremely sensitive teeth completely pain-free. A concentrated solution of 5% lidocaine with 1:80,000 epinephrine has been shown to produce effective anesthesia in most instances when conventional local anesthetic preparations have failed.[32] Lidocaine is the only amide marketed as a single agent for topical anesthesia in dentistry. Formulations of lidocaine hydrochloride include a 2% gel, a 2% viscous solution, a 4% solution, and in Canada a 10% topical spray. Lidocaine base is marketed in a 2.5% and 5% ointment and solution and a 10% aerosol spray. A mucosal adherent patch 2 cm long × 1 cm wide and containing 46.1 mg of lidocaine is also available.

Mepivacaine hydrochloride

Mepivacaine is an amide product of xylidine and N-methylpipecolic acid. Similar in many respects to lidocaine, mepivacaine hydrochloride is marketed in a 2% concentration with 1:20,000 levonordefrin and as a 3% solution without vasoconstrictor. In contrast to some ester local anesthetics, cross-allergenicity is rare between mepivacaine and related agents.

Prilocaine hydrochloride

In contrast to other amide anesthetics, prilocaine is a secondary amino derivative of toluidine. Less potent than lidocaine, prilocaine hydrochloride is marketed as a 4% solution with and without 1:200,000 epinephrine. Because the systemic toxicity of prilocaine is approximately half that of lidocaine, toxic effects on a milliliter basis are essentially equal. Instances of cyanosis observed after large doses of prilocaine (>400 mg) result from its metabolic breakdown to *o*-toluidine, an inducer of methemoglobinemia. Prilocaine has also been associated with a greater incidence of nerve damage after inferior alveolar nerve block injections than seen with lidocaine or mepivacaine.

Articaine hydrochloride

Articaine is unique among the amides because it is based on a thiophene ring structure. Marketed in North America in a 4% concentration with 1:100,000 or 1:200,000 epinephrine, articaine has become a popular agent for routine use in dentistry. The rapid hydrolysis of the ester side chain helps reduce toxicity associated with slow absorption from the injection site; conversely, the high concentration of the agent may accentuate the danger of intravascular injection and the risk

of nerve damage in the immediate area of injection, especially affecting the lingual and inferior alveolar nerves after inferior alveolar nerve blocks.

Bupivacaine hydrochloride
Bupivacaine is a homologue of mepivacaine rendered highly lipid-soluble by replacement of the N-methyl group with a butyl chain. Bupivacaine is approximately four times as potent and as toxic as mepivacaine; it also has a slightly higher pK_a and a slower onset of action. For dentistry, 0.5% bupivacaine hydrochloride is available with 1:200,000 epinephrine. Bupivacaine with epinephrine given for nerve block produces operative anesthesia several times longer than that afforded by other drugs. Additionally, the formulation provides postoperative analgesia averaging 8 hours in the mandible and 5 hours in the maxilla. Bupivacaine is less effective and shorter acting than lidocaine (both with epinephrine), however, for pulpal anesthesia after maxillary supraperiosteal injection. Bupivacaine is so lipid-soluble that the agent is largely absorbed by the mucosal tissues, leaving little free drug to diffuse into bone.

Ropivacaine hydrochloride
In contrast to the previous agents, ropivacaine is currently unavailable in dental cartridge form. Ropivacaine is a derivative of mepivacaine in which a propyl chain replaces the N-methyl moiety. The formulation is unusual in that only the S-enantiomer is present (mepivacaine is a racemic mixture), which is thought to reduce cardiac toxicity. In dentistry, 0.75% ropivacaine has been shown to produce long-lasting local anesthesia after inferior alveolar nerve block.[8,33] Ropivacaine may be useful when vasoconstrictors are contraindicated and a longer duration of action than that produced by 3% mepivacaine is desired.

Agents Limited to Surface Application

Topical anesthetics are used in the oral cavity for various purposes. Formulations marketed as pressurized sprays produce widespread surface anesthesia appropriate for making impressions or intraoral radiographs. Such preparations are potentially hazardous, however, and only products with metered valve dispensers to help prevent inadvertent overdose should be used. Topical liquids, which avoid the possibility of aerosol inspiration, may also be used for anesthetic coverage of large surface areas. Nonaqueous topical preparations are suitable for most other procedures. Common local anesthetic vehicles include lanolin, petrolatum, sodium carboxymethylcellulose, and polyethylene glycol.

Benzocaine
Benzocaine is a derivative of procaine in which the amino terminus is lacking. Poorly soluble in aqueous fluid, benzocaine tends to remain at the site of application and is not readily absorbed into the systemic circulation. Because of its low toxic potential, benzocaine is especially useful for anesthesia of large surface areas within the oral cavity. Benzocaine is not totally innocuous, however; cases of methemoglobinemia have been reported after the administration of very large doses, especially in unmetered spray form. Benzocaine is available in a variety of preparations; a 20% concentration in the form of an aerosol spray, gel, ointment, paste, and solution is most commonly advocated for intraoral use. A mucosal gel patch (containing 36 mg per 2 cm long × 1 cm wide patch) is also available.

Tetracaine hydrochloride
Tetracaine is an ester derivative of *p*-aminobenzoic acid in which a butyl chain replaces one of the hydrogens on the *p*-amino group. The drug has approximately 10 times the toxicity and potency of procaine. It is no longer available for injection in dentistry; for surface application it is most commonly marketed as a 2% hydrochloride salt in combination with 14% benzocaine and 2% butamben in an aerosol spray, solution, gel, and ointment under the proprietary name Cetacaine. Tetracaine is one of the most effective topical anesthetics, but the drug's toxic potential after surface application should dictate caution in its use.

Dyclonine hydrochloride
Dyclonine is unusual because it has a ketone linkage between the aromatic moiety and the rest of the anesthetic molecule. Available in lozenge form for topical use, dyclonine hydrochloride is not administered by injection because of its propensity for producing tissue irritation. Dyclonine may be used in patients allergic to derivatives of *p*-aminobenzoic acid.

Chlorobutanol
Chlorobutanol is a weak local anesthetic usually formulated with other agents. The drug is used primarily in obtundent dressings to relieve acute pulpitis and postextraction wound pain.

Cocaine hydrochloride
Cocaine, the first anesthetic used in dentistry and medicine, is a naturally occurring benzoic acid ester. The pharmacologic characteristics of cocaine are unique among the local anesthetics because the drug inhibits the uptake of catecholamines by adrenergic nerve terminals. Cocaine potentiates the action of endogenously released and exogenously administered sympathomimetic amines. As a result, cocaine may cause pupillary mydriasis, vascular constriction, and other manifestations of sympathetic nervous system activity. Cocaine is also a powerful CNS stimulant and a popular drug of abuse (see Chapter 51). Restricted to therapeutic applications in which its vasoconstricting property is of special benefit (as in intranasal surgery), cocaine has no place in the routine practice of dentistry.

Lidocaine/prilocaine
Marketed under the acronym of EMLA, a eutectic mixture of 2.5% lidocaine and 2.5% prilocaine is available in the form of a cream for topical anesthesia of the skin. When placed under an occlusive dressing for 1 hour, EMLA obtunds the pain of venipuncture and is useful in young children and other patients intolerant of needle insertion. Although this formulation is not intended for topical anesthesia of the oral cavity (it has a poor taste and unfavorable physical characteristics for intraoral use), several investigations have proved its superiority over other topical anesthetics in relieving pain associated with manipulation of oral tissues. EMLA significantly relieved the discomfort of palatal injections after a 5-minute application[83] and allowed deeper probing of the gingival sulcus without discomfort than did 5% topical lidocaine.[31]

An intraoral preparation with the same active ingredients of EMLA has been marketed with the trade name of Oraqix. A low-viscosity fluid at room temperature, the anesthetic mixture becomes an elastic gel after being applied to the gingival sulcus to provide local anesthesia for periodontal scaling and root planing.[36] The packaging of Oraqix is intended to avoid the possibility of administering the drug by parenteral injection. The overall effect is a 50% reduction of treatment pain.[53]

Compound topical anesthetics
In recent years, topical anesthetic preparations have been made and sold by various compounding pharmacies across the United States, often through the Internet.[51] A typical example

is TAC 20 percent Alternate, which contains 20% lidocaine, 4% tetracaine, and 2% phenylephrine. Although such products offer the possibility of improved efficacy over existing formulations (because of their concentrated strengths of multiple agents), they have not been approved by the FDA—which deems them to be illegal—and have not been rigorously tested for safety, efficacy, or stability. Several deaths have occurred with some formulations, and it seems a prudent course is to avoid them generally until regulatory approval is obtained.

LOCAL ANESTHETICS

Nonproprietary (generic) name	*Proprietary (trade) name*
Agents for parenteral administration	
Articaine	Septocaine, Astracaine,* Astracaine Forte,* Septanest,* Septanest SP,* Ultracaine D-S,* Ultracaine Forte D-S,* Zorcaine
Bupivacaine	Marcaine, Sensorcaine, Vivacaine
Chloroprocaine	Nesacaine
Etidocaine*	Duranest
Levobupivacaine	Chirocaine
Lidocaine	Xylocaine, Lignospan, Lignospan Forte, Octocaine
Mepivacaine	Carbocaine, Isocaine, Polocaine, Scandonest
Prilocaine	Citanest, Citanest Forte
Procaine	Novocain
Ropivacaine	Naropin
Tetracaine	Pontocaine
Agents limited to surface application	
Benzocaine	Americaine, Gingicaine, Hurricaine, Topicale, in Cetacaine
Butamben	Butesin Picrate, in Cetacaine
Cocaine	—
Dibucaine	Nupercainal
Dyclonine	in Sucrets
Lidocaine/prilocaine	EMLA, Oraqix
Pramoxine	Prax, Tronothane
Proparacaine	Alcaine, Ophthaine

*Not currently available in the United States.

CHAPTER 17

Principles of General Anesthesia

JOHN A. YAGIELA AND DANIEL A. HAAS

HISTORY

The pioneering use of anesthetics is credited to two dentists: Horace Wells and his one-time pupil and partner, William T.G. Morton, who practiced dentistry in New England in the early 1800s. Their achievements were preceded by the contributions of many others and came at a time when still others were carrying out experiments that would lead them to compete for recognition as the discoverers of anesthesia.

The history of anesthesia is no doubt as old as humankind itself, for surely since the dawn of time people have sought ways to alleviate pain. Records spanning thousands of years make it clear that patients about to undergo painful procedures have sought recourse in prayer; magic; the intervention of witch doctors and medicine men; techniques such as compression of nerves and blood vessels; and various plant products such as opium, mandragora, and coca. Modern anesthesiology had its beginnings in the eighteenth and early nineteenth centuries. The development of physics and chemistry led to the discovery of elements and simple molecules, including numerous gases. Joseph Priestley, an English scientist, is credited with the discovery of carbon dioxide, oxygen, and, in 1772, nitrous oxide. Although he thought oxygen might have some medical use, Priestley was unaware of the anesthetic properties of nitrous oxide. In 1795, Humphry Davy, a 17-year-old surgeon's assistant in England who later became a distinguished scientist himself, began experiments with nitrous oxide. He inhaled the gas and used it on one occasion to relieve the pain of his erupting third molar (although at this time nitrous oxide was still considered to be extremely poisonous). He noted in his published studies of nitrous oxide the giddiness, pleasurable sensations, relaxation of muscles, and diminution of pain that were produced by inhalation of the gas. In 1799, Davy constructed the first machine for the storage and inhalation of nitrous oxide.

The development of anesthesia was carried further by Michael Faraday, Davy's student, who in 1818 noted the anesthetic properties of diethyl ether (then known as "sweet vitriol"), and by Henry Hills Hickman, an English surgeon who carried out painless surgery on laboratory animals with carbon dioxide gas as the anesthetic. In 1824, Hickman published a pamphlet, "A Letter on Suspended Animation," in which he suggested that patients could be made unconscious before surgery.

In the United States in the early 1800s, there was scientific and popular interest in ether and nitrous oxide. Itinerant entertainers who called themselves professors went about delivering lectures on these substances and demonstrating their effects. One of the earliest of these demonstrations was conducted in 1824 by Joseph Dorfeuille, a museum director from Cincinnati, who gave nitrous oxide to a dozen spectators. "Laughing gas" parties and "ether frolics" became common among medical students; because of his experiences at such an ether party, William E. Clarke, one such medical student, administered ether from a towel to a young woman having a tooth extracted in Rochester, New York. This use of ether in 1842 is the first on record.

Crawford W. Long, a Georgia physician who had been trained at the University of Pennsylvania Medical School, had attended ether frolics while a student, and, later in 1842, he used ether when he removed two small tumors from the neck of James Venable, a friend who had previously experienced the effects of inhaling ether. Credit for the first use of ether in a nondental procedure belongs to Dr. Long. His anesthetic fee, also the first on record, was $2. Because Long wanted to include observations of the effects of ether in major surgical procedures, he did not publish reports of his pioneering use of ether until 1849, 3 years after the accounts of Morton's use of ether had appeared. A letter from Long written in 1844 suggests that he was visited by a dentist and a surgeon from Boston, that the dentist was Morton or Wells, and that it was from Long that they learned the technique of administering ether during surgery.

On December 10, 1844, Horace Wells attended a demonstration, staged by Gardner Quincy Colton in Hartford, Connecticut, of the effects of "laughing gas." One subject who volunteered to take the gas injured himself in the leg. Wells noticed that he was unaware of his injury and apparently had no pain until the effects of the gas wore off. The next day, Wells persuaded John Riggs, a prominent Hartford dentist, to remove one of his own teeth while under nitrous oxide anesthesia administered by "Professor" Colton. Wells claimed that he felt no more than a pinprick. Wells then obtained permission to demonstrate his technique before a class at the Harvard Medical School and administered nitrous oxide to a student, who proceeded to scream loudly while his tooth was being removed. The boy later said he had felt no pain. Discouraged by the apparent failure of his demonstration and by the hostile reception that followed, Wells became ill and was unable to practice dentistry on a regular basis. He nevertheless continued to administer nitrous oxide, with mixed success, for dental and medical operations. Wells also experimented with ether in 1845 and with chloroform when its anesthetic effect became known (in November 1847). Wells died in January 1848 when he became deranged by overexposure to chloroform and committed suicide while in jail for having accosted a prostitute. Nitrous oxide was abandoned after his death until 1863, when Colton reintroduced its use for dental extractions.

William T.G. Morton of Boston, a former student and partner of Wells, had begun to use ether topically for its local numbing effect on his dental patients. With the help of his chemistry professor at Harvard, Charles T. Jackson, Morton refined his technique and successfully administered anesthesia to a patient for the extraction of a molar tooth. Convinced of the importance of his discovery, he obtained an invitation to demonstrate his technique for John C. Warren, a surgeon at Massachusetts General Hospital. On October 16, 1846, Morton prepared a young patient for the surgical removal of a large mandibular tumor. Morton is credited with the discovery of anesthesia and the custom of saying, "Doctor, your patient is now ready."

Morton was anxious to patent the substance he called "Letheon," but several physicians from the Massachusetts General Hospital thought it unsuitable to patent a medical discovery and indicated that they would not continue to use it if its chemical nature remained a secret. Morton then offered to make known the nature of the substance and to serve as an anesthetist at various hospitals. He abandoned his medical studies and his dental practice and became the first professional anesthetist. In 1846, Holmes addressed a letter to Morton suggesting that the term *anesthesia* be given to the state produced by ether and that the agent itself be called an *anesthetic*.

After Morton's demonstration in Boston, the use of anesthesia spread rapidly despite opposition from various groups, many of whom still believed that there was something spiritually ennobling about pain, particularly the pain of childbirth. In 1847, James Young Simpson first used ether in his obstetric practice and in the same year successfully delivered a child using chloroform. Later, when Queen Victoria delivered her seventh child while under chloroform anesthesia, most ecclesiastic opposition was stilled.

No new anesthetic agents were added until the 1920s and 1930s, when ethylene, cyclopropane, and divinyl ether were introduced. Since the early 1950s, a series of halogenated agents containing fluorine have been introduced clinically and have essentially replaced other inhalation agents except nitrous oxide.

Intravenous agents, mainly the thiobarbiturates (e.g., thiopental), became popular in the late 1930s. Other ultrashort-acting barbiturates were added to the list and were supplemented in the late 1960s by ketamine and the neuroleptanalgesic combination of droperidol-fentanyl. Additional newer intravenous anesthetics include etomidate, midazolam, and propofol.

Neuromuscular blocking drugs were added to the practice of anesthesia in 1942 with the introduction of curare to facilitate endotracheal intubation and relaxation of muscles for abdominal surgery. Opioid anesthesia, in which morphine and subsequently fentanyl and its congeners found use as principal agents in obtunding autonomic responses to surgical stimulation, originated with cardiac surgery in the late 1950s. Dexmedetomidine, a centrally acting α_2-adrenergic receptor agonist related pharmacologically to clonidine, represents yet another approach to providing sedation and analgesia during operative procedures.

Finally, the use of nitrous oxide by dentists has exhibited a cyclic pattern of popularity every 25 to 30 years since Wells first used it. Nitrous oxide is currently enjoying an extended fifth cycle as a sedative agent. As an agent for general anesthesia, nitrous oxide is slowly losing popularity, however, for reasons described subsequently and in Chapter 18.

COMMON TERMS

Consciousness is the mental state in which the individual is capable of a rational response to commands and has all protective reflexes intact, including the ability to maintain a patent airway.

Sedation describes a state of partial or complete awareness of the environment but with a significant reduction of anxiety and restlessness. As described in Chapter 48, three levels of sedation have been defined: minimal sedation, in which the patient responds normally to verbal command; moderate sedation, in which the patient responds purposefully to verbal command either alone or accompanied by light tactile stimulation; and deep sedation, in which the patient cannot be easily aroused but responds purposefully after repeated or painful stimulation.

Analgesia refers to a reduced perception of and responsiveness to noxious stimuli (i.e., stimuli that are described as painful) but without amnesia or loss of consciousness. Other modes of sensory perception remain intact (e.g., vision and hearing).

Amnesia refers to a loss of memory of the surgical experience, although the patient may be aware of the environment during surgery.

Anxiolysis indicates a selective reduction or elimination of fear and apprehension produced without amnesia or loss of consciousness.

Induction is the phase of anesthesia beginning with the administration of anesthetic and continuing until the desired level of patient unresponsiveness is reached.

Unconsciousness is the state in which the patient is no longer aware of the environment and does not respond to familiar or non-noxious stimuli such as calling the patient's name.

Unresponsiveness refers to a loss of reaction to noxious and non-noxious sensory stimuli.

Muscle relaxation is a reduction or loss of central nervous system (CNS) regulation of skeletal muscle tone and reflexes that produces a state of flaccid paralysis and unresponsiveness of muscle to stretching and surgical cutting.

Surgical anesthesia is the state of unconsciousness, unresponsiveness, anxiolysis, amnesia, analgesia, and muscle relaxation that allows the goals of surgery to be accomplished.

Maintenance is the process of keeping a patient in surgical anesthesia.

Recovery is the phase of anesthesia beginning when surgery is complete and the delivery of the anesthetic is terminated and ending when the anesthetic has been eliminated from the body.

Emergence refers to the stage of recovery during which the patient is regaining consciousness.

Minimum alveolar concentration (MAC) is the alveolar concentration of anesthetic at which 50% of patients do not respond to a standard surgical stimulus. MAC is used for quantifying the relative potencies of inhalation anesthetics.

GOALS OF ANESTHESIA

General anesthesia may be defined as "a drug-induced reversible depression of the CNS resulting in the loss of response to and perception of all external stimuli."[4] In practice, this simple definition is inadequate because it neglects the contributions of unconsciousness, amnesia, immobility, and autonomic stability to the anesthetic state and the fact that general anesthetics differ significantly in the effects they achieve.

A complete anesthetic is one that produces unconsciousness, unresponsiveness, amnesia, analgesia, and muscle relaxation by itself without eliciting undue homeostatic disturbances in the patient. An example of such a complete anesthetic is diethyl ether (known simply as ether). Although there are other complete anesthetics, the tendency in modern anesthe-

siology is to use a combination of drugs to take advantage of the best properties of each and to minimize unwanted side effects. Combining anesthetics from different drug classes allows for a reduction in the dose of each agent as the majority of such interactions are supra-additive in nature.

Among the agents that may be used preoperatively are the antimuscarinic drugs to minimize salivation, laryngospasm, and reflex bradycardia and various analgesics and CNS depressants to provide preoperative pain relief, sedation, and amnesia. Drugs that are used during the administration of general anesthesia in addition to the primary anesthetic may include nitrous oxide; intravenous opioids (which lessen the total required dose of anesthetic and increase analgesia); midazolam or another amnestic drug to prevent recall; drugs that paralyze skeletal muscle; antiemetics such as ondansetron to limit postoperative nausea and vomiting; and, if necessary, drugs that help maintain cardiovascular stability and renal function.

The primary goals of general anesthesia are to preserve the life of the patient, to provide the operator with an adequate surgical field, and to obtund pain. A general anesthetic ideally should (1) provide a smooth and rapid induction; (2) produce a state of unconsciousness or unresponsiveness; (3) produce a state of amnesia; (4) maintain essential physiologic functions while blocking reflexes that might lead to bronchospasm, salivation, and arrhythmias; (5) produce skeletal muscle relaxation, but preferably not of the respiratory muscles, through the blockade of various efferent impulses; (6) block the conscious perception of sensory stimuli so that there is adequate analgesia to perform the procedure; and (7) provide a smooth, rapid, and uneventful emergence and recovery with no long-lasting adverse effects.

The goals of anesthesia for general surgery also apply to dental surgery, but there are some important differences. Dental patients are generally outpatients; in most circumstances, particularly situations not involving extensive oral surgery, the procedures are not as traumatic as general surgical procedures, and it is neither necessary nor desirable to render the patient unconscious. Although general anesthesia is sometimes necessary, specific techniques have been developed for producing sedation in dental patients (see Chapter 48).

MECHANISMS OF ANESTHESIA

Since the introduction of general anesthetics, considerable efforts have been directed toward discovering the mechanism of action of these agents. Our incomplete knowledge of the structure and behavior of membrane constituents and subcellular organelles, neurotransmitters, and neurologic circuits, coupled with an imperfect understanding of behavioral states relevant to clinical anesthesia such as consciousness, sleep, pain, and anxiety, makes elucidation of what causes anesthesia extremely difficult. Information has been gleaned for each of the above-mentioned functions, however, and is summarized in the following sections.

Molecular Mechanisms of Action

Many investigators have sought to describe the action of the extremely diverse chemicals known to be general anesthetics by their ability to perturb the molecular structure and function of neurons. Most early anesthetic agents seemed to be indiscriminate in affecting biophysical properties of cellular and subcellular membranes, and for many years it was generally agreed that there were no specific receptors for general anesthetics (and therefore no direct antagonists) as there are for neurotransmitters. In this setting, a universal mechanism of action of general anesthesia based on the physicochemical properties of anesthetic agents was postulated. More recently, many actions of general anesthetics have been documented,

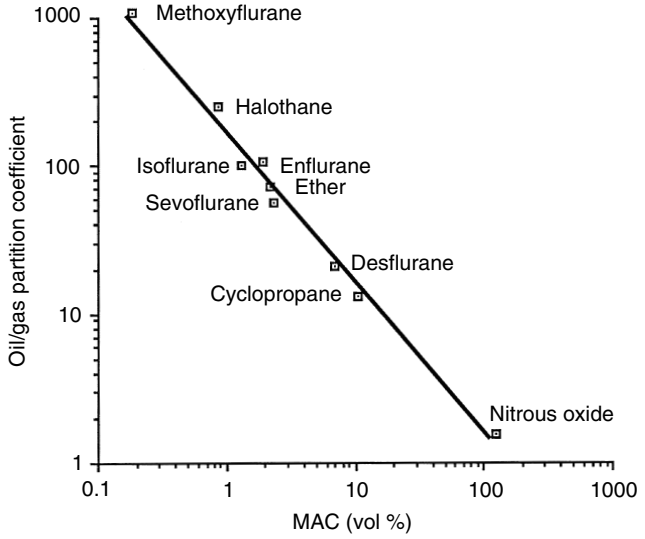

FIGURE **17-1** Linear correlation between anesthetic potency and lipid solubility. Potency is indicated by the minimum alveolar concentration (*MAC*) and lipid solubility by the olive oil/gas partition coefficient.

and it is now believed that diverse molecular perturbations may result in unconsciousness and lack of response to external stimuli.

Correlates of anesthetic potency

Various mechanistic theories of general anesthesia began to appear shortly after the landmark demonstration of ether-induced insensibility by Morton, but the first important observation was made independently by Meyer in 1899 and Overton in 1901, who emphasized the correspondence between the lipid solubility of an agent and its anesthetic potency (Figure 17-1). The Meyer-Overton correlation suggested that anesthesia begins when any chemical substance has attained a certain molar concentration in the hydrophobic phase of the cell membrane. When olive oil is used to represent the hydrophobic medium, this concentration is approximately 50 mmol/L. Experiments with different lipid media indicate that the best fit between solubility and anesthetic potency is obtained with lipids that are amphophilic (i.e., they have polar and nonpolar attributes) and can serve as hydrogen bond acceptors. These characteristics are descriptive of membrane phospholipids and cholesterol.

In 1954, Mullins, in his critical volume hypothesis, modified the original correlation to include consideration of the volume of the hydrophobic region occupied by the anesthetic agent. He reasoned that large anesthetic molecules would have greater effects on the membrane than would smaller molecules.

Membrane lipid theories

Numerous investigators since Mullins have sought to link the notion of a critical number or volume of anesthetic molecules with plasma membrane disturbances that could result in general anesthesia. Until the early 1980s, most attention was directed at the lipid bilayer of the plasma membrane, specifically the ability of anesthetics to cause membrane expansion, lipid fluidization, or lateral phase separation. With each of these effects, it was postulated that, as a result of the alteration in the lipid bilayer, the neuronal membrane becomes unable to facilitate the changes in protein configuration that are required for such essential steps in the transmission of nerve impulses as ion gating, synaptic transmitter release, and binding of the transmitter to the receptor.[31]

The membrane expansion theory was a natural outgrowth of the critical volume hypothesis. It holds that the absorption of anesthetic molecules by the lipid phase causes the membrane to expand, preventing important intrinsic membrane constituents from functioning properly. Measurements indicate that the expansion associated with general anesthesia is approximately 0.4%. Fluidization, or disordering, of lipids by anesthetic agents was noted in studies of lipid bilayers prepared with phospholipid and cholesterol to mimic cell membranes. Parallel shifts in measures of lipid fluidization and the activity of membrane-bound enzymes suggested that this perturbation of the normal lipid structure may result in functional changes sufficient to disrupt nerve transmission. The lateral phase separation theory was based on the idea that membrane lipids exist in two states: a high-volume, disordered sol state and a compact, ordered gel state.[31] The ability of lipids to convert from the sol to the gel configuration, or to be compressed laterally within the membrane, was thought to accommodate conformational changes that need to occur for the opening of ion channels.

These lipid perturbation theories were supported by findings that hyperbaric pressures and certain convulsant drugs antagonize anesthesia, presumably by reversing membrane expansion or re-establishing order. It is now understood, however, that pressure or drug reversal of anesthesia arises from a physiologic antagonism of anesthetic action brought on by independent neurologic stimulation. Different anesthetics are affected differently by the same pressure, including chloral hydrate, whose anesthetic effect is immune to pressure reversal. Evidence has also mounted to cast doubt on membrane expansion or lipid perturbation per se as a cause of anesthesia. Direct measurements of the expansion of lipid bilayers and red blood cell membranes in response to anesthetic concentrations of ethanol and halothane yield values that are effectively insignificant, and other measurements have shown nonanesthetic long-chain alcohols to cause membrane expansion similar to that of inhalation anesthetics. Regarding fluidization or sol-gel transformations, changes equivalent to those associated with anesthesia can be attained by temperature elevations less than 1° C.[32]

Calculations based on the Meyer-Overton relationship argue in general against a significant effect of anesthetic drugs on membrane lipids. At concentrations sufficient to produce surgical anesthesia, there is only about one molecule of drug in the membrane for every 60 to 80 molecules of the much larger lipid constituents. Unless anesthetic molecules are distributed unevenly in the membrane (e.g., concentrated in lipids adjacent to ion channels) or the lipid phase serves as a barrier to the diffusion of anesthetic agents (i.e., limiting access of anesthetics to their effector site) or as a reservoir for them (i.e., retaining anesthetic molecules where they have direct access to their effector sites), it is unlikely that membrane lipids play a major role in the mechanism of anesthesia.

Mechanisms involving membrane proteins

Membrane proteins constitute a second hydrophobic environment with which anesthetic molecules may interact.[9] The idea that membrane proteins are the targets of anesthetic action is attractive for several reasons. First, it is consistent with the mode of action of most drugs that influence the CNS. Second, allosteric selection (described in Chapter 1) of a protein conformation by the binding of even a single small molecule can have pronounced effects on protein function. Third, it can best explain differences in action among the various anesthetics by assuming that these agents exert different effects on the same protein or influence different proteins altogether.

Although technical difficulties have long inhibited direct examination of anesthetic drug interactions with membrane proteins, the firefly enzyme luciferase provided a good initial model for study.[7] Luciferase is a water-soluble protein that produces light when it cleaves its substrate, luciferin. For a wide variety of agents, anesthetic potency correlates directly with the ability to inhibit luciferin binding and prevent light emission. The binding site on the enzyme is amphophilic in nature and capable of accepting a hydrogen bond. Similarly, numerous potential sites exist for direct anesthetic interactions with proteins: hydrophobic regions within globular or folded polypeptides, between polypeptides joined in an oligomeric structure, and at the protein-lipid or protein-water interface.

The synthesis of a water-soluble four-stranded α-helical protein bundle similar in structure to peptides forming ligand-gated ion channels has allowed characterization of direct anesthetic-protein interactions.[14] A hydrophobic cavity within the bundle binds halothane best when the cavity is lined with methionine and aromatic acid residues. Halothane binding stabilizes the protein in a conformation that putatively promotes anesthesia.

A close correspondence between the anesthetic potencies of stereoisomers of halothane and isoflurane and their ability to perturb ion channel function provides strong evidence that these membrane proteins are the immediate targets for general anesthetic action. It is now firmly established that certain classes of general anesthetics inhibit or activate specific ligand-gated ion channels in clinically relevant concentrations. Binding studies indicate a specific active site for volatile anesthetics on neuronal nicotinic receptors.[2,19] Specific mutations on the M_2 domains of the nicotinic receptor, which correspond to the α-helix segments that form the aqueous pore of the receptor's ion channel, enhance the blocking action of anesthetics such as isoflurane and alcohols such as octanol.[5] It is postulated that hydrophobic general anesthetic agents bind at a discrete site in the vicinity of the mutation loci. The more polar alcohols gain access to the same site preferentially after channel opening, suggesting that the binding site is within the channel itself. Inhibition of nicotinic receptors in skeletal muscle probably contributes to the ability of volatile anesthetics to enhance muscle relaxation. Actions at neuronal nicotinic receptors promote effects such as amnesia, hyperalgesia, and excitation observed at subanesthetic concentrations of volatile anesthetics and barbiturates.

The γ-aminobutyric $acid_A$ ($GABA_A$) receptor has been implicated in the CNS depressant effect of most anesthetic drugs.[4,30] Specific binding sites for benzodiazepines, barbiturates, other intravenous anesthetics, and volatile anesthetics have been described.[4] Stimulation of these receptor sites increases the activity of GABA at its own separate site; many agents other than benzodiazepines can also open the $GABA_A$ Cl^- channel in the absence of GABA. Hyperpolarization of the affected neuron inhibits neuronal activity. Glycine receptors constitute another group of inhibitory receptors that are activated by at least some general anesthetics (inhalation anesthetics, alcohols, thiopental, and propofol) in clinically relevant concentrations.

Excitatory receptors blocked by specific anesthetic agents include N-methyl-D-aspartate (NMDA), kainate, and α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) receptors. Ketamine and nitrous oxide[13] selectively inhibit NMDA receptors, whereas barbiturates and certain inhalation anesthetics block AMPA and kainate receptors.[4]

In addition to the classic ligand-gated ion channels described previously, other ion channels may be involved in the actions of specific general anesthetics. Several types of 2-pore-domain K^+ channels (identified by their acronyms TREK1, TREK2, TASK1, TASK3, and TRESK) are variably activated by inhalation anesthetics.[4,6] These channels are responsive to intracellular second messengers and are believed to regulate background neuronal excitability and neurotransmitter release. Several types of Ca^{++} channels and Na^+ are

inhibited by clinical concentrations of drugs and may contribute an inhibitory influence on neurotransmitter release.

Several G protein–coupled receptors (GPCRs) are influenced by clinical concentrations of general anesthetics. An important example is the α_2-adrenergic receptor effector system. Stimulation of this system by the selective α_2 agonist dexmedetomidine significantly potentiates the anesthetic potency of volatile anesthetics. Similar potentiation can be obtained by drugs that stimulate opioid receptors or block nitric oxide synthase.[15] Demonstration of a blocking action of halothane on the GPCR rhodopsin underscores the possibility that similar interactions with other GPCRs may support the effects of inhalation anesthetics on consciousness, nociception, and various autonomic effects observed during general anesthesia.

Table 17-1 categorizes anesthetics into three groups based on their relative abilities to provoke hypnosis and amnesia, provide analgesia, and cause immobility (unresponsiveness). Group 1 drugs, including most intravenous induction agents, are noted for their ability to stimulate GABA transmission. Group 2 agents are characterized by their selective inhibition of NMDA receptor–mediated transmission. Group 3 anesthetics, representing the volatile anesthetics, noted for their ability to produce immobility, combine the clinical attributes and molecular targets of the previous groups.

Other sites

Several investigators have raised the possibility that proteins other than membrane receptors/ion channels may be involved in the mechanism of anesthesia. Certain anesthetics have been shown to impair the ability of synaptosomes (isolated nerve terminals) to sequester and retain catecholamine neurotransmitters and of mitochondria to produce adenosine triphosphate (ATP) and to take up Ca^{++}. Although the latter effect has been used to explain the finding that anesthetics hyperpolarize cells in direct relation to their anesthetic potency,[23] a lack of correlation between catecholamine influences and general anesthesia and a failure of ATP concentrations in the brain to decrease during anesthesia provide arguments against a primary role for these other sites in producing anesthesia. Nevertheless, demonstration of altered responses to volatile anesthetics in nematodes (*Caenorhabditis elegans*) expressing mutated proteins responsible for synaptic exocytosis (i.e., SNARE complex proteins) or closely associated with various membrane channels (i.e., stomatin) promotes the likelihood for a site of action involving neurotransmitter release.[21,25]

Children with the same specific mitochondrial mutation found in nematodes bred to be highly sensitive to inhalation anesthetics display a similarly unusual sensitivity to sevoflurane anesthesia.[20] This finding suggests that a specific anesthetic effect on mitochondrial function cannot be ignored as a possible mechanism of action.

Neurophysiologic Mechanisms of Anesthesia

Molecular influences of general anesthetics may provide a fundamental explanation of their pharmacodynamic properties, but are not useful in describing the selective changes in consciousness, pain perception, and muscle relaxation observed clinically. Much research has been directed toward determining the neurologic sites and pathways affected by the various anesthetics. A first step to unraveling these more complex issues is to identify the component of the neuronal circuit most affected by anesthetic action. Studies of the sympathetic nervous system have conclusively shown that synaptic transmission is much more susceptible to anesthetic block than axonal conduction.[17] Nevertheless, this finding does not rule out an axonal contribution to general anesthesia. Anesthetic agents in clinical concentrations can diminish the amplitude of the action potential, which may impair synaptic transmission prejunctionally by reducing the evoked release of neurotransmitter. Conduction block is strongest at branch points of small-diameter axons and becomes even more prominent as the frequency of nerve transmission increases.

Evidence in favor of a direct presynaptic site of action includes some observations that anesthetics depress excitatory neuroeffector responses to prejunctional nerve stimulation, but not to iontophoretic application of the appropriate neurotransmitter. Release of epinephrine and norepinephrine from chromaffin cells by K^+ or acetylcholine has also been reported to be reduced by various anesthetics.[26] The most likely mechanism of action for this effect is a depression of Ca^{++} influx through presynaptic voltage-gated Ca^{++} channels or interference with the proteins involved in vesicle docking and neurotransmitter release.

A postsynaptic action at specific sites in the CNS is supported by decreased responses to directly applied stimulatory neurotransmitters such as acetylcholine, aspartate, and gluta-

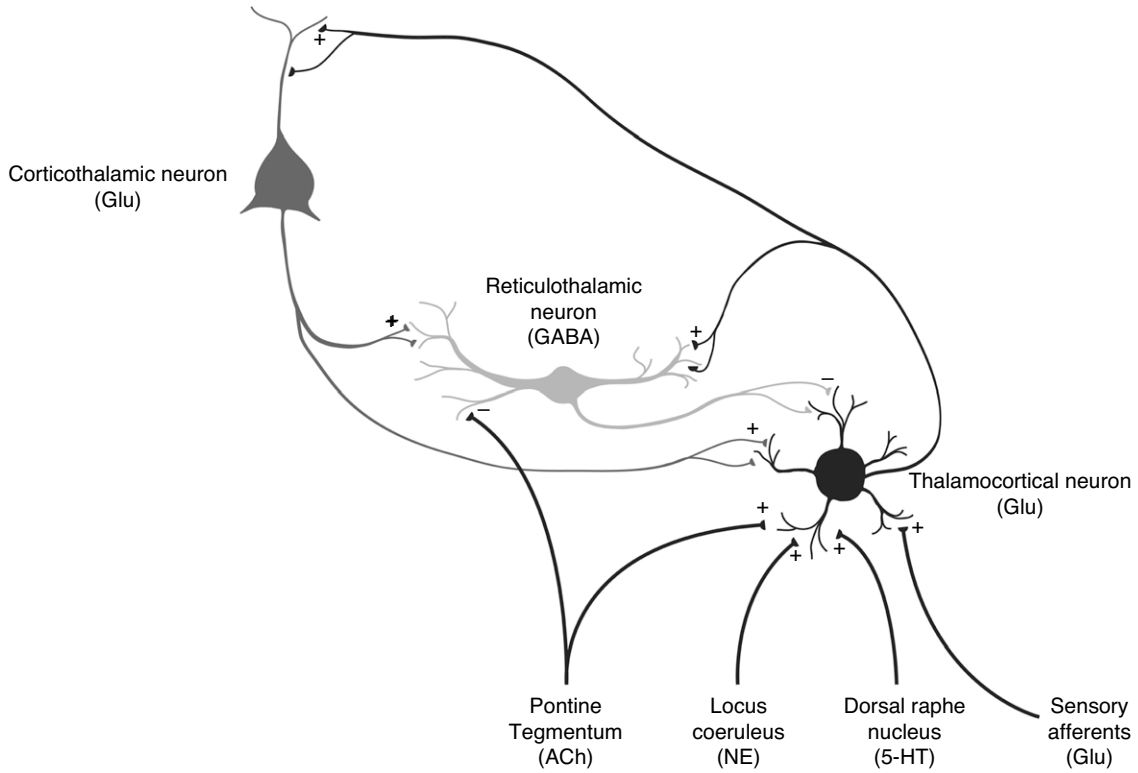

FIGURE **17-2** Thalamocortical pathways in consciousness and general anesthesia. In this simplified scheme, sensory stimuli and ascending arousal inputs from the reticular formation (including the dorsal raphe nucleus, locus coeruleus, and pontine tegmentum) activate *(+)* thalamocortical neurons and promote integrated transfer of information to the cerebral cortex. This transfer is aided by pontine inhibition *(–)* of reticulothalamic neurons, which relieves their tonic suppression of thalamocortical neurons. General anesthetics, among other actions, block the ascending arousal pathways, facilitate reticulothalamic inhibition of thalamocortical neurons, and disrupt normal processing of sensory information. Bereft of external activation, thalamocortical neurons spontaneously discharge in oscillatory bursts termed *sleep spindles*. Synchronous recruitment of cortical neurons produces slow δ waves on the electroencephalogram analogous to that seen in deep sleep. Major neurotransmitters released by each neural system are listed in parentheses. *5-HT*, 5-hydroxytryptamine; *ACh*, acetylcholine; *Glu*, glutamate; *NE*, norepinephrine.

mate. At the neuromuscular junction, general anesthetics seem to reduce the sensitivity of the motor end plate to acetylcholine by increasing the closing rate of ion channels opened by nicotinic receptor activation and by increasing receptor desensitization. Conversely, numerous anesthetics increase transmission at inhibitory synapses by increasing activation of $GABA_A$ receptors and Cl^- conductance. In addition, inhalation anesthetics and some intravenous agents may affect $GABA_B$ receptors and activate an inhibitory K^+ current.

A crucial unknown in the study of general anesthesia is the site at which unconsciousness is produced. Areas in the CNS that have been implicated in this primary anesthetic action include the dorsal lamina of the spinal cord (substantia gelatinosa), the reticular system (including the midbrain reticular formation), sensory relay nuclei of the thalamus, and cortical areas.

Much attention has been directed toward the role of the mesencephalic reticular activating formation. This system, which receives various nonspecific sensory inputs, is a major center supporting consciousness and alertness of higher brain centers. As the activity of the system is depressed, the ascending influences on the limbic system and cortical structures are reduced, and unconsciousness ensues. Gross lesions that abolish the arousal effect of the reticular formation as recorded on electroencephalography (EEG) may leave the animal behaviorally awake. This complex of neurons may also respond quite differently to various anesthetics. Barbiturates and most volatile anesthetics cause depression of spontaneous electrical activity, whereas ketamine alters the pattern of firing. All agents seem to block neuronal responses in the reticular formation to sensory input.

General anesthetics in clinically relevant concentrations may also exert direct effects on various nuclei of the thalamus, the hippocampus, the olfactory cortex, and various circuits in the cerebral cortex. Most reactions are consistent with the inhibition of excitatory neuronal pathways or facilitation of inhibitory influences, or both. As with the reticular formation, however, net excitatory reactions also occur depending on the anesthetic administered and region studied.

Numerous investigators have argued for a central role of thalamocortical-corticothalamic loop circuits in maintaining consciousness.[6,12] As illustrated in Figure 17-2, these circuits are highly active in the conscious state and are associated with high-frequency, low-amplitude brain waves on EEG. Direct sensory input and ascending excitatory stimuli arising from the reticular activating system help maintain this activity. Loss of excitatory tone and release of inhibitory stimuli in response to general anesthetic administration reveals rhythmic depolarizations of thalamocortical neurons that recruit numerous neurons to fire synchronously. The resulting δ waves on EEG are reflective of deep sleep and occur in concert with loss of consciousness.

Amnesia, which may be present in an awake patient or absent in an apparently unconscious patient, is most closely

Changes in physiologic functions are shown for the different stages and planes of Guedel's classification. Examples of surgery that can be performed at these anesthetic levels are given in parentheses.

linked to anesthetic-induced suppression of the limbic system structures (e.g., amygdala, hippocampus). Drugs that potentiate the actions of GABA are likely to have specific amnestic properties.

Because of its role in modulating pain, the spinal cord has been studied as a possible site of anesthetic action. Investigators have shown that the analgesic action of nitrous oxide involves the laminar structures (substantia gelatinosa) of the dorsal horns, often referred to as the gateway for nociceptive impulses into the CNS. The similarity of analgesia produced by opioids, nitrous oxide, and ketamine suggests a common mode of action. Cross-tolerance to the analgesic effect of morphine and nitrous oxide and the ability to block nitrous oxide analgesia with the opioid antagonist naloxone indicate that nitrous oxide may release endogenous opioid substances.[35] That the endogenous opioid system cannot be invoked as a mechanism of anesthesia generally is shown by the failure of naloxone to block the analgesic action of several anesthetics and the anesthetic action of nitrous oxide (and other drugs).[18,29]

The analgesic action of nitrous oxide involves α_1-adrenergic and α_2-adrenergic receptor activation. Blockade of either α_1 receptors by prazosin or α_2 receptors by yohimbine negates the analgesic effect of nitrous oxide in animals.[24] A possible sequence of events underlying nitrous oxide (and ketamine) analgesia is as follows: (1) nitrous oxide inhibition of NMDA receptors,[13] (2) release of endogenous opioid neurotransmitters,[35] (3) activation of descending norepinephrine pathways,[36] (3) activation of α-adrenergic receptors in the spinal cord,[24] and (4) inhibition of the classic nociceptive pathways. The analgesic action of isoflurane and dexmedetomidine may also be explained by their ability to stimulate α_2 receptors.[16]

Immobility is a central component of anesthesia. In addition to the ability of general anesthetics to elicit analgesia by influencing sensory processing in the dorsal horn, specific inhibition of spinal motor neurons also contributes to a lack of observable response to noxious and non-noxious stimuli.

Behavioral Manifestations of Anesthesia

Progressive depression

In 1920, Guedel[8] divided the course of ether anesthesia into a sequence of four stages and subdivided the third, or surgical, stage further into four planes (Figure 17-3). Each of these stages and planes represented a progressive and deepening depression of the CNS. In modern anesthesiology, these observations are no longer used in their entirety because the anesthetic signs are obscured by the presence of other drugs used before and during the anesthetic period, and because different anesthetics create different patterns of responses. Nevertheless, Guedel's scheme is useful in describing some of the effects caused by various anesthetic drugs. The classic stages of anesthesia, as described by Guedel, are stage I, analgesia; stage II, delirium; stage III, surgical anesthesia (planes 1, 2, 3, and 4); and stage IV, medullary paralysis.

Stage I starts with the beginning of anesthetic administration and ends with the loss of consciousness. The patient is unresponsive to mild pain-provoking stimuli and is able to respond to verbal commands. This stage is followed by delirium in *stage II,* during which uncontrolled movements, retching, and laryngospasm can occur. It is desirable to traverse this stage rapidly; propofol or another intravenous anesthetic is often given to bypass this stage and induce anesthesia immediately. *Stage III* has been subdivided, as indicated previously, into four planes in order of increasing depth of anesthesia by

using various indices, including the diameter of the pupil; loss of ocular, oropharyngeal, and other reflexes; muscle relaxation; depth and regularity of respiration; and separation of the thoracic and abdominal (diaphragmatic) phases of respiration. *Stage IV* begins with the disappearance of the purely diaphragmatic respiration of stage III plane 4 and ends with complete respiratory and circulatory collapse, culminating in death if the anesthetic is not discontinued and the patient given support for the cardiopulmonary systems.

The recovery from general anesthesia is the reverse of the process of induction. The patient progressively regains reflexes, and a short period of excitement similar to that previously encountered during stage II may occur, followed by emergence to consciousness with residual analgesia.

Although the stages of anesthesia can be useful in a descriptive sense, the further subdivision of the surgical stage into planes is no longer useful. Anesthetic agents currently used do not produce the same pattern of concentration-dependent changes in autonomic, motor, and reflex activity observed with ether, and many adjunctive drugs used during anesthesia tend to obscure these same signs. Muscular relaxation can hardly be used to gauge the depth of anesthesia if a neuromuscular blocking agent has been administered, and the arterial blood pressure cannot be useful if an adrenergic amine has been given to prevent hypotension. Nevertheless, measures autonomic function, such as progressive reduction of blood pressure and alterations in heart rate, can be valuable guides to the patient's status during anesthesia in the absence of medications that specifically obscure these functions.

In modern anesthesiology, the depth of anesthesia is determined to some extent by the needs of surgery. Because there is a diversity of purposes in surgery, along with various types of anesthetic agents, an assessment of the desirable depth of anesthesia is made for each type of procedure. If the procedure necessitates a bloodless field, as in plastic surgery, anesthetic agents may be chosen for their hypotensive properties. The end point of anesthesia becomes the production of hypotension, and other indices of depth, such as respiratory movements, have little direct bearing on the choice of anesthetic depth for the surgical procedure.

The effects of anesthetic agents depend on the degree of sensory input and the dose of the anesthetic used. With surgical stimulation, the respiratory and cardiovascular systems tend to be less depressed, and the patient can appear to be in a lighter plane of anesthesia than the injected dose or inspired concentration would indicate.

Selective depression

Generally, volatile anesthetic agents follow Guedel's scheme of progressive anesthesia. Certain discrepancies noted with these agents and experience with injectable drugs (e.g., ketamine), however, make clear the fact that surgical anesthesia is not synonymous with generalized CNS depression.[34] A quantitative autoradiographic analysis of brain glucose metabolism graphically demonstrates this point.[11] Although thiopental reduces metabolic activity throughout the rat brain in vivo, etomidate selectively depresses the forebrain, and ketamine has a mixed effect, inhibiting some areas but more strongly stimulating others, such as the hippocampus. This work and complementary neurophysiologic investigations indicate that amnesia and a loss of responsiveness to painful stimuli can occur with or without comprehensive CNS depression. In the latter case, the psychomotor unresponsiveness of surgical anesthesia apparently devolves from a functional disorganization of the activated neurons' interactions with one another. Although motor output may be enhanced, as shown by muscular rigidity, coordinated motor activity is gone, resulting in an unresponsive surgical patient.

UPTAKE AND DISTRIBUTION OF INHALATION ANESTHETICS

The depth of anesthesia produced by an inhalation anesthetic depends on the concentration of the anesthetic agent in the brain. The speed of induction and the speed of recovery follow the rate at which the concentration of the agent changes in the brain. During induction, the gas must move from the anesthetic apparatus to the pulmonary alveoli, from the alveoli to the blood, and from the blood to the brain. On termination of anesthesia, the inhaled gas moves in the opposite direction across the same interfaces. The principal force governing this movement of anesthetic gas is the diffusion or concentration gradient, and the behavior of the gases as they move from one compartment to another across biologic interfaces is defined by two gas laws. Dalton's law deals with the partial pressure (or tension) of gases and states that in a mixture the partial pressure of each component gas is directly related to its concentration in the mixture. Henry's law describes the solubility of gases in liquids and states that the quantity that will dissolve in a liquid is proportional to the partial pressure of that gas in direct contact with the liquid.

The partition coefficient is an expression of the relative solubility of a substance in two immiscible phases. When applied to anesthetic gases, it compares the relative amount of gas dissolved in one phase when one part is present in the other phase. The blood/gas partition coefficient of 2.5 for halothane indicates that 2.5 parts of halothane are dissolved in blood for every part contained in an equal volume of alveolar air. These relationships are shown schematically in Figure 17-4.

As mentioned earlier, during induction the various compartments of the body are brought into equilibrium regarding the inhaled anesthetic gas. When equilibrium is reached, the tensions of the anesthetic gas in the inspired air, alveolar air, arterial blood, body tissues, and mixed venous blood become equal, but the concentrations vary in concert with the relative solubility of the agent in each compartment. The speed with which equilibrium is achieved is influenced by many variables,

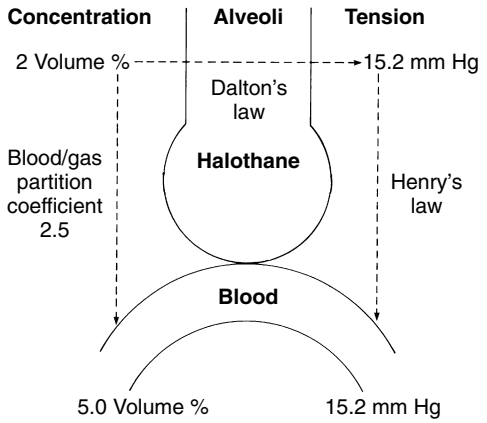

FIGURE **17-4** Effect of the blood/gas partition coefficient and the tension (partial pressure) exerted by halothane 2% (by volume) in the inspired air. Across the top of the diagram is the statement of Dalton's law that 2% (by volume) of halothane exerts 15.2 mm Hg pressure (0.02 × 760 mm Hg = 15.2 mm Hg) at 1 atmosphere pressure. Application of Henry's law indicates that, at equilibrium, the tension of the gas in the inspired air equals the tension of the gas in the blood (*right*), but the concentration dissolved in the blood is the product of the concentration in the air and the blood/gas partition coefficient (2% [by volume] × 2.5 = 5% [by volume], *left*).

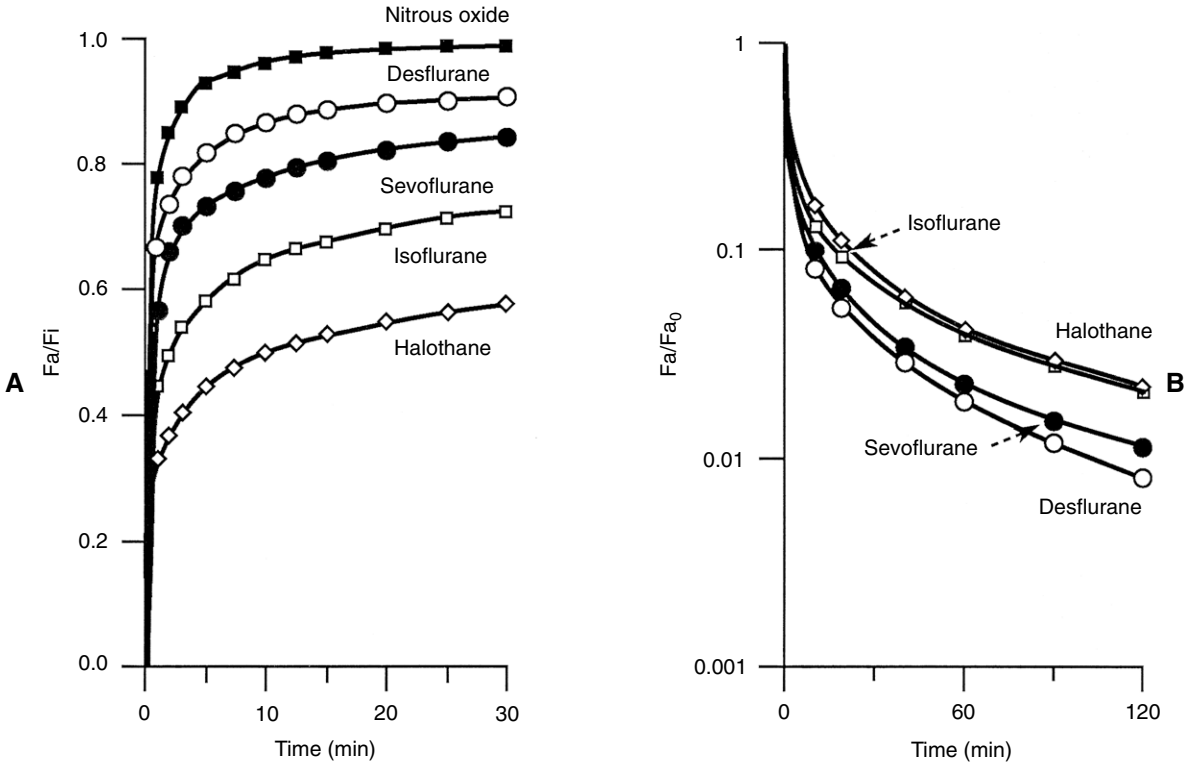

FIGURE **17-5** Rate of change of alveolar anesthetic tension during induction (**A**) and recovery (**B**). For induction, the ratio of the alveolar concentration (*Fa*) to the inspired concentration (*Fi*) is plotted against the time of drug administration. For recovery, the ratio of Fa to the Fa at the end of drug administration (Fa_0) is plotted against the time after termination of anesthetic delivery. (Adapted from Yasuda N, Lockhart SH, Eger EI II, et al: Comparison of kinetics of sevoflurane and isoflurane in humans, *Anesth Analg* 72:316-324, 1991.)

and each of these is considered subsequently, particularly regarding how it affects the alveolar concentration.

The alveolar concentration of an inhalation anesthetic is of pivotal importance to the onset of anesthesia. Because the brain is extremely well perfused, the tension of an inhaled anesthetic in the brain closely follows that of the arterial blood, which itself is equilibrated with the alveolar tension as the blood passes through the pulmonary microvasculature. Within broad limits, anything that increases delivery of anesthetic to the alveoli, and increases its partial pressure, would hasten anesthesia, and anything that enhances its removal from the lungs—in other words, anything that increases overall systemic uptake—would reduce its alveolar partial pressure and delay anesthesia.

The rate of change of alveolar concentration for some common anesthetic agents during induction and emergence is shown in Figure 17-5. Initially, the alveolar concentration increases quickly as the inspired gas mixes with the air in the lungs. Mathematically, this process can be defined as follows:

$$Fa/Fi = 1 - e^{-T \cdot \dot{V}_a/FRC}$$

where Fa is the alveolar concentration, Fi is the inspired concentration, T is the time in minutes, $\dot{V}_a$ is the minute alveolar ventilation, and FRC is the functional residual capacity of the lungs. For a gas that is extremely insoluble in blood, Fa usually reaches 95% of Fi within 2 minutes given a healthy individual breathing normally. Inhalation anesthetics by their nature all are at least somewhat soluble in blood, however. The rate of increase in Fa slows as removal by the pulmonary circulation becomes a significant fraction of the inhaled gas. The removal of anesthetic from the lungs by the pulmonary circulation can be expressed as follows:

$$\dot{V}_b = \lambda \cdot Q \cdot (Pa - Pv)/PB$$

where $\dot{V}_b$ is the anesthetic uptake, λ is the blood/gas partition coefficient, Q is the cardiac output, Pa and Pv are the alveolar and venous tensions, and PB is the barometric pressure. The function (Pa – Pv)/PB represents the gradient for diffusion and approaches zero as the body becomes equilibrated with the inspired gas. At that point Fa = Fi.

Concentration in Inspired Air

The greater the concentration of the anesthetic gas in the inspired air, the more rapid is the induction of anesthesia. This inspired tension normally is not held constant during induction. With irritating agents such as isoflurane, the tension is increased slowly. With sevoflurane, which is nonirritating, or in situations in which acceleration of the speed of induction is desired, the concentration at the outset may be two to three times what it would be during the maintenance phase of anesthetic administration. This technique, sometimes referred to as *overpressurization*, is analogous to administering a loading dose of drug (see Chapter 2).

Ventilation Rate and Depth

The greater the ventilation of the lungs, the more anesthetic is delivered to the alveoli and to the brain, resulting in a more rapid induction. This factor is most significant during the initial phase of induction when the air of the lungs is mixing with, and being replaced by, the inspired gases. As the primary

TABLE **17-2**

Properties of Inhalation Anesthetics

ANESTHETIC	BLOOD/GAS PARTITION COEFFICIENT*	BRAIN/BLOOD PARTITION COEFFICIENT	FAT/BLOOD PARTITION COEFFICIENT	MAC (%)†

†*MAC* is defined as the alveolar concentration (in volume %) of a gas necessary to prevent a skeletal muscle response to a standard surgical stimulus in 50% of patients.

physiologic variable influencing the delivery of anesthetic to the lung, it is also important in replacing gas removed from the alveoli by the pulmonary circulation. In this regard, alveolar ventilation is of less importance with insoluble agents such as nitrous oxide and desflurane, which achieve high (near equilibrium) blood tensions rapidly, than it is with more soluble drugs such as halothane, which equilibrate with the blood more slowly. In patients who are breathing spontaneously, high concentrations of inhalation anesthetics can decrease anesthetic uptake by inhibiting ventilatory drive. This action can help protect against overmedication during induction when overpressurization is being used.

Concentration and Second Gas Effects

The concentration effect occurs when nitrous oxide, a relatively nonpotent anesthetic, is administered in high concentrations (e.g., 75%) during induction of general anesthesia. Initially, nitrous oxide is taken up rapidly by the pulmonary circulation. This uptake would create a vacuum in the lungs were it not for the fact that fresh gas flows into the alveoli to replace the absorbed nitrous oxide. The net result is that alveolar ventilation is effectively increased, and more agent is available for absorption into the circulatory uptake than would otherwise be the case. A second, related contribution to the concentration effect is that the alveolar concentration of nitrous oxide does not decrease as greatly between breaths as one would expect. If half of the alveolar nitrous oxide was absorbed when breathing 75% nitrous oxide, replacement by additional gas flow would keep the alveolar concentration of nitrous oxide around 65%. A potent anesthetic given in a concentration of 0.75% with air, for comparison, would yield an alveolar concentration of only 0.38% after removal of half of the drug by the circulation because there would be essentially no flow of gas needed to maintain the ambient barometric pressure in the lungs.

Although the concentration effect is negligible with potent drugs given in low concentrations, if a potent anesthetic is administered along with nitrous oxide, it too will be delivered to the alveoli in increased amounts as gas rushes inward to replace the nitrous oxide absorbed by pulmonary blood. This phenomenon is called the *second gas effect*. Oxygen delivery to the lungs is also enhanced during induction of anesthesia by the second gas effect when nitrous oxide is administered in high concentrations.

Solubility in Blood

Blood solubility is a major factor in the rate of induction of anesthesia. Solubility is generally expressed as the blood/gas partition coefficient, which, as previously mentioned, is the ratio of the concentration of the anesthetic gas in arterial blood to that in the alveolar air at 37° C when the partial pressures in the two compartments are the same. The anesthetic gases are generally divided into three groups: agents of low solubility in blood (e.g., desflurane, nitrous oxide), agents of intermediate solubility (e.g., halothane, isoflurane), and agents of high solubility (e.g., methoxyflurane, ether). The blood/gas partition coefficients for the respective anesthetics are shown in Table 17-2.

If an agent is poorly soluble in blood, as is true of nitrous oxide and desflurane, only a small percentage of it is removed from the alveolar air before equilibrium is reached between pulmonary blood and alveolar gas. The alveolar concentration of gas increases quickly, the attainment of anesthetic concentrations in the brain is rapid, and the induction phase is short. With agents of very high blood solubility, such as ether, large fractions of gas are removed from the alveolar air, and large amounts have to be delivered over time from the inspired air before the uptake abates significantly. The alveolar tension increases slowly, and induction is similarly slow. Agents of intermediate solubility have an induction time slower than that of nitrous oxide and faster than that of ether.

Inasmuch as recovery or emergence is essentially a reversal of the process of induction, anesthetics that are insoluble in blood leave the blood very rapidly after the anesthetic gas is removed from the inspired air, and recovery is very rapid. Conversely, recovery is slow with ether. High solubility is not completely disadvantageous, however, because transient fluctuations of the anesthetic's concentration in the inspired air during maintenance has little effect on the depth of anesthesia.

Cardiac Output and Blood Flow

Cardiac output influences anesthetic uptake and onset of anesthesia in opposite ways. On the one hand, if the cardiac output is very high, it removes large quantities of gas from the alveoli and reduces the alveolar tension, delaying the achievement of equilibrium between inspired air and arterial blood. On the other hand, a high cardiac output delivers a greater amount of anesthetic to the tissues as a whole, hastening the rate at which the body comes to equilibrium with the arterial blood. Because the brain follows the arterial partial pressure of anesthetics closely, increasing total cardiac output generally slows the induction of general anesthesia.

The tissue uptake of an anesthetic agent depends on several parameters: the local blood flow, the arterial gas

tension, and the blood/tissue coefficient, which varies according to the amount of lipid present. As shown in Table 17-2, halothane is 1.9 times as concentrated in the brain and 51 times as concentrated in fat as it is in blood. Muscle tissue has an affinity for anesthetic agents similar to that of the brain. Lipids have a high affinity for anesthetic agents, and fatty tissues act as a reservoir for anesthetic gases.

The uptake of anesthetic gases proceeds sequentially into three main compartments of the body, based on differences in vascularity and lipid content of the tissues. Initially, the most active compartment is the vessel-rich group (VRG), consisting of the heart, liver, kidneys, lungs, and brain. As previously stated, equilibration between blood and brain is usually very rapid because the brain receives a large share of the cardiac output and because the brain/blood coefficient is relatively low (see Table 17-2). Nitrous oxide is initially absorbed into the VRG compartment at a rate of 1 L/min for the first 10 to 15 minutes. The uptake decreases to less than 0.5 L/min over the next 1 to 1½ hours, during which time the anesthetic fills the muscle compartment. If anesthetic administration is continued beyond this time, the uptake rate decreases still further (to <0.1 L/min) until the fat group of tissues is equilibrated. The sequence of halothane uptake is similar to that of nitrous oxide except that considerably more time is needed for equilibration of each compartment.

In patients who are mechanically ventilated, high concentrations of anesthetic may hasten anesthesia by inhibiting cardiac output. During induction, this effect increases the danger of overmedication when overpressurization is being used.

ELIMINATION AND METABOLISM OF ANESTHETIC GASES

The same factors that determine the uptake of anesthetic gas and the rate of induction are also important during the elimination phase. This process is initiated by the removal of the gas from the inspired air mixture so that the inspired air tension of anesthetic gas decreases to zero. When this happens, the anesthetic begins to diffuse from the blood through the alveoli, and as the blood tension decreases, there is a decrease in tissue tension. The less soluble the agent, the more completely and quickly the anesthetic is removed from the blood and tissues, and the more rapid is the recovery.

Although Figure 17-5 seems to suggest that recovery is a near mirror image of induction, several important differences do exist. The delivery of anesthetic to the lungs is not under the control of the clinician, but is a function of the cardiopulmonary status of the patient. Also, many differences arise because anesthesia is normally terminated well before equilibrium with the inspired gas is attained in the various tissue compartments, at least for anesthetics other than nitrous oxide. Often muscle and fat continue to absorb anesthetic from blood and the VRG for some time after administration has ceased. A possible outcome of this redistribution is a rapid recovery from short anesthetic courses.

Nevertheless, the high fat/blood partition coefficients of most agents indicate that anesthetic retention may last for many hours and that recovery from prolonged anesthesia can be delayed. A final disparity between induction and recovery is the influence of metabolism. It was long believed that inhalation anesthetics were eliminated through the lungs without any metabolic transformation. It is now recognized, however, that most agents are biotransformed in the liver, some quite extensively; 20% to 40% of administered halothane is metabolized in humans to trifluoroacetic acid, Cl^-, and Br^-. Because the enzymes responsible for this metabolism are capacity limited, this percentage may increase during the recovery phase, hastening emergence from anesthesia. Approximately 50% of methoxyflurane is metabolized, resulting in plasma F^- concentrations that can cause nephrotoxicity, severely limiting the use of this drug. Table 18-2 lists, for each currently used, the percentage of agent metabolized.

CHEMICAL PROPERTIES OF INHALATION ANESTHETICS

The wide diversity of chemical substances capable of producing the anesthetic state precludes any uniform statements regarding their chemical properties. Although numerous drugs can produce general anesthesia, the volatile liquids or gases are often preferred because the administration by inhalation permits rapid and precise control of the dose.

None of the current halogenated anesthetics or the obsolete agents chloroform and trichloroethylene presents a flammability or explosion hazard under normal circumstances. Ether is flammable and explosive, however. Cyclopropane, a three-carbon cyclic hydrocarbon, is a highly explosive gas. The only inorganic anesthetic in use, nitrous oxide, is not flammable but supports combustion of other substances.

Other chemical reactions besides fire and explosion can occur with anesthetic agents. Ether, when exposed to air (oxygen) and light, forms peroxides that reduce the ignition temperature for the anesthetic. Chloroform in the presence of high temperature or flame is converted to phosgene, an extremely toxic, irritating gas. Brass and aluminum are subject to corrosion when exposed to halothane and water. Trichloroethylene is decomposed by soda lime used to absorb carbon dioxide in closed systems; the resultant product is toxic and explosive. Sevoflurane also breaks down on exposure to traditional carbon dioxide absorbents, when administered in low flows, yielding fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl ether, more simply known as compound A. Although there is little evidence of human toxicity, some question remains regarding prolonged exposure to high concentrations of compound A. Finally, volatile inhalation agents are absorbed in soda lime and in the rubber or plastic connections used in the administration system, and are difficult to leach out of the anesthetic circuit.

PHARMACOLOGIC EFFECTS OF INHALATION ANESTHETICS

The pharmacology of individual anesthetic agents is discussed in Chapter 18. Included here for discussion are the major effects common to inhalation anesthetics in general.

Cardiovascular System

All inhalation agents depress myocardial contractility; the extent is related to the potency of the particular agent used, its concentration, and the duration of anesthesia. As a group, the halogenated anesthetics are the worst offenders in affecting contractility and in sensitizing the automaticity and conducting properties of the myocardium to norepinephrine and epinephrine. Cardiac rates are variably influenced, and the anesthetic effects are often masked by the preoperative administration of atropine or glycopyrrolate, both of which block activity of the vagus nerve. Agents that can directly excite discharge of the sympathoadrenal axis include ether, nitrous oxide, cyclopropane, desflurane, and possibly isoflurane. Other agents may indirectly increase sympathetic tone by depressing respiration or arterial blood pressure. Nevertheless, baroreceptor sensitivity, as measured by a change in heart rate in response to a vasoactive drug, is generally depressed.

Inhalation agents tend to decrease peripheral vascular resistance, although nitrous oxide may increase it mildly, and

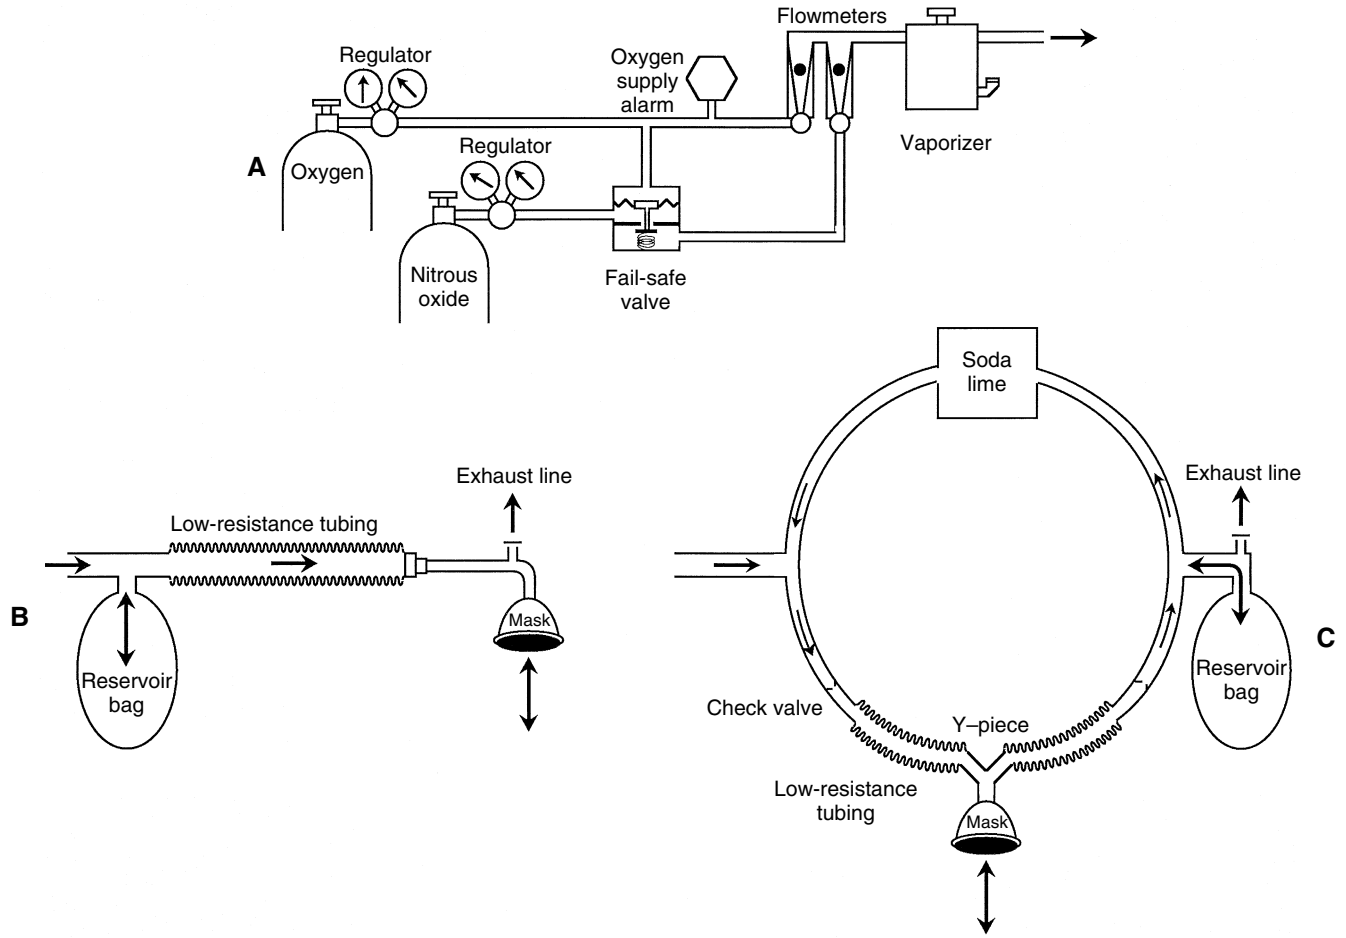

FIGURE **17-6** Major delivery systems for anesthesia. **A,** Diagram of the essential features of an anesthesia machine. A dedicated nitrous oxide–oxygen machine lacks the vaporizer. **B,** Mapleson A (or Magill) anesthetic circuit. Rebreathing of exhaled gas in a spontaneously ventilating patient does not occur if the fresh gas flow is at least 100% of the minute ventilation. **C,** Circle system anesthetic circuit. Partial or full rebreathing is made possible by the removal of exhaled carbon dioxide (as with soda lime).

the effect of halothane is mild in concentrations up to 3 MAC. When it was in clinical use, cyclopropane was preferred for patients in shock states because of its minimal effect on vascular smooth muscle. Isoflurane strongly relaxes vascular smooth muscle, producing a hypotension that can be useful in procedures such as surgical repair of an intracranial aneurysm.

Respiration

The effect of most anesthetics on the respiratory centers in the brain is depression; the amount of respiratory depression is related to the type and concentration of anesthetic used. Respiratory depression with inhalation anesthetics, measured by decreased medullary responsiveness to carbon dioxide tensions, is associated with a progressive decline in tidal volume. This effect is accompanied by a pronounced increase in respiratory rate. The most sensitive component of respiration to inhalation anesthetics is the ventilatory response to hypoxemia. Peripheral chemoreceptors that normally respond to low oxygen tensions are strongly inhibited by concentrations of 0.1 MAC and become completely inoperative during general anesthesia. Hypercarbia resulting from depressed ventilatory exchange excites the sympathoadrenal system, causing a release of catecholamines. When breathing is impaired, increased oxygen tensions or mechanical respiratory assistance may be necessary.

Liver

Liver function tests indicate that almost all inhalation anesthetic agents cause some alterations in hepatic function. In most cases, the effects are reversible and not serious. Halothane has been associated with serious hepatic necrosis, however, especially if the patient has had prior anesthesia with halothane or has preexisting liver disease. There is evidence that a reactive metabolite, trifluoroacetyl chloride, combines with hepatic proteins to form antigens that can trigger a fulminant allergic reaction.

Kidney

General anesthetics depress glomerular filtration and urine output by reducing renal blood flow. These alterations in renal function are transitory and readily reversible. The release of F^- from methoxyflurane has occasionally produced serious renal damage, which has led to its discontinued use in North America.

Skeletal Muscle

Although most general anesthetics produce muscle relaxation by their actions on spinal cord and brainstem motor reflex centers, the volatile anesthetic agents have an additional effect on the neuromuscular junction. Ether is most prominent in this respect and can produce sufficient muscle relaxation by itself for surgical procedures. Even agents with a lesser degree of action, such as isoflurane, can decrease the dose of a neu-

romuscular blocker by 65%. Cholinesterase inhibition by neostigmine does not antagonize this effect as it does for such nondepolarizing blocking agents as tubocurarine and vecuronium.

ADMINISTRATION OF ANESTHETIC GASES

Various delivery systems have been used since the inception of anesthesia; these range from simple techniques such as the open-drop method on a facemask or nose cone to anesthetic machines that incorporate numerous technical devices. Figure 17-6 illustrates the major components of modern delivery systems, including the nonrebreathing system used for nitrous oxide administration in dentistry, and the circle system commonly used in the hospital in which the patient rebreathes at least a portion of the exhaled gas.

Anesthesia delivery systems incorporate the following features: (1) gases, including oxygen, stored in either local tanks or a central delivery system; (2) regulators to control the pressure of gases delivered; (3) safety systems that warn of dangerous pressures and shut off flow if oxygen delivery is interrupted; (4) mixing valves (adjustable flowmeters) to regulate the percentages of gases; (5) vaporizers to volatilize anesthetic liquids; (6) carbon dioxide absorber system (not required for nonrebreathing systems); (7) reservoir bag, ventilator, or both; (8) assorted tubing and one-way valve systems; (9) facemask, laryngeal mask, or endotracheal tube; and (10) vacuum exhaust line.

Central to the administration of volatile general anesthetics is the temperature-compensated, variable-bypass vaporizer (Figure 17-7). This device provides the simple selection of anesthetic concentration because it automatically compensates for changes in total gas flow and for changes in the ambient temperature. In the case of desflurane, which boils at 23° C, the vaporizer must be heated electrically to 39° C to ensure controlled delivery.

Several considerations in the administration of anesthetic gases in modern anesthesiology should be mentioned. First, although some older agents (e.g., ether and cyclopropane) were highly effective, certain deficits caused their abandonment in favor of newer agents, such as isoflurane, which do not share the same problems. In particular, the explosive character of cyclopropane has caused its use to be banned. Second, some newer agents, such as desflurane, are expensive, so closed systems for their administration are favored. Third, retrospective surveys have provided evidence that operating room personnel (surgeons, anesthesiologists, nurses) and dentists and their employees exposed to nitrous oxide may be adversely affected by trace amounts of inhalation anesthetics. Specifically, exposed health care workers reported a higher incidence of hepatic, renal, and neurologic disorders; increased congenital malformations in children born to exposed women; and increased spontaneous abortions in exposed women and wives of exposed men.[1]

Animal studies indicate that nitrous oxide is the agent of major concern and that the threshold concentration of nitrous oxide for producing a biologic response is approximately 500 ppm to 1000 ppm.[33] Although retrospective studies that used examination of public health registries could find no link between working in an operating room (or being exposed to anesthetic gases) and increased risk of miscarriage or congeni-

BOX **17-1**

Steps to Reduce Nitrous Oxide Exposure

Facility and Equipment Preparation
- Purchase scavenging nitrous oxide delivery systems with air sweeper capabilities
- Check plumbing for leaks by pressure retention of closed system
- Check all fittings for leaks with disclosing solution or nitrous oxide analyzer
- Ensure exhaust system vents to the outside away from air intake
- Maximize room air circulation
- Consider use of a local exhaust system

Daily Use
- Adjust vacuum setting to manufacturer's maximum recommended value
- Place hood on nose before administering nitrous oxide
- Adjust flow to patient's minute respiratory volume
- Instruct patient to exhale through nose
- Instruct patient not to talk
- Use rubber dam whenever possible
- Use high-vacuum suction when mouth is open
- Administer 100% oxygen for 3 to 5 minutes before removing hood

Monitoring
- Inspect delivery apparatus each day of use, particularly the reservoir bag
- Periodically monitor exposure by passive dosimetry or nitrous oxide analyzer
- Record monitoring results

tal malformation,[3,10] Rowland and coworkers[27,28] have linked reproductive toxicity in dental assistants to nitrous oxide exposure of more than 3 to 5 hours per week. Most authorities therefore favor using anesthetic delivery devices in conjunction with scavenger exhaust systems and ventilation systems that remove leaked anesthetic gases from the vicinity of the patient.[22] Because many dentists function as anesthetist and surgeon, the nonrebreathing flow machine is most commonly used. Its simplicity of operation and compatibility with minimal-moderate sedation is coupled with the major disadvantage of exposing operatory personnel to potentially high concentrations of anesthetic gases (i.e., nitrous oxide) unless a concerted effort is made to minimize pollution, as is outlined in Box 17-1. The National Institute for Occupational Safety and Health has prepared a monograph to assist dentists in minimizing exposure to nitrous oxide in the workplace.[22]

CHAPTER 18

Agents Used in General Anesthesia and Sedation

DANIEL A. HAAS AND JOHN A. YAGIELA

General anesthesia can be induced by many compounds of diverse chemical structure, including inorganic compounds, halogenated hydrocarbons, simple alcohols, aromatic agents, steroids, and other drugs that affect the central nervous system (CNS). General anesthetics are available as gases, volatile liquids, and solutions suitable for parenteral injection. When administered in lower doses, many of these same drugs may cause clinically useful sedation. This chapter describes the pharmacologic features of drugs used in general anesthesia and various levels of sedation. The application of these agents in dentistry, in particular for sedation, is reviewed in Chapter 48.

INHALATION AGENTS

Gases and volatile liquids are the oldest known anesthetic agents and have been the most widely used. Today, the only commonly used gas is nitrous oxide. Although general anesthetic agents administered by inhalation are often divided into gases and volatile liquids, there are few differences between these two classes of substances other than boiling point (Table 18-1) and solubility in various tissues (see Table 17-2). Regarding boiling point, which determines the vapor pressure of the gaseous phase, liquids need vaporizers, which produce and maintain an adequate amount of anesthetic in the inspired air. Because tissue solubility (i.e., solubility in brain membranes) is normally greater with the volatile liquids than gases, a smaller concentration of volatile agent is required in the inspired air to produce general anesthesia. An ideal inhalation anesthetic should possess numerous characteristics as outlined in Box 18-1.[44]

Nitrous Oxide

Nitrous oxide is arguably the oldest general anesthetic agent (see Chapter 17 for a review of the discovery of anesthesia) and the only gaseous anesthetic currently in use. Nitrous oxide is also the only inorganic substance used clinically as an anesthetic. Several features unique to nitrous oxide among available agents include a minimum alveolar concentration (MAC) greater than 100%, strong analgesic properties in subanesthetic concentrations, and minimal relaxation of skeletal muscle.

Physical and chemical properties

Nitrous oxide is a colorless, nonirritating gas with a pleasant, mild odor and taste. The structural formula is shown in Figure 18-1. Its blood/gas partition coefficient of 0.47 means that it is poorly soluble in blood. It is nonflammable but can support combustion in the absence of oxygen. It is available in pressurized steel cylinders as a liquid in equilibrium with its gas phase. As the nitrous oxide gas is delivered from the cylinder, liquid nitrous oxide spontaneously vaporizes to replace the lost gas phase. Cylinder pressure is maintained unaltered by this process until all the liquid has vaporized, at which point approximately four fifths of the contents have been released. This vaporization process requires heat, which is provided from the cylinder and the air around it, causing the tank to become cold.

Anesthetic properties

Because of its very low solubility in blood, a state of equilibrium between the alveolar and arterial tensions is quickly reached, allowing induction and awakening to occur very rapidly. The primary disadvantage of nitrous oxide as a general anesthetic is its lack of potency, as reflected by its high MAC of approximately 105%. (A concentration >100% value unobtainable at ambient conditions is achieved by placing the subject in a hyperbaric chamber.) At normal concentrations and when given with adequate amounts of oxygen, nitrous oxide is incapable of producing full surgical anesthesia by itself, and it is most commonly used as a supplement to volatile anesthetics. To ensure adequate oxygenation of the patient, nitrous oxide is normally not used at a concentration greater than 70%. When it is administered with other anesthetic agents, the maintenance concentration normally used is 50% to 70%.

In dentistry, nitrous oxide is usually administered in subanesthetic concentrations of 20% to 50% to provide mild-moderate sedation and analgesia. Concentrations above this range may impair the patient's ability to maintain consciousness and lead to a greater incidence of adverse effects, such as nausea or dysphoria. At a 40% concentration, there is good hard and soft tissue analgesia. Awareness of sensory input is reduced, with the exception that sounds may seem louder and qualitatively different.[94]

When nitrous oxide is used with a more potent agent, it is possible to reduce the concentration of the other drug and still achieve a more rapid induction and a shorter recovery period. This phenomenon is a reflection of the fact that the MAC of the rapidly acting nitrous oxide is additive with that of other, slower acting inhalation anesthetics. The addition of 70% nitrous oxide, which is approximately 0.6 MAC, reduces the MAC of halothane from 0.75% to 0.29% and the MAC of isoflurane from 1.15% to 0.5%, each approximately a 60% reduction. In addition, the concentration and second gas effects described in Chapter 17 can help hasten the onset of anesthesia.

Cardiovascular effects. In contrast to the volatile anesthetics in current use, nitrous oxide does not usually produce any clinically significant cardiovascular effects. It has a weak, dose-

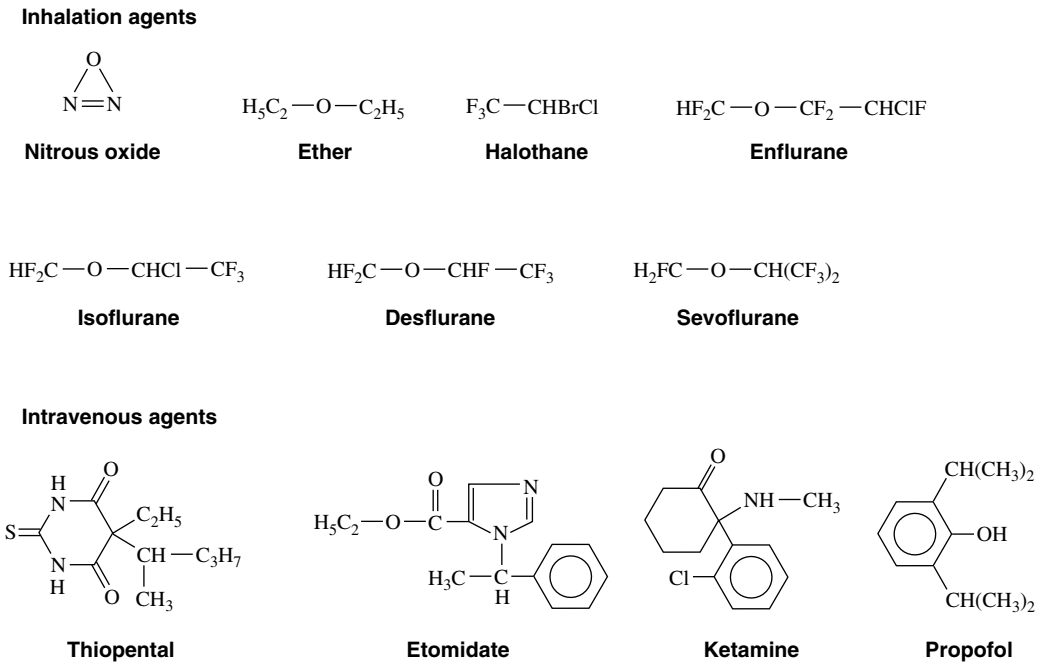

FIGURE **18-1** Structural formulas of anesthetic drugs.

TABLE **18-1**

Physical Properties of Inhalation Anesthetics

AGENT	MOLECULAR WEIGHT	BOILING POINT (°C [1 atm])	VAPOR PRESSURE (mm Hg [20°C])
Nitrous oxide	44	–88.5	38,770 (gas)
Desflurane	168	23.5	669
Ether	74.1	34.6	440
Isoflurane	184.5	48.5	238
Halothane	197.4	50.2	243
Sevoflurane	200	58.6	157

BOX **18-1**

Ideal Characteristics of an Inhalation Agent

Stable in light, alkali, and soda lime
Nonflammable
Highly potent, allowing use with high concentrations of oxygen
Low solubility in blood to allow rapid induction and rapid recovery
No or minimal biotransformation
No toxicity
Nonirritating to respiratory mucosa
Minimal cardiovascular and respiratory effects

dependent myocardial depressant effect and a mild sympathomimetic effect.[46] These opposing influences tend to cancel each other, leading to minimal to no change in cardiac output. Patients at increased risk of the cardiac depressant effects of nitrous oxide include patients with chronic hypertension, left ventricular failure, and advanced atherosclerotic disease.

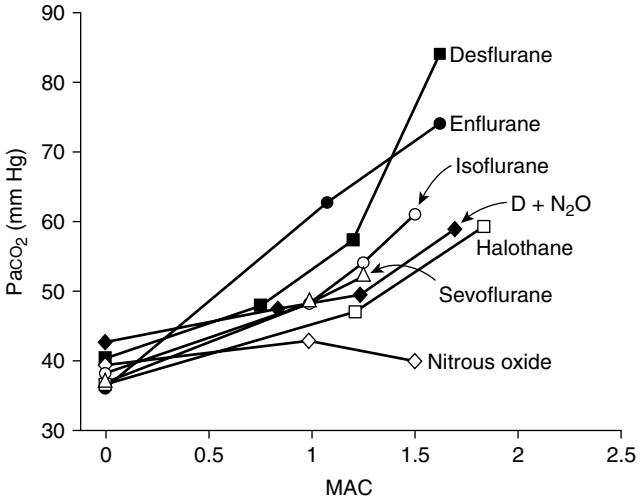

FIGURE **18-2** Arterial carbon dioxide tension ($Paco_2$) in spontaneously breathing volunteers as a function of the minimum alveolar concentration (*MAC*). (Adapted from Doi M, Ikeda K: Respiratory effects of sevoflurane, *Anesth Analg* 66:241-244, 1987; Eger EI II: Isoflurane: a review, *Anesthesiology* 55:559-576, 1981; and Lockhart SH, Rampil IJ, Yasuda N, et al: Depression of ventilation by desflurane in humans, *Anesthesiology* 74:484-488, 1991.)

Respiratory effects. Nitrous oxide is not a strong respiratory depressant (Figure 18-2), but it decreases tidal volume and increases respiratory rate. Even so, there is likely to be less respiratory depression than would be caused by an equal depth of anesthesia induced by a single potent anesthetic drug. Although nitrous oxide has little effect on respiration in normal individuals, whose ventilation is regulated by the arterial carbon dioxide tension ($Paco_2$), patients with severe chronic obstructive pulmonary disease whose ventilatory drive depends on the arterial oxygen tension may become severely hypoxic on exposure to even sedative concentrations

of anesthetic.[101] Even if hypoxemia is prevented by the high concentration of oxygen that is being coadministered (which by itself blunts the hypoxic drive for respiration), hypoventilation and respiratory acidosis are likely outcomes.

Elimination. Nitrous oxide is eliminated unchanged in the exhaled gas; however, 0.004% undergoes reductive metabolism to nitrogen by bacteria in the gastrointestinal tract.

Adverse effects

When used for sedation, nitrous oxide usually provides a feeling of relaxation, along with the possible symptoms of body warmth, tingling of the hands and feet, circumoral numbness, auditory effects, and euphoria. As the dose increases, the patient is more likely to develop adverse symptoms such as dysphoria and nausea.[27,28] Some patients may develop acute tolerance to these effects.[75]

For general anesthesia, high concentrations are used, and because its solubility in blood greatly exceeds that of nitrogen, nitrous oxide increases the volume of any enclosed air pocket in the body. There are several situations in which this property can be problematic: with a pneumothorax or lung bullae, injection of air into the ventricles during a pneumoencephalogram, an obstructed bowel, a blocked eustachian tube (with potential damage to the tympanic membrane), or after eye surgery that uses intraocular gases. With respect to vitreoretinal surgery, such as the surgical repair of retinal detachments and macular holes, perfluoropropane or sulfur hexafluoride is introduced within the eye to act as a tamponading agent. These gases may persist in the eye for up to 3 months. Administration of general anesthesia during this interval has led to case reports of irreversible loss of vision.[9,35,96] These case reports suggest that nitrous oxide should be avoided in patients who have had vitreoretinal surgery with intraocular gas infusion in the past 3 months.

High concentrations of nitrous oxide may also result in a considerable accumulation of dissolved gas within the body, and when the administration is stopped, large volumes of nitrous oxide diffuse from the blood into the lung alveoli, diluting oxygen. This temporary reduction in the amount of alveolar oxygen is termed *diffusion hypoxia* and can be prevented by administering 100% oxygen for 3 to 5 minutes after the cessation of nitrous oxide.

Nitrous oxide is not acutely toxic, but it can affect DNA synthesis by inducing changes in folate and amino acid metabolism. Its administration leads to an increase in homocysteine and 5-methyltetrahydrofolate.[33] Nitrous oxide oxidizes the cobalt atom in vitamin B_{12}, which renders inactive the vitamin B_{12}–dependent enzyme methionine synthase. Methionine synthase is required to form the essential amino acid methionine (from homocysteine) and to transform 5-methyltetrahydrofolate into an active form for subsequent reactions. The enzyme is quickly inactivated in vivo by brief exposures to nitrous oxide.[25,56] This inactivation increases with the nitrous oxide concentration and duration of exposure, is permanent, and requires synthesis of new enzyme for restoration of normal metabolism.[55,80] Methionine deficiency is believed to be associated with degenerative nervous system changes. It has been suggested that preoperative administration of methionine may counteract some of the adverse effects of nitrous oxide on the hematologic and nervous systems,[17] and methionine has been used in the treatment of nitrous oxide–induced neuropathy.[91]

Continuous inhalation of nitrous oxide can result in altered hematopoiesis because of the suppression of DNA synthesis. Patients exposed to 50% nitrous oxide for 6 hours may begin to show evidence of impaired thymidylate metabolism; hematopoietic changes suggestive of pernicious anemia occur after 24 hours of continuous inhalation.[1] Intermittent exposures have a cumulative effect if spaced more frequently than once every 3 to 4 days.[71] These findings have limited the use of nitrous oxide as an analgesic agent for extended use and for procedures that must be repeated often, such as debridement of burned skin.

The inhibition of methionine synthesis by nitrous oxide has been associated with an increased risk of myocardial ischemia in patients undergoing vascular surgery.[4] Patients at special risk include patients with genetic mutations that cause a deficiency in 5,10-methylenetetrahydrofolate reductase activity.[70] This enzyme generates the 5-methyltetrahydrofolate required for methionine synthesis; its deficiency potentiates the pathway block caused by nitrous oxide. Pretreatment with B vitamin supplements for 1 week before anesthesia can prevent the hyperhomocysteinemia believed to cause these adverse effects.

Similar to other mood-altering drugs, nitrous oxide may be abused by individuals with access to the drug, including members of the dental profession. This abuse is associated with myeloneuropathic changes indicative of a pernicious anemia–like syndrome: numbness and paresthesia, muscular weakness and incoordination, altered spinal reflexes, impotence, and shooting sensations on flexion of the neck (Lhermitte's sign).[62]

Nitrous oxide has been shown to inhibit the release of luteinizing hormone–releasing hormone by the hypothalamus, which theoretically may impair fertility.[59,60] Potential reproductive toxicity has also been proposed to be caused by the sympathomimetic effects of nitrous oxide leading to vasoconstriction and diminished uterine blood flow.[36,68] Clinical use in pregnant women carries no apparent increased risk to the fetus, however, over other acceptable forms of pain control.[23,67] Long-term exposure has been strongly implicated in other reproductive abnormalities, such as spontaneous abortion[19] and impaired fertility,[79] but these effects have not been substantiated by controlled prospective studies.

The possibility that long-term exposure to trace concentrations of nitrous oxide may be a health hazard to dental office and operating room personnel is discussed in Chapter 17.[19] An early report of inhaled concentrations of as little as 50 ppm over a 2-hour span causing impairment in audiovisual performance tasks[12] has not been reproduced.[21,89] Nevertheless, this finding prompted the National Institute for Occupational Safety and Health to recommend 25 ppm as a maximum permissible time-weighted exposure limit per anesthetic administration for all health care workers. This level may not be achievable with some existing scavenging systems,[100] so other measures (e.g., using rubber dam, using high-velocity suction, limiting the patient's talking) must be used to minimize the gas escaping into the room. As discussed in Chapter 17, the issue of controlling waste anesthetic gas in the workplace continues to evolve.

Therapeutic uses

Nitrous oxide is a widely used inhalation anesthetic and continues to play a major role in the delivery of medical and dental anesthesia. It is valuable in reducing the concentration of volatile anesthetics during inhalation anesthesia and as a component of "balanced anesthesia."* Historically, nitrous oxide was first used for dental surgery, but with the advent

**Balanced anesthesia* is a term used to describe a concept in which combinations of drugs are used to produce general anesthesia, with each drug chosen for a specific effect. In this context, the following drugs might be selected: nitrous oxide for its analgesic and anesthetic actions, a benzodiazepine for amnesia, a neuromuscular blocking drug for muscle relaxation, and an opioid for additional analgesia and hemodynamic stability.

of local anesthetics, it was replaced as the drug of choice for providing pain control sufficient for most dental procedures. Since the late 1950s, there has been an upsurge in the use of nitrous oxide, not to provide dental anesthesia, but to provide relief from anxiety in the form of minimal-moderate sedation. In this role, it is often the agent of first choice. Its therapeutic application in dentistry is described in Chapter 48. Conversely, its use for general anesthesia in medicine is declining because of the increasing reliance on intravenous anesthesia coupled with concerns about occupational exposure to the gas. In these settings the potential for nitrous oxide to increase homocysteine concentrations and the risk of postoperative vascular thrombosis, myocardial ischemia, and stroke become significant.

Ether

Ether (diethyl ether) was the most widely used volatile anesthetic in the century that followed the first successful demonstration of general anesthesia in 1846. As described in Chapter 17, the sequential effects of ether inhalation were the basis for Guedel's stages of anesthesia. Ether has been superseded by newer inhalation agents and is rarely used as a general anesthetic in North America. A brief description is included because of its historical importance.

Ether is flammable, explosive, and an irritating liquid with a pungent odor. This last property, combined with a blood/gas partition coefficient of 12.1, makes its induction and recovery periods slow and unpleasant. Ether's advantages are its ability to produce good analgesia and muscle relaxation and to maintain respiration and circulation, its relative freedom from myocardial sensitization and organ toxicity, and its ease of administration. The drug's main disadvantages are its flammability and explosive potential, slow induction, slow recovery, irritation to the upper airway causing copious mucus secretion, and prominent emetic properties.

Halothane

Halothane was one of the most widely used anesthetics after its introduction into clinical anesthesia in 1956 in the United Kingdom and in 1958 in the United States. Its use in developed countries has greatly declined with the introduction of newer volatile agents; halothane is no longer marketed in the United States. Nevertheless, halothane is the only volatile anesthetic recognized by the World Health Organization as an essential medicine, and it remains the standard with which other inhalation anesthetics are compared.

Physical and chemical properties

Halothane is a halogenated hydrocarbon; it is nonflammable, has a characteristic sweet odor, and is available in brown glass bottles with thymol added to maintain chemical stability. Its physical and solubility properties are summarized in Tables 17-2 and 18-1.

Anesthetic properties

Table 18-2 compares the pharmacologic properties of halothane with other inhalation anesthetics. With a MAC of 0.75%, halothane is a potent general anesthetic that can be administered with excess amounts of oxygen. With its blood/gas partition coefficient of 2.5, the induction time of halothane is faster than that of older drugs such as ether, but slower than that of nitrous oxide and the newer volatile agents currently in use. Halothane has poor analgesic properties; at surgical anesthetic levels, an unconscious patient may respond to a noxious stimulus with increased motor activity and alteration of autonomic parameters. For this reason, halothane is most often used with nitrous oxide or an opioid analgesic or both. Because halothane produces incomplete muscle relaxation, it is also often combined with neuromuscular blocking agents.

Cardiovascular effects. Halothane decreases the mean arterial blood pressure, primarily as a result of decreased cardiac output, and at 1 MAC it decreases by 25% (Figure 18-3). The decrease in cardiac output is greater than that found with equipotent amounts of isoflurane. Halothane, similar to other volatile general anesthetics, has a direct, significant, and dose-dependent depressant effect on myocardial contractility and, to a lesser degree, on vascular smooth muscle.[81] The negative inotropic effect is attributed to a decrease in the influx of Ca^{++} through the slow channels of the sarcolemma, a decrease in Ca^{++} accumulation in the sarcoplasmic reticulum, and a decrease in Ca^{++} sensitivity of contractile proteins.

Halothane exerts a direct negative chronotropic effect at the sinoatrial node as a result of reduced cardiac sympathetic activity and vagal predominance. This depression leads to a

FIGURE **18-3** Cardiovascular effects of inhalation anesthetics as a function of the minimum alveolar concentration (*MAC*). *HR*, Heart rate; *MAP*, mean arterial blood pressure; *SVR*, systemic vascular resistance. (Adapted from Malan TP Jr, DiNardo JA, Isner RJ, et al: Cardiovascular effects of sevoflurane compared with those of isoflurane in volunteers, *Anesthesiology* 83:918-928, 1995; and Weiskopf RB, Cahalan MK, Eger EI II, et al: Cardiovascular actions of desflurane in normocarbic volunteers, *Anesth Analg* 73:143-156, 1991.)

slowing of the heart rate and possible junctional rhythms. Halothane also depresses the baroreceptor reflex and suppresses the expected increase in heart rate caused by hypotension.[5] Halothane is a vasodilator; the peripheral systemic vascular resistance may be decreased, especially in patients with high sympathetic tone (e.g., patients with congestive heart disease or hypertension).

There is no stimulation of sympathoadrenal discharge with halothane and no increase in plasma catecholamines. Halothane sensitizes the myocardium to catecholamines, however, which can predispose to cardiac dysrhythmias,[7] and this effect may be potentiated further by thiopental or hypercarbia. Dysrhythmias can occur as a result of catecholamines released endogenously in response to an elevated $Paco_2$ or surgical stress, or after the injection of pressor agents given to augment blood pressure. Of direct relevance to dentistry is the use of epinephrine as the vasoconstrictor in local anesthetics and gingival retraction cords. For submucosal administration, it is recommended to limit exogenous epinephrine administration to 1 μg/kg if halothane is used with thiopental and 2 μg/kg if used alone.[18] Avoidance of hypoxia, hypercarbia, and electrolyte abnormalities also reduces the likelihood of this adverse event.

Respiratory effects. Halothane induces dose-dependent respiratory depression. At light anesthetic levels, breathing becomes shallow and rapid, and the $Paco_2$ is maintained at a concentration 25% higher than normal (see Figure 18-2). Tidal volume decreases. As with all inhalation anesthetics, the ventilatory response to carbon dioxide is diminished, and controlled ventilation is frequently necessary in deeper planes of anesthesia. Halothane virtually eliminates the respiratory stimulant effect of hypoxia at concentrations ≥0.1 MAC. Halothane is an effective bronchodilator, which is beneficial in the asthmatic patient.

Other effects. Halothane depresses the cerebral metabolic rate. Intracranial pressure usually increases, as does cerebral blood flow. The production of cerebrospinal fluid is decreased, but so too is its absorption. Halothane relaxes uterine smooth muscle. Halothane also causes a dose-dependent decrease in renal blood flow and glomerular filtration, which is thought to parallel the decrease in cardiac output.

Metabolism. A significant portion (≥20%) of the administered halothane is biotransformed in the liver, primarily by oxidation by the cytochrome P450 microsomal oxidase system.[14,24] Reduction accounts for 2% of the metabolism. In contrast to other inhalation anesthetics, hepatic metabolism is an important contributor to the elimination of halothane. The metabolites include trifluoroacetic acid, which may be responsible for toxic effects in the liver (as described later), and Cl^- and Br^-.

Adverse effects

Halothane has been associated with delayed hepatotoxicity, which may manifest as one of two syndromes.[29,32] The first is a mild, self-limited form of liver dysfunction that may occur after an initial exposure and has an incidence approximating 20%. This disturbance, usually recognized by an increase of liver enzymes in the plasma, may result from a direct effect of the drug or its metabolites. It may be exacerbated by liver hypoxia because it is strongly associated with impaired hepatocyte oxygenation because of preexisting liver disease, hypoxemia, or decreased hepatic blood flow.

The second syndrome, known as halothane hepatitis, is characterized by the development of massive hepatic failure

with a high mortality rate.[10] This latter syndrome has an incidence approximating 1:10,000 in adults (1:100,000 in children) and is associated with repeated exposure to halothane. The clinical features of halothane hepatitis include gastrointestinal upset, jaundice, fever, rash, eosinophilia, and serum autoantibodies.[5,77] This more fulminant form is caused by an immunologic mechanism. The oxidative metabolism of halothane leads to a reactive trifluoroacetyl halide metabolite. This metabolite induces antigenic changes to hepatic microsomal proteins, producing neoantigens and subsequent autoantibodies. Because of this syndrome, halothane is generally contraindicated in adults, especially individuals who have previously been exposed to halothane, or in any patient regardless of age who has shown signs of liver toxicity on previous exposure to halothane or related anesthetics.[32,78] Halothane is also contraindicated for any abdominal surgery likely to decrease the alveolar ventilation or liver blood flow.

Malignant hyperthermia is a rare adverse effect of general anesthesia involving halothane, other volatile anesthetic agents, and the neuromuscular blocking drug succinylcholine. In the United States, the incidence of malignant hyperthermia is 1:50,000 in adults and 1:15,000 in children. It is a genetic disorder of multifactorial etiology. Most cases are associated with mutations in the ryanodine receptor (type 1), which forms a Ca^{++} channel in the sarcoplasmic reticulum and is involved in Ca^{++}-induced Ca^{++} release. Malignant hyperthermia can be associated with the following disorders: central core disease; Duchenne's muscular dystrophy; King-Denborough syndrome; other myopathies; and musculoskeletal congenital defects, such as cleft palate, scoliosis, clubfoot, ptosis, strabismus, cryptorchidism, and congenital hernias.[11,92]

An acute crisis of malignant hyperthermia is a hypercatabolic reaction that often manifests initially as masseter or generalized muscle rigidity; other early signs include elevation of oxygen use and carbon dioxide production, tachypnea, and tachycardia. Cardiovascular instability, cardiac dysrhythmias, electrolyte disturbances, and elevation in temperature are other classic signs. The body temperature, often unaffected early in an acute attack, progressively increases to alarming and sometimes fatal levels. The elevated heat production, associated with increased Ca^{++} concentrations in the myoplasm and hypermetabolic activity of skeletal muscle, is responsible for the hyperthermia.[41]

Immediately on recognition, all triggering agents should be discontinued, and hyperventilation with 100% oxygen should be instituted. Dantrolene, an inhibitor of Ca^{++} transport (see Chapter 10), must be administered intravenously as soon as possible because this drug provides lifesaving, definitive treatment.[40] Dantrolene should be administered as a bolus intravenously at a dose of 2 mg/kg to 3 mg/kg and then titrated in response to the patient's clinical condition. If present, metabolic acidosis and any dysrhythmias or electrolyte disturbances should be treated. Cooling in the form of cold intravenous solutions, packing the patient in ice, and ice water lavage of body cavities should be performed to increase heat loss and reduce body temperature. Effective treatment rendered quickly after prompt recognition of malignant hyperthermia has reduced its mortality rate from 70% to less than 10%.

Therapeutic uses

Halothane was one of the most widely used general anesthetics in the two decades after its clinical introduction. Although its use has greatly diminished with the introduction of newer inhalation and intravenous agents, halothane may still be considered when a child is to be induced by inhalation because it does not have a strong odor and is nonirritating to the respiratory tract. Its primary drawback is its potential hepatotoxicity.

Isoflurane

After its release in the United States in 1981, isoflurane became the most widely used volatile anesthetic. It is an isomer of enflurane, which was a halogenated methyl ethyl ether introduced into clinical use in the United States in 1972, but since withdrawn from use. Isoflurane combines the desirable cardiovascular properties of enflurane with a freedom from seizure activity and less respiratory depression and hepatic metabolism. Although the newer, less soluble volatile anesthetics have made inroads in its use, isoflurane is less expensive and remains a useful anesthetic for many purposes.

Physical and chemical properties

The blood/gas partition coefficient of 1.4 for isoflurane results in a more rapid onset of action compared with halothane. Isoflurane is chemically stable, nonflammable, and marketed in brown glass bottles. The vapor is pungent and irritating to breathe.

Anesthetic properties

Isoflurane may be thought of as an improved but less potent (MAC of 1.15%) version of halothane. Induction should theoretically be relatively rapid with isoflurane, but it is limited by its pungent odor, which, if induction is allowed to proceed too rapidly, leads to breath holding, laryngospasm, and coughing. This problem is usually overcome by inducing the patient with an intravenous agent. Isoflurane is sufficiently potent to provide muscle relaxation adequate for any surgical procedure, but neuromuscular blocking agents are normally used instead of the high concentrations of anesthetic needed to secure muscle relaxation. As with other potent inhalation anesthetics, isoflurane increases the action of the nondepolarizing neuromuscular blocking drugs.

Cardiovascular effects. Similar to all volatile anesthetics, isoflurane produces a dose-dependent depression of myocardial contractility, but it is considerably less than that seen with halothane. Isoflurane also causes coronary vasodilation, mostly at the distal (resistance) arterioles.[74] Although this effect may be beneficial for heart muscle, it was also proposed to cause "coronary steal" in patients with ischemic heart disease, a situation in which blood flow is redistributed from myocardial tissues supplied by atherosclerotic arteries to areas with healthy coronary vessels. Coronary steal develops only when the coronary perfusion pressure is decreased, is more likely to occur with excessive tachycardia, and is most probably not a special concern with isoflurane. Cardiac output is well maintained with isoflurane (see Figure 18-3), even though stroke volume is decreased, by virtue of an increase in the heart rate, showing isoflurane's greater preservation of baroreceptor reflexes. Decreases in arterial blood pressure are similar to the decreases produced by halothane, however, because of the greater vasodilator effect of isoflurane. Isoflurane does not significantly sensitize the heart to dysrhythmias; the permissible injected dose of epinephrine during isoflurane anesthesia is three times that with halothane.

Respiratory effects. Respiratory depression is greater than that with halothane (see Figure 18-2) and manifests as a decreased ventilatory response to hypercapnia with a complete loss of sensitivity to hypoxia. Isoflurane increases respiratory rate only up to 1 MAC. Bronchodilation is similar to halothane.

Other effects. Isoflurane depresses cerebral metabolism in a manner similar to halothane. It is a less powerful cerebral vasodilator, however, and causes little change in the cerebrospinal fluid pressure. Isoflurane does not significantly alter

cerebrospinal fluid production. All these effects intracranially are beneficial in neurosurgery.

Metabolism. In contrast to halothane, biotransformation of isoflurane is quite low (≤0.2%). This finding suggests that it is neither nephrotoxic nor hepatotoxic, a conclusion supported by observations that repeated and prolonged exposures to isoflurane have not caused hepatorenal injury in animals. It is biotransformed by the same enzymatic pathway as halothane. Although there are a few case reports of hepatic necrosis after isoflurane administration,[15,39] it is currently believed that isoflurane is highly unlikely to be responsible for postoperative hepatotoxicity.[77]

Therapeutic uses

Isoflurane is a suitable drug whenever a potent inhalation anesthetic is to be administered except when a mask induction of anesthesia is contemplated. In pediatric patients, induction with isoflurane is more likely to elicit coughing, salivation, and laryngospasm[69] than induction with halothane. These effects can be prevented by prior administration of an intravenous induction agent. Isoflurane has numerous advantages: it is chemically stable, nonflammable, and potent; induction is rapid, and muscle relaxation is adequate; and it is not dysrhythmogenic or toxic to the kidneys or liver. Isoflurane depresses the cardiovascular and respiratory systems. It is also contraindicated in patients with a history of malignant hyperthermia.

Desflurane

Desflurane, approved for clinical use in 1992, is the first volatile anesthetic agent whose blood/gas partition coefficient (0.42) compares favorably with that of nitrous oxide (0.47). The theoretic advantages desflurane should have regarding rapid induction and recovery of anesthesia are partially offset by the drug's tendency to irritate the airway during induction. Nevertheless, desflurane is particularly suited for ambulatory anesthesia and is commonly used for other situations in which an inhalation anesthetic is indicated. Also, the increased cost of desflurane is counterbalanced by the faster recovery of the patient.

Physical and chemical properties

Desflurane is chemically very similar to isoflurane, with only a single substitution of fluorine for a chlorine atom (see Figure 18-1). Desflurane shows marked chemical stability, possibly because of the additional fluorine, which provides resistance to breakdown in soda lime and to biotransformation. The anesthetic has a high vapor pressure of 664 mm Hg at 20° C, becomes a gas (vapor pressure 760 mm Hg) at 23° C, and is not flammable at concentrations less than 17%. The low potency and high volatility of desflurane requires the use of a heated vaporizer to enable the delivery of this agent.[13]

Anesthetic properties

The low solubility of desflurane in blood results in rapid onset, recovery, and adjustment of anesthetic depth, similar to that found with nitrous oxide.[31,102] A propensity to cause breath holding, coughing, and laryngospasm during mask induction precludes its routine use as a primary induction agent.

With a MAC of 6% (in middle-aged adults), desflurane is less potent than the other volatile agents. Its physiologic effects are similar, however, to those induced by isoflurane. The systemic vascular resistance, mean arterial blood pressure, and stroke volume are reduced, but the cardiac output is maintained by a progressive increase in heart rate.[97] As shown in Figure 18-3, discernible increases in heart rate occur as the anesthetic concentration exceeds 1.25 MAC. Similar to isoflurane, desflurane theoretically may cause coronary steal in hypotensive cardiac patients.[30] There is no significant sensitization of the myocardium to catecholamines. Desflurane causes a dose-related decrease in tidal volume and, despite an increase in the respiratory rate, a significant depression of minute ventilation. As with other halogenated ethers, respiratory depression is reduced if desflurane is used with nitrous oxide for anesthesia (see Figure 18-2).

Desflurane is contraindicated in patients susceptible to malignant hyperthermia because it can trigger the syndrome in the swine model and has been linked to malignant hyperthermia in the clinical setting. Because desflurane is notable for having minimal biotransformation, it has a very low likelihood for causing serious hepatotoxicity.[54]

Therapeutic uses

Despite its favorable blood/gas partition coefficient, desflurane is not indicated for the induction of anesthesia, especially in pediatric patients and patients with heart disease. When anesthesia has been achieved with other agents, desflurane may be administered for maintenance purposes. Desflurane then permits a more rapid control over the depth of anesthesia than other inhalation agents and a more rapid recovery, allowing for a more precise duration of general anesthesia.

Sevoflurane

First synthesized in the United States in 1968, sevoflurane became widely used in Japan in 1990 and available for clinical use in the United States in 1995. A pleasant odor, lack of airway irritation, and rapid onset of action make sevoflurane an attractive alternative to halothane for mask induction of anesthesia in pediatrics.[63]

Physical and chemical properties

Sevoflurane is characterized by a low blood/gas partition coefficient (0.65) and chemical stability under normal storage conditions. A potential drawback is the agent's reactivity to chemicals (e.g., soda lime) used as carbon dioxide absorbents.

Anesthetic properties

As would be expected, the low solubility of sevoflurane results in rapid onset, recovery, and adjustment of anesthetic depth. Similar to other volatile agents in current use, sevoflurane is relatively potent, with a MAC of 2%. Sevoflurane undergoes oxidative defluorination by the hepatic enzyme CYP2E1. This same enzyme may also be largely responsible for the degradation of isoflurane and desflurane.[30] The degree of biotransformation is approximately 2% to 3%, with plasma inorganic F^- concentrations similar to those previously found in patients with renal dysfunction after methoxyflurane anesthesia. However, plasma F^- declines much more rapidly with sevoflurane, a lack of renal metabolism precludes excessive formation of F^- in kidney cells, and there is no evidence of nephrotoxicity in humans.[20,37] Sevoflurane is not believed to be hepatotoxic because it is not broken down to yield the trifluoroacetyl halide metabolite.

The cardiovascular effects induced by sevoflurane are intermediate between those of halothane and isoflurane.[30,43] At 1 MAC, sevoflurane causes a decrease in cardiac output, peripheral vascular resistance, and arterial blood pressure. At greater than 1 MAC, further decreases in peripheral vascular resistance and myocardial contractility are partially offset by an increase in heart rate. Sevoflurane does not significantly sensitize the myocardium to catecholamines. There is a decrease in alveolar ventilation similar to that observed with isoflurane.

Therapeutic uses

Sevoflurane has the advantages of a rapid onset, good control over the depth of anesthesia, and a rapid recovery, as previ-

ously noted for desflurane. One important advantage of sevoflurane over desflurane is that it is much less irritating to the respiratory tract, which, combined with its rapid induction and maintenance of heart rate, makes it suitable for induction of anesthesia in children.[47,82] A potential drawback is that it breaks down in soda lime to compound A,[93,103] greatly limiting its potential use in low-flow systems with conventional carbon dioxide absorbers. This problem can be circumvented by avoiding low gas flows (<2 L/min) or by using specific carbon dioxide absorbents without this characteristic. One other drawback is the potential for emergence delirium when used in pediatric patients.[63]

INTRAVENOUS AGENTS

Intravenous agents are used widely in anesthesiology. Historically, their primary role was as induction agents for inhalation general anesthesia, for which they were usually administered as a single dose. In recent years, they also have been commonly used for maintenance in total intravenous anesthesia and for various modes of sedation, as described in Chapter 48. Total intravenous anesthesia has increased in popularity because of (1) the introduction of drugs combining rapid redistribution with shorter elimination half-lives, (2) freedom from the risk of malignant hyperthermia associated with volatile anesthetics, and (3) continued concern regarding occupational exposure to inhalation agents. For this technique, the drugs are ideally administered by continuous infusion, with intermittent boluses as needed to adjust the anesthetic depth rapidly.

The primary clinical advantage of intravenous agents is their rapid distribution into the vessel-rich group of tissues, which includes the brain. (Reduced cardiovascular depression is an additional advantage.) The rapid uptake into the CNS facilitates a rapid onset of action. The high lipid solubility of these drugs allows for a smooth and rapid induction. For most intravenous anesthetics, the termination of effect depends largely on redistribution of the drug out of the brain. Metabolic inactivation generally assumes a more central role when the agent is administered over an extended period. With the exception of the benzodiazepines and dexmedetomidine, these drugs can easily induce anesthesia, at which time maintenance may be carried out by either inhalation agents or continued infusion of the intravenous drug. Suggested ideal properties for an intravenous anesthetic drug are listed in Box 18-2.[42,98]

Although short-acting and ultrashort-acting barbiturates were previously widely administered to produce all modes of anesthesia and sedation, drugs from other classes are now used more frequently. These agents include various combinations of antianxiety drugs, opioids, and anesthetics such as propofol and ketamine. The relatively short action of most of these drugs and their relative freedom from emetic properties (except for opioids and ketamine) make their use especially suited for sedation or general anesthesia in dentistry. The basic pharmacologic features of many intravenous agents are discussed elsewhere in this book, and a more complete review of their use in the control of fear and anxiety for the dental patient is provided in Chapter 48.

Barbiturates

Ultrashort-acting barbiturates were the first drugs widely adopted as intravenous anesthetics. Much of what is known about intravenous anesthesia was developed through their use. Barbiturates available for this purpose include thiopental and methohexital. The use of both drugs has greatly diminished since the introduction of propofol, described subsequently.

Thiopental

Thiopental, the thiobarbiturate analogue of pentobarbital, is the most commonly used intravenous barbiturate in medicine and is prototypic of the group. Its molecular structure is depicted in Figure 18-1.

Physical and chemical properties. Thiopental, a weak acid (pK_a 7.4), is available as the sodium salt. When reconstituted for injection, the solution is buffered to a pH of 10 to 11. When injected, the alkalinity is neutralized, and approximately half the drug converts to the highly lipophilic free acid. Because of their high lipid solubility, the ultrashort-acting barbiturates have the ability to penetrate all tissues after injection. The amount of drug entering a given tissue primarily depends on the regional blood flow. How this property influences tissue uptake is illustrated in Figure 2-9. The vessel-rich group of tissues, which includes the brain, receives the highest proportion of the cardiac output relative to tissue mass and attains the highest concentration of thiopental. Later, as the agent is redistributed to more poorly perfused tissues, such as muscle and then fat, a progressive decline in the blood and brain concentrations occurs. With a redistributional half-life of 4.6 to 8.5 minutes, the concentration of thiopental in the CNS diminishes from the peak value at 1 minute to less than 10% at 30 minutes. Thiopental is biotransformed in the liver to inactive products; only 1% is eliminated unchanged by the kidney. The mean metabolic half-life in adults is 11.6 hours but may exceed 24 hours in obese patients and in late preg-

BOX **18-2**

Characteristics of an Ideal Intravenous Anesthetic Agent

PHYSICAL PROPERTIES	PHARMACOKINETIC PROPERTIES	PHARMACODYNAMIC PROPERTIES
Soluble in water	Rapid onset of action	Reliable induction of anesthesia
Stable in solution	Ability to titrate	Anxiolytic at subanesthetic doses
Stable to light exposure	Predictable duration of effect	Analgesic at subanesthetic doses
Absence of pain on injection	Short duration of effect	Amnestic at subanesthetic doses
No local irritation	Short elimination half-life	Antinauseant at subanesthetic doses
Long shelf life	Rapid recovery	Minimal respiratory effects
	Rapid biotransformation	Minimal cardiovascular effects
	Inactive metabolites	No effects on other systems
	Nontoxic metabolites	High therapeutic index
		Small interindividual variation
		No allergy

nancy.[48] Thiopental is approximately 80% bound to plasma proteins.

Anesthetic properties. Thiopental is primarily an induction agent, although it may also be used for maintenance in short surgical procedures or to treat seizures or elevated intracranial pressure. Induction is smooth and rapid, with the patient losing consciousness within seconds after a rapid bolus intravenous injection. Generally, however, induction is accomplished by administering the drug over a 30-second period, after which inhalation anesthesia is initiated. After a single dose, the patient regains consciousness in 10 to 20 minutes. Repeated doses required for extended anesthesia may cause cumulative effects and a prolonged recovery period (see Figure 2-18).

Cardiovascular Effects. Induction doses in a normovolemic patient decrease blood pressure by 10 mm Hg to 20 mm Hg, followed by a reflex increase in heart rate of 15 to 20 beats/min. Selective venodilation is largely responsible for the hypotension; total peripheral resistance remains unchanged, and myocardial depression is modest. After high doses, there is a more marked depressant effect on the cardiovascular system, which reduces blood pressure and may alter the redistribution pattern of the drug. Profound hypotension and cardiac arrest may occur during induction of anesthesia in a hypovolemic or septic patient. Extra caution with elderly patients is warranted to avoid cardiovascular collapse. Intraoperatively, heart rate and blood pressure may increase as a result of painful stimuli, partly because the barbiturates are hyperalgesic. Thiopental is not inherently dysrhythmogenic.

Respiratory Effects. Respiratory depression occurs in a dose-dependent manner and accounts for the major toxic effects of the barbiturates. Tidal volume is decreased, respiratory rate is usually depressed, and patients are predisposed to apnea, especially if other respiratory depressants are coadministered. Coughing, laryngospasm, and bronchospasm may develop as a result of irritation from premature manipulation of the airway or insertion of an endotracheal tube. Histamine release and increased sensitivity of the pharynx to stimulation may contribute to these adverse effects, although barbiturates are considered to be safe in patients with asthma.

Other Effects. Thiopental is hyperalgesic at subanesthetic doses and may necessitate concurrent use of an analgesic. Cerebral blood flow is decreased as a result of a reduction in mean arterial pressure. Cerebral metabolic rate and intracranial pressure are decreased as well. Thiopental is an anticonvulsant.

Therapeutic uses. The usual induction doses are approximately 4 mg/kg for adults and 6 mg/kg in infants. Thiopental is irritating to tissue, so care must be taken to prevent intra-arterial injection or extravasation, either of which may result in tissue necrosis. The high alkalinity of the solution and the chemical nature of the drug itself are responsible for this effect. Intra-arterial injection may cause intense vasospasm. As with all barbiturates, thiopental is contraindicated in patients with certain forms of porphyria (acute intermittent, variegate, and hereditary coproporphyria types).[51] The drug should be used cautiously in elderly patients and in patients with acute asthma, congestive heart failure, and shock states. Although thiopental is able to induce the synthesis of several important microsomal enzymes, it is unlikely that single induction doses would result in clinically significant drug interactions.

Methohexital

Methohexital, a methylated barbiturate, is used less commonly than thiopental for the induction of general anesthesia in hospital operating rooms, but has been used more widely for anesthesia in dentistry. The two drugs are similar except that methohexital is 2.5 times more potent, has a shorter half-life in distribution and elimination, and has a shorter duration of action. The sleep time after a single dose is 5 to 7 minutes, and the mean elimination half-life is 3.9 hours. Methohexital is biotransformed in the liver, with a clearance rate three times greater than that of thiopental.[48] Excitatory phenomena, such as hiccoughs, spontaneous movements, and seizures, occur more frequently than with other barbiturates used clinically. These excitatory phenomena represent the primary disadvantage of methohexital. Methohexital does not induce histamine release. Although it is more likely than thiopental to cause pain on intravenous injection, methohexital in a 1% concentration is much less damaging after intra-arterial injection or extravasation into local tissues. Its primary advantage is the rapid recovery and lower cumulative effect compared with thiopental, making it more suitable for outpatient procedures. Methohexital also is much more stable when reconstituted with sterile water; a 1% solution can be stored at room temperature and used for 6 weeks (versus 1 week for thiopental when refrigerated). Manufacturers state that unused reconstituted drug should be discarded after 24 hours, however, to avoid concerns about loss of sterility.

Propofol

Propofol (2,6-diisopropylphenol) is unrelated to any other general anesthetic. Its structure is illustrated in Figure 18-1. Propofol is formulated in an oil-in-water emulsion containing soybean oil, glycerol, and egg lecithin.

Anesthetic properties. Clinically, the pharmacokinetic properties of propofol include a rapid onset of action; an initial distributional half-life of 1 to 8 minutes, which results in an extremely short duration of action; and a terminal elimination half-life reported to be as short as 2 hours. It is extensively conjugated in the liver to inactive glucuronide and sulfate metabolites, with less than 0.3% of an administered dose appearing in the urine as the unchanged drug. Propofol's extensive plasma (98%) and tissue protein binding contributes partly to an enormous steady-state volume of distribution of 2 L/kg to 12 L/kg.[90] The clearance of propofol exceeds the hepatic blood flow, implying that continued tissue uptake and extrahepatic metabolism are factors in its removal from the blood.[85] After a continuous 10-day infusion of propofol that produces tissue saturation, the volume of distribution approaches 60 L/kg with a metabolic half-life of 1 to 3 days. After bolus administration, the plasma concentrations of propofol and thiopental are similar initially, but propofol subsequently disappears from the bloodstream more rapidly.[90]

Cardiovascular Effects. Propofol can depress mean arterial pressures by 20% to 30% without eliciting a reflex increase in heart rate. This finding may be attributed to the drug's ability to decrease myocardial contractility, to dilate the peripheral vasculature, to depress baroreflex activity, and possibly to inhibit the sympathetic nervous system.[84] Effects on cardiac output vary, depending on the $Paco_2$. Clinically, these hemodynamic effects are transient and rarely require pharmacologic correction.[49] The cardiovascular effects are well tolerated in healthy patients, but significant hypotension may ensue in elderly patients, hypovolemic patients, or patients with limited cardiac reserve.[90]

Respiratory Effects. Apnea is the most significant respiratory effect of propofol, with a reported incidence varying from 22% to 45% after an induction dose. Other respiratory effects include decreased sensitivity to carbon dioxide, decreased laryngeal reflexes, and decreased functional residual capacity.

Propofol does not release histamine and generally is safe for use in asthmatic patients.

Other Effects. Propofol decreases cerebral blood flow, cerebral metabolic rate and oxygen consumption, and intracranial pressure. Although it is believed to have anticonvulsant properties,[6] there are reports of grand mal seizures, opisthotonus (spasm of back muscles inducing an arched back and hyperextension of the neck), and unusual muscle activity with propofol.[34,83] The drug should be administered cautiously to epileptic patients. The most common adverse reaction is pain on injection, which is noted more frequently when propofol is administered in the small veins on the dorsum of the hand. The incidence of pain may be reduced by using larger veins (e.g., antecubital veins), diluting the drug with a rapidly flowing intravenous line, or mixing the drug with lidocaine. Propofol is associated with less postoperative nausea and vomiting compared with inhalation anesthetics, and it has antiemetic properties in low doses.[90] Propofol may have antipruritic properties.[6] There is no analgesic effect.

Therapeutic uses. Propofol's major advantage is its extremely rapid recovery in patients.[2] In addition to induction, propofol can be used for maintenance of general anesthesia or for intravenous sedation. The dose for induction is 2 mg/kg to 2.5 mg/kg. For total intravenous anesthesia, a maintenance infusion rate of 50 μg/kg/min to 300 μg/kg/min is recommended, depending on the age and health of the patient. If used alone, a dose of 25 μg/kg/min to 75 μg/kg/min should maintain moderate sedation in healthy adults after an initial infusion of 100 μg/kg/min to 150 μg/kg/min for 3 to 5 minutes. Doses must be reduced in elderly patients, debilitated patients, and when propofol is used with other CNS depressants. An allergy history to any of the emulsion constituents (e.g., soybeans) potentially contraindicates the use of propofol. Because the soybean vehicle is an excellent bacterial culture medium, strict antiseptic technique should be used when administering propofol, and any unused portion should be discarded after 6 hours.

Infusion of propofol is also used long-term in intensive care units to provide sedation. A rare syndrome has been described when propofol is administered in high doses (>4 mg/kg/hr) for long durations (≥48 hours). This potentially fatal "propofol infusion syndrome" involves only critically ill patients,[52] primarily children.[8] The main features of this syndrome include acidosis, bradyarrhythmia, and rhabdomyolysis of cardiac and skeletal muscle, signs that mimic mitochondrial myopathies.[99] The use of propofol in lower doses or shorter durations has not been associated with these outcomes.

Ketamine

Ketamine, a relative of the psychedelic drug phencyclidine (PCP, angel dust), produces a unique state known as dissociative anesthesia, which is characterized by profound analgesia, amnesia, and catalepsy.[98] This excitatory state is quite different from that seen after administration of other general anesthetic agents previously discussed. It has been suggested that this dissociative state is a result of a functional and electrophysiologic dissociation between the thalamoneocortical and limbic systems. In this state, it is believed that the brain fails to transduce correctly afferent impulses because of disruption in normal communications between the sensory cortex and the association areas. The molecular structure of ketamine is shown in Figure 18-1.

Ketamine is an antagonist of the N-methyl-D-aspartate (NMDA) class of glutamate receptors, which is largely responsible for its anesthetic and behavioral effects.[57] NMDA inhibition produces catalepsy, consistent with the effect of ketamine administration. Ketamine also produces profound analgesia, which seems to be at least partially mediated by μ opioid receptors, in addition to its binding to the phencyclidine binding site on the NMDA receptor.[88]

Anesthetic properties. The onset of action and peak plasma concentrations occur within 1 minute after intravenous administration, 5 to 15 minutes after intramuscular injection, and 30 minutes after oral ingestion. The distributional half-life ranges from 11 to 16 minutes, and the elimination half-life is 2 to 3 hours. Ketamine is highly lipid-soluble, and little binds to plasma proteins (12%), which facilitates rapid transfer across the blood-brain barrier. The duration of anesthesia is about 5 to 10 minutes after a bolus intravenous infusion and 10 to 20 minutes after intramuscular injection. The dissociative state resembles catalepsy, in which the eyes may remain open with slow nystagmus and intact corneal and pupillary reflexes. Most protective reflexes are maintained. Varying degrees of skeletal muscle hypertonus may be present, along with nonpurposeful skeletal muscle movements that are independent of surgical stimulation.

Cardiovascular Effects. Ketamine differs from most anesthetic agents in that, in a normal patient, it stimulates the cardiovascular system, producing increases in heart rate, cardiac output, and blood pressure.[42] The mechanism for this effect is not well understood because ketamine can depress myocardial contractility directly and enhance vasodilation. Ketamine's induction of central sympathetic stimulation and its ability to inhibit catecholamine uptake usually overrides the negative inotropism.[65] Its ability to maintain arterial blood pressure is useful in hypovolemic patients and patients in cardiogenic shock.

Caution should be used when ketamine is administered to critically ill patients or patients who have chemical-induced or trauma-induced sympathectomy, in which case it may lead to myocardial depression and cardiovascular collapse. Ketamine increases pulmonary vascular resistance and may exacerbate pulmonary hypertension or cor pulmonale. The sympathomimetic and cardiovascular stimulating effects contraindicate the use of ketamine in patients in whom an elevation of blood pressure or heart rate should be avoided, such as patients with cerebrovascular accident, significant hypertension, or advanced ischemic heart disease.

Respiratory Effects. Compared with other anesthetic agents, ketamine seems to be unique in its ability to maintain functional residual capacity on induction of anesthesia,[87] decreasing the chances of intraoperative hypoxemia.[38] During ketamine anesthesia in spontaneously breathing patients, the minute ventilation may be maintained at the same level as in the awake state.[95] Ventilatory responses to hypercarbia and airway reflexes seem to be preserved. Ketamine has other beneficial effects on the respiratory apparatus, including increased lung compliance and decreased airway resistance. Ketamine is safe for asthmatic patients because it causes bronchodilation and does not induce histamine release. Ketamine is a potent stimulator of salivary and tracheobronchial secretions, however, and antimuscarinics are often administered concurrently.

Other Effects. In doses less than those used to induce general anesthesia, ketamine may produce sedation, analgesia, and amnesia. Excitatory activity in the thalamus and limbic systems, without clinical evidence of seizure activity, has been recorded. This electrical activity does not seem to spread to the cortex, and ketamine has been shown to have anticonvulsant properties.[78] Ketamine strongly dilates cerebral blood vessels, increasing cerebral blood flow by 60% to 80%, which increases intracranial pressure in patients with compromised intracranial compliance.

Emergence phenomena have been the most frequently reported adverse effects of ketamine. These reactions, occuring in <5% of patients in some studies and >30% of patients in others, include a feeling of floating, vivid dreams, hallucinations, and delirium. The incidence is related to the dose and rate of drug administration and is reduced when benzodiazepines are administered concomitantly.[58] The frequency of emergence delirium is less in children than in adults.

Therapeutic uses. Ketamine may be administered by the intravenous, intramuscular, oral, and rectal routes. Induction of anesthesia may be achieved typically by an intravenous dose of 1 mg/kg to 2 mg/kg or intramuscularly at a dose of 4 mg/kg to 6 mg/kg. Intramuscular injection may be necessary when a patient is unable to cooperate. Anesthesia can be maintained by repeated injections or by using a continuous infusion, the latter in a dose of 15 μg/kg/min to 90 μg/kg/min. Smaller doses or infusion rates are useful for sedation and analgesia. Ketamine is safe for use in malignant hyperthermia patients, although it may induce some signs (e.g., muscle rigidity, tachycardia) that mimic the early stages of a crisis. Ketamine is usually administered with drugs such as midazolam or propofol to reduce the incidence of untoward excitatory effects.

Etomidate

Etomidate, a carboxylated imidazole derivative, is chemically and pharmacologically unrelated to other intravenous anesthetics. Its pharmacokinetic profile is similar, however, to that of thiopental. Onset of anesthesia is rapid, and the duration of action is brief after conventional doses.

Etomidate is believed to modulate the action of the inhibitory neurotransmitter γ-aminobutyric acid (GABA) on $GABA_A$ receptors. The amplitude and duration of inhibitory currents are increased. Etomidate has the advantages over thiopental of causing only mild respiratory depression and little effect on the cardiovascular system. Induction doses of 0.3 mg/kg elicit a mild (15%) decrease in total peripheral resistance, which is mirrored by similar decrements in cardiac output and myocardial oxygen consumption. Coronary blood flow is mildly increased. Nevertheless, this drug is noted for its cardiovascular stability. Several significant liabilities limit the use of etomidate, however. The drug inhibits adrenocorticosteroid synthesis after prolonged administration; causes severe pain on injection in up to 50% of patients; and is associated with a high incidence of nausea and vomiting, thrombophlebitis, involuntary myoclonic movements, hypertonus, and hiccough. These adverse events have greatly limited the clinical application of etomidate for general anesthesia to the small group of patients who require the cardiovascular stability afforded by it.

Dexmedetomidine

Serendipitous findings that clonidine, an α_2-adrenoceptor agonist used to treat hypertension (see Chapters 6 and 28), significantly reduces the MAC of inhalation anesthetics and produces significant analgesia independently of the opioid system generated attempts to develop congeners for use as sedatives and anesthetic adjuncts. The first successful outcome of this effort was dexmedetomidine, approved by the U.S. Food and Drug Administration (FDA) in 1999 for sedation of initially intubated and mechanically ventilated patients in the intensive care unit. Administration is usually initiated with a loading infusion of 1 μg/kg for the first 10 minutes, followed by a maintenance infusion of 0.2 μg/kg/hr to 0.7 μg/kg/hr. In 2008, dexmedetomidine was approved for preoperative and intraoperative sedation of nonintubated patients.

Structurally similar to etomidate (see Figure 18-1), dexmedetomidine is approximately seven times more selective than clonidine for the α_2-adrenergic receptor. Stimulation of the α_{2A}-adrenoceptor subtype in the nucleus tractus solitarius and locus coeruleus of the brainstem reduces sympathetic outflow and elicits sedation. Similarly, release of excitatory neurotransmitters by nociceptive afferent axons in the dorsal horn is inhibited, reducing pain. Activation of α_{2A}-adrenoceptors by dexmedetomidine facilitates K^+ efflux through inwardly rectifying K^+ channels, depresses a slow depolarizing current termed *Ih*, and inhibits voltage-gated Ca^{++} channels in affected neurons.[16,86]

Dexmedetomidine has several pharmacokinetic advantages over clonidine. After bolus injection, dexmedetomidine displays a distributional half-life of about 6 minutes (versus 11 minutes for clonidine) and an elimination half-life of 2 hours (versus 9 hours for clonidine). The drug is completely transformed to inactive metabolites in the liver, most of which are excreted in the urine. A significant range in context-sensitive half-times exists, with values ranging from 4 minutes after a 10-minute infusion to 4 hours after an 8-hour infusion.

Clinically, dexmedetomidine is remarkable for its ability to produce a natural sleep from which the patient can be easily aroused. The sedation is characterized by anxiolysis, profound analgesia, blunting of cardiovascular responses to stress, and freedom from respiratory depression. Although intravenous injection initially can cause a transient increase in peripheral vascular resistance and arterial blood pressure by stimulating vascular α_2 receptors, the subsequent response is a decrease in blood pressure and heart rate in response to the centrally mediated sympatholytic and vagal-stimulating effects. Cardiovascular responses are minimized by slow infusion of low doses. The most common side effects of dexmedetomidine in approved doses are hypotension, bradycardia, and xerostomia. Large, accidental overdoses may produce significant vasoconstriction, profound bradycardia, and decreases in cardiac output possibly leading to cardiovascular collapse. The potential for cardiovascular derangements precludes the use of dexmedetomidine as a sole agent for general anesthesia, and the delayed recovery after prolonged infusions limits its use in outpatient surgery to short procedures. The development of atipamezole, a selective α_2-adrenoceptor antagonist used to reverse the effects of dexmedetomidine in veterinary medicine, suggests that such agents may become available to terminate the effects of dexmedetomidine in humans.[73]

Benzodiazepines

Benzodiazepines have enjoyed widespread use as adjuncts to general anesthesia, as induction agents in patients with serious cardiovascular abnormalities, and as agents for all levels of sedation. Their pharmacologic advantages have given them a major role in the management of fear and anxiety in dentistry (see Chapter 48). As described in Chapter 13, all benzodiazepines are capable of producing in varying degrees anxiolysis, sedation, anterograde amnesia, skeletal muscle relaxation, and anticonvulsant activity. There is minimal depression of the cardiovascular and respiratory systems when benzodiazepines are administered alone in therapeutic doses, reflecting the fact that benzodiazepines have a wide safety margin in the absence of interacting drugs.[76] These agents are useful for their ability to attenuate the stress response and associated catecholamine release.[26]

Although all benzodiazepines share similar pharmacodynamic effects, they are differentiated by their pharmacokinetic characteristics. The agents most commonly used in anesthesia and dentistry are diazepam, midazolam, triazolam, and lorazepam. Although rarely used alone for general anesthesia because they lack analgesic properties and may be insufficient to induce or maintain general anesthesia in some

patients, benzodiazepines are routinely used with other agents in balanced anesthesia for their superior sedative and amnestic effects and relative freedom from cardiovascular depression.

Diazepam

Diazepam, the prototypic benzodiazepine, has had a long and successful history of use as an agent for sedation when administered orally or intravenously. In recent years, diazepam has been superseded by other oral and parenteral benzodiazepines considered to have superior properties. Diazepam is classified as a long-acting agent, with an elimination half-life that increases from 20 to 70 hours in rough concert with the patient's age. A high lipid solubility means that diazepam is taken up by adipose tissue, which may cause postanesthesia drowsiness as the drug is slowly released from fat. Nevertheless, the drug is relatively short acting when used in a single dose. The duration of effect of an intravenous injection of diazepam is approximately 1 hour, similar to that of the short-acting midazolam. Diazepam has a rapid onset of action (<1 minute intravenously), with a distributional half-life of 10 to 15 minutes. Peak plasma concentrations are achieved in 30 to 120 minutes when the drug is given orally.

Intramuscular administration does not significantly improve absorption. Diazepam is not water soluble; in the United States it is solubilized with propylene glycol, which predisposes to phlebitis when the formulation is administered intravenously into small-caliber veins. Propylene glycol also contributes to the delayed and variable absorption from intramuscular sites. An emulsion of diazepam in soybean oil, glycerol, and various lipids is available outside the United States that minimizes these problems.

Although efficacious, diazepam's drawbacks are the long elimination half-life, active metabolites, and common formulation in an irritating vehicle for parenteral administration. For induction of general anesthesia, intravenous doses of 0.3 mg/kg to 0.5 mg/kg are appropriate.

Midazolam

Midazolam, the first water-soluble benzodiazepine, is prepared in an aqueous vehicle buffered to a pH of 3.5. Below a pH of 4, the benzodiazepine ring is open, making the molecule highly polar. Above a pH of 4, as is found physiologically, the ring closes, making midazolam very lipid-soluble and leading to a rapid onset of action. This pharmaceutical sleight of hand eliminates the problem of thrombophlebitis on intravenous administration and improves uptake after intramuscular administration, both important advantages over diazepam. Midazolam is biotransformed into metabolites with no significant activity (although they may contribute sedative effects after oral administration), another advantage over diazepam.

Midazolam is classified as a short-acting agent because its elimination half-life is approximately 1.7 to 2.6 hours in young adults. Cimetidine, erythromycin, and other CYP3A4 enzyme inhibitors may slow intestinal and hepatic biotransformation, resulting in higher-than-expected midazolam concentrations in the plasma after oral administration and prolonged drug effects with all routes of administration. Of special interest to dentistry, interactions between oral midazolam and erythromycin leading to oversedation have been reported.[45,72] The usual intravenous dose for induction of general anesthesia is 0.2 mg/kg, but in common practice midazolam is usually provided as an anxiolytic premedication, or as an adjunctive agent to smooth the overall process.

Lorazepam

Lorazepam is classified as an intermediate-acting benzodiazepine, but its effects after a single administration last considerably longer than for other benzodiazepines used in anesthesia. The drug is most useful as an oral or parenteral premedicant, where its slow onset of action is not a significant problem. The usual induction dose is 0.1 mg/kg.

Triazolam

Triazolam has effective anxiolytic, hypnotic, and amnestic properties, with a rapid onset of action after oral use that peaks within 90 minutes. The drug has a short elimination half-life of 1.5 to 5.5 hours, and it is converted into inactive metabolites. CYP3A4 inhibitors may block hepatic biotransformation, resulting in higher than expected plasma concentrations. Triazolam is available only for oral use.

Opioids

The opioid analgesics play a major role in facilitating the delivery of general anesthesia and sedation, primarily as adjuncts used in combination with other agents. They also have a role as regional analgesics when administered as part of an epidural or spinal anesthetic. As described in more detail in Chapter 20, all opioids share the properties of analgesia; sedation; mood alteration; and the potential for tolerance, physical dependence, and addiction. Their antitussive effect may be valuable in the immediate postoperative period or for procedures such as bronchoscopy. Nausea and vomiting are common adverse effects and are characteristically exacerbated if the patient is ambulatory. Opioids decrease the MAC of inhalation anesthetics.

An important action is respiratory depression caused by a dose-dependent decrease in the response of the medullary respiratory center to carbon dioxide. High doses can totally block spontaneous respiration, sometimes without inducing unconsciousness. In susceptible patients, this effect may be seen in low to medium doses. Clinically, the respiratory depression manifests as a decrease in the breathing rate, with an overall decrease in minute ventilation and a compensatory increase in tidal volume. The $Paco_2$ is elevated in a dose-dependent manner. Because of these respiratory effects, opioids must be administered with extreme caution to patients with respiratory disorders, such as chronic obstructive pulmonary disease.

Specific sedation techniques with opioids are discussed in more detail in Chapter 48. Opioid doses should be reduced in elderly patients, in patients with preexisting respiratory disease, and in patients with significant hepatic disease. Several drugs, most notably sufentanil, may be used as primary agents for cardiac anesthesia. Their cardiac stability is attributable to a lack of negative inotropic effects. The anesthetic properties of individual opioids used for anesthesia and sedation are discussed next.

Morphine

Morphine, the prototypic opioid analgesic, has been widely used as an adjunct to general anesthesia. It has been administered by numerous techniques, including high doses with oxygen or as a supplement to inhalation agents, to obtain profound analgesia. When used as an adjunct to general anesthesia, the recommended dose of morphine is 0.1 mg/kg intravenously. Because of advantages (discussed subsequently) found in the newer opioids, many centers favor these other medications over morphine when used during general anesthesia. Morphine still has wide acceptance, however, as an inexpensive choice for analgesia during general anesthesia.

Anesthetic properties. Peak action after intravenous administration takes ≥20 minutes (Table 18-3). This delay reflects morphine's poor lipid solubility and limited ability to cross the blood-brain barrier.

Cardiovascular Effects. Morphine exerts little direct effect on cardiovascular function. This discovery led to the use of morphine for a time as a primary anesthetic for patients with

TABLE **18-3**

Comparison of Opioids Used for Sedation/Anesthesia

DRUG (PROPRIETARY [TRADE] NAME)	EQUIPOTENT DOSE (mg)	TIME TO PEAK ANALGESIC EFFECT (min)	DURATION OF ANALGESIA	PROTEIN BINDING (%)	ELIMINATION HALF-LIFE (hr)
Morphine	10	20	4-5 hr	30	2-3
Meperidine (Demerol)	80	5-7	2-4 hr	60	2.5-4
Fentanyl (Sublimaze)	0.1	3-5	30-60 min	85	3-4
Alfentanil (Alfenta)	0.7	1-2	10-15 min	92	1-2
Sufentanil (Sufenta)	0.015	3-5	15-30 min	93	2-3
Remifentanil (Ultiva)	0.05	1-2	5-10 min	70	0.05-0.1
Pentazocine (Talwin)	60	15-30	2-3 hr	65	2-3
Nalbuphine (Nubain)	10	30	3-4 hr	50	2-5
Butorphanol (Stadol)	2	30	2-4 hr	80	2.5-4

significant cardiovascular disease. High doses, such as 1 mg/kg, significantly decrease systemic vascular resistance and mean arterial pressure, however, predisposing the patient to orthostatic hypotension. Hypotension may also result from morphine-induced histamine release, bradycardia, or a sympatholytic action. Bradycardia is believed to be caused by stimulation of the vagal nuclei in the brainstem. There may also be a direct depressant effect at the sinoatrial node of the heart. The hypotensive actions of morphine lead to an increased requirement for fluid administration. In combination with nitrous oxide, morphine administration can result in cardiovascular depression, decreased cardiac output, and hypotension.

Respiratory Effects. The maximum respiratory depression from morphine occurs approximately 30 minutes after intravenous injection. Increased intracranial pressure may also result because of hypercarbia. Morphine should not be used in patients for whom increased intracranial pressure is a concern, such as patients with an intracranial lesion or traumatic head injury.

Other Effects. Emesis is a result of direct stimulation of the chemoreceptor trigger zone. There is also decreased gastrointestinal motility and increased secretions (which contributes to the direct emetic effect). Sphincter tone is increased, which in the case of the sphincter of Oddi (which controls the bile duct flow into the duodenum) can lead to increased bile pressure and epigastric distress that may mimic anginal pain.

Therapeutic uses

Precautions apply to asthmatic patients because of the histamine release and cough suppression. The same precautions are relevant to patients with a history of chronic obstructive pulmonary disease or other causes of decreased respiratory reserve. As with the administration of all opioids, severely ill or elderly patients are generally more susceptible to the depressant effects of morphine. Chest wall rigidity has been reported and tends to occur when morphine is administered rapidly and in combination with nitrous oxide.

Meperidine

For many years, meperidine was the most widely used opioid for outpatient sedation and anesthesia in dentistry. This synthetic opioid has approximately one tenth the potency of morphine and has atropine-like properties in addition to its opioid agonist effects. The vagolytic actions may result in a decrease in upper respiratory tract secretions and an increase in heart rate, although these effects are minimal in the usual doses administered for sedation. At equianalgesic doses, meperidine has the same effects as morphine except that it differs from morphine in having a shorter duration of action, more complex biotransformation, and greater lipid solubility. Meperidine has a high hepatic extraction ratio, leading to a strong first-pass effect if the drug is administered orally.

Cardiovascular effects of meperidine administration include hypotension caused by a direct negative inotropism, decreased systemic vascular resistance, and decreased venous return. Orthostatic hypotension is commonly seen because of interference with compensatory sympathetic reflexes. As with morphine, meperidine is contraindicated when histamine release or increased intracranial pressure is undesirable and when decreased respiratory reserve exists.

Meperidine is biotransformed into several metabolites. One of them, normeperidine, has a long elimination half-life, can accumulate, and has been associated with CNS toxicity. The adverse reaction manifests as excitation, including agitation, seizures, and hallucinations, particularly in patients with hepatic and renal disease.

Exaggerated toxic responses to meperidine are especially likely in patients concurrently taking monoamine oxidase (MAO) inhibitors or amphetamines. Potential interactions between meperidine and amphetamines include increased risk of hypotension, possibly leading to cardiovascular collapse, severe respiratory depression, and convulsions. Potential interactions between meperidine and MAO inhibitors can be similar but are particularly characterized by unpredictable excitatory effects such as seizures, delirium, rigidity, coma, and hypertension leading to cardiovascular collapse. Meperidine is contraindicated in patients having taken an MAO inhibitor within the past 3 weeks. The ability of meperidine to increase 5-hydroxytryptamine concentrations at serotonergic synapses within the CNS has also led to concerns about interactions regarding serotonin reuptake inhibitors, such as fluoxetine, paroxetine, sertraline, venlafaxine, citalopram, and others.

Fentanyl

The synthetic opioid agonist fentanyl is approximately 100 times as potent as morphine and is characterized by a rapid onset and short duration of action after a single dose. It is most commonly administered intravenously but may be given intramuscularly, transmucosally in the oral cavity, and, for chronic pain, transdermally. Fentanyl's high lipid solubility contributes to its rapid onset because it readily crosses the blood-brain barrier. It also contributes to rapid redistribution and significant accumulation in peripheral tissues. The subsequent slow release of fentanyl from muscle and fat lengthens the terminal half-life to beyond that of morphine. (See Figure 2-18 for an illustration of the influence of infusion duration

on the plasma half-life of fentanyl.) Histamine is not released, which makes it preferable in patients predisposed to bronchospasm.

Intravenous doses of less than 10 μg/kg can be given as an adjunct to volatile agents in general anesthesia to minimize cardiovascular responses to specific stimuli such as pain, anxiety, or endotracheal intubation. Doses of 50 μg/kg to 150 μg/kg have been used alone to produce general anesthesia. These large doses are used because of the hemodynamic stability as a result of the lack of direct myocardial depression, absence of histamine release, and suppression of stress responses to surgery. Rapid administration of fentanyl is associated with bradycardia, an event more common in children. It is a potent respiratory depressant, but this lasts only 5 to 15 minutes if doses less than 100 μg are given. Chest wall rigidity has been reported but is unlikely to occur if fentanyl is administered at a rate of 1 μg/kg/min or less. The incidence of nausea is reported to be less than with morphine or meperidine.

Alfentanil

An analogue of fentanyl, alfentanil is 5 to 10 times less potent and is characterized by a rapid elimination half-life. This property contributes to a duration of action that is much shorter than that of fentanyl after prolonged infusion. Alfentanil has an especially rapid onset of action because of its low pK_a causing most of the drug to be uncharged at plasma pH. The drug can be used for induction of anesthesia after bolus administration and maintenance by infusion. For bolus administration, recovery is more rapid than with fentanyl or sufentanil, whereas no significant differences occur with short infusions. Because alfentanil is not prone to significant accumulation after continuous infusion, it is an opioid of choice for total intravenous anesthesia in the outpatient setting.

Sufentanil

Sufentanil is 5 to 10 times as potent as fentanyl and has a more rapid recovery after prolonged intravenous infusion. It is more lipid-soluble than fentanyl but has a smaller volume of distribution and a shorter elimination half-life. Cardiovascular effects are similar to effects found with fentanyl; however, sufentanil produces better hemodynamic stability during cardiac anesthesia and exhibits a more favorable ratio of analgesia to respiratory depression. Histamine is not released. High doses of sufentanil may reduce the dose of neuromuscular blocker required. As with fentanyl and alfentanil, sufentanil can be used for induction of anesthesia after bolus administration and maintenance by infusion.

Remifentanil

Remifentanil is also an opioid agonist used as an adjunct in general anesthesia. It is structurally unique because it contains ester linkages, which lead to distinctive pharmacokinetic characteristics. Compared with fentanyl, remifentanil has a more rapid onset and offset of action. Entry into brain tissue is hastened by a comparatively high percentage of drug in the nonionized state. The ultrashort duration of action is not caused by redistribution of the drug but by its unique metabolic inactivation by nonspecific esterases in the blood and tissue. A small volume of distribution also helps to hasten metabolism. One of the most notable characteristics of remifentanil is its invariant context-sensitive half-life, which approximates 3 to 4 minutes regardless of the duration of infusion.[53] The drug is almost always given by intravenous infusion because less controlled administration results in unstable effects and easily leads to chest wall rigidity or respiratory depression or both. Addition of remifentanil to a propofol infusion has been shown to provide a more rapid recovery and reduced use of propofol.[61]

Opioid agonist-antagonists

Opioid agonist-antagonists are sometimes used for anesthesia and sedation in lieu of pure opioid agonists. Although the analgesic and respiratory depressant effects of the agonist-antagonists are similar to the effects of morphine and other agonists in conventional doses, a ceiling effect occurs as the dose is increased. These drugs are not indicated as replacements for high-dose opioids as used in open-heart surgery. Pentazocine, butorphanol, and nalbuphine all have been administered for outpatient sedation procedures.

Pentazocine depresses myocardial contractility, but myocardial oxygen demand is greater than normal because of increases in peripheral resistance, systolic blood pressure, and plasma catecholamines. Although the antagonist action of pentazocine is weak, it is sufficient to precipitate opioid withdrawal reactions in physically dependent individuals. Adverse reactions include a potential for psychotomimetic effects, such as disorientation, confusion, depression, hallucinations, and dysphoria. Doses that produce sedation have also been associated with diaphoresis and dizziness. Butorphanol shares many of the cardiovascular and psychotomimetic side effects of pentazocine, although it is less likely to precipitate withdrawal in an opioid-dependent individual. Nalbuphine is a strong μ receptor antagonist, but it does not increase blood pressure or heart rate, which makes it the agonist-antagonist of choice in patients with cardiac disease. The strong ability of nalbuphine to reverse the sedative and analgesic effects of pure opioids can lead to marked and potentially dangerous withdrawal reactions in patients dependent on opioids.

Other Agents Used for Sedation

Numerous drugs described elsewhere in this book have application in sedation. They are summarized next, and details of their application in sedation for dentistry are included in Chapter 48.

Antihistamines

Many H_1 antagonists possess sedative, antiemetic, and anticholinergic properties, which make them beneficial for use as sedatives. Promethazine is a phenothiazine antihistamine sometimes used for oral and intramuscular sedation, particularly of pediatric patients. It has an onset of action of 15 to 60 minutes after oral ingestion, 20 minutes after rectal administration, and 20 minutes after intramuscular injection. The sedative effect lasts 2 to 8 hours.

There have been several reports of death after convulsive seizures when the combination of promethazine, an opioid, and a local anesthetic was administered. These outcomes may have been caused by a lowering of the convulsive threshold or by respiratory depression in an overly sedated and undermonitored patient. Nevertheless, they emphasize the need for reduced doses when CNS depressants are administered together. Other side effects include extrapyramidal reactions, exaggerated effects in elderly patients, and an intensification of side effects in patients taking MAO inhibitors.

Hydroxyzine is another antihistamine with clinically useful anxiolytic and antiemetic properties. It is rapidly absorbed, with an onset of action of 15 to 30 minutes, a terminal half-life of 20 to 25 hours, and a duration of 4 to 6 hours. It may be administered orally or intramuscularly. Hydroxyzine is relatively free of toxic effects, but anticholinergic side effects such as xerostomia may occur.

Alcohols

Chloral hydrate has been widely used as a sedative agent in pediatric dentistry and for minor procedures such as diagnostic imaging.[22] Its use is fading because the benzodiazepines have proved to be safer alternatives. Chloral hydrate is well absorbed; peak effects occur in approximately 1 hour; the

duration of action is 4 to 8 hours; and it has an elimination half-life of 8 to 10 hours. Chloral hydrate is biotransformed into the active metabolite trichloroethanol, which is primarily responsible for its effects. It can cause gastrointestinal disturbances (nausea, vomiting, and diarrhea) and has the potential for cardiac dysrhythmogenicity and decreased myocardial contractility in higher doses. Deep sedation may be induced, especially if other CNS depressants, including nitrous oxide, are coadministered.[64] Chloral hydrate is contraindicated in patients with marked hepatic impairment, severe renal disease, gastritis or gastric ulcers, severe cardiac disease, or acute intermittent porphyria. At a recommended dose of 50 mg/kg up to a maximum of 1 g, chloral hydrate is approximately as effective as diazepam for oral sedation in children.[3] Larger doses are more effective; however, the level of CNS depression moves beyond that of moderate sedation, and complete recovery can take more than 24 hours in sensitive patients.[66] Reduced doses must be used if chloral hydrate is combined with another sedative.

Antimuscarinic drugs

Scopolamine, similar to atropine, has been used as a premedication for its antimuscarinic properties, usually in combination with an opioid or a barbiturate. It can also be used to produce minimal-moderate sedation with marked amnesia. Scopolamine has no analgesic properties and may produce excitation and delirium in a painful situation.

ANESTHETIC ADJUVANTS AND PREMEDICATION

Numerous drugs may be used for premedication or as anesthetic adjuvants. The pharmacologic features of the neuromuscular blocking agents, which are frequently used during anesthesia to provide greater muscle relaxation, are discussed in Chapter 10. Many of the sedatives, analgesics, antihistamines, and antimuscarinics previously mentioned in this chapter and reviewed elsewhere in the book are administered to the patient minutes to several hours before anesthesia and surgery. Table 18-4 lists commonly used drugs for premedication.

Indications for premedication include relief of anxiety; induction of sedation, analgesia, and amnesia; vagal blockade; reduction of secretions in the upper respiratory tract; and prevention of nausea and vomiting. Premedicants are also used to decrease the acidity and volume of gastric secretions. Finally, they are administered to reduce the dose of the general anesthetic agent needed for a smooth induction.

An effective method of alleviating preoperative anxiety is the preoperative visit by the anesthesiologist, which allows information to be given to the patient and permits questions to be answered. The following classes of drugs, whose pharmacologic features are described elsewhere in this text, are routinely used as adjuncts to the careful psychological preparation of the patient.

Opioid analgesics offer analgesia, euphoria, and sedation. Complicating problems include respiratory depression, nausea and vomiting, gastric retention, and reduced sympathetic tone. Benzodiazepines can relieve anxiety without significant effects on respiration or cardiovascular function. They are also effective in providing amnesia and sedation. The antimuscarinics atropine, glycopyrrolate, and scopolamine may be used as premedicants to block vagal reflexes and inhibit salivation and respiratory tract secretion. They may also oppose the bradyarrhythmias that may accompany the use of other drugs in anesthesia, such as succinylcholine. Scopolamine also has central effects leading to sedation and amnesia. Glycopyrrolate does not cross the blood-brain barrier, is a more efficacious antisialagogue than atropine, and is less likely to induce tachycardia. H_1 and H_2 antihistamines may be given for premedication. H_1 antagonists, such as hydroxyzine or promethazine, offer antiemetic effects and some sedation. H_2 antagonists, such as cimetidine or ranitidine, decrease gastric secretion and acidity. These effects are important in certain patients because general anesthesia eliminates the usual protective reflexes that prevent aspiration after regurgitation of stomach contents.

TABLE **18-4**

Agents Used for Premedication in General Anesthesia

DRUG (PROPRIETARY [TRADE] NAME)	ADULT DOSE (mg)	ROUTE OF ADMINISTRATION	INDICATIONS
Antimuscarinics			
Atropine	0.5	IV, IM	Secretion decrease, vagal blockade
Glycopyrrolate (Robinul)	0.2	IV, IM	Secretion decrease
Scopolamine	0.3	IV	Secretion decrease, sedation, amnesia
Antihistamines			
Hydroxyzine (Atarax, Vistaril)	25-100	Oral	Anxiolysis, sedation, antiemetic effect
Promethazine (Phenergan)	25-50	IM	Sedation, antiemetic effect
Ranitidine (Zantac)	150	Oral	Aspiration prophylaxis
Benzodiazepines			
Diazepam (Valium)	5-20	Oral, IV	Anxiolysis, sedation, amnesia
Lorazepam (Ativan)	0.5-4	Oral, IV	Anxiolysis, sedation, amnesia
Midazolam (Versed)	2-5	IM, IV*	Anxiolysis, sedation, amnesia
Triazolam (Halcion)	0.125-0.5	Oral	Anxiolysis, sedation, amnesia
Prokinetic Metoclopramide (Reglan)	5-15	IV	Aspiration prophylaxis
Opioids			
Fentanyl (Sublimaze)	0.025-0.1	IV	Sedation, analgesia
Meperidine (Demerol)	50-100	IM	Sedation, analgesia
Morphine	5-10	IM	Sedation, analgesia

*Midazolam is also administered orally and intranasally to children.

The dopaminergic antagonist metoclopramide is also sometimes administered to speed gastric emptying.

Postoperative nausea and vomiting are common adverse events after general anesthesia. To improve comfort and safety, patients who are predisposed to nausea and vomiting may be given one of a wide variety of antiemetics, which include the dopamine antagonists droperidol and prochlorperazine; anticholinergics/antihistamines, such as scopolamine and hydroxyzine; the adrenocorticosteroid dexamethasone; and 5-HT_3 antagonists, including ondansetron, granisetron, and dolasetron. Although droperidol is an effective antiemetic, its use has been greatly limited after the FDA placed restrictions on its use based on reports of its association with prolonged QT interval and related arrhythmias. The applicability of these reports to the small, prophylactic doses of droperidol used in anesthesiology has been widely questioned.[50]

AGENTS USED IN GENERAL ANESTHESIA AND SEDATION

Nonproprietary (generic) name	*Proprietary (trade) name*
Inhalation agents	
Gases	
Nitrous oxide	—
Volatile liquids	
Desflurane	Suprane
Ether*	—
Halothane*	Fluothane
Isoflurane	Forane
Sevoflurane	Ultane
Injectable agents	
Barbiturates	
Methohexital	Brevital
Thiopental	Pentothal
Alkylphenol	
Propofol	Diprivan
Arylcycloalkylamine	
Ketamine	Ketalar
Carboxyimidazole	
Etomidate	Amidate
α_2-Adrenoceptor agonist	
Dexmedetomidine	Precedex
Benzodiazepines (intravenous drugs)	
Diazepam	Valium
Lorazepam	Ativan
Midazolam	Versed
Opioids	
See Table 18-3	
Others	
See Table 18-4

CHAPTER 19

Introduction to Antinociceptive Drugs

HYUNGSUK KIM AND RAYMOND A. DIONNE

Pain has always been a barrier to dentistry, serving as a continuing motivation for the use of drugs to prevent, block, or attenuate pain in the perioperative period. Despite the efficacy of local anesthesia, many procedures can result in substantial postoperative discomfort and edema, limiting mouth opening for several days. Poorly controlled pain in the perioperative period also contributes to anxiety about future dental therapy, leading to postponed or canceled appointments.[2,10,16] Effective control of orofacial pain facilitates the delivery of care, reduces anxiety about dentistry, and may even improve dental health by promoting preventive and routine dentistry as an alternative to general neglect with episodic care for acute problems. Emerging basic and clinical studies have shown that the use of antinociceptive drugs to attenuate perioperative pain can prevent the development of hyperalgesia manifesting as increased pain hours to days after a procedure. The availability of safe, effective antinociceptive drugs now permits effective prevention and management of perioperative pain for the mutual benefit of the patient and the dental practitioner.

The multiplicity of pain mechanisms and the difficulty of separating nociceptive processing from physiologic pain perception represent significant barriers to improving pain therapy. In addition to the molecular events associated with tissue injury, inflammation, development of sensitization, and activation of ascending and descending pathways, it is now recognized that gender and genetic factors also contribute to individual variation in pain perception, processing, and evaluation of nociceptive input. Because of this mechanistic complexity, use of analgesic drugs in fixed doses that have been validated in a relatively homogeneous patient sample may not result in effective therapy when used in a patient population with wide genetic diversity in pain processing and drug metabolism. Although individual variation in the human pain experience is traditionally explained by various factors such as cultural or psychological influences, more recent studies in animal and human pain models show phenotypic differences in pain sensitivity that may result from genetic factors.[6,22,26,38,44] This genetic variation among patients, along with other sources of variation, provides a physiologic rationale for individualizing pain treatment.

The management of chronic pain has a long history of therapeutic misadventures, including the misuse of drugs for symptomatic relief of chronic orofacial pain. There is still no generally accepted agreement about the cause of chronic orofacial pain; its natural history; the need for aggressive treatment; and the effectiveness, safety, and indications for most clinical practices. Differences of opinion on these issues are often fostered by a lack of appreciation of the difference between clinical observations, which may form the basis for therapeutic innovation, and the need to verify the efficacy and safety of treatments in studies that control for factors that can mimic clinical success. Drug classes for the treatment of pain associated with temporomandibular joint (TMJ) disorders range from short-term treatment with nonsteroidal anti-inflammatory drugs (NSAIDs) and muscle relaxants for pain of presumed muscular origin to long-term administration of antidepressants and anticonvulsants for less well-characterized pain (see Chapter 23). The management of pain associated with TMJ disorders rests on the same principles that apply to the use of all drugs: demonstrated efficacy for the indication, an acceptable incidence of adverse reactions for the condition being treated, and safety when used in numerous patients for prolonged periods.

Growing numbers of elderly people in the population increase the prevalence of age-related painful conditions, such as osteoarthritis and various neuropathies. Improvements in the management of cancer increase life expectancy but are accompanied by an increase in the cumulative incidence of cancer-related pain and painful conditions associated with cancer treatment (e.g., chemotherapy, radiotherapy, surgery). In these patients with a complicated history, currently available analgesic modalities are often not helpful or effective. Despite astonishing advances in understanding of the neurobiology of pain, pain continues to produce severe distress, dominating and disrupting the lives of many patients from lack of adequate pain relief or the consequences of its treatment.

PATHWAYS OF OROFACIAL PAIN

Pain Transduction and Transmission in the Periphery

Noxious stimuli, which can produce tissue damage, are detected by the terminal endings of two major classes of nociceptive (pain-detecting) afferent nerve fibers (Figure 19-1). These nociceptors are distributed throughout the skin, oral mucosa, and tooth pulp. Aδ fibers are fast-conducting, lightly myelinated neurons responding primarily to noxious mechanical stimuli. Aδ fibers are thought to mediate the initial sensation of pain, which has a sharp perceptual quality. The second group of nociceptive fibers comprises C fibers, which are slowly conducting unmyelinated neurons that respond to thermal, mechanical, and chemical stimuli. C fibers likely mediate secondary pain, which occurs after the initial sharp, pricking pain and is generally described as having a dull, aching, or burning perceptual quality. There are approximately three to five times more C fibers than Aδ fibers.[29] Other classes of cutaneous fibers have been described but are not as well characterized.

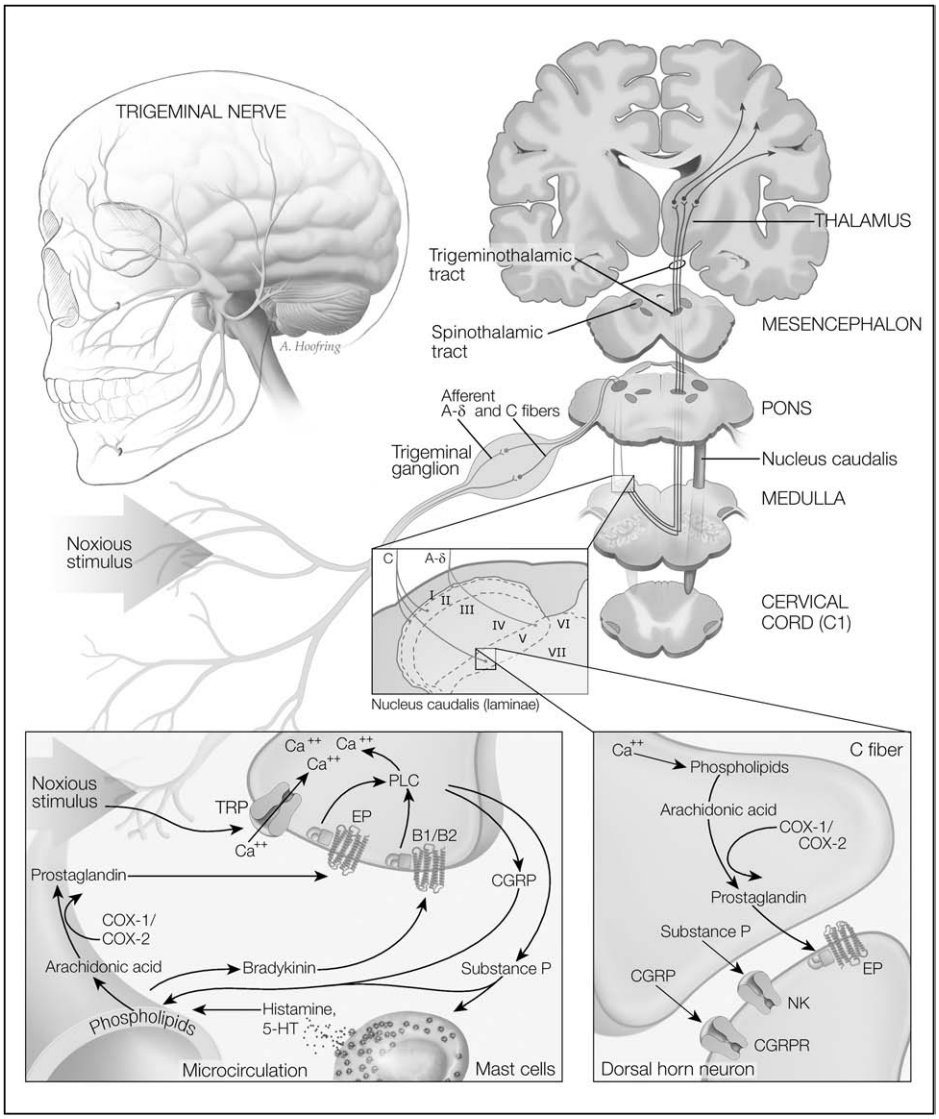

FIGURE **19-1** Diagram of trigeminal nociceptive pathways. After a noxious stimulus is applied in the orofacial region, multiple chemical mediators are released from damaged cells and from local nerve terminals and inflammatory cells (*lower left*). Some mediators act on their receptors and directly activate nociceptors, evoking pain. Others act together to produce a sensitization of the nervous system. Small Aδ and C afferents synapse with nociceptive-specific trigeminothalamic neurons in the nucleus caudalis (*center*). By the released neurotransmitters from the primary afferents (*lower right*), trigeminothalamic neurons are activated, and noxious information is transmitted directly to the thalamus and ultimately to the cerebral cortex.

The detection of noxious stimuli in the orofacial region and the encoding of pain are conveyed primarily by nerves of the trigeminal system. The trigeminal nerve, or fifth cranial nerve, is the largest of the cranial nerves; its three branches (ophthalmic, maxillary, and mandibular branches) innervate most of the face and anterior scalp. The trigeminal nerve also innervates the mucous membranes and gingivae of the mouth; the teeth and jaws; the anterior two thirds of the tongue; the nasopharynx, nasal cavities, and sinuses; and a portion of the meninges. The facial (seventh cranial) nerve encodes pain from the skin of the mastoid region and the external auditory meatus; most of the sensory function of this nerve is involved in taste sensation. The glossopharyngeal (ninth cranial) nerve innervates the back of the tongue, tonsillar region, tympanic cavity, and antrum and oronasal portions of the pharynx. The vagus (tenth cranial) nerve innervates the larynx and parts of the pharynx, ear, and external auditory meatus. These cranial nerves provide the peripheral innervation necessary for the detection of orofacial and dental pain.[19]

Pain Modulation in the Brainstem

The Aδ and C fibers from the orofacial region transmit nociceptive signals primarily by the branches of the trigeminal nerve to the trigeminal nucleus caudalis; noxious information from additional regions is conveyed by other cranial nerves. Most clinical and laboratory data indicate that the nucleus caudalis is the principal brainstem relay site for trigeminal nociceptive information.[36] The nucleus caudalis is located in the medulla; its laminated structure, types of cells, and function in processing pain signals are similar to the area on the dorsal aspect of the spinal cord termed the *dorsal horn*.

As previously stated, the small-diameter afferents carrying nociceptive information from the various craniofacial tissues predominantly terminate in laminae I, II, and V of the nucleus caudalis. By contrast, primary afferent A fibers conducting low-threshold mechanosensitive (tactile) information terminate primarily in the most rostral components of the trigeminal brainstem complex and in laminae III to VI of the nucleus caudalis. More recent studies have also revealed increases in immunocytochemical markers of neuronal activity in caudalis neurons after noxious stimulation of craniofacial tissues.[36] Additionally, numerous studies using microelectrode recording have shown that many neurons in the nucleus caudalis are activated by cutaneous nociceptive input from the craniofacial region. For these reasons, the nucleus caudalis has been termed the *medullary dorsal horn*.[37]

The medullary and spinal dorsal horns contain four major components related to the processing of noxious stimuli: central terminals of afferent fibers, local circuit neurons, projection neurons, and descending neurons. The first component, primary nociceptive afferents (Aδ and C fibers), enter the medullary dorsal horn by way of the trigeminal tract. Nerves that enter the spinal dorsal horn traverse the lateral aspect of the tract of Lissauer. For medullary and spinal dorsal horns, Aδ and C fibers terminate mainly in laminae I, IIa, and V. The primary nociceptive afferents transmit information by the synaptic release of neuropeptides (e.g., substance P, calcitonin gene–related peptide [CGRP]) and amino acids (e.g., glutamate).

The second component of the dorsal horn—the local circuit neurons—consists of two major subtypes, the islet cells and stalked cells. Islet cells are found throughout lamina II and are thought to be inhibitory interneurons possibly using γ-aminobutyric acid (GABA) or enkephalin as neurotransmitters. Stalked cells are found primarily at the junction between laminae I and II and have been proposed to be excitatory interneurons conveying nociceptive output from primary afferents to projection neurons located in lamina I. The local circuit neurons play a crucial role in conveying and modulating nociceptive signals from the primary afferents to the projection neurons.

Projection neurons constitute the third component of the dorsal horn. Their function, and that of the descending neurons, is described later. Projection neurons and local circuit neurons can be divided into two major classes: wide dynamic range and nociceptive-specific neurons. The wide dynamic range neurons are activated by weak mechanical stimuli but respond maximally to intense and potentially tissue-damaging stimuli. In contrast, nociceptive-specific neurons respond only to intense noxious forms of mechanical, thermal, or chemical stimuli.

Pain Perception and Modulation by the Cerebral Cortex

Two major projections carrying noxious information from the medullary and spinal dorsal horns are the trigeminothalamic tract and the spinothalamic tract. These tracts are composed of axons from the wide dynamic range and nociceptive neurons. These axons cross to the contralateral side of the medulla or spinal cord and ascend rostrally to the thalamus. From the thalamus, additional neurons convey this information to the cerebral cortex (see Figure 19-1).

Axonal collaterals of the trigeminothalamic and spinothalamic tracts terminate in the rostral medullary reticular formation and the periaqueductal gray. The projection and local circuit neurons encode information about the location, intensity, duration, and type of noxious input.

The fourth component of the dorsal horn is composed of the terminal endings of descending neurons. These neurons form an important component of the endogenous pain modulatory system. Because the cerebral cortex is an important center for integrating all perceptual modalities together with higher functions, such as expectation and recall of previous events, it is not surprising that the cortex is involved in pain perception and response. Evidence suggests that the cerebral cortex is involved with the sensory discriminative aspect of pain and that it may serve as the most rostral activator of the endogenous analgesic system.[19]

PERIPHERAL MECHANISMS OF PAIN AND ANALGESIC DRUG ACTIONS

Activation of Nociceptors

Most noxious stimuli are transduced into electrical activity at the peripheral terminals of Aδ and C fibers by specific receptors or ion channels sensitive to heat, mechanical stimuli, protons, or cold. Ligand-gated channels expressed on nociceptive neurons include excitatory amino acid receptors, GABA receptors, nicotinic acetylcholine receptors, serotonergic (tryptaminergic or 5-hydroxytryptamine) receptors, and adenosine triphosphate P2X receptors. These receptors permit primary nociceptive neurons to respond to a wide range of mediators.[28]

Among the many channel types that modulate the passage of charged ions across cell membranes, Ca^{++} channels are particularly important in cellular homeostasis and activity, and the surface of each cell holds thousands of these channels that precisely control the timing and entry of Ca^{++}. Small conformational changes cause these channels to open, allowing more than 10 million ions per second to flow through each channel. The opening of Ca^{++} channels is the crucial link between cell depolarization and Ca^{++} entry, which can result in local intracellular Ca^{++} concentrations up to 100 μmol/L. The subsequent binding of Ca^{++} to intracellular molecules can lead to many significant responses, including triggering of neurotransmitter release, the activation of second messenger systems, and Ca^{++} spikes (action potentials in which the depolarizing current is carried predominantly by Ca^{++}).[28]

Transient receptor potential (TRP) channels are the vanguard of sensory systems, responding to temperature, touch, pain, osmolarity, and other stimuli. TRPV1, also known as the *vanilloid receptor 1*, is a Ca^{++}-permeable channel that is opened by heat (>43° C) and decreased pH. TRPV1 contributes to acute thermal nociception and hyperalgesia after tissue injury. TRPV2, which is 50% identical to TRPV1 in primary structure, may mediate high-threshold (>52° C) noxious heat sensation, perhaps through lightly myelinated Aδ nociceptors. The ankyrin-like protein with transmembrane domains 1 channel is a Ca^{++}-permeable, nonselective channel distinguished by approximately 14 amino-terminal ankyrin repeats. It is activated by noxious cold temperature (<15° C) but bears little similarity to the menthol-sensitive TRPV8 channel. It is found in a subset of nociceptive sensory dorsal root ganglion neurons in the company of capsaicin-sensitive TRPV1 channels.[4]

Activation of nociceptors is not the only way to trigger pain. After peripheral tissue injury or damage to the nervous system, low-threshold sensory fibers, which normally produce only innocuous sensations such as light touch, can begin to produce pain—a substantial change in the normal functional specificity of the sensory system. Although this pain no longer represents the presence of a damaging external stimulus, to the individual it feels as if the pain arises in the periphery from a noxious stimulus. With inflammation, components of the "inflammatory soup" such as bradykinin or prostaglandins bind to G protein–coupled receptors and induce activation of protein kinases A and C in nociceptor peripheral terminals, which phosphorylate ion channels and receptors. As a result,

the threshold for activation of transducer receptors such as TRPV1 is reduced.

One of the best-established pronociceptive substances derived from nerve endings is substance P. Substance P causes vasodilation and extravasation of plasma proteins from capillaries, which contribute to the edema associated with inflammation and to the generation of bradykinin from kininogen. Because the neurokinin-1 receptor is the major receptor for substance P, neurogenic inflammation is markedly attenuated by receptor antagonists specific for this receptor. Another putative mediator of neurogenic inflammation is CGRP, which produces vascular leakage and vasodilation leading to inflammation and tenderness. Immune cells may be involved in inflammatory pain, cancer pain, and pain after nerve injury. They are activated in the periphery and within the central nervous system (CNS) in response to tissue damage, inflammation, or mechanical nerve lesions. The immune reaction may increase nociception through the release of cytokines, but granulocytes and monocytes can also promote analgesia by secreting β-endorphin and enkephalin.

Inflammatory Pain

Inflammation represents a complex series of physiologic reactions required for normal healing after physical injury or infection. Mediators formed during the evolution of the inflammatory process contribute to the genesis of acute pain by stimulating or sensitizing primary afferent neurons by peripheral and central mechanisms. The biochemical composition of the local environment of inflamed tissue is complex. Protons, cytokines, prostanoids, leukotrienes, neuropeptides, histamine, bradykinin, and free radicals are ingredients of the inflammatory soup that defines the biochemical environment of inflamed tissue. Although each of these molecular species may directly or indirectly contribute to inflammation, inflammatory pain probably results from an interplay of neuronal signals generated by inflammatory mediators, resulting in synergistic biochemical interactions with primary afferent neurons.

If a particular biochemical in the inflammatory soup is a primary contributor to the genesis of inflammatory pain, drugs that block its actions or synthesis should provide significant analgesia. Agents that block the actions of histamine or substance P and the synthesis of bradykinin or prostaglandins all possess analgesic activity in animal models of inflammation. In addition, combinations of these agents can exert summative effects, consistent with the view that the total composition of the inflammatory soup governs the genesis and maintenance of inflammatory pain.

Analgesic Mechanisms Acting Primarily in the Periphery

Pharmacologic management of pain can be accomplished by blocking either the nociceptive input at the receptor or the nociceptive impulse along the peripheral nerve. As previously mentioned, various biochemicals at inflammatory sites affect nociceptive input by direct or indirect mechanisms. Prostaglandins, especially PGE_2, sensitize nociceptive nerve endings and potentiate the actions of other inflammatory mediators such as bradykinin. Sensitization of peripheral nociceptors is minimized in the absence of PGE_2, and pain sensations are attenuated. Drugs designed to block prostaglandin synthesis or function should be effective analgesics for some inflammatory pain.

Aspirin-like drugs, which include aspirin, acetaminophen, and NSAIDs, exert their actions in damaged tissue. These drugs inhibit generation of the pain signal and accompanying sensitization at the nerve ending through blockade of prostaglandin synthesis.[13,14] In addition, NSAIDs have been reported to possess moderate efficacy for inhibiting postoperative edema.[45] There seems to be a maximal effect, or ceiling effect, however, beyond which additional increments of drugs do not produce significantly greater analgesia. This ceiling effect probably reflects the contribution of other inflammatory mediators that are unaffected by aspirin-like drugs.

The physiologic mechanism for the synthesis of prostaglandins is the activation of phospholipase A_2 and cyclooxygenase during the process of tissue damage (e.g., during surgery). This information has an important practical application—pretreating patients with NSAIDs before surgery. The rationale for this therapy is the blockade of enzymes before the initiation of tissue damage. Although the advantages of pretreatment have been most clearly established for ibuprofen,[21] several other drugs, including flurbiprofen, have been shown to reduce pain. Pretreating patients with ibuprofen delays the onset and reduces the magnitude of postoperative pain. This therapeutic strategy emphasizes how clinicians can improve patient care by knowledge of pain physiology.[19]

Inhibition of prostaglandin synthesis can also be accomplished by administering glucocorticoids. This group of steroids has very potent anti-inflammatory activity. Glucocorticoids inhibit all phases of inflammation, including capillary dilation, migration of leukocytes, and phagocytosis. Steroids have been shown to activate synthesis of a protein inhibitor of phospholipase A_2 called *lipocortin*.[27] Blockade of arachidonic acid formation by inhibiting phospholipase A_2 is an early step in the cascade and prevents formation of cyclooxygenase and lipoxygenase end products. In addition, glucocorticoids induce the synthesis of angiotensin-converting enzyme, a peptidase that degrades bradykinin and decreases the capillary permeability, probably from the increased synthesis of peptides promoting vascular stability or the reduced release of proteolytic enzymes.[5] These multiple mechanisms for the suppression of inflammatory mediators probably account for the impressive anti-inflammatory efficacy of steroids.

Another approach to peripheral pain management is to block the nociceptive impulse as it moves along the nerve axon. Local anesthetics prevent the propagation of action potentials in peripheral nerves by interfering with Na^+ channel permeability (see Chapter 16). Nociceptive Aδ and C fibers are very susceptible to blockade by local anesthetics. Local anesthetics with increased potency and prolonged duration of action have been developed on the basis of their enhanced physicochemical properties, such as increased lipid solubility and greater protein binding. Sustained blockade of Aδ and C fibers can result in prolonged suppression of postoperative pain.

Many studies indicate that the immune system can interact with peripheral sensory nerve endings to inhibit pain within inflamed tissue. In contrast to the traditional view that opioid antinociception is mediated exclusively within the CNS, peripheral opioid receptors have been discovered and shown to mediate analgesic effects when activated by locally applied opioid agonists.[41] Opioid receptors are present on peripheral sensory nerves and are upregulated during the development of inflammation. Their endogenous ligands—opioid peptides—are expressed in resident immune cells within peripheral inflamed tissue. These findings have led to the concept that endogenous opioid peptides can be secreted from immunocytes, occupy opioid receptors on sensory nerves, and produce analgesia by inhibiting either the excitability of these nerves or the release of excitatory, proinflammatory neuropeptides.[42] It seems that peripheral opioid receptors can modulate sensory nerve impulses in a way similar to spinal presynaptic opioid receptors. The local application of exogenous opioids[11] or enzyme inhibitors preventing the degradation of endogenous opioid peptides may provide a new approach to pain management by producing analgesia without central side effects.

CENTRAL MECHANISMS OF PAIN AND ANALGESIC DRUG ACTIONS

Neurotransmitters Involved in Nociceptive Signaling

The central endings of trigeminal nociceptive primary afferents within the nucleus caudalis contain certain excitatory amino acids (e.g., glutamate) and neuropeptides (e.g., substance P, CGRP) that transmit the nociceptive signals to the second-order trigeminal neurons. In lamina II, the axons of most substantia gelatinosa neurons arborize locally within the trigeminal brainstem complex and release neuromodulatory substances such as enkephalin or GABA. The substantia gelatinosa receives a mix of inputs from other areas in the brain and craniofacial afferent input, and it is one of the main sites where peripheral afferents and brain centers modulate somatosensory transmission.[37] Glutamate is a particularly important excitatory neurotransmitter in trigeminal nociceptive mechanisms.[12] It is released from the central endings of trigeminal nociceptive afferents and activates caudalis nociceptive neurons. This process involves two different ionotropic receptors for glutamate—N-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors—as well as metabotropic receptors.

Substance P and the neurokinin-1 receptor are also concentrated in afferent endings in the superficial and deep laminae of the nucleus caudalis, where the nociceptive neurons predominate. Noxious craniofacial stimulation is reported to result in the release of substance P within the nucleus caudalis, presumably from the nociceptive afferent terminals within the substantia gelatinosa, and the released substance P acts through neurokinin receptors to produce a delayed but sustained excitation of the nociceptive neurons.

Central Convergence of Neurons Signaling Pain

Many nociceptive and wide dynamic range neurons can be excited by stimulation of cutaneous or mucosal receptive fields and seem to play an important role in the localization, detection, and discrimination of superficial noxious stimuli. These same neurons can also be excited by peripheral afferents from other tissues such as cerebral blood vessels, tooth pulp, TMJ, or muscle. The extensive convergent afferent input patterns are particularly characteristic of nociceptive-specific and wide dynamic range neurons in the nucleus caudalis. The presence of a cutaneous and a deep receptive field for most of these neurons may explain the poor localization of deep pain and contribute to the spread and referral of pain typical of deep pain conditions involving the TMJ and associated musculature. The poor localization of pain and the frequent occurrence of pain referral with toothache and headache may also be related to analogous convergence patterns from tooth pulp and cerebrovascular afferents onto the nociceptive neurons.

Development of Central Sensitization

The convergence of afferent input may also contribute to central neuronal changes that can be induced by inflammation or injury of peripheral tissues or nerves. Several chemicals released from the peripheral tissue or primary afferent nerve endings by tissue injury or inflammation can increase the excitability of peripheral nociceptors. This increase in excitability produces a barrage of nociceptive primary afferent input into the CNS. Peripheral nerve damage or lesions can also increase nociceptive afferent input. Whatever the cause, this nociceptive afferent barrage can lead to prolonged functional alterations in the nucleus caudalis (and spinal dorsal horn) collectively termed *central sensitization*. The nociceptive afferent activity caused by damage or inflammation of tooth pulp, TMJ, or muscle induces spontaneous activity, receptive field expansion, lowering of the activation threshold, and enhancement of responses of caudalis nociceptive-specific and wide dynamic range neurons that may include a gradually augmenting response to a series of repeated noxious stimuli.[37]

These alterations indicate that the afferent inputs and brainstem circuitry are not "hard-wired" but reflect neuroplastic changes in the receptive fields and response properties of the nociceptive neurons. The changes are thought to result, at least in part, from the unmasking and increased efficacy of the extensive convergent afferent input to the nociceptive neurons noted earlier. The responses of the neurons to this input are enhanced, and their receptive fields are enlarged, reflecting a greater amount of more effective input. This central sensitization apparently is produced by a cascade of events that starts with the nociceptive afferent barrage causing the release centrally of a number of chemical mediators such as substance P (mentioned previously). These substances prolong neuronal depolarization and increase the excitability of the nociceptive neurons by actions at glutamate receptors and G protein–coupled receptors.

Activation of these receptors is associated with removal of the voltage-dependent Mg^{++} block of the NMDA receptor, the entry of Ca^{++} into the neurons, phosphorylation of the NMDA receptor, and a change in neuronal kinetics. These changes may also involve other ionotropic and metabotropic excitatory amino acid receptors, neurotrophins, and kinases active in the phosphorylation of receptors. A loss of central inhibitory processes may contribute to the increased neuronal excitability that is characteristic of central sensitization.[7]

The increased central excitatory state depends on peripheral nociceptive afferent input for its initiation but may not fully depend on peripheral afferent drive for its maintenance. Central sensitization can last days or weeks and is thought to contribute to persistent pain and to the spontaneous pain and tenderness that characterize many clinical cases of injury or inflammation. Central sensitization can explain the hyperalgesia that is a feature of many persistent pain conditions, by virtue of the increase in excitability to Aδ-fiber and C-fiber nociceptive input that it produces in central nociceptive neurons. It also may cause low-threshold mechanosensitive afferent input (which is not normally associated with pain) to serve as nociceptive signals after peripheral injury or inflammation and could contribute to the allodynia that is often associated with pain conditions. Peripheral sensitization can also contribute to hyperalgesia and allodynia by increasing the excitability and decreasing the activation threshold of primary afferents. Many pain conditions may involve a mixture of peripheral and central sensitization phenomena.[37]

Central Effects of Opioid Drugs

Traditional pharmacologic pain management usually involves the administration of opioid analgesics. Parenteral opioid analgesics are the standard of care for severe pain in hospitalized patients. The profound analgesic efficacy of opioid drugs results from their ability to mimic the actions of the family of endogenous opioid peptides. Because endogenous opioids and their receptors are present at all levels of the endogenous analgesic system, opioid drugs can activate this system to suppress the transmission of nociceptive signals at the medullary and spinal dorsal horns. The oral efficacy of most opioid drugs is poor. An additional problem with opioids is their propensity to cause nausea in ambulatory patients. Opioids for most orofacial pain are limited, therefore, to an adjunctive role. Generally, the combination of an aspirin-like drug with an opioid increases analgesia at the cost of an increased incidence of side effects.[19]

Three opioid receptor classes are generally recognized, and experimental observations indicate that a common mechanism of opioid action is the cellular inhibition of neuronal activity. Although the opioid inhibitory effects may be cell dependent, accumulating evidence suggests a link to the receptor-mediated suppression of voltage-gated Ca^{++} chan-

nels, the activation of inwardly rectifying K^+ channels, and the inhibition of adenylyl cyclase activity. Opioid effects in sensory neurons are inhibitory and excitatory, however, and opioids can suppress a Na^+-dependent inward current. High levels of endogenous opioid peptides and opioid receptors are found within the periaqueductal gray, rostral ventral medulla, and dorsal horn, and neurons in these areas can be activated by opioids. Because opioid receptors generally produce inhibitory effects on neuronal firing, the ability of endogenous opioid peptides or opioid drugs to activate neurons within these brain regions depends on an anatomic arrangement in which opioid receptors inhibit GABAergic (inhibitory) interneurons. Neurons of the rostral ventral medulla that project to the dorsal horn activate enkephalinergic interneurons that are located in the dorsal horn.[28]

GABA is present in highly diverse inhibitory interneurons and projection neurons throughout the brain. The wide-ranging and ubiquitous role of GABA as an inhibitory transmitter is supported by evidence linking numerous neuropsychiatric disorders with altered GABA function and the degradation of GABAergic neurons. In the past, the action of GABA was considered to be solely inhibitory, on the basis of the observation that GABA receptor activation moves the membrane potential of a cell away from the action potential threshold. The role of GABA is more complex, however. During development, GABA may also function as an excitatory transmitter causing neuronal depolarization.

Analgesic Actions of Antidepressant Drugs

Descending noradrenergic projections from the locus coeruleus or from related noradrenergic nuclei in the dorsal pons inhibit dorsal horn neurons and contribute to descending analgesia. The role of norepinephrine in descending analgesia may explain the analgesic effects of tricyclic antidepressants, including those of selective norepinephrine reuptake inhibitors, which are often effective in the treatment of neuropathic pain. Although many individuals with chronic neuropathic pain have depression, the analgesic effects of these agents are clearly independent of their antidepressant effects because the analgesic effects occur at lower doses and after shorter periods of treatment.

MOLECULAR-GENETIC INFLUENCES ON PAIN AND ANALGESIC DRUG ACTIONS

Progress is being made in discerning the molecular and cellular mechanisms that operate in sensory pathways to generate the neural signals that we ultimately interpret as pain.[35] It is now possible to assess entire pathways that might be relevant to disease or to drug responses at the DNA, mRNA, and protein levels.

Mendelian traits exist when a single mutation at a locus results in large, often discrete phenotypic effects. In contrast to mendelian traits, pain is one of the complex traits in which many genes are involved, each with usually a small effect. Moderate heritability estimates combined with findings that specific polymorphisms in humans are linked to responses to painful stimuli[25,39,43] may be sufficient evidence to support a genetic contribution to pain sensitivity. For traits such as individual differences in pain sensitivity, variations are generally not attributable to different alleles at a single locus. Rather, many different genes, each with allelic variations, contribute to the total observed variability in a trait, with no particular gene having a single large effect. An individual phenotype results from the sum total of the effects of all the numerous contributing loci.[34] Certain genes, such as those for opioid receptors or cytochromes P450, are involved in many different types of pain. The lack of concordance between pain sensitivities suggests, however, that there is not one "global" insensitive—or sensitive—pain phenotype. Remarkably little is known about the genetic architecture underlying pain. Since the completion of the human genome sequence, genetic variation discovery projects (SNP Consortium, International HapMap project) are presenting new opportunities for unraveling the complex genetic basis of nonmendelian disorders on the basis of large-scale, genome-wide association studies.

Sensory input in humans is filtered through an individual's genetic composition and through prior learning, current physiologic status, idiosyncratic appraisals, expectations, current mood state, and the sociocultural environment.[46] These influences manifest as variability in pain sensitivity, perception, and tolerance. The relative contribution and interaction of these many factors to individual variations in pain is currently unknown. One of the underlying mechanisms mediating the influence of environmental factors on pain sensitivities is the epigenetic phenomenon. Although epigenetic changes such as methylation or acetylation of DNA do not induce sequence deterioration, they still influence expression of genes and eventually alter phenotypes. It is likely that expression of genes related to pain also can be affected by these epigenetic factors. Even monozygotic twins show tremendous differences in their epigenetic profiles, and this fact may explain behavioral differences between genetically identical twins.[15] The first evidence of epigenetic modification of pain in animals was reported more recently.[3]

Adverse reactions to prescription drugs cause at least 100,000 deaths each year in the United States and are responsible for more than 10% of hospital admissions in some European countries.[1] The study of pharmacogenetics that relate heritability to individual variation in drug response (see Chapter 4) is expected to lead increasingly to associations between genotype and analgesic drug response that have prognostic value. Genetic predictors are most likely to be used to avoid adverse effects or select which of several alternative drugs would have the highest efficacy. Initial pharmacogenetic findings have already been reported for analgesics, including cyclooxygenase inhibitors and opioid-like drugs.* On the basis of these findings, it is likely that no single analgesic can reduce all forms of pain in all patients. Even for the individual patient with a given painful condition, molecular genetic mechanisms underlying the pain and analgesic responses to it may change over time.

Further progress in analyzing an individual's genomic and epigenomic profiles using next-generation sequencing technologies is being made.[20] De novo whole genome sequencing or epigenetic profiling of unique individuals—such as a person absolutely insensitive to capsaicin[31]—may provide deep insights of pain mechanisms. As knowledge of molecular and cellular mechanisms accumulates along with advanced technologies, it is likely that patients in the future will be given individually tailored prescription drugs on the basis of their genetic and epigenetic profiles to treat common diseases or to reduce the risk of adverse reactions.[17]

THERAPEUTIC STRATEGIES FOR USING ANTINOCICEPTIVE DRUGS

Pain Prevention

Interfering with nociceptive input into the CNS, especially in the perioperative period, also interferes with processes that contribute to the development of central sensitization. The consequence of central sensitization is that innocuous sensations may be interpreted as painful (central hyperalgesia) and may persist long after the initiating stimulus has ended. This phenomenon and the related process of sensitization of nociceptors are probably additive and contribute to the intensity

*References 1, 23, 24, 30, 32, 33, 40 and 47.

and the duration of pain postoperatively. Recognition of the possible clinical importance of the development of central sensitization has led to attempts to block its development and minimize postoperative pain and reduce analgesic use during recovery. The ability to reduce analgesic use is particularly desirable in ambulatory patients who are much more sensitive to the adverse effects of opioid drugs. Decreasing pain and adverse drug effects makes the postoperative period less unpleasant, enhances return to normal function, and likely alleviates apprehension about future clinical procedures.

Translating these observations and hypotheses into the management of pain in the dental environment can be readily achieved with currently available drugs. The use of either a NSAID or a long-acting local anesthetic before a dental procedure results in less pain during the first 4 to 8 hours postoperatively[8,9] and seems to attenuate pain intensity over the first 2 to 3 days thereafter.[18] The administration of a NSAID before pain onset suppresses the release of inflammatory mediators such as prostaglandins that contribute to the sensitization of peripheral nociceptors. Patients have a much slower onset and less intense pain postoperatively after NSAID pretreatment, lessening nociceptive input and the development of central sensitization. The combination of NSAID pretreatment and the use of a long-acting local anesthetic greatly reduce pain after oral surgery; many patients report little pain in the first 6 to 7 hours postoperatively and reduced pain at 24 and 48 hours compared with standard treatment.

Pain Management

NSAIDs such as ibuprofen are among the most widely used drugs for dental pain and are generally more efficacious than aspirin, acetaminophen, or oral opioids in most studies, presumably because of the inflammatory cause of most dental pain and the prominent anti-inflammatory effects of NSAIDs. When possible, NSAID therapy is preferable for ambulatory patients who generally have a high incidence of side effects when given an opioid. NSAIDs also modestly suppress swelling after surgical procedures, providing additional therapeutic benefit without the potential liabilities of administering steroids. These considerations and the vast clinical experience gained through 25 years of clinical experience with ibuprofen make NSAIDs the drug class of choice for dental pain for patients who do not have any contraindications to their use.

Limitations to orally administered NSAIDs for dental pain include delayed onset compared with an injectable opioid, the inability to relieve severe pain consistently, and an apparent lack of effectiveness when given repeatedly for chronic pain. For patients who do not receive satisfactory relief from a NSAID alone, combining it with an opioid may provide additive analgesia but will also be accompanied by more frequent side effects. Chapters 20 and 21 review the pharmacology of opioids and NSAIDs, and the clinical use of these agents for acute pain is discussed in Chapter 47.

CHAPTER 20

Opioid Analgesics and Antagonists

MICHAEL H. OSSIPOV, GERALD F. GEBHART, AND FRANK PORRECA

Opioids are primarily used for the relief of pain and consequently find widespread application in dentistry. Opioids also possess therapeutically useful antitussive (cough suppressant) and antidiarrheal effects in addition to several undesirable effects, including sedation and somnolence, unwanted constipation, nausea and vomiting, respiratory depression, and urinary retention. Repeated use of opioids for control of pain can lead to analgesic tolerance and physical and sometimes psychological dependence. These shortcomings notwithstanding, no other drugs are more efficacious as analgesics than opioids. Three groups of opioid agents are discussed in this chapter: pure agonists, pure antagonists, and agonist-antagonists, which are compounds that in the same molecule possess agonist and antagonist properties. Drugs that are pure agonists and those that are mixed agonist-antagonists are used principally for relief of pain; pure antagonists prevent or reverse the effects of pure agonists and mixed agonist-antagonists and are used principally to reverse opioid intoxication.

OPIOID ANALGESICS

Morphine, the prototypic opioid analgesic, and codeine are natural phenanthrene alkaloids contained in opium, which is derived from the poppy plant *Papaver somniferum*. The unripe seed capsules of the plant are incised, and the milky exudate is collected, dried, and powdered. Opium powder contains 5% to 20% morphine and 0.5% to 2.5% codeine, depending on the source, and many other alkaloids. None of the other alkaloids is therapeutically useful in pain control; one constituent, papaverine, has been used as a smooth muscle relaxant.

The first documented descriptions of *Papaver somniferum* appeared in approximately 1550 BC in the Ebers papyrus of ancient Egypt.[35] Later, in the third century BC, writings of the Greek philosopher Theophrastus contained references to poppy juice. The active analgesic and constipative principle of the poppy plant was not isolated, and the drug was not named (after Morpheus, the Greek god of sleep) until 1806, when Sertürner first isolated morphine from opium and described its properties. Currently available opioid analgesics in addition to morphine and codeine are either semisynthetic congeners of morphine (e.g., hydromorphone, oxymorphone, hydrocodone, and oxycodone) or entirely synthetic (e.g., meperidine, fentanyl, methadone, and propoxyphene).

Basis of Opioid Action

The mechanisms by which opioids act at specific central nervous system (CNS) and peripheral sites to produce their effects are fairly well understood. In the early 1970s, binding sites in the CNS were discovered that stereospecifically, saturably, and reversibly combined with opioids.[37] These receptors were later shown to be the natural effectors of opioid action; that is, specific pharmacologic effects were produced by binding of opioids to these receptors. The discovery of opioid receptors naturally raised questions about their biologic significance, spurring research that led to the discovery of endogenous opioid receptors and peptides. Subsequently, several families of endogenous opioid peptides and numerous opioid receptors have been characterized.

Endogenous opioid peptides

There are four families of endogenous opioid peptides: endomorphins, endorphins, enkephalins, and dynorphins. Figure 20-1 illustrates their biologic derivations and structural relationships. The pentapeptide enkephalins—methionine-enkephalin (met-enkephalin) and leucine-enkephalin (leu-enkephalin)—were the first endogenous opioids to be discovered.[13] These peptides were subsequently shown to be potent opioid receptor agonists in the same biologic systems in which morphine is active. Initially, the enkephalins were thought to be derived from a larger 91-amino acid peptide, β-lipotropin, but it is now clear that β-lipotropin gives rise to a separate group of opioid peptides, the endorphins (see later).

Endomorphin-1 and endomorphin-2 are newly discovered endogenous opioid peptides.[47] Both are short tetrapeptides (NH_2-Tyr-Pro-Trp/Phe-Phe-$CONH_2$) and structurally distinct from the other opioid peptides (see later). The endomorphins have been localized to areas in the CNS associated with pain processing (e.g., spinal dorsal horn, trigeminal nucleus, midbrain periaqueductal gray) and in the endings of sensory neurons that terminate in the spinal dorsal horn. Although the genes for the endorphins, enkephalins, and dynorphins are known, the gene for the endomorphins has yet to be isolated.

The precursor of the enkephalins, proenkephalin, is present in the CNS and the adrenal medulla. Although proenkephalin in the brain is similar, if not identical, to proenkephalin in the adrenal medulla, processing of the large precursor polypeptide differs in the two locations. In the brain, cleavage of proenkephalin is generally more complete, and free enkephalins are the predominant products (four copies of met-enkephalin, one copy of leu-enkephalin, and one copy each of a heptapeptide and an octapeptide). In the adrenal medulla, large enkephalin-containing polypeptides predominate.

Prodynorphin is the common precursor for several larger opioid peptides, three dynorphins and two neoendorphins, all of which share with the enkephalins the same N-terminal amino acid sequence: NH_2-Tyr-Gly-Gly-Phe-Met/Leu. The

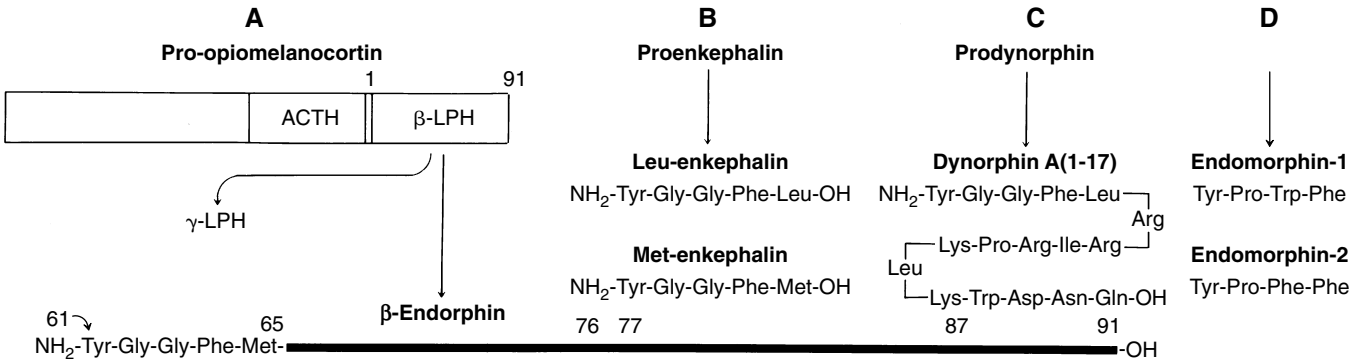

FIGURE **20-1** Derivations and structures of endogenous opioids. **A,** Endorphins. Proteolysis products of the pituitary hormone β-lipotropin (*β-LPH*), endorphins are ultimately derived from the precursor molecule pro-opiomelanocortin. Other peptides of biologic importance obtained from pro-opiomelanocortin include adrenocorticotropin (*ACTH*), γ-lipotropin (*γ-LPH*), and several melanotropins (not shown). The initial amino acid sequence of β-endorphin is shown (*at bottom left*) to illustrate its structural relationship to the enkephalins and dynorphins; the numbers refer to amino acid residues of β-LPH. **B,** Enkephalins. In addition to met-enkephalins and leu-enkephalins, proenkephalin may give rise to at least two other biologically active molecules, a heptapeptide and an octapeptide, both of which contain met-enkephalin as part of their structure. **C,** Dynorphins. A common precursor, prodynorphin, yields several dynorphins, including dynorphin A(1-17) (shown here), dynorphin A(1-8), dynorphin B(1-13), and at least two other peptides, α-neoendorphin and β-neoendorphin. **D,** Endomorphins. The precursor for these two endogenous opioid peptides is unknown.

products of prodynorphin are often found in association with the enkephalins within the CNS.

The endorphins are a group of endogenous peptides that are larger in size and are distributed differently in the CNS than the endomorphins, enkephalins, or dynorphins. The precursor for the endorphins, pro-opiomelanocortin, gives rise to several important hormones, including adrenocorticotropic hormone and β-lipotropin, which are further processed to form biologically active products. The most important opioid derived from β-lipotropin is β-endorphin, the 30-amino acid carboxy terminal sequence of β-lipotropin. Shorter cleavage products of β-endorphin, such as α-endorphin and γ-endorphin, have been isolated from the pituitary, but their function is uncertain.

Sites in the CNS where opioid peptides are located differ for the different peptides, confirming that they are involved in different functions. It is a mistaken impression that all opioid peptides in all locations are involved in the modulation of pain. Neurons containing endomorphins are not as widely distributed in the CNS as neurons containing other opioid peptides, but endomorphins are located in pain-processing areas where they are considered to function as neurotransmitters that act at opioid receptors. Neurons containing enkephalins are widely distributed throughout the brain (e.g., striatum, limbic system, midbrain, and medulla) and the spinal cord where they, too, are considered to function principally as neurotransmitters.[22] Prodynorphin-derived peptides are abundant in the pituitary, hypothalamus, midbrain, and striatum. Differential processing of proenkephalin and prodynorphin in various brain areas leads to different products having different functions.

The endomorphins, enkephalins, and dynorphins are stored in nerve terminals and are quickly destroyed by peptidases (aminopeptidase N [EC 3.4.11.2] and neutral endopeptidase [EC 3.4.24.11]) when released. β-Endorphin is present in high concentrations in the intermediate lobe of the pituitary and in neurons in the mediobasal hypothalamus, whose axons terminate in the amygdala, periaqueductal gray matter, and brainstem. β-Endorphin coexists with adrenocorticotropic hormone in pituitary secretory granules, and both peptides can be released simultaneously. β-Endorphin is believed to function more as a neurohormone than as a neurotransmitter, mediating diverse autonomic and psychological responses to pain and stress.

Opioid receptors

Three opioid receptors have been cloned: mu (μ), kappa (κ), and delta (δ) (Table 20-1).[15,32] They share considerable structural homology (approximately 60% to 65%), contain seven membrane-spanning α-helical segments, and are coupled to transducing G proteins (Figure 20-2). G proteins couple opioid receptors to intracellular effectors and exist as heterotrimers; there is structural and functional diversity in the three G protein subunits. Each heterotrimer consists of an α subunit isoform (of which there are at least 18) and a dimer of β-γ subunits (which also exist in multiple isoforms) that link with specific (and potentially diverse, given the numbers of isoform combinations that are possible) effector systems. Specifically, opioid receptors couple in this way with adenylyl cyclase and ion channels to reduce neurotransmitter release (see later).

The amino acid sequences of the three opioid receptors are most homologous in the transmembrane domains and intracellular loops; the sequences share little homology in the extracellular loops and N- and C-termini. Each receptor is distributed differently in the CNS, peripheral nervous system, and smooth muscle of the gastrointestinal tract. A receptor with high sequence homology to the three cloned opioid receptors, termed *ORL-1* (for opioid receptor–like, an "orphan" receptor), has been discovered.[21,33] Despite its structural similarity to opioid receptors, opioids do *not* bind to ORL-1 with high affinity. A heptadecapeptide termed *orphanin FQ* (or nociceptin), which is structurally similar to the endogenous opioid peptide dynorphin, seems to be the endogenous ligand for ORL-1 (which has been renamed the *N/OFQ receptor [NOP]*). Nociceptin does not act at any of the three cloned opioid receptors, however, and the nociceptin–NOP ligand–receptor complex may instead function to facilitate pain at some sites.

Another heptadecapeptide, termed *nocistatin*, is also derived from the same gene that gives rise to nociceptin. Nocistatin is reported to "block" the effects of nociceptin, but nocistatin does not displace nociceptin from its receptor

TABLE **20-1**

Characterization of Opioid Receptors and Their Ligands

(ORL-1),[26] indicating that the opposing effects of nocistatin are produced at a yet to be identified receptor.[49] It is believed now that nocistatin exerts an inhibitory effect through a presynaptic G_i/G_o-coupled receptor not related to either the opioid receptors or the NOP receptor.[5]

The μ receptor is the site at which all the currently available pure agonists act to produce analgesia. Morphine and other similar pure agonists have greatest affinity for μ receptors in the CNS and peripheral nervous system and lower affinity for δ and κ receptors. Among the endogenous opioid peptides, the endomorphins have the highest affinity for the μ receptor; β-endorphin and the enkephalins also exert some of their effects at μ receptors. Two subtypes of μ receptor have been characterized by pharmacologic means: μ_1, which is associated with supraspinal analgesia, and μ_2, which subserves spinal analgesia, respiratory depression, and gastrointestinal actions. Pharmacologic studies have also implied the existence of two subtypes of δ receptor, at which the endogenous enkephalins are considered to be the prototypic agonists, although the enkephalins also interact with μ receptors. The δ receptor is also involved in analgesia, mainly through spinal mechanisms, and in causing, along with μ receptors, opioid reinforcement (see Chapter 51).

Dynorphins, representing the third class of endogenous opioid peptides, have been proposed to be ligands for the κ receptor, of which three subtypes have been characterized pharmacologically. Two κ receptors mediate spinal (κ_1) and supraspinal (κ_3) analgesia and are principally responsible for the analgesic effects of the mixed agonist-antagonist group of opioid analgesics currently available. Although the endomorphins selectively bind to the μ opioid receptor,[48] other endogenous opioids and clinically available drugs do not bind selectively to specific opioid receptors. Although morphine and other pure agonists preferentially bind at μ receptors, they can produce effects at δ and κ opioid receptors as well, particularly as the dosage is increased.

Despite pharmacologic evidence for the existence of multiple subtypes of opioid receptors, only one of each opioid receptor has been cloned. There is no evidence at present for the existence of genes other than those that give rise to the already cloned μ, δ, and κ receptors. It is possible that not all opioid receptor genes have been cloned, but molecular mechanisms and other factors most likely explain the pharmacologic diversity of effects produced by various ligands at opioid receptors. Receptor isoforms may be produced by alternative splicing in the coding regions of the three cloned opioid receptors.[7] Variant mRNAs have been reported for all three opioid receptors, although their expression is typically very low, and it is not clear that splice variants can be distinguished pharmacologically. It seems more likely that other mechanisms (e.g., post-translational regulation, variable activation of receptors by different ligands, receptor dimerization, intracellular interactions with proteins associated with different effectors) explain the pharmacologic diversity of opioid receptor subtypes. Many G protein–coupled receptors exist as dimers (two receptors linked), and heterodimerization of δ and κ receptors could result in a complex pharmacologic profile.

The sigma (σ) receptor, initially considered to be an opioid receptor, is now known to mediate the dysphoric and psychotomimetic effects of opioids and those of phencyclidine, a nonopioid hallucinogen. This phencyclidine receptor has been identified as an inhibitory component of the N-methyl-D-aspartate receptor complex, which modulates opioid tolerance and dependence.

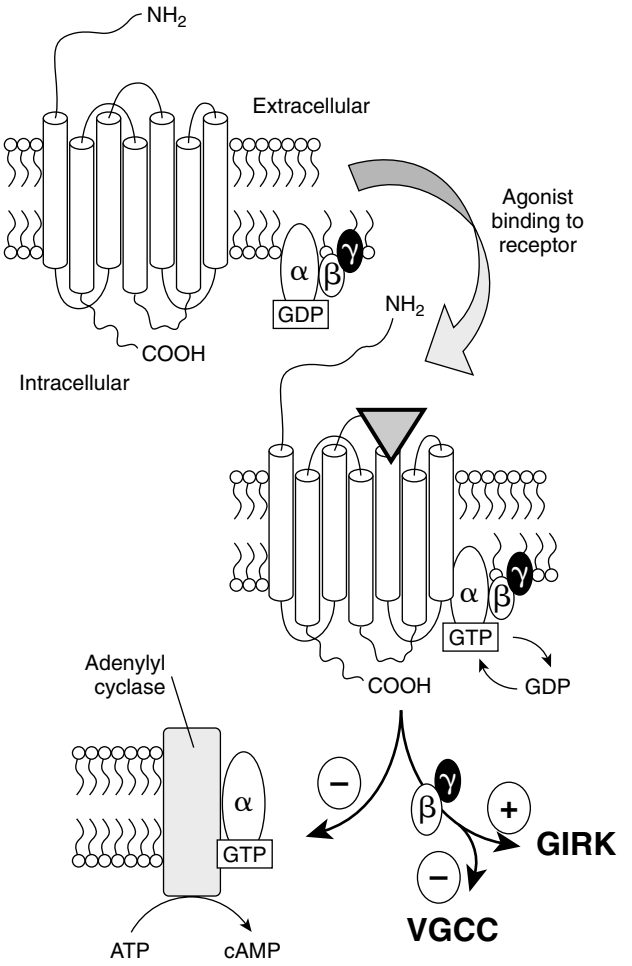

FIGURE **20-2** Diagram of a G protein–coupled opioid receptor. Opioids bind within the hydrophobic membrane-spanning domains of the receptor. Opioid agonist effects at the receptor are mediated by G proteins, an α subunit associated with guanosine diphosphate (*GDP*), and a β-γ dimer. When an opioid agonist binds, the conformation of the receptor is changed as the membrane-associated G proteins assemble with the receptor. GDP is exchanged with guanosine triphosphate, and this activated G_α complex negatively regulates adenylyl cyclase. The β-γ dimer activates conductance in a G protein inwardly rectifying K^+ (*GIRK*) channel and inhibits voltage-gated Ca^{++} channels (*V*GCC) in the cell membrane. (See Chapters 1 and 5 for more details on signal transduction.) *ATP,* Adenosine triphosphate; *cAMP,* cyclic 3′5′-adenosine monophosphate.

Physiologic functions

Much remains to be learned about the physiologic roles of the endomorphins, enkephalins, dynorphins, and endorphins. It is established that enkephalins, present principally in local circuits or interneurons in the CNS, have an inhibitory effect on other cells. Endogenous opioids tonically modulate the secretion of gonadotropins from the pituitary. When the opioid receptor antagonist naloxone is administered to normal subjects, the plasma concentrations of luteinizing hormone and follicle-stimulating hormone are increased because naloxone releases hypothalamic neurons from a tonic endogenous opioid inhibition.

Considerable attention has been given to the notion that endogenous opioid peptides tonically modulate nociception (pain). One would expect occupation of opioid receptors by naloxone to prevent any action by endogenous opioid peptides and lower the response threshold for pain if endogenous opioids tonically modulated nociception. A number of studies have shown that the administration of naloxone to normal human volunteers does not affect their resting pain thresholds or responses to experimental pain stimuli. In other situations, naloxone has been reported to attenuate the analgesic effects of acupuncture and of placebo administration after minor oral surgery and to be hyperalgesic in humans after major surgery.[31] From these and other findings,[8] it seems that endogenous antinociceptive opioid systems are normally quiescent but can become physiologically active and affect pain processing when significant injury or stress is present. It seems that endogenous opioid activity can be enhanced by the anticipation of pain relief, producing naloxone-reversible placebo effects that diminish the perception of pain (i.e., elicit analgesia).[6]

Sites and mechanism of action

Among the many effects of opioids, analgesia has been most thoroughly studied. We now know that opioids acting at opioid receptors in the periphery and at spinal and supraspinal sites can produce clinically effective analgesia. Knowledge of the central sites of opioid action came first; documentation of direct peripheral analgesic actions of opioids is relatively recent.[38]

Early investigators attempted to determine the central locus of morphine's analgesic action by administering morphine directly into selected brain sites. These studies succeeded in identifying an area of the brainstem surrounding the cerebral aqueduct as a site important to morphine analgesia. Corollary studies found that electrical stimulation of this same area in the midbrain in animals and humans produced a potent, long-lasting analgesia partially mediated by endogenous opioids.[11] Morphine and other opioid agonists acting at this site produce analgesia by engaging a descending system of pain inhibition.[8]

As illustrated in Figure 20-3, information about pain from nociceptors—that is, peripheral receptors in skin, muscle, joints, and viscera that respond to pain-producing stimuli—can be influenced at the first central synapse (spinal or medullary dorsal horn) by this descending system of pain inhibition. It is important to appreciate two features of this pain-modulating system: the descending pathway from the midbrain is indirect (there is a synaptic relay in the medulla or the dorsolateral pons or both), and although engaged by an opioid acting at opioid receptors in the midbrain, the neurotransmitters in the spinal cord or medullary dorsal horn that ultimately inhibit pain transmission are nonopioids such as 5-hydroxytryptamine (5-HT, serotonin) and norepinephrine.[8] Engagement of the descending pain inhibitory circuit is also responsible for placebo-induced analgesia.

A second means by which morphine and other opioid agonists modulate pain is by acting at opioid receptors in the brain at sites not associated with activation of the descending pain inhibitory system. Actions of opioids at these brain sites do not affect the response threshold to a painful stimulus but rather influence the interpretation of and emotional reaction to the stimulus.[31] This so-called motivational-affective component of the response to pain is discussed later in this chapter.

A final means by which morphine and other opioid agonists produce analgesia is by acting at opioid receptors located on the peripheral and central terminals of nociceptors. Opioid receptors are located on the terminals of these specialized nerve fibers, typically Aδ and C fibers, which connect the periphery directly with the CNS. Analgesic effects of opioids can be produced by direct administration of an opioid into a joint or, more commonly, the epidural or intrathecal space.[46]

Opioids can act at several sites, each of which can contribute independently to the analgesia produced. When given

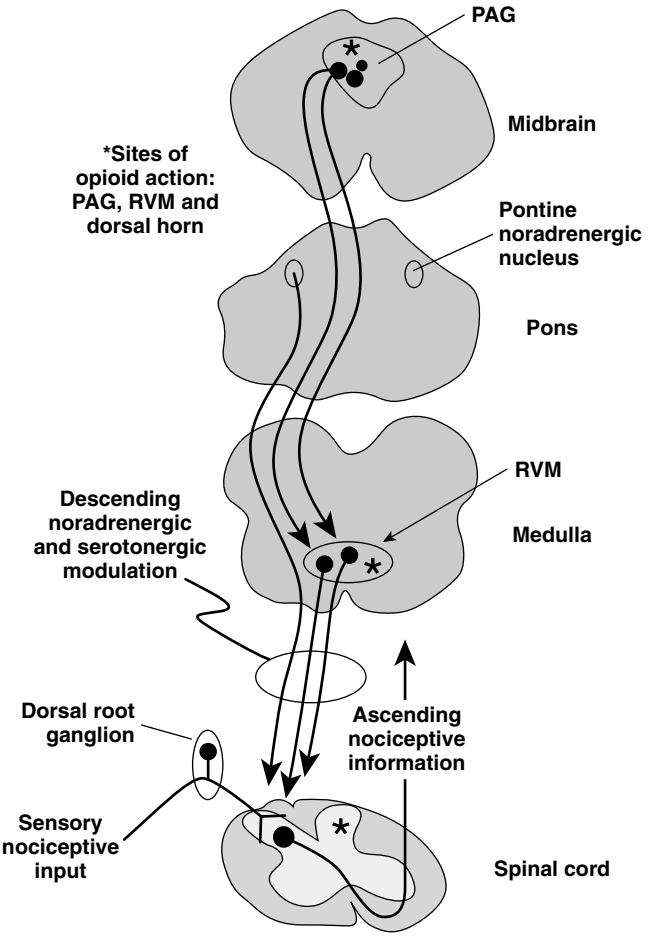

FIGURE **20-3** Descending pain-modulating pathways from the brainstem to the spinal cord. Descending influences, whether activated in the midbrain periaqueductal gray (*PAG*) or rostroventral medial medulla (*RVM*) by endogenous or exogenous opioids (*) or stimulation, are mediated at the level of the spinal cord by noradrenergic and serotonergic receptors.

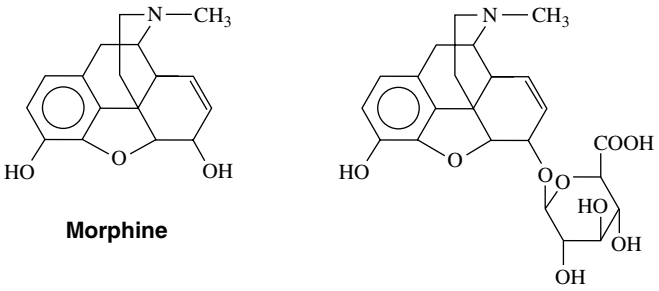

FIGURE **20-4** Structural formulas of morphine and its active metabolite morphine-6-glucuronide.

systemically, opioids have access to all potential sites of action, and the analgesia produced is likely a product of peripheral, spinal, and supraspinal interactions with opioid receptors. These mechanisms are likely to be synergistic resulting in increased opioid potency and, consequently, reduced toxicity. This knowledge can be used to improve pain control and limit the incidence or severity of undesirable opioid effects. Because pain modulation descending from the brainstem is mediated in the spinal cord by norepinephrine and 5-HT, the direct effects of an opioid given into the epidural space can be enhanced by epidural administration of an α-adrenoceptor agonist such as clonidine.[24]

Tricyclic antidepressants, which block the reuptake of norepinephrine and 5-HT, are also effective adjuvants (although antidepressants such as amitriptyline also possess analgesic efficacy unrelated to their effects on monoamine reuptake). This strategy allows reduction of the dose of opioid without compromising the analgesia produced. Two drugs, tramadol and tapentadol, produce analgesic actions by engaging multiple mechanisms, including activity at the opioid receptors and inhibition of reuptake of norepinephrine or serotonin or both. By requiring less opioid for adequate pain control, undesirable opioid effects, such as urinary retention, respiratory depression, sedation, and development of analgesic tolerance, can be reduced. It has also been documented that administration of very low doses of morphine directly into the knee joint after arthroscopic knee surgery can control postoperative pain.[38]

The mechanisms by which opioids produce their effects are best established for direct actions at opioid receptors located on neurons. Actions commonly produced at all three opioid receptors include inhibition of adenylyl cyclase, inhibition of Ca^{++} conductance, activation of K^+ conductance, and inhibition of neurotransmitter release (see Figure 20-2). Acute inhibition of adenylyl cyclase by an opioid leads to a decrease in intracellular cyclic 3′,5′-adenosine monophosphate, decreasing an inward, nonselective cation current and decreasing cell excitability. All three opioid receptors also activate a G protein inwardly rectifying K^+ conductance and inhibit voltage-activated Ca^{++} currents, both events mediated by G protein β-γ subunits. Because Ca^{++} influx is required for the stimulus-secretion coupling of neurotransmitter release, opioids decrease the release of excitatory neurotransmitters, such as glutamate, substance P, and calcitonin gene–related peptide, from nociceptor terminals and attenuate the transmission of nociceptive information at the first central synapse. Because opioids activate this G protein–rectifying K^+ conductance, they produce a relative hyperpolarization of neurons, making them more difficult to excite.

Morphine

The structure of morphine is shown in Figure 20-4. Morphine is the prototypic opioid analgesic (pure agonist) and the one about which most is known. Morphine is widely used for pain control and can be given by virtually any route of administration. All opioid analgesics share with morphine the ability to produce analgesia, respiratory depression, constipation, gastrointestinal spasm, and physical dependence; none has yet been shown to be significantly different from or superior to morphine regarding its important pharmacologic features. The incidence of untoward effects (e.g., respiratory depression) and the intensity of action of pure agonists are qualitatively similar and differ little when compared at doses that produce equivalent analgesia. Consequently, morphine is discussed in greater detail than other opioid analgesics, and what is stated for morphine applies in general to other pure agonists. Significant differences that exist between morphine and other opioids are mentioned as each individual agent is discussed.

Central pharmacologic effects

The CNS effects of morphine are a combination of stimulation and depression and include analgesia, drowsiness, euphoria-dysphoria, respiratory depression, suppression of the cough reflex, pupillary constriction, suppression of the secretion of some (luteinizing hormone) and enhancement of other (prolactin) pituitary hormones, and initial stimulation of the

medullary chemoreceptor trigger zone for emesis followed by depression of vomiting.

Analgesia. The analgesia produced by morphine and other pure agonists occurs without loss of consciousness. When opioids are administered for relief of pain (or for a cough or diarrhea), they provide only symptomatic relief without alleviation of the cause of the pain (or cough or diarrhea). The analgesia produced by opioid analgesics is dose-dependent and selective in that other sensory modalities (e.g., vision, audition) are unaffected at therapeutic doses. The standard parenteral analgesic dose of morphine, 10 mg/70 kg of body weight, is considered a therapeutic dose for relief of moderate-severe pain. Because pain is a highly subjective and personal experience, however, adequate pain relief is best achieved by titrating the dose to the needs of the patient.

As already discussed, the sites of opioid-produced analgesia include the periphery and spinal and supraspinal brain areas. It is generally accepted that opioid-induced analgesia involves the sensory-discriminative and motivational-affective components of pain. The sensory-discriminative component of pain is associated with identification and localization of the source of pain, whereas the motivational-affective component of pain is related to one's reaction to pain.[33] Pain is not a simple sensation associated with a single pain pathway from the periphery to the cortex, but rather, it is a complex experience that can be influenced by the environment in which the pain arises: prior experience and expectation; attention, anxiety, mood, and stress levels; and other societal, emotional, and cognitive contributions. The nociceptive component of pain may not be as much affected by opioid analgesics as is the reaction to pain. A common report from patients after receiving an opioid for relief of pain is that the pain is still present, but that it is not discomforting. Clinical impressions and patients' reports suggest a prominent action by opioid analgesics on the motivational-affective component of pain, presumably resulting from opioid actions at opioid receptors within the limbic system of the brain.

An additional significant feature of opioid analgesics is that they are generally more effective against continuous, dull, aching pain than sharp, intermittent pain. It is also known that sensitivity to pain and the ability to clear morphine decrease with age, whereas the elimination half-life of morphine increases with age; the pain relief provided by morphine typically increases with age.[14,28]

Respiratory depression. Morphine and its congeners depress respiration in a dose-related fashion. Respiratory depression represents the principal undesirable, potentially life-threatening effect of opioids as a group. Opioids are capable of depressing the tidal volume and the rate of respiration. In humans, morphine decreases the response of brainstem respiratory centers to the carbon dioxide tension of the blood. It also significantly depresses pontine and medullary centers that regulate respiratory frequency.[2] Irregular rhythms and periodic breathing are common after toxic doses of morphine or its congeners, and the normal respiratory rate of 16 to 18 breaths/min may be reduced to 3 to 4 breaths/min. All currently available opioid analgesics are capable of depressing respiration in a manner similar to that of morphine when administered in doses that produce equal analgesia.

Cough suppression. Morphine and other pure agonists are effective antitussives; codeine is widely used in cough preparations for this purpose. Morphine itself is not commonly used as a cough suppressant. Opioids exert their antitussive effect by depressing an area in the brainstem. Although the brainstem sites for the respiratory depressant and antitussive effects of opioids are anatomically close, there is no apparent relationship between opioid depression of one or the other because suppression of the cough reflex occurs at opioid doses lower than those required to produce an analgesic effect or to depress respiration.

Pupillary reaction. At therapeutic doses, morphine and most of its congeners produce pupillary constriction (miosis) in humans. The emphasis on humans is significant because in some other species, such as cats, in which opioids exert primarily an excitatory effect, the pupils are dilated by morphine. The miosis produced by opioids results from a central effect mediated by the oculomotor nerve and not from a direct action on the circular or radial muscles of the iris of the eye. Although tolerance to opioids has not yet been discussed, it is appropriate to indicate here that tolerance to the pupillary-constricting effect of morphine and some other opioids does not develop to any appreciable extent. Consequently, long-term users of morphine and heroin continue to have constricted pupils, although they likely will have developed tolerance to many other opioid effects.

Nausea and vomiting. Opioids directly stimulate the chemoreceptor trigger zone in the medulla and can produce emesis. Opioids are commonly given before, during, and after surgery, and nausea and vomiting are highly undesirable. After the initial period of stimulation, however, opioids depress the brainstem medullary center for vomiting. This subsequent depression occurs at therapeutic concentrations and is virtually total; other opioid analgesics or emesis-inducing agents administered during this time are generally ineffective in causing emesis. There is also apparently a vestibular component to the nausea produced by morphine and its congeners because nausea occurs more frequently in ambulatory than in recumbent patients.

Peripheral pharmacologic effects

Morphine exerts important influences on smooth muscle tone that have therapeutic and toxic implications. The drug also affects gastrointestinal activity by reducing glandular secretions and by promoting absorption of fluid from the gastrointestinal lumen.

Gastrointestinal tract. The use of opium for relief of diarrhea and dysentery antedated by centuries the use of opium for relief of pain. Opioids exert significant effects on smooth muscle all along the gastrointestinal tract. The overall action of morphine and its congeners is constipating, an effect that is useful therapeutically. Opioid analgesics, acting principally at opioid receptors in the gastrointestinal tract but also at opioid receptors in the CNS,[41] increase smooth muscle tone and decrease propulsive motility throughout the gastrointestinal tract. In the large intestine, muscle spasms can result from the marked increase in muscle tone and nonpropulsive muscle contractions. Spasm of the smooth muscle of the biliary tract, which can be very painful, can also occur after the administration of therapeutic doses of morphine and related drugs.

Morphine and other pure agonists delay gastric emptying. In addition, gastric acid secretion is usually depressed, and pancreatic, biliary, and intestinal secretions are routinely depressed by opioid administration. Inhibiting intestinal hypersecretion and promoting reabsorption are important contributors to the beneficial effect of morphine in the treatment of diarrhea.

Other smooth muscle. Morphine and other pure agonists also increase muscle tone in smooth muscle of organs other than those of the gastrointestinal tract, such as the ureters, urinary bladder, uterus, and bronchioles, but at therapeutic doses the effect of opioids on these muscles is generally unremarkable.

Urinary retention, characterized by urgency and increased tone of the bladder sphincter, is common after all routes of opioid administration. In addition to effects on tone and contractility of smooth muscle, opioids also possess antidiuretic effects. Although opioids increase uterine tone, they do not generally influence the duration of labor. Likewise in the bronchial musculature, opioids administered at usual therapeutic doses do not produce significant bronchoconstriction, even though they may aggravate an asthmatic condition or precipitate an asthmatic attack resulting in part from histamine release.

In large doses, opioid effects on all these smooth muscles may be significant. Contraction of the ureter contributes to cessation of urine flow; increased uterine tone significantly prolongs labor and may increase neonatal morbidity rates; and bronchoconstriction occurs.

Cardiovascular system. The effects of morphine and other pure agonists on blood pressure, heart rate, and cardiac work are generally minor at analgesic doses. The vasomotor center of the medulla is relatively unaffected by opioid analgesics, and blood pressure is maintained near normal even after intoxicating doses of opioids. The decrease in blood pressure observed during acute opioid intoxication is primarily caused by hypoxia that results from opioid-induced respiratory depression.

Morphine and several other opioid analgesics release histamine and produce some vasodilation of the peripheral vasculature, often resulting in an overall sensation of warmth accompanied occasionally by itching of the face and nose. There also seems to be a poorly understood contribution by the CNS to peripheral vasodilation. The resultant decrease in peripheral resistance is the primary cause of the orthostatic hypotension and fainting that occur occasionally in some recumbent patients when the head-up position is suddenly assumed. Opioids have no direct effect on the vasculature and circulation of the brain, but cerebral vasodilation is a common consequence of opioid administration. Cerebral vasodilation is considered to be a consequence of the respiratory depression produced by morphine and its congeners and the subsequent retention of carbon dioxide in the blood. The result is an increase in cerebrospinal fluid pressure, which requires that opioids be used cautiously in cases of cranial trauma and head injury, where cerebrospinal fluid pressure may already be elevated. Morphine is also occasionally used in the treatment of pulmonary edema, where it is quite effective. The mechanism by which morphine exerts this beneficial action is unclear, but morphine seems to inhibit adrenergic tone centrally, promoting redistribution of blood to the periphery and reducing pressure in the pulmonary veins and capillaries without causing concomitant reduction of systemic arterial pressure.

Peripheral analgesia. An increasingly important peripheral action of opioids—analgesia—is now appreciated.[38] As indicated earlier in this chapter, opioid receptors are located on the central and peripheral terminals of nociceptors. When tissue is insulted and inflamed, peripheral opioid receptors upregulate (increase in number or are inserted into peripheral nociceptor terminals in greater number). This event is presumably part of the normal response to tissue insult where endogenous opioid peptides contained in monocytic cells or lymphocytes, attracted to the site of injury, are released to modulate pain associated with the tissue insult. Therapeutically, the upregulation of opioid receptors can be taken advantage of by application of exogenous opioid agonists directly to the site of insult (e.g., intra-articular injection of morphine, topical application of μ opioid receptor agonists).

Acute opioid intoxication

Death from acute intoxication by an opioid analgesic is the result of profound, direct respiratory depression. The cardinal signs of acute opioid intoxication (overdose) represent an extension of the pharmacologic features of these drugs: stupor, constricted pupils, and depressed respiration. As the severity of intoxication increases, coma ensues, and the blood pressure, initially maintained close to normal, steadily decreases if the hypoxia associated with the respiratory depression is unaltered. Measures must be instituted to support respiration in cases of intoxication; pupillary dilation and shock, both caused by persistent hypoxia, precede death in the absence of alteration in the respiratory status of an intoxicated individual.

The essential principle of treatment of acute opioid intoxication is restoration of adequate ventilation. Restoration of ventilation is most rapidly and dramatically achieved by administration of an opioid receptor antagonist (e.g., naloxone), but in the absence of immediately effective opioid receptor antagonism, a patent airway must be established, and efficient pulmonary gas exchange must be restored, by artificial respiration if necessary. Restoration of adequate pulmonary ventilation prevents the hypoxic cardiovascular sequelae of opioid intoxication. Although opioid antagonists have not yet been discussed, it is important to interject two notes of caution regarding their use in cases of opioid intoxication. First, the duration of action of naloxone, the standard opioid receptor antagonist, is shorter than that of most opioid analgesics (which have been given or taken in excess). Consequently, an opioid-intoxicated individual typically requires continued monitoring and readministration of additional naloxone as necessary. Second, administration of an opioid receptor antagonist to an acutely intoxicated, opioid-dependent individual can precipitate a withdrawal syndrome that cannot readily be attenuated during the period of action of the antagonist.

Tolerance

Tolerance is a decreased effect of a drug as a consequence of prior administration of that drug. Increasingly greater doses of drug must be administered over time to produce an effect equivalent to the effect produced on initial administration. Tolerance does not develop uniformly to all opioid effects. Generally, tolerance develops to the depressant effects of opioids but not to the stimulant effects. Tolerance develops to opioid-induced analgesia, euphoria, drowsiness, and respiratory depression but not, to any appreciable extent, to opioid effects on the gastrointestinal tract or the pupil.

In the therapeutic setting, the initial indication that tolerance has developed is generally reflected in a shortened duration or reduced analgesic effect. The rate at which tolerance develops is a function of the dose and the frequency of administration and perhaps other, nonpharmacologic factors. Although some patients remain normally sensitive, most patients treated for 5 to 7 or more days exhibit tolerance to the analgesic (and other) effects of opioids. Generally, the greater the opioid dose and the shorter the interval between doses, the more rapidly tolerance develops. Tolerance can develop to such an extent that the lethal dose of the opioid is increased significantly. For any individual, however, there always exists an opioid dose capable of producing death by respiratory depression, regardless of the extent to which tolerance has developed.

The mechanisms by which tolerance develops to opioids are controversial. One hypothesis points to a role of internalization of G protein–coupled receptors, which include opioid receptors, after being bound by an agonist. Internalization is a multistep process in which opioid receptors are uncoupled from their heterotrimeric G proteins, phosphorylated by a receptor kinase, and targeted for endocytosis by clathrin-coated pits.[39] When in the intracellular endosomal compartment, opioid receptors can be recycled for reinsertion into the

cell membrane, sustaining agonist activity (i.e., diminishing tolerance), or degraded, which can result in receptor downregulation (a reduction in the number of receptors) and enhancing opioid tolerance.[20] Although acute desensitization is common to virtually all G protein–coupled receptors and occurs rapidly (seconds to minutes) after occupation of a receptor by its agonist, the time course of these cellular effects does not seem to match loss of agonist activity observed in humans. Tolerance may represent longer term desensitization and downregulation of receptor-effector coupling by mechanisms not yet fully understood.[20]

In a second hypothesis, more recent studies point to neuroplastic changes in the neuraxis as underlying tolerance to the analgesic action of opioids. Persistent exposure to opioids triggers an activation of pain modulatory pathways from the brainstem that can promote the increased responses of spinal cord neurons to input from peripheral nociceptor afferents.[16,27] This situation results in increased transmission of painful signals arriving from peripheral sites and an increase in pain signals that are transmitted to the brain. This increase in "gain" requires increased doses of opioids to produce inhibition and to offset the augmented pain. The consequence is a requirement for increased doses of opioids resulting in a rightward displacement of the dose-response function and the manifestation of analgesic tolerance.[16,27]

Dependence

In contrast to tolerance, which becomes apparent during repeated drug administration, dependence is apparent only in the absence of drug. Dependence can be physical or psychological. *Physical dependence*, as defined by the American Society of Addiction Medicine, is a state of physiologic adaptation that is manifested by a drug class–specific withdrawal syndrome that can be produced by abrupt cessation of the drug, rapid dose reduction, decreasing blood content of the drug, or administration of an antagonist. Just as the rate of development of tolerance to opioids is dose related, so too is the development of physical dependence. The greater the opioid dose and the longer the duration of administration, the greater the degree of physical dependence and the more intense the withdrawal syndrome. The mechanisms underlying the development of tolerance to and physical dependence on opioids are not fully understood. Although tolerance and physical dependence develop concurrently, they develop through different mechanisms and are apparently not related phenomena.

Physical dependence results from adaptations at cellular, synaptic, and systemic levels that in some ways are analogous to adaptive processes better understood as nervous system plasticity in the context of learning and memory (i.e., *long-term potentiation*).[34] The underlying cellular and synaptic mechanisms that contribute to the development of opioid physical dependence are unknown.

Psychological dependence is more difficult to define and measure. Psychological dependence contributes more to drug-seeking behavior than physical dependence and contributes significantly to addiction. As defined by the American Society of Addiction Medicine, *addiction* is the extreme of compulsive drug use and is characterized by continued use, impaired control over drug use, and craving despite harm. Physical dependence can exist in the absence of psychological dependence, and it is inappropriate to identify as "addicted" an individual who becomes physically dependent after repeated opioid administration during hospitalization. All three phenomena—tolerance, physical dependence, and psychological dependence—are reversible, although psychological dependence provides a strong drive to drug abuse. It is now well documented that drugs that release or prolong the actions of the monoamine neurotransmitter dopamine in the mesocortical or mesolimbic systems potently activate endogenous reward pathways in the brain. Although the commonly abused drugs are structurally and pharmacologically heterogeneous (e.g., nicotine, alcohol, opioids, cannabinoids, cocaine), they all possess the ability to activate the mesocorticolimbic system, a brain network important to initiating and maintaining drug craving.

Opioid analgesics are often rated in terms of "dependence liability" to indicate opioids considered to be more likely to produce significant physical dependence than others (Table 20-2). It is unclear how significant the differences are among opioid analgesics when they are compared at equianalgesic doses given by the same route of administration and at appropriate intervals. When opioid analgesics are compared in terms of how they are generally used therapeutically, however, differences in dependence liability are apparent. Morphine has a greater dependence liability than codeine when both are used in traditional therapeutic modes (i.e., morphine given parenterally for moderate-severe pain and codeine given orally for mild-moderate pain).

Health professionals and patients alike are concerned about the use of opioids for pain control, particularly in cases of persistent pain. This "opiophobia" is a reaction to fear of dose escalation, which is caused by the development of tolerance and erroneously interpreted as a sign of physical dependence (also erroneously termed "addiction") associated with treatment for pain that lasts more than a few days. Most knowledge about analgesic tolerance and physical dependence derives from studies that use models of acute pain or repeated dosing with opioids in the absence of persistent pain. More recent clinical investigations and observations in patients with chronic pain have led to modification of views on the potential importance of analgesic tolerance and physical dependence to adequate pain control.[29,42] It has been found that dose escalation for pain control is usually required only at the start of therapy (i.e., when titrating the dose to provide adequate analgesia), and that dose requirements tend to stabilize thereafter for long periods. It is of utmost importance to stress that development of analgesic tolerance, in and of itself, is not a sign of dependence.

Absorption, fate, and excretion

Morphine in particular and most opioids in general are not nearly as effective when given orally as when given parenterally in the same dose. For morphine, oral administration for relief of pain is approximately one third to one sixth as potent as the same dose given parenterally. Because absorption of morphine is good after oral administration, most of the difference in effect between the oral and parenteral routes is caused by metabolic inactivation during morphine's first pass through the liver. The primary pathway for the metabolism of morphine is conjugation with glucuronic acid, and the principal metabolite is morphine-3-glucuronide (approximately 55% of the administered dose). Morphine is also glucuronidated at the 6 position (approximately 10% of the administered dose; see Figure 20-4). Morphine-6-glucuronide has a high affinity for the μ receptor and is a potent and efficacious analgesic, especially when injected to bypass the blood-brain barrier.[9,30] Because it accumulates in the bloodstream, morphine-6-glucuronide may be largely responsible for the analgesic effects of morphine administered on a long-term basis.

Most of the conjugated morphine is eliminated from the body by the kidney; only small amounts of free morphine are found in the urine. Some morphine glucuronide also appears in the bile, and a small percentage is eventually excreted in the feces. Morphine does not generally accumulate in tissues; the total excretion of an administered dose is usually approximately 90% complete in the first 24 hours.

TABLE **20-2**

Comparison of Opioid Analgesics

NONPROPRIETARY (GENERIC) NAME	PROPRIETARY (TRADE) NAME	USUAL THERAPEUTIC DOSE (mg)	ROUTE OF ADMINISTRATION	DURATION (hr)	DEPENDENCE LIABILITY
Alfentanil	Alfenta	0.5-2*	IV	0.5	High
Buprenorphine†	Buprenex	0.3-0.6	IM, IV	4-6	Low
Butorphanol†	Stadol	1-4	IM	3-4	Low
		0.5-2	IV	2-4	Low

Oxycodone	In Percodan	5-10	Oral	4-5	High
Oxymorphone	Numorphan	1-1.5	IM, SC	4-6	High
		0.5	IV	4-6	High
Pentazocine†	Talwin	30	IM, IV, SC	3-4	Low
	Talwin NX	50	Oral	3-4	Low
Propoxyphene	Darvon	32-65	Oral§	4-6	Low-moderate
Sufentanil	Sufenta	0.01-0.025*	IV	0.5-1	High
Tramadol	Ultram	50-100	Oral	4-6	Low

Estimates of duration and dependence liability are based on information in the literature and are not definitive.
*Larger doses may be used for general anesthesia.
†Mixed agonist-antagonist.
‡Heroin is a Schedule I drug and is unavailable for routine clinical use.
§The efficacy of oral meperidine and propoxyphene is controversial.
IM, Intramuscular; *IV,* intravenous; *SC,* subcutaneous.

Although morphine is subject to significant first-pass metabolism after oral administration, it is widely used orally for the management of chronic pain (e.g., management of cancer pain). The oral dose of morphine in liquid form can range from less than 10 mg every 4 hours to 2500 mg every 4 hours; most patients require no more than 200 mg/day. Morphine is also available for oral use in controlled-release tablets to produce longer lasting analgesia (e.g., 12 hours). Regarding the wide dose ranges reported necessary for pain control in cases of chronic pain, it first must be appreciated that chronic pain is controlled by titration of the dose to prevent pain breakthrough and, second, that analgesic tolerance is likely present or will develop. Dosages of morphine required to manage chronic pain can be quite high. In terminally ill patients, there should be no concern about the development of physical dependence.

General therapeutic uses

Pain is a common symptom that initiates a visit to a dentist or physician. Pain is almost always present after invasive procedures or surgery. Morphine and other pure agonist opioid analgesics are the most efficacious analgesic drugs known and are without peer in their ability to control pain. As emphasized earlier, these drugs provide only symptomatic relief of pain without influencing its underlying cause. The opioids, when administered at therapeutic doses to produce analgesia, also produce a drowsiness from which the patient is generally easily aroused and a tranquilization. There is without doubt a significant antianxiety or sedating component in the analgesic effect of opioids. Although nausea and vomiting, respiratory depression, constipation, and tolerance and physical dependence can be drawbacks to their use, opioids undeniably produce an important combination of desirable effects (e.g., analgesia and sedation) in patients with pain.

Aside from their application for pain relief, opioids can be useful in inducing sleep, provided that sleeplessness is caused by pain or coughing. Opioid analgesics should not be used for nighttime sedation in the absence of coughing or pain. Morphine is also effective in the treatment of pulmonary edema. The use of morphine and other opioids in anesthesia is discussed at the end of this section.

Codeine

Codeine, similar to morphine, is a naturally occurring alkaloid present in opium powder. It differs from morphine only in that a methoxy substitution (–OCH_3) replaces the hydroxyl group at position 3 of the molecule (Figure 20-5). This subtle structural change provides codeine with significant oral effec-

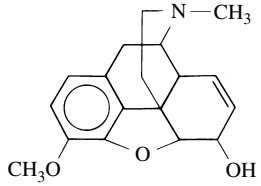

FIGURE **20-5** Structural formula of codeine.

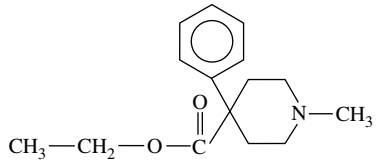

FIGURE **20-6** Structural formula of meperidine.

tiveness. Codeine is primarily used as an orally administered analgesic and antitussive. Similar to morphine, codeine is metabolized primarily by the liver and is excreted chiefly in the urine, largely in inactive forms. Additionally, a small percentage (approximately 10%) of codeine is demethylated at position 3 to form morphine, and free and conjugated morphine are found in small quantities in the urine after therapeutic doses of codeine. This conversion, plus the fact that codeine itself binds poorly to the μ receptor, has led to consideration of codeine as a prodrug insofar as its analgesic action is concerned.

As with all opioid analgesics, the analgesic and antitussive actions of codeine (and its respiratory depressant and sedative effects) are central in origin. Codeine is frequently classified as a weak or mild opioid analgesic. That codeine is a mild analgesic incapable of providing an analgesic effect equivalent to morphine is an erroneous, but widely held, impression. Morphine as an analgesic is about 12 times more potent than codeine when both drugs are administered intramuscularly. This ratio simply means that approximately 120 mg of codeine is required to produce an analgesic effect equivalent to 10 mg of morphine. At present, however, doses of codeine greater than 60 mg (orally) are not commonly used and are not officially recognized as generally safe and effective by the U.S. Food and Drug Administration (FDA). Consequently, the impression remains that codeine has limited analgesic efficacy and that a dose of 60 mg of codeine represents an "analgesic ceiling" above which increasing doses would not provide greater analgesic effect. This widely held belief, although supported by legal regulation, is inconsistent with clinical evaluations regarding the analgesic efficacy of codeine.[12]

The recommended analgesic dose of codeine is 30 to 60 mg orally; the recommended antitussive dose is 15 to 20 mg orally. At these doses, the side effects of codeine are few and generally insignificant; nausea, constipation, dizziness, and sedation are most frequently observed. At greater doses, the incidence of nausea and vomiting is increased, a particularly undesirable effect in individuals who have undergone dental surgery. Among the opioids, codeine is especially suitable for relief of pain in ambulatory individuals because it is orally effective; can provide significant analgesia and relief of dull, continuous pain; and can be taken for relatively long periods with little or no risk of physical dependence. A dose of 60 mg of codeine taken three to four times daily over 6 to 8 weeks is not associated with the development of significant physical dependence. Tolerance develops to the analgesic effect of codeine over time, however, and it is likely that the dose will need to be gradually increased.

The demonstrated analgesic usefulness of codeine in some situations that show little or limited response to nonopioid analgesics makes codeine a useful drug for certain pain states. Dental pain associated with inflammation should not be treated with codeine alone because neither codeine nor any of the other opioids has anti-inflammatory properties. Rather, aspirin or another nonsteroidal anti-inflammatory drug alone or in combination with codeine is appropriate for cases of dental pain involving or arising from inflammation.

Dihydrocodeine, Oxycodone, and Hydrocodone

Dihydrocodeine (contained in Synalgos DC), oxycodone (contained in Percodan), and hydrocodone (contained in Vicodin) are phenanthrene opioids similar in structure to morphine and codeine. Similar to codeine, these drugs have a methoxy substitution (–OCH_3) for the hydroxy group at position 3 of the basic morphine molecule. They have good oral efficacy and are primarily used as oral analgesics. They do not differ significantly from morphine in terms of their important pharmacology. Oxycodone is approximately equipotent with morphine when given parenterally; it is used only in oral preparations, however, in the United States. An oral dose of 5 mg of oxycodone is approximately equivalent to 30 to 60 mg of codeine. A controlled-release preparation of oxycodone (OxyContin) has been the subject of controversy because of abuse potential and toxicity. The abuse potential for this form of oxycodone seems to be caused, at least in part, by the higher net quantity of the drug present in the controlled-release formulation. Hydrocodone is slightly less potent than oxycodone; as an antitussive, it is approximately 2.5 times more potent than codeine. The usual analgesic dose of dihydrocodeine is half that of codeine.

Meperidine

Meperidine is a synthetic phenylpiperidine analgesic drug that is structurally dissimilar to morphine (Figure 20-6). Meperidine was initially developed as an atropine-like drug but was subsequently discovered to possess significant analgesic efficacy. In 1939, it was introduced as an analgesic, sedative, and antispasmodic drug effective against most types of pain and supposedly free of many of morphine's undesirable properties. Over time, however, it has become clear that meperidine does not differ significantly from morphine in its important pharmacology, and in therapeutic doses (80 to 100 mg parenterally) it produces analgesia, sedation, respiratory depression, and the other CNS actions common to opioids as a class. Meperidine is approximately one eighth to one tenth as potent as morphine; when given parenterally at equianalgesic doses, the degree of sedation and respiratory depression is the same for both drugs. Because it retains some atropine-like action, pupillary constriction is less with meperidine, as is the incidence of spasm of the biliary tract. Similar to other opioid analgesics, meperidine can be spasmogenic to the smooth muscle of the gastrointestinal tract, but it differs from other opioids in that it is generally not considered to be valuable in the treatment of diarrhea. A meperidine congener, diphenoxylate (contained in Lomotil), is widely used for that purpose.

Meperidine, more than other pure agonists, is used as an analgesic in labor and delivery. Its peak analgesic effect occurs soon after parenteral administration, and its duration of action is short (3 to 4 hours). Maternally administered meperidine can produce neonatal respiratory depression, and the content of normeperidine, an active metabolite, in fetal blood increases over time; studies have not reported additional neonatal risks when meperidine was used, however.[19]

Meperidine is often mistakenly considered to be a useful oral analgesic drug at approximately the same dose given

parenterally (50 to 100 mg). Its oral effectiveness is approximately one fourth of its parenteral effectiveness; approximately four times the dose of meperidine must be administered orally to produce analgesia equivalent to the analgesia achieved with parenteral meperidine. The duration of action of meperidine is shorter than that of morphine, necessitating more frequent administration of meperidine for relief of continuing pain. Acute intoxication associated with meperidine also differs from intoxication associated with morphine in that CNS excitation, produced by the normeperidine metabolite and manifested as tremors and convulsions, can occur instead of the stupor and coma typically associated with morphine intoxication.

Finally, meperidine is commonly abused by health professionals who mistakenly believe that meperidine has a lower dependence liability and is easier to stop using than morphine. Meperidine dependence has been widely documented since the drug was first introduced, and meperidine has significant abuse potential.

Methadone

Methadone is a synthetic pure agonist opioid analgesic qualitatively similar in its pharmacology to other opioids. The diphenylheptane structure of methadone is shown in Figure 20-7; although it does not resemble morphine, methadone is induced by steric factors to assume the configuration that apparently is required for agonist interaction with μ-opioid receptors. Methadone is approximately equipotent to morphine and, aside from methadone's greater oral efficacy, differs little from morphine. Similar to morphine, methadone produces analgesia, sedation, respiratory depression, miosis, antitussive effects, and subjective effects similar to those of morphine. It also is constipating and can cause biliary tract spasm. It is well absorbed from the gastrointestinal tract and eventually becomes localized in the lung, kidney, and liver, where it undergoes extensive biotransformation. The major metabolites of methadone are excreted in the urine and in the bile, along with small quantities of unchanged drug.

Because methadone is a potent, orally effective analgesic agent, it was initially restricted by law for use in the treatment of opioid addiction. Methadone possesses a combination of properties that make its use in maintenance programs superior to other opioids. As already indicated, methadone has significant oral efficacy. Although its duration of action is similar to that of morphine after a single administration, methadone exhibits a persistent effect when given repeatedly. Methadone's duration of action is effectively increased, permitting single daily dosage to suppress withdrawal symptoms in opioid-dependent individuals.

The term *blockade* was used when the use of methadone in maintenance programs for heroin addicts was initially reported. Blockade of the effects of heroin and a disappearance of "drug hunger" in heroin addicts after the administration of relatively high doses of methadone were claimed. This description is misleading, however, because it promotes the interpretation that methadone's action is equivalent to receptor antagonism, endowing methadone with a pharmacologic property it does not possess. Methadone is not an opioid receptor antagonist; it is a pure agonist, as are the other opioids discussed in this section. The use of methadone (or any other opioid agonist) in maintenance programs relates to cross-tolerance and cross-dependence and not to some unique ability of methadone to "block" heroin's effects.

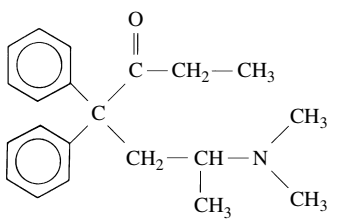

FIGURE **20-7** Structural formula of methadone.

Cross-tolerance among opioids means that if an individual has become tolerant to the effects of one opioid (e.g., heroin), he or she will also exhibit tolerance to the effects of other opioids. When cross-dependence exists, an individual physically dependent on one opioid can be switched to a different opioid to prevent the expression of withdrawal symptoms. These are general statements of principles that apply to the opioids as a class because the μ receptor is the principal receptor at which these agonists act. In practice, because there are differences among opioid agonists, cross-tolerance and cross-dependence are incomplete. As used in maintenance programs, methadone simply represents the substitution of one opioid for another, and methadone is used rather than other opioids primarily because it can be given orally and has an extended duration of action.

Propoxyphene

Propoxyphene is a synthetic opioid analgesic structurally related to methadone. Propoxyphene was initially introduced and legally classified as a "non-narcotic" analgesic. Currently, it is listed in Schedule IV of the Controlled Substances Act of 1970, whereas codeine, the opioid with which propoxyphene is usually compared, is listed in Schedule II. It has been amply shown that propoxyphene is subject to abuse and that physical dependence does develop during high-dose, long-term use. Overall, the dependence liability of propoxyphene is estimated to be slightly less than that of codeine.

Despite the foregoing, propoxyphene is either as efficacious or less efficacious than aspirin or acetaminophen for relief of pain.[23] Its toxicity is considerably more worrisome than that of these analgesics or of codeine, however, and its clinical use is diminishing. Although propoxyphene produces CNS effects that seem qualitatively similar to the CNS effects of codeine and other opioids, it is not generally agreed that analgesia is one of those central actions, at least at the doses commonly used. Nevertheless, propoxyphene has been widely used as an analgesic, and it is claimed that approximately 65 mg of propoxyphene hydrochloride or 100 mg of propoxyphene napsylate is equivalent in analgesic efficacy to 65 mg of codeine.

The currently recognized use of propoxyphene is for treatment of mild-moderate pain, and propoxyphene is often prescribed in place of codeine, apparently because of unjustified overconcern regarding the dependence liability of codeine. Acute intoxication with propoxyphene occurs at doses close to the therapeutic range, however, and can produce respiratory and CNS depression, confusion, hallucinations, and symptoms not typically associated with opioids, such as CNS excitation, convulsions, cardiotoxicity, and nephrogenic diabetes insipidus. Propoxyphene is also associated with an elevated degree of lethality, and its toxicity is enhanced by alcohol consumption. Its toxicity is due principally to the toxic metabolite, nordextropropoxyphene. For this reason, its use is not recommended in patients with renal insufficiency, patients with hepatic disorders, and elderly patients. Its low risk-to-benefit ratio has earned it a "black box" warning from the FDA, and it is being withdrawn from the market in the United Kingdom.[1]

Fentanyl and Congeners

Fentanyl, alfentanil, sufentanil, and remifentanil are 4-anilopiperidines (Figure 20-8). They are potent analgesics with

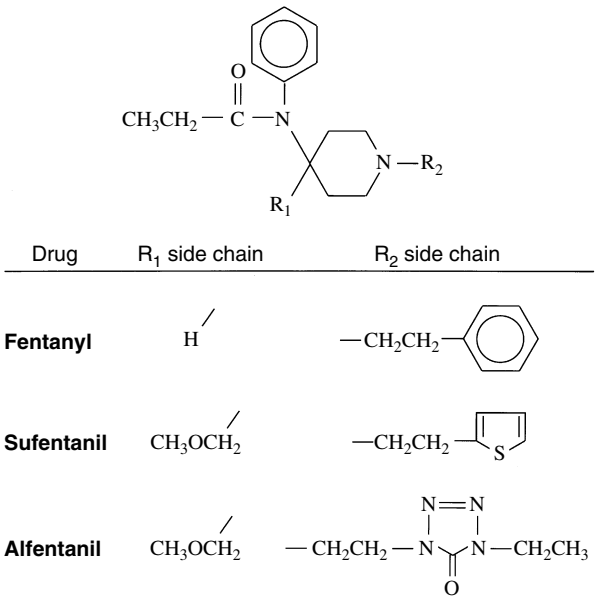

FIGURE **20-8** Structural formulas of fentanyl, sufentanil, and alfentanil.

relatively short durations of action used often as intravenous supplements during general anesthesia with inhalation or intravenous anesthetic drugs or as the principal component of balanced anesthesia (e.g., with nitrous oxide and a neuromuscular blocking drug), especially for cardiac surgery. The primary advantage of these more potent opioids is the cardiovascular stability they provide during surgery.[3]

Analgesic anesthesia with morphine dates to the turn of the twentieth century, when morphine was combined with scopolamine for surgery. Meperidine was subsequently tested because of the incomplete amnesia, histamine release, hypotension, and postoperative respiratory depression associated with the high doses of morphine that were required during surgery. Meperidine presented other disadvantages (e.g., poor cardiovascular stability), however, and has since been replaced by fentanyl and its congeners, all of which are more effective than morphine in reducing the endocrine and metabolic responses to surgery and maintaining cardiovascular stability.

Although these newer agents have found widespread application in current anesthetic practice, particularly for cardiac surgery, they are not without limitations. The most serious disadvantage associated with opioids used as analgesic anesthetics is that they are not anesthetics, and their use is associated with a high incidence of signs of inadequate anesthesia (e.g., sweating, pupillary dilation, or opening of the eyes during surgery). Use of the term *anesthetic* to describe the pharmacologic characteristics of these agents is inappropriate. In addition, awareness during surgery and inadequate amnesia after surgery are common. Other disadvantages include hypertension after sternotomy (which can result in myocardial ischemia and infarction); bradycardia (which can be prevented by pretreatment with atropine); respiratory depression; and muscle rigidity, particularly of the abdominal and thoracic cavities. Although these opioids provide improved cardiovascular stability during induction and throughout an operation, the "anesthesia" produced may be incomplete.

Fentanyl is much more lipid-soluble than morphine, which largely accounts for its more rapid onset and shorter duration of action; fentanyl is also 80 to 100 times more potent than morphine. The speed of onset allows fentanyl to play a role in the induction of anesthesia. Sufentanil is 5 to 10 times more potent than fentanyl, whereas alfentanil is less potent than fentanyl. Similar to fentanyl, these drugs are rapidly acting when given parenterally and have short durations of action. Because of its rapid onset and short duration of action even after repeated administrations, alfentanil has become a drug of choice for outpatient anesthesia. Remifentanil, the newest of the anesthetic opioids, is quickly broken down in the bloodstream and tissues by esterases. It has the shortest duration of action of all 4-anilopiperidine opioids and may play a special role in brief procedures when a temporary analgesic effect is desired.

In addition to its use in cardiac surgery, fentanyl is currently available in two unique dosage forms for pain control. Because fentanyl is lipophilic, it is available as an adherent skin patch for transdermal delivery of drug. This formulation, used principally for treatment of chronic pain (e.g., cancer pain), provides continuous drug delivery in therapeutic concentrations with reduced incidence of constipation and nausea.[4,10] Patients with chronic pain often have what is termed *breakthrough pain* while taking opioids for pain control. Fentanyl formulated as a lollipop is available for rapid onset (sublingual absorption) analgesia to control episodes of breakthrough pain.

Other Opioids

A number of opioid analgesics, some listed in Table 20-2, have not been discussed because they offer little or no therapeutic advantage over morphine or codeine and for the most part are not widely used. New opioid analgesics continue to be developed, particularly agents with mixed agonist-antagonist properties (see later), and it is likely that some of these will find clinical application.

MIXED AGONIST-ANTAGONISTS AND OPIOID RECEPTOR ANTAGONISTS

Drugs possessing agonist and antagonist efficacy were first synthesized 100 years ago. They possessed predominant antagonist effects (e.g., nalorphine) and were initially used to reverse or block the effects of pure opioid agonists. Today, naloxone and naltrexone, both of which are pure opioid receptor antagonists, have supplanted the use of nalorphine, a mixed agonist-antagonist used for years as an opioid receptor antagonist to reverse acute opioid intoxication. Naloxone is used almost exclusively to reverse the effects of opioid agonists (e.g., in acute opioid intoxication); naltrexone is used in the maintenance of detoxified opioid abusers. An injectable extended-release formulation of naltrexone that needs to be administered only once monthly has been approved for the control and prevention of alcohol abuse.[18,40]

The number of mixed agonist-antagonists has grown since the early 1950s because it was hoped that such drugs would be potent analgesics devoid of dependence and abuse liability. Chemical manipulation of the opioid structure produced compounds with varying agonist and antagonist properties. It was anticipated that the correct combination of such properties would yield a potent and efficacious analgesic drug that would not be abused. It was quickly learned, however, that drugs having agonist and antagonist properties were often unsuitable for clinical use as analgesics because of undesirable dysphoric side effects. The opioid receptor–blocking aspect of their pharmacologic profile does not prevent their abuse or free these drugs from tolerance and dependence.

In carefully controlled studies in animals, mixed agonist-antagonists have been established to possess reinforcing properties that lead to self-administration. In this respect, the

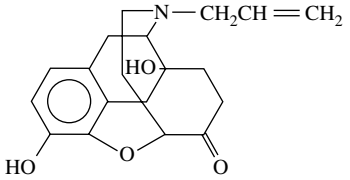

FIGURE **20-9** Structural formula of naloxone.

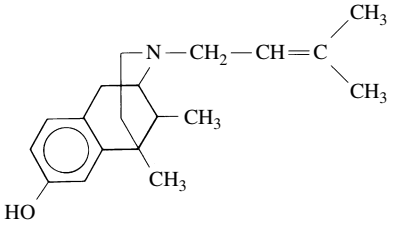

FIGURE **20-10** Structural formula of pentazocine.

mixed agonist-antagonists are similar to pure opioid agonists (e.g., morphine), although they have less reinforcing efficacy than the pure opioid agonists. Tolerance develops to the agonist, but not antagonist, effects of these drugs. Subjects who repeatedly use mixed agonist-antagonists may become physically dependent, just as can occur with repeated use of morphine and other pure opioid agonists, although the withdrawal symptoms differ from symptoms produced by morphine-like agonists.

Naloxone, Naltrexone, and Nalmefene

Naloxone (Figure 20-9), naltrexone, and nalmefene are the opioid receptor antagonists currently available that are essentially devoid of opioid agonist effects. In addition to antagonizing the effects of opioids, these drugs can block the agonist actions of most mixed agonist-antagonists. This is an important point because the respiratory depression produced by pentazocine, a mixed agonist-antagonist, is reversible by naloxone, naltrexone, and nalmefene but not by mixed agonist-antagonist drugs used as analgesics. The principal use of pure opioid receptor antagonists is in the treatment of acute opioid intoxication. These pure opioid antagonists are specific and rapidly improve ventilation. These antagonists are not general respiratory stimulants, however. Conversely, they do not diminish respiration further if administered to individuals with respiratory depression produced by other drugs (e.g., barbiturates and alcohol). The lack of response to naloxone, naltrexone, or nalmefene in a case of respiratory depression of unknown cause would be highly suggestive of nonopioid drug intoxication.

Naloxone, which is not effective when given orally, has an almost immediate onset and a short duration of action (1 to 4 hours) when given parenterally. Additional doses may be required at 20- to 60-minute intervals, especially if naloxone is being used to reverse intoxication by a long-acting opioid agonist. Naltrexone differs from naloxone in that it is effective orally and has a remarkably long duration of action. A single oral dose can suppress the effects of opioid agonists for 48 to 72 hours. These attributes suggest that naltrexone may be useful in the maintenance of an opioid-free state in detoxified, formerly opioid-dependent individuals. A single daily administration of the drug can effectively block the action of 25 mg of heroin injected intravenously 24 hours after the last dose of naltrexone. Naltrexone may also prove useful in treating morphine overdose because it might obviate the need to monitor the patient for a relapse of respiratory depression. Nalmefene is an orally active drug that has an even longer duration of action than naltrexone.[40]

Mixed Agonist-Antagonists

Pentazocine

Pentazocine is an agonist at κ opioid receptors and a partial agonist or weak antagonist at μ receptors. A benzomorphan derivative, pentazocine is structurally related to morphine (Figure 20-10), but it has an allyl-like substitution on the nitrogen of the piperidine ring (as do many opioid receptor antagonists). Pentazocine is an early product of continuing efforts to develop efficacious opioid analgesics with little or no dependence liability or abuse potential. Pentazocine was initially promoted as being free of dependence liability, but similar to other mixed agonist-antagonist and pure agonist opioids, it produces its major effects on the CNS and gastrointestinal tract and induces morphine-like subjective effects and euphoria. Physical and psychological dependence can develop to pentazocine, and the drug has been widely abused. Pentazocine tablets for oral use were crushed and self-administered intravenously, often in combination with the antihistamine tripelennamine, to produce a euphoric effect. To prevent this use of pentazocine in the United States, the opioid receptor antagonist naloxone (0.5 mg) was added to the formulation, and the proprietary name of the drug was changed to Talwin NX.

Because naloxone has little effect when taken orally, use of pentazocine as directed produces the desired analgesia. When used intravenously, however, the amount of naloxone present in the formulation is sufficient to antagonize completely the CNS effects of pentazocine. In contrast to codeine (or other pure agonists), pentazocine does not suppress withdrawal symptoms in individuals dependent on other opioids, but it also cannot antagonize morphine-induced respiratory depression. Pentazocine can precipitate signs of withdrawal in an opioid-dependent individual, however, because of its residual antagonist activity at μ receptors.

Pentazocine is well absorbed from the gastrointestinal tract. It is metabolized primarily in the liver to glucuronide conjugates, although small quantities of free pentazocine are excreted in the urine. It is approximately one third as potent an analgesic as morphine when given intramuscularly. As used orally, generally in place of codeine, approximately 50 mg of pentazocine is considered equivalent to 60 mg of codeine for relief of pain. Pentazocine's ability to relieve pain at greater doses is not comparable to that of pure opioid agonists. Generally, the maximal analgesic effect of mixed agonist-antagonist analgesics is less than that of morphine or other pure opioid agonists. At therapeutic doses, pentazocine exhibits effects on the CNS and gastrointestinal tract that are qualitatively similar to effects of other opioids (e.g., dizziness, nausea, and sedation and analgesia). In contrast to most other opioids, pentazocine can increase heart rate and blood pressure. In toxic doses, it produces dysphoric effects and characteristic opioid-like respiratory depression, although the respiratory depression does not increase proportionately with increasing doses as it does for pure opioid agonists.

Butorphanol

Butorphanol, buprenorphine, and nalbuphine are traditionally grouped together as examples of drugs with a mixture of opioid agonist and antagonist properties. These drugs are significantly different from each other, however, and such a grouping may not be justified. The major thrust in developing compounds having predominant effects at the κ opioid receptor was the belief that such drugs would retain significant analgesic activity but would be devoid of the respiratory depression and dependence liability associated

with morphine-like drugs whose prominent analgesic and respiratory depressant effects are produced at the μ opioid receptor. This effort has been partially successful. Although at therapeutic doses these drugs cause respiratory depression equivalent to that produced by 10 mg of morphine, the depression does not increase proportionately with increasing doses. The analgesia does not increase either, however.

Butorphanol is a morphinan derivative approximately four to six times more potent than morphine as an analgesic. Butorphanol is an agonist at κ opioid receptors and a weak partial agonist at the μ receptor. The drug is unlikely to precipitate withdrawal symptoms in opioid-dependent individuals, but it shows no cross-dependence either. As an analgesic substitute for morphine, butorphanol has a low abuse potential, and respiratory depression tends to plateau beyond therapeutic doses. Butorphanol has been tested as an analgesic anesthetic (similar to the pure agonist fentanyl), but because it has a tendency, similar to pentazocine, to increase cardiac work, it is not well suited for this application. Another limitation of butorphanol is the possibility of dysphoric side effects.

Butorphanol is subject to significant first-pass metabolism; approximately 80% of an oral dose is metabolized initially, and bioavailability after oral administration is low. Based on this pharmacologic profile, butorphanol, which was already available in an injectable form for obstetric use, was marketed as a nasal spray formulation as a nonscheduled drug for acute pain in 1992 and was most often used for migraine headache in the United States. Within 3 years of the release of the noninjectable formulation, reports of adverse reactions increased about sevenfold and included reports of dependence and addiction. It has since been declared a Schedule IV narcotic by the Drug Enforcement Administration.[17]

Nalbuphine

Nalbuphine is structurally related to naloxone, but is equipotent with regular analgesic doses of morphine. It has a pronounced antagonist action at the μ receptor, which distinguishes it from other available mixed agonist-antagonists. Nalbuphine is an agonist at κ opioid receptors, but produces few dysphoric reactions. Because of its unique blend of agonistic and antagonistic efficacy, nalbuphine has been used to reverse respiratory depression produced by other opioids without causing a loss of analgesia. Its greatest application is in debilitated surgical patients for whom the abrupt loss of pain relief caused by naloxone reversal can be life-threatening. Also beneficial in this setting is the fact that nalbuphine produces minimal myocardial depression. Nevertheless, opioid reversal even with nalbuphine is potentially dangerous in a patient at risk of heart attack. Nalbuphine should not be considered a replacement for naloxone for treatment of drug overdose in other settings.

Nalbuphine is marketed only as an injectable solution in the United States, and it is rarely used outside the hospital setting. Probably because it is uncommon to encounter nalbuphine outside such controlled environments, it is rarely found in forensic analyses and remains at present as the only opioid analgesic not scheduled under the Controlled Substances Act.

Buprenorphine

Buprenorphine is a strong partial agonist at the μ opioid receptor and is 25 to 50 times more potent an analgesic than morphine. It differs from other agonist-antagonists in that it is a potent κ receptor antagonist and has fewer psychotomimetic effects than pentazocine or butorphanol. Its agonistic effects are qualitatively similar to the effects of morphine, and buprenorphine produces a physical dependence described by former addicts as morphine-like. Buprenorphine possesses two properties, however, that place it in a unique niche, making it useful as an analgesic and in the treatment of opioid dependence. Buprenorphine binds to the μ receptor with an affinity two orders of magnitude greater than that of morphine and readily displaces morphine from the receptor. Because it is a partial agonist, its pharmacologic effect is limited in range, and increasing the dose of buprenorphine beyond the maximally effective dose only serves to occupy the μ receptors without increasing the pharmacologic effect. Buprenorphine acts as an antagonist at higher doses.

Because of this combination of properties, buprenorphine can be used to produce a moderately strong analgesic effect and serves to limit the activity of stronger opioids. Consequently, administration of buprenorphine to an opioid-dependent individual can precipitate an immediate abstinence syndrome, even as it can relieve withdrawal symptoms caused by prior opioid withholding. Buprenorphine mimics the effects of morphine in drug-free patients, but antagonizes pure agonists on coadministration.

Dezocine

Dezocine, an aminotetralin derivative, is a μ receptor antagonist and a κ receptor agonist. The drug may increase the cardiac index and pulmonary vascular resistance but lowers peripheral vascular resistance and is generally benign to the heart. In conventional doses, the potency and duration of action of dezocine are similar to those of morphine.

Novel Compounds

Tramadol is an aminocyclohexanol derivative, and it is used as a racemic mixture. The (+) enantiomer of tramadol is a weak agonist at the μ opioid receptor and inhibits the reuptake of serotonin. The (–) enantiomer of tramadol is a norepinephrine reuptake inhibitor. Additionally, the O-demethylated metabolite is a potent κ receptor agonist. All of these properties contribute to the analgesic actions of this drug. The analgesia caused by tramadol is only partially reversed by naloxone. As a perioperative analgesic, tramadol can relieve moderate-severe pain and is generally well tolerated.[36] The most common adverse effects include nausea, vomiting, and drowsiness; effects on respiratory or cardiovascular parameters are not clinically relevant at recommended doses in adults or children. Seizures have been reported for tramadol. The drug is used orally and has a terminal half-life of approximately 7 hours. Tramadol, which is not scheduled as a controlled substance, is generally regarded as lacking abuse liability. Some reports of abuse have occurred in previously opioid-dependent individuals.[44]

Tapentadol is a compound that is related mechanistically to tramadol and approved more recently for the management of acute pain. In contrast to tramadol, tapentadol is not a racemate and has strong μ opioid agonist activity and norepinephrine reuptake inhibition. Its potency is greater than that of tramadol and similar to morphine. The dual mechanism of action may contribute to an improved side-effect profile with diminished nausea and vomiting and constipation.[43]

USE OF OPIOIDS IN THE CONTROL OF PAIN

A full discussion of the differentiating features of acute and chronic pain is beyond the scope of this chapter, but some comment is required to understand better the use of opioids in the clinical management of pain. Opioid agonists and mixed agonist-antagonists can be used satisfactorily as analgesics for the relief of acute pain. The long-term use of opioids in clinical pain states raises questions, however, regarding the choice of opioid, the route of administration, and the role played by the development of tolerance and physical depen-

dence in therapy.[29,42] The use of mixed agonist-antagonists in chronic pain management is limited. Escalating doses of pentazocine and related drugs are associated with undesirable psychotomimetic effects. More importantly, the antagonistic properties of mixed agonist-antagonists at the μ receptor restrict the ability to switch between pure agonists and mixed agonist-antagonists for the control of pain.

Heroin was initially considered the drug of choice for management of cancer pain, but it has been established that heroin offers no therapeutic advantage over morphine. Heroin is a prodrug that is metabolized to morphine. Although bioavailability of morphine is limited because of first-pass metabolism, the dose can be adjusted for successful pain control by oral administration in liquid or sustained-release tablet form. Methadone is a useful alternative to morphine, but because its plasma half-life averages 24 hours, methadone accumulates with repeated dosing, and greater care is required with its use.

Oral administration is generally considered optimal for the treatment of chronic pain, but epidural, intrathecal, and intravenous routes of administration are also used, more recently in situations of patient-controlled analgesia. Although an exaggerated fear of "addicting" patients exists, as well as concern that allowing patients to self-administer opioids for the control of pain will lead to uncontrolled use, studies indicate that the total amount of opioid that is self-administered by patient-controlled analgesia is usually no more and often less than that given conventionally by health professionals. The use of patient-controlled analgesia gives patients control over when to treat their pain and has been found to provide psychological benefit.

The fear of addiction held by health professionals and patients often limits adequate opioid dosing for the control of pain. Physical dependence undeniably develops with repeated opioid administration, but evidence that psychological dependence and opioid abuse are a consequence of long-term medical use of opioids is virtually nonexistent.

USES IN DENTISTRY

Opioids used in dentistry are primarily those available for oral administration, including codeine, hydrocodone, oxycodone, and pentazocine. Morphine, meperidine, and fentanyl are used parenterally (as described in Chapter 47). Although these drugs all possess therapeutically useful actions in addition to analgesia, they are used in dentistry exclusively for pain relief. Pain of dental origin frequently arises from or is accompanied by inflammation, however. Because opioids are not anti-inflammatory, nonopioid analgesic drugs with anti-inflammatory efficacy (e.g., aspirin, ibuprofen) are often the first choice for relief of pain. Opioids are particularly useful when additional pain control is required. Combinations of opioids with acetaminophen, aspirin, or ibuprofen are commonly used and are rational because different, complementary central and peripheral mechanisms of pain relief are invoked. Although aspirin and ibuprofen have anti-inflammatory efficacy, acetaminophen is not anti-inflammatory and is not a good choice when it is desired to reduce inflammation and pain.

Of opioids available for use in dentistry, codeine, hydrocodone, and oxycodone are the most commonly used. Tramadol is gaining acceptance as an analgesic after dental procedures and is a safe and effective alternative for individuals who cannot tolerate opioids in combination with acetaminophen or nonsteroidal anti-inflammatory drugs.[25,45] As previously indicated, the analgesic efficacy of propoxyphene is questionable, and its use is now generally discouraged. Similarly, the efficacy and utility of meperidine given orally in conventional doses are also being reconsidered.

IMPLICATIONS FOR DENTISTRY

The opioid analgesics are subject to abuse, and significant physical and psychological dependence can develop. The pharmacologic and sociologic aspects of opioids are discussed in Chapter 51. Additional implications for dentistry relate to the possible interactions of opioids with other drugs that dentists may prescribe or that patients may be taking for medical reasons. Drug interactions with orally administered opioids are uncommon or not usually of great clinical importance when they do occur. There are recognized interactions, however, between opioids and CNS depressants, neuroleptics, tricyclic antidepressants, monoamine oxidase inhibitors, local anesthetics, and oral anticoagulants that can be clinically significant, particularly if opioids are given parenterally.

Generally, the coadministration of CNS depressants produces summation of effects and occasionally a greater than anticipated depression (i.e., supra-additive effect). Opioids and phenothiazines (e.g., chlorpromazine) are known to produce at least additive CNS depression, including respiratory depression. This combination may also produce a greater incidence of orthostatic hypotension than either drug administered alone. Increased hypotension has also been reported with combinations of opioids and tricyclic antidepressants. When combinations of opioids and other CNS depressants are used in dentistry, the drugs are commonly given by intravenous infusion, and the effects can be titrated to the desired level. When used orally, doses should have a sufficient margin of safety to avoid dose-dependent toxicity. The clinical significance of these interactions, particularly at the doses of opioids used orally in dentistry, is uncertain.

The coadministration of local anesthetics and parenteral opioid analgesics is a common and generally safe practice. Large doses of these classes of drugs display supra-additive toxicity, however. It is likely that respiratory acidosis caused by an opioid can increase the entry of a local anesthetic into the CNS.

Interaction of opioids with oral anticoagulants has been reported to result in an enhanced response to the latter, but the clinical significance has not been established, and it is unlikely that short-term opioid administration has an appreciable effect on the patient's response to oral anticoagulants.

A well-documented interaction of meperidine and monoamine oxidase inhibitors results in severe and immediate reactions that include excitation, rigidity, hypertension, and sometimes death. Chemically unrelated opioids are unlikely to cause a similarly violent reaction.

OPIOID ANALGESICS AND ANTAGONISTS

Nonproprietary (generic) name	*Proprietary (trade) name*
Agonist analgesics	
Alfentanil	Alfenta

CHAPTER 21

Nonopioid Analgesics, Nonsteroidal Anti-inflammatory Drugs, and Antirheumatic and Antigout Drugs

ELLIOT V. HERSH, PAUL J. DESJARDINS, CLARENCE L. TRUMMEL, AND STEPHEN A. COOPER

Nonopioid analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), and agents used in the control of rheumatoid arthritis and gout represent a diverse group of chemical compounds whose mechanism of action typically involves the inhibition of one or more components of the inflammatory response. Acute pain, which typically accompanies inflammatory insults, results from various dental surgical procedures and can often be controlled by the use of the nonopioid analgesic acetaminophen or NSAIDs such as ibuprofen. In addition, NSAIDs play an important role in the symptomatic relief of the inflammation and pain that accompany arthritis. These agents do not eliminate or reduce the underlying causes of the arthritic disease, however, and joint damage can continue to progress despite the long-term use of these drugs.

Disease-modifying antirheumatic drugs (DMARDs) play a major role in the management of rheumatoid arthritis. They represent a group of chemically unrelated agents that have additional uses in medicine, ranging from the treatment of malaria and cancer to the prevention of transplanted organ rejection. In some instances, these agents can slow and arrest some of the pathologic changes seen in rheumatoid arthritis. They are fraught with serious adverse effects, however, and many patients cannot tolerate their long-term use.

CAUSE OF INFLAMMATION

Inflammation typically represents the response to tissue injury and includes products of activated mast calls, leukocytes, and platelets; prostaglandins (PGs); leukotrienes; and complement-derived products. The clinical features of inflammation include *tumor* (edema), *rubor* (redness), *calor* (heat), *dolor* (pain), and loss of function.

Although inflammation is often thought of as only a pathologic event, it serves a normal homeostatic function. In the case of tissue injury from minor trauma or a dental surgical procedure, the inflammatory process results in a series of well-regulated humoral and cellular events leading to localization of injury, removal of noxious agents, repair of physical damage, and restitution of function in the injured tissue. In patients unable to mount a competent inflammatory response, such as patients with agranulocytosis induced by some cancer chemotherapeutic drug regimens (see Chapter 42), the results are often fulminant infection and death.

The inflammatory response is not always beneficial to the host. If it becomes excessive or chronic, as is the case with rheumatoid arthritis, it may result in the progressive destruction of joint tissue and a host of untoward systemic effects. Drugs are now being developed with relatively favorable therapeutic indices that show promise in halting some of the destructive inflammatory events of chronic rheumatic diseases.

Inflammation can be divided into three phases: acute inflammation, subacute inflammation, and chronic inflammation. In acute inflammation, small preformed inflammatory mediators such as histamine are released, causing vasodilation and increased capillary permeability. In the subacute stage, inflammatory cells migrate and invade the site. PGs, leukotrienes, platelet-activating factor (PAF), and cytokines also play major roles. The third, or chronic, stage of inflammation involves the lymphocytic phase of injury cleansing and repair. Cytokines, especially interleukins and tumor necrosis factor-α (TNF-α), are prominent in this stage. In reality these phases are not distinct entities. Components of the subacute phase participate in the acute inflammatory process, and acute inflammatory mediators are present in chronic inflammatory disorders such as arthritis. Even so, this classification still offers a useful way to categorize this highly complex process. The following section briefly reviews some of the key mediators of the inflammatory process. Table 21-1 provides a more complete list of inflammatory mediators.

Tissue Mediators

Histamine

Histamine is the first mediator for which a role in the inflammatory process was clearly established. This vasoactive amine is formed by decarboxylation of histidine and is widely distributed in the body. Although some free histamine exists in tissues, most is stored in mast cell and basophil granules in a physiologically inactive form. (For a more complete discussion, see Chapter 22.) Various physical and chemical stimuli, such as antigens, complement fragments, or simple mechanical trauma, can cause extrusion of the granules and release of active histamine into the extracellular fluid.

One of the most characteristic actions of histamine is dilation of vessels of the microcirculation and a marked, but transient, increase in the permeability of capillaries and postcapillary venules, reflecting an activation of H_1 receptors in these tissues. These vascular changes are similar to the changes that occur in tissue after injuries of all sorts. The evidence that histamine released from the ubiquitous mast cell is responsible for the initial permeability changes seen in an inflammatory response is extensive. The histamine content of tissue fluid at the site of injury increases within minutes after the insult and then decreases. Concurrent with these changes, mast cells in the area of damage are found to be degranulated.

TABLE **21-1**

Classification of Some Endogenous Mediators of Inflammation

MAJOR GROUPS	MAJOR MEDIATORS
Tissue	
Lymphocyte products	MCP-1
	GM-CSF
	Other chemoactive factors
	Interferon-γ
	Interleukins
	Skin reactive factor
Macrophage products	Interleukin-1
	Interferon-γ
	TNF-α
	PAF
Mast cell products	Histamine
	Cytokines
	TNF-α
	Leukotrienes
	Prostaglandin D_2
	PAF
Eosinophil products	Lysosomal enzymes
	Major basic protein
	Other cationic proteins
	Leukotrienes
	PAF
Others	Reactive metabolites of oxygen
	Endogenous pyrogens from leukocytes
	Leukocytosis factors
Plasma	
Kinin system	Bradykinin
Complement system	C3 fragments
	C5 fragments
	C5b67 complex
	Membrane attack complex
Clotting system	Fibrinopeptides
	Fibrin degradation products

GM-CSF, Granulocyte-macrophage colony-stimulating factor; *MCP-1,* monocyte chemoattractive protein-1; *PAF,* platelet-activating factor.

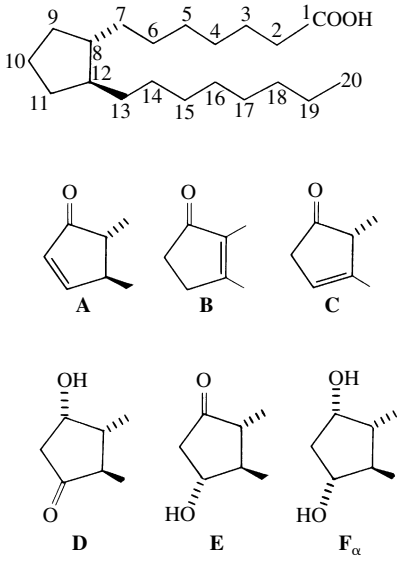

FIGURE **21-1** Molecular structure of prostaglandins (PGs). *Top,* Structure of prostanoic acid, a hypothetical compound of which the PGs can be considered analogues. *Bottom*, Basic ring structures of PG groups *A* through *F*.

It has been shown that prior depletion of tissue histamine stores by various means or pretreatment with classic antihistamines (H_1 receptor blockers) reduces the initial vascular response to injury.[101] Inhibition of initial histamine-dependent events does not block the further development of the inflammatory response, however.

In patients with chronic inflammation caused by rheumatoid arthritis, increased concentrations and penetration depth of mast cells in synovial tissue are found, possibly related to the expression of stem cell factor by synovial fibroblasts. Astemizole, a potent antihistamine, does not affect the clinical course of this disease.[139] The role played by histamine in inflammation is early, transient, and nonessential for subsequent events that may lead to lasting tissue alterations.

Antihistamines have little use as general anti-inflammatory agents. In certain situations, such as immediate allergic reactions, large amounts of histamine are released locally or systemically from sensitized mast cells and basophils as a consequence of antigen-antibody reactions. In these instances, antihistamines that block the H_1 receptor are useful in reducing symptoms attributable to histamine. As discussed in Chapter 22, antihistamines that block the action of histamine at the H_2 receptor have a supporting role in the management of anaphylaxis and a major role in the treatment of gastric hyperacidity conditions.

Prostaglandins

The PGs are a unique family of closely related acidic lipids found in all tissues. The basic structure of all PGs is a prostanoic acid skeleton composed of a 20-carbon polyunsaturated fatty acid with a five-member ring at C8 through C12 (Figure 21-1). Similar to the leukotrienes described subsequently, PGs are derived from arachidonic acid and similar 20-carbon polyunsaturated fatty acids that are liberated from the cell membranes of local tissues by the action of acylhydrolases, principally phospholipase A_2, and, in platelets, diacylglycerol lipase. Inflammatory cells, including human monocytes and mast cells, also have the ability to generate PGs. Although multiple oxygenation products are derived from arachidonic acid, the PG molecules all contain a five-membered carbon ring. The alphabetical PG nomenclature (A-F) is based on the structure of this cyclopentane ring. PGE and PGF_α differ only in the presence of a ketone or hydroxyl group at C9. Also in the nomenclature, a subscript 1 indicates the presence of a double bond at C13 to C14 (PGE_1), a subscript 2 indicates the presence of an additional double bond at C5 to C6 (PGE_2), and a subscript 3 indicates the presence of a third double bond at C17 to C18 (PGE_3).

A key event in the acute inflammatory process is the liberation of arachidonic acid from damaged cell membranes on exposure to phospholipase A_2 (Figure 21-2).[55] This step can be inhibited indirectly by a powerful group of anti-inflammatory agents known as *glucocorticoids,* which are described in detail in Chapter 35. From this point, the oxidative metabolism of arachidonic acid can proceed along two divergent pathways. One pathway uses the enzyme cyclooxygenase (COX), also known as PG *endoperoxide synthase,* and the second pathway uses the enzyme lipoxygenase. Virtually all cells in the body, with the exception of red blood cells, contain the COX enzyme, whereas lipoxygenase seems to be limited to inflammatory cells (neutrophils, mast cells, eosinophils, and macrophages).

COX catalyzes the transformation of arachidonic acid to the short-lived cyclic endoperoxide PGG_2. PGG_2 is converted

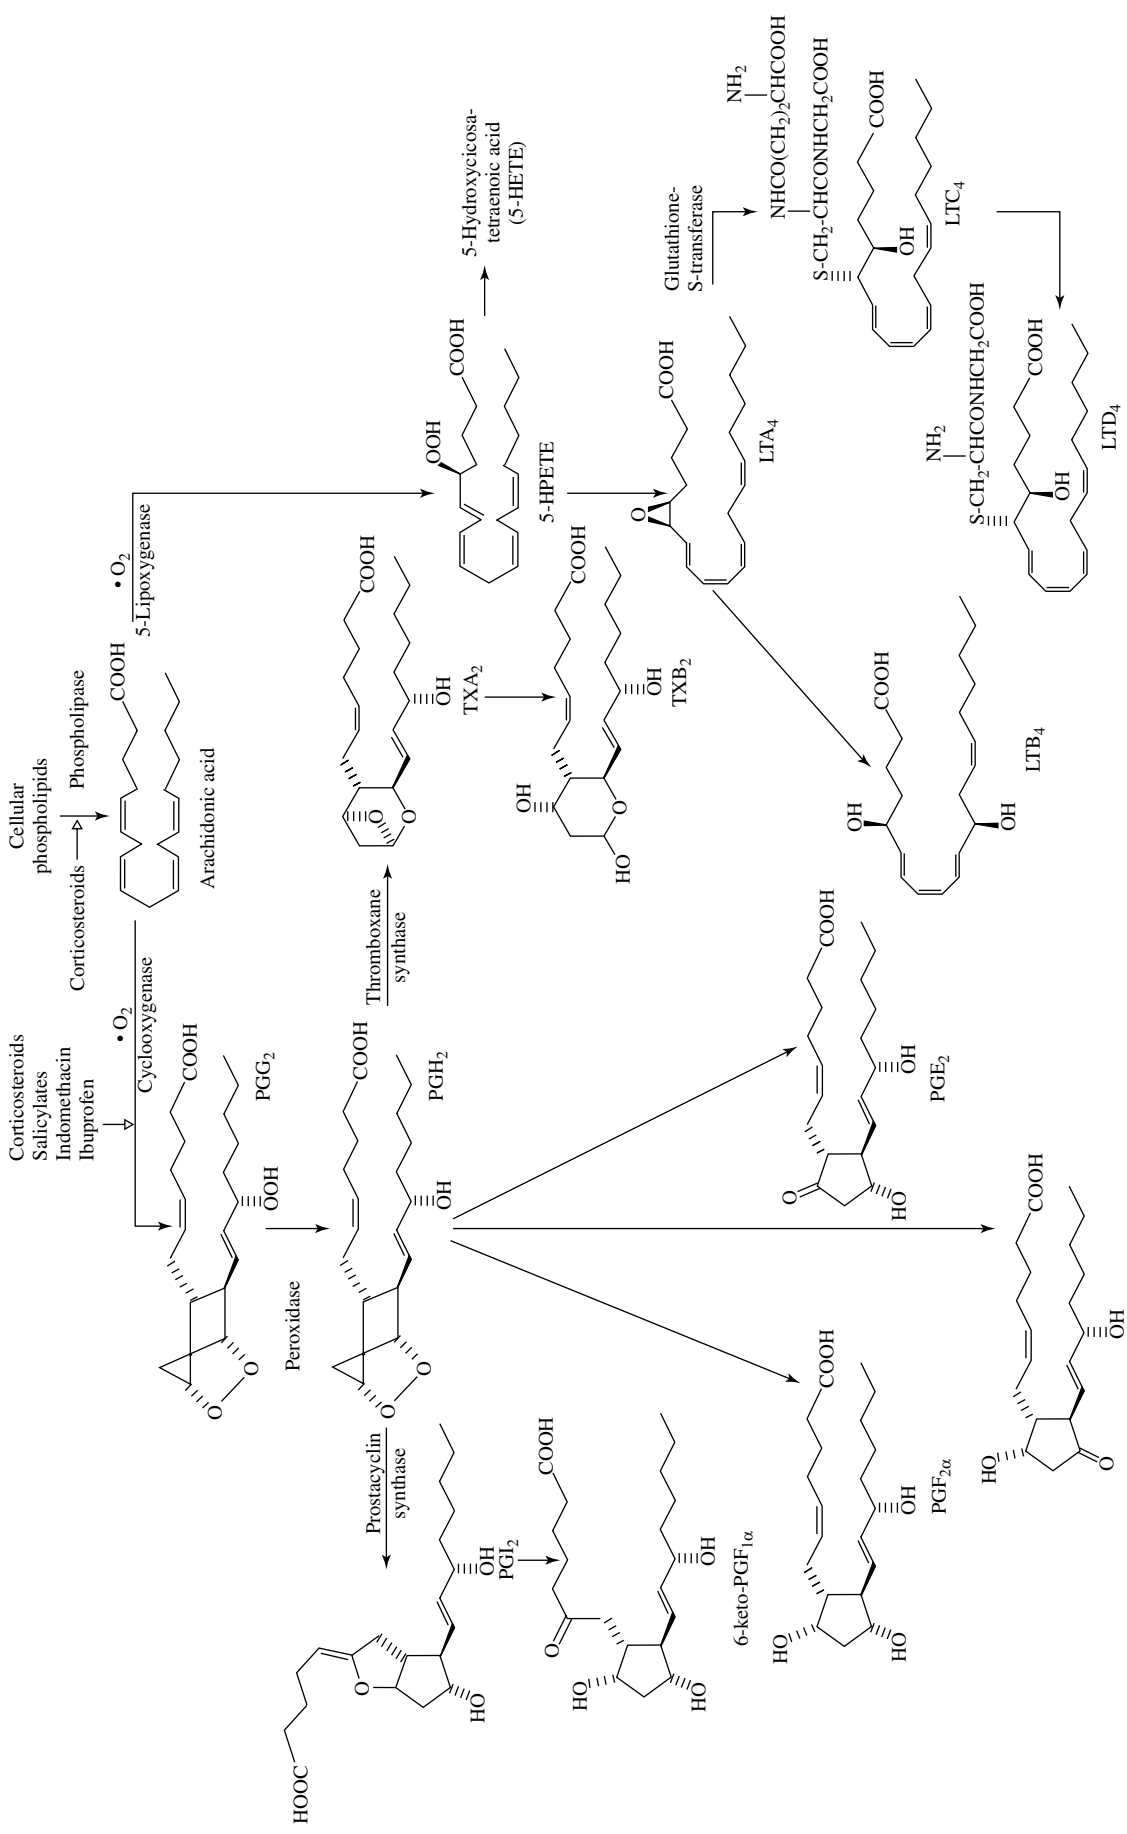

FIGURE **21-2** Pathways of arachidonic acid metabolism to prostaglandins (PGs) and related compounds and to leukotrienes (LTs). The cyclooxygenase pathway leads to the formation of the cyclic endoperoxides PGG_2 and PGH_2 and subsequently to prostacyclin (*PGI_2*), thromboxane (*TX*), or the stable PGs (*E_2*, *$F_{2\alpha}$*, and *D_2*). The lipoxygenase pathway yields 5-hydroperoxyeicosatetraenoic acid (*5-HPETE*) and subsequently leukotrienes A_4, B_4, C_4, and D_4. The open arrows indicate the metabolic steps that are inhibited by corticosteroids or nonsteroidal anti-inflammatory drugs such as aspirin and ibuprofen. Not shown are LTE_4 and LTF_4 and other lipoxygenase pathways.

to PGH_2 by peroxidation, which is an additional function of COX. Unstable and potentially tissue-toxic oxygen radicals can be liberated by this process. From this point, PGH_2 is converted to the stable PGs E_2 and $F_{2\alpha}$, thromboxanes, or prostacyclin (PGI_2) by appropriate enzymes.

It is now well established that COX exists in two isoforms. Both are 72-kDa proteins but differ in terms of their sequence homology (approximately 60%) and their genomic regulation.[47,149,150] COX-1 is regarded as the constitutive or housekeeping isoform and is the major isoform found in healthy tissues. It is always present in a number of tissues, including the central nervous system (CNS), gastric mucosa, platelets, and kidneys.[36] In the gastric mucosa, COX-1 plays a major role in the synthesis of PGs involved in the formation of the mucous protective barrier (so-called cytoprotection) against stomach acid. In platelets, COX-1 is the key enzyme involved in thromboxane production and its subsequent platelet aggregatory properties necessary for proper hemostasis.

COX-2 is, for the most part, an inducible isoform upregulated by such products as cytokines, growth factors, and mitogens in human monocytes, macrophages, endothelial cells, chondrocytes, synoviocytes, and osteoblasts.[36] It is associated with elevated concentrations of PGs during inflammation, pain, and fever. Figure 21-3 illustrates some of the physiologic roles of the COX isoforms. Although initially it was hoped the COX-2 products participated only in inflammatory and other pathologic processes, it is now known that oxidation products of the COX-2 isoform help regulate some normal physiologic processes, including the maintenance of adequate water and Na^+ excretion by the kidneys, the inhibition of excessive platelet aggregation, and dilation of certain vascular beds.[77]

PGs and the other active metabolites of the intermediate endoperoxides (e.g., PGI_2 and thromboxane A_2 [TXA_2]) exert a multitude of effects in almost every biologic process examined so far. These processes include smooth muscle contraction and relaxation, vascular permeability, renal electrolyte and water transport, gastrointestinal (GI) and pancreatic secretion, various CNS and autonomic nervous system functions, release of hormones (e.g., growth hormone, steroids, and gonadotropins), luteolysis and parturition, lipolysis, bone resorption, and platelet aggregation. Not only are the affected processes diverse and the effects complex, but also the different PGs and related molecules sometimes seem to have antagonistic actions. PGE_2 and PGI_2 generally cause vasodilation and inhibit platelet aggregation, whereas TXA_2 causes vasoconstriction and induces platelet aggregation. The effects of $PGF_{2\alpha}$ on vascular tone depend on the vascular bed.

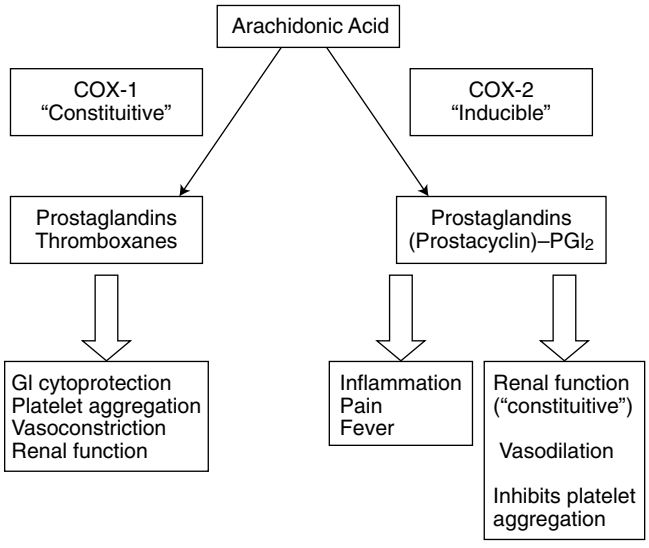

FIGURE **21-3** Some physiologic roles of the cyclooxygenase (COX) isoforms. Renal, vascular, and platelet functions are influenced by both COX isoforms. *GI*, Gastrointestinal. (From Hersh EV, Lally ET, Moore PA: Update on cyclooxygenase inhibitors: has a third COX isoform entered the fray? *Curr Med Res Opin* 21:1217-1226, 2005.)

Qualitative and quantitative differences in response to the PGs exist among mammalian species, further complicating elucidation of the biologic roles of these substances. It is axiomatic that generalizations about the actions of PGs and related compounds are misleading; the response to a given agent must be considered in the context of the particular tissue involved, the assay system used, and the species of experimental animal.

There is abundant evidence that PGs and the intermediate endoperoxides are mediators of inflammation.[42,107] Arachidonic acid and other fatty acid precursors of PGs present in the membrane phospholipid of cells can be released by hydrolase enzymes activated by direct cellular damage or by any nondestructive perturbation of the membrane, whether physical, chemical, hormonal, or neurohumoral. PG synthesis can ensue as shown in Figure 21-2. In acute inflammatory reactions, PGs appear in fluids and exudates later (2 to 12 hours after injury) than some other mediators, such as histamine and bradykinin. PGs are being formed at a time when tissue damage and disintegration are more prominent. It is possible that some of the PG content found in sites of inflammation is derived from infiltrating neutrophils and macrophages because these cells are capable of PG synthesis.[1]

When released in tissue, PGs may contribute to the inflammatory response in multiple ways. The evidence that they do so can be summarized as follows[42]: (1) PGs are found in experimentally or naturally produced inflammatory fluids; (2) neutrophils and macrophages produce PGs during phagocytosis; (3) PGI_2 and PGE_2 injected intradermally are potent inducers of vasodilation and of increased vascular permeability, an effect that is greatly augmented by the presence of histamine or 5-hydroxytryptamine and may last for several hours; (4) minute amounts of PGI_2 and PGE_2 injected intradermally markedly increase the pain sensitivity to other mediators, such as bradykinin and histamine; (5) PGE_2 is pyrogenic when injected into the cerebral ventricles or anterior hypothalamus, suggesting a mediator function; (6) a severe disabling arthritis is produced in animals by injecting PGs into the knee joint, and rheumatoid synovial cells produce PGs in culture; and (7) certain anti-inflammatory drugs that are potent inhibitors of PG synthesis reduce experimentally produced inflammation.

Although PGs stimulate certain inflammatory events, they inhibit or modulate others. The fact that PGs inhibit the proliferation and release of certain inflammatory mediators from neutrophils and activated lymphocytes and the fact that some effects of PGE_2 are opposed by $PGF_{2\alpha}$ provide evidence of a modulating function.

The precise roles of PGs in the inflammatory process are far from established, but these unique compounds clearly have the potential to act as mediators, modulators, or both. If both functions are involved, PGs could occupy a central regulatory position. A balance between enhancement and suppression of inflammatory events could be achieved by local regulation of PG metabolism because in some systems PGs have been shown to be either stimulatory or inhibitory depending on their concentration. Altering the relative concentrations of PGE and PGF could provide an additional means of balance because different PGs have diverse and occasionally antagonistic actions in the same system (e.g., PGE_2 causes bronchodilation, whereas $PGF_{2\alpha}$ causes broncho-

constriction; PGI_2 inhibits platelet aggregations, whereas TXA_2 stimulates platelet aggregation).

Leukotrienes

The term *slow-reacting substance* (SRS) was first applied to a lipid-soluble material produced by treatment of lung tissue with cobra venom. This material was characterized by its production of a slow, prolonged contraction of a smooth muscle preparation in contrast to the rapid and transient action of histamine. A chemically and biologically similar material was subsequently found in the lungs of sensitized guinea pigs challenged with specific antigen in vitro.[153] This material was designated as the *SRS of anaphylaxis* (SRS-A) to distinguish it from SRS produced by nonimmunologic mechanisms. Studies of the biologic properties of SRS-A indicated that it might be an important mediator of anaphylactic and other immediate allergic reactions. SRS-A can be found in most tissues, especially in the lung, after appropriate antigenic challenge. It is released along with histamine and other active products from mast cells.

Although SRS-A was known for some time to be an acidic, sulfur-containing lipid of low molecular weight, elucidation of its exact structure and biosynthesis was delayed until intensive study of the metabolism of arachidonic acid showed that SRS-A belonged to a class of compounds known as *leukotrienes*.[103,132] Leukotrienes are formed by the conversion of arachidonic acid to noncyclized, 20-carbon carboxylic acids with one or two oxygen substitutes and three conjugated double bonds (see Figure 21-2). The critical step in the biosynthetic pathway is generation of a 5,6-epoxide of arachidonic acid (leukotriene A_4) by the combined actions of 5-lipoxygenase and leukotriene A synthase. Leukotriene A_4 may be converted to leukotriene B_4 by a hydrolase enzyme or, alternatively, to leukotriene C_4 by the addition of glutathione. Removal of glutamate from leukotriene C_4 generates leukotriene D_4.

These lipid-peptide derivatives apparently account for all the biologic activity of SRSs found in immediate allergic reactions. Leukotrienes C_4 and D_4 constitute SRS-A. Asthmatic reactions may also involve other leukotrienes, however. The ability of cells to produce leukotrienes seems to be limited to the lung, leukocytes, blood vessels, and epicardium. In contrast, all cells except erythrocytes can convert arachidonic acid to PGs and related compounds by the action of COX.

Leukotrienes C_4 and D_4 are potent in vivo and in vitro constrictors of bronchial smooth muscle in the guinea pig. Both compounds have similar effects in human bronchial muscle preparations, in which they are approximately 1000 times more potent than histamine. Because these leukotrienes also increase vascular permeability, it seems likely that either one or both play a role in the bronchial constriction and mucosal edema of asthma. Leukotriene B_4 can enhance chemotactic and chemokinetic responses in human neutrophils, monocytes, and eosinophils.[60] These findings suggest that leukotrienes may be involved in localized inflammatory processes and in asthma. Drugs that block leukotriene receptors or inhibit leukotriene synthesis by blocking the enzyme lipoxygenase are used in the treatment of asthma (see Chapter 32).

Lysosomal products

The lysosomes of neutrophils contain various enzymatic and nonenzymatic factors that play important roles in the manifestations and sequelae of inflammatory reactions (Box 21-1). During phagocytosis of bacteria or foreign material by neutrophils, the contents of lysosomes are released into the extracellular environment. They are also released on lysis of the cell. Cationic proteins from lysosomes contribute to the inflammatory process by triggering mast cell degranulation, which leads to increased vascular permeability. Other lysosomal enzymes may contribute to the inflammatory response in several ways. Several of these enzymes have the potential to damage host tissues. Collagen, elastin, mucopolysaccharides, basement membrane, and other structural elements may be degraded. Lysosomal proteases cause the production of kinin-like substances from plasma kininogen and can generate chemotactic factors for neutrophils from complement, as described in a later section. Leukotrienes and PAF are also released by neutrophils. Neutrophils may play a central role in perpetuating the inflammatory response by their dual ability to cause tissue damage and to elaborate specific mediators of inflammation. Another source of lysosomal factors, especially in chronic inflammatory lesions, may be the mononuclear phagocyte, or macrophage, the lysosomes of which contain substances similar to those of the neutrophil.[1] These substances are released into the extracellular environment on activation of macrophages by various soluble factors, such as leukotriene B_4, C5a complement factor, and PAF, and during the process of phagocytosis of bacteria or other particulate matter.

BOX 21-1

Factors in the Neutrophil with Inflammatory Potential

Tissue-damaging enzymes	Elastase
	Cathepsins B and G
	Collagenase
	Other proteases
Microbicidal enzymes	Myeloperoxidase
	Lysozyme
Permeability factors	Leukotrienes
	PAF
	Leukokinin-forming enzyme
	Basic peptides
Leukotactic factors	Leukotrienes
	PAF
	C5-cleaving enzyme
	Basic peptides (chemotactic for monocytes)

PAF, Platelet-activating factor.

Lymphocyte products

Delayed allergic reactions may be involved in some inflammatory processes, especially chronic processes in which there is a persistent antigenic stimulus (e.g., in tuberculosis). These reactions are mediated by factors called *cytokines* (*lymphokines* if derived from lymphocytes), which are produced by sensitized thymus-dependent lymphocytes, or T cells, after specific antigenic challenge. Although many putative cytokines have been described, their role in inflammatory reactions with an immune component is not firmly established. Some of the better studied cytokines that may function in inflammation-related events are (1) interleukins that stimulate the function of T cells and bursa-dependent lymphocytes (B cells); (2) monocyte chemoattractive protein-1, which promotes accumulation of monocytes; (3) granulocyte/macrophage colony-stimulating factor; (4) other chemotactic factors that are specific attractants for neutrophils, macrophages, basophils, and eosinophils; (5) interferon-α, which has antiviral and macrophage activation properties; and (6) skin reactive factor, which mimics a delayed allergic reaction when injected into normal skin (i.e., it causes increased vascular permeability and migration of mononuclear cells).

Macrophage products

Similar to lymphocytes, macrophages apparently have little involvement in acute inflammatory responses, but they play a very prominent role in chronic inflammation and are crucial in the immune response. In addition to their phagocytic activity, macrophages have a major secretory function in established inflammatory lesions. Secretory products include the constituents of lysosomes (see earlier), reactive metabolites of oxygen, interferon-α, interleukin-1 (IL-1), and TNF-α. The latter two substances are crucial mediators of the complex interplay between macrophages and lymphocytes, which largely determines the course and eventual outcome of an inflammatory process. IL-1 is produced by macrophages exposed to bacterial, viral, and fungal products; antigens; or macrophage activation factor. It may have several roles, but chief among these seems to be the stimulation of differentiation of a pre–T-lymphocyte population to T cells capable of responding to an antigen processed and presented by macrophages.

Another mediator of inflammation produced by macrophages and other cells is PAF. PAF is a closely related family of substances derived from phosphatidylcholine generated in the metabolism of arachidonic acid. It is also synthesized in other cells, including mast cells and eosinophils. Platelets also contain PAF. PAF initiates various actions, including platelet activation, vasodilation, vascular permeability, neutrophil chemotaxis, and discharge of lysosomal enzymes. It also contributes to allergic and inflammatory responses.

Mast cell products

Mast cells release numerous inflammatory mediators in addition to histamine, including cytokines (e.g., TNF-α), leukotrienes, PGD_2, and PAF. Mast cells can become activated by IgE antibodies that bind to the plasma membrane and sensitize the mast cell to specific allergens. Several allergic reactions, including allergic asthma, involve this mechanism. Basophils have many of the same characteristics as mast cells.

Eosinophil products

Eosinophils release many enzymes and toxins that can lead to tissue destruction. Major basic protein is a toxic substance that can cause tissue damage and destruction of parasites. Eosinophils also release leukotrienes and PAF.

Plasma Mediators

Kinins

The term *kinins* refers primarily to two small peptides that are similar in structure and actions: bradykinin and lysyl-bradykinin (or kallidin). Bradykinin can be considered the prototype. It is a linear nonapeptide with a molecular weight of 1060 Da. As with the release of histamine, almost any process causing tissue injury can trigger the series of events leading to the production of bradykinin. Bradykinin exists in plasma as an inactive precursor (kininogen) and is released in a cascade of reactions beginning with activation of Hageman factor (clotting factor XII). Hageman factor can be activated by exposure to numerous substances, including cartilage, collagen, basement membrane, sodium urate crystals, proteolytic enzymes, and bacterial lipopolysaccharides. Hageman factor activates an enzyme called *prekallikrein* to yield kallikrein. Kallikrein cleaves bradykinin from kininogen, an α_2-globulin precursor. (In addition, activated Hageman factor triggers the clotting cascade by activating factor XI and the fibrinolytic system by activating plasminogen proactivator, ultimately yielding plasmin.) Kinins may also be produced extravascularly from tissue kininogen. After release, bradykinin is rapidly metabolized by enzymes present in plasma and tissues.

Bradykinin has striking pharmacologic effects in humans and animals. It is a potent but transient vasodilator of arteries and veins by a direct action on smooth muscle. Intradermal injection of bradykinin causes marked increases in vascular permeability; in this regard, it is more potent than histamine on a molar basis. Bradykinin applied to a blister base or injected intradermally or intra-arterially in humans evokes sharp pain. Experimental pain can also be produced by a bradykinin-like substance isolated from human blister fluid and from synovial fluid obtained from acutely inflamed joints. In extraction sockets, local concentrations of immunoreactive bradykinin and PGs increase in patients after the removal of impacted third molar teeth.[129,159] All these phenomena implicate bradykinin in various aspects of acute inflammatory reactions, including acute pain.

Complement system

The complement system plays an important role in the inflammatory process. In humans, this system consists of at least 20 component proteins that react in a fixed sequence (Figure 21-4). An immune complex on a cell surface activates the first component, C1, and a cascade of events results in the formation of a complex that leads to membrane damage and cell lysis.

This so-called classic pathway of complement activation can be initiated by most antigen-antibody complexes and by nonimmune factors such as trypsin and plasmin. Other substances, such as complex polysaccharides, aggregated IgA, and

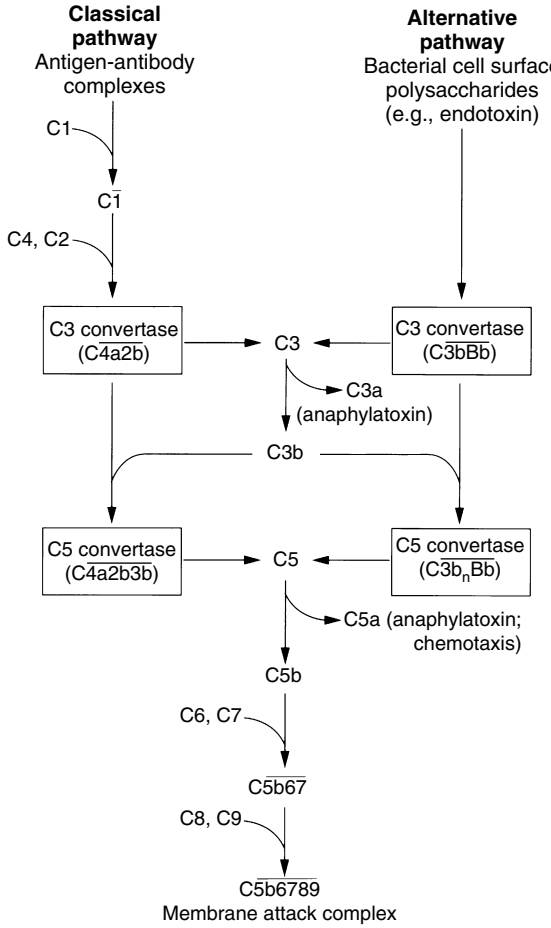

FIGURE **21-4** Complement cascade. The classic and alternative pathways of complement activation are shown. Activated components are designated by a horizontal bar above the component number (e.g., $\overline{C5b67}$). The steps by which bacterial polysaccharides interact with several plasma proteins (B, D, and properdin) to generate the C3 convertase of the alternative pathway, $\overline{C3bBb}$, are not shown.

bacterial endotoxin, may trigger an alternative pathway in which the first component to be activated is C3, followed by the usual components in the activation scheme.

In addition to the above-mentioned direct cellular damage, certain fragments produced during the cascade of complement activation have important biologic properties. Two of them (C3a and C5a) cause increased vascular permeability by inducing the release of histamine from mast cells. These substances are referred to as *anaphylatoxins* and have been implicated in anaphylaxis and other allergic reactions. The C5a anaphylatoxin is also a potent chemotactic factor. Neutrophils, monocytes, and eosinophils exhibit directed locomotion in response to it. Enhancement of phagocytosis and release of lysosomal enzymes have been attributed to other components of the activation scheme.

Complement fragments can be produced by mechanisms extrinsic to the complement system (e.g., by plasmin, trypsin, and bacterial proteases). This action suggests that complement fragments may participate in tissue injury and in the subsequent inflammatory response without classic or alternative complement activation.

Nitric oxide

The small gaseous molecule nitric oxide (NO) apparently plays a regulatory and a proinflammatory role in various inflammatory conditions, including arthritis, asthma, and inflammatory bowel disease.[38,95,127] In mammalian cells (similar to COX), two isoforms of the NO-producing enzyme nitric oxide synthetase are constitutively expressed, and a third inducible isoform, inducible nitric oxide synthetase (iNOS), is upregulated in response to bacterial products and proinflammatory cytokines.[92,94] Compounds that inhibit iNOS expression or activity possess anti-inflammatory properties.[94,133] Currently approved drugs that target the nitric oxide system, such as nitroglycerin to treat angina (see Chapter 26) and the male erectile dysfunction drug sildenafil (Viagra) (see Chapter 28), increase NO levels; specific iNOS inhibitors are being developed to treat various inflammatory disorders.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

NSAIDs include some of the most frequently taken medications. Because these agents share a common mechanism of action, they exert qualitatively similar therapeutic and toxic effects. For the treatment of pain and inflammation that accompany various dental surgical procedures, the short-term use (typically ≤1 week) of NSAIDs has generally proved to be highly efficacious and safe. Compared with opioid-combination drugs (described later in this chapter), NSAIDs lack various undesirable CNS depressant effects that contribute to the high incidence of drowsiness, dizziness, and nausea commonly seen with opioid-containing agents. This favorable efficacy and safety profile has led the U.S. Food and Drug Administration (FDA) to approve three NSAIDs (ibuprofen, naproxen sodium, and ketoprofen) in addition to aspirin for over-the-counter (OTC) use. Use of these drugs under OTC package insert guidelines mandates no more than 10 days of consecutive dosing for pain and only 3 days for fever, plus absolute maxima on single and daily doses that are lower than the prescription use of these drugs.[81]

When treating chronic inflammatory conditions such as rheumatoid arthritis, the duration of NSAID therapy is typically measured in months or years, and the daily doses required to control the arthritic symptoms are often twofold to threefold higher than doses required to control acute pain. This type of therapy leads to a greatly increased incidence of minor and major side effects, requiring more vigilant monitoring of these patients.

The development of NSAIDs that are highly selective COX-2 inhibitors seemed to offer a safety advantage regarding some of the more serious adverse effects seen with long-term NSAID therapy, specifically GI ulcers, perforations, and bleeds.[16,143] More recent studies showing increased cardiovascular risk with long-term use of these agents compared with placebo in colon polyp prevention trials[19,151] and increased cardiovascular risk with 10 days of dosing in the treatment of patients with pain after coronary artery bypass graft (CABG) surgery[119] have led to the removal of several of these drugs from the worldwide marketplace.

Salicylates

The salicylates are among the oldest known drugs. Hippocrates recommended the consumption of the juices of the poplar and willow bark some 2400 years ago, which later were discovered to contain salicin (a glycoside of salicylic alcohol), for the treatment of the pain of childbirth. In 60 AD, Discorides reported that a boiled extract of willow bark could be used to treat various maladies, including corns, gout, and earache. In a report to the Royal Society in London in 1763, the Reverend Edward Stone made one of the earliest references to the antipyretic effect of willow bark extracts. The active principle of willow and poplar preparations, salicylic acid, was first extracted in 1835 from natural sources and later prepared by chemical synthesis. Kolbe was credited with the first full-scale commercial synthesis of salicylic acid and its derivative sodium salicylate. In 1853, Charles Frederich von Gerhardt was the first to synthesize aspirin (acetylsalicylic acid) by treating sodium salicylate with acetyl chloride. Despite the untoward GI effects of large doses of salicylic acid and sodium salicylate, the development of salicylates culminated in the introduction of aspirin into medicine in 1899 by Heinrich Dresser of the Bayer Company of Germany. The popularity of aspirin was immediate, and today it remains one of the most consumed drugs in the world.

Several additional salicylates have also been marketed. Choline salicylate, magnesium salicylate, and their combination product are ion complexes of salicylate. Salsalate is an ester composed of two salicylate molecules, which are freed as the molecule is hydrolyzed. These salicylate formulations are said to have fewer GI side effects than aspirin. Because released salicylate is the active moiety of all these drugs, however, the rest of their pharmacology is quite similar to aspirin. The structure of aspirin and some of the related salicylates is shown in Figure 21-5. Aspirin may be considered a prototype of the NSAIDs and is the standard of reference against which these agents are compared and evaluated.

Mechanism of action

The efficacy of salicylates and all related NSAIDs as analgesic, anti-inflammatory, and antipyretic agents results from their ability to inhibit COX activity, preventing the synthesis and release of COX products, most prominently the PGs. All salicylates and almost all the currently available NSAIDs, with the exception of the highly selective COX-2 inhibitors, inhibit COX-1 and COX-2. Most of these nonselective COX-inhibiting NSAIDs, including aspirin, are more potent or at least equipotent inhibitors of COX-1,[128,169] which accounts for some of the more important adverse effects of these drugs. Figure 21-6 shows the relative COX-2 versus COX-1 selectivity of some representative NSAIDs. As shown in this figure, aspirin is an approximately 100-fold more selective inhibitor of COX-1 than COX-2. The published COX selectivities of individual drugs vary with the assay system being used.

Aspirin uniquely inactivates COX by irreversibly acetylating the enzyme. Acetylation occurs on serine 530 of COX-1.[105] A comparable serine on COX-2, serine 516, is also acetylated by aspirin. The later modification not only inhibits

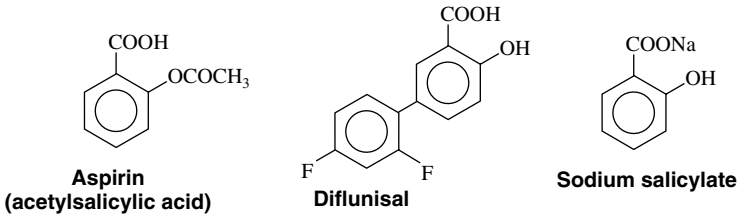

FIGURE **21-5** Structural formulas of aspirin and other salicylates.

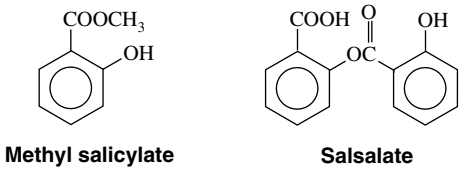

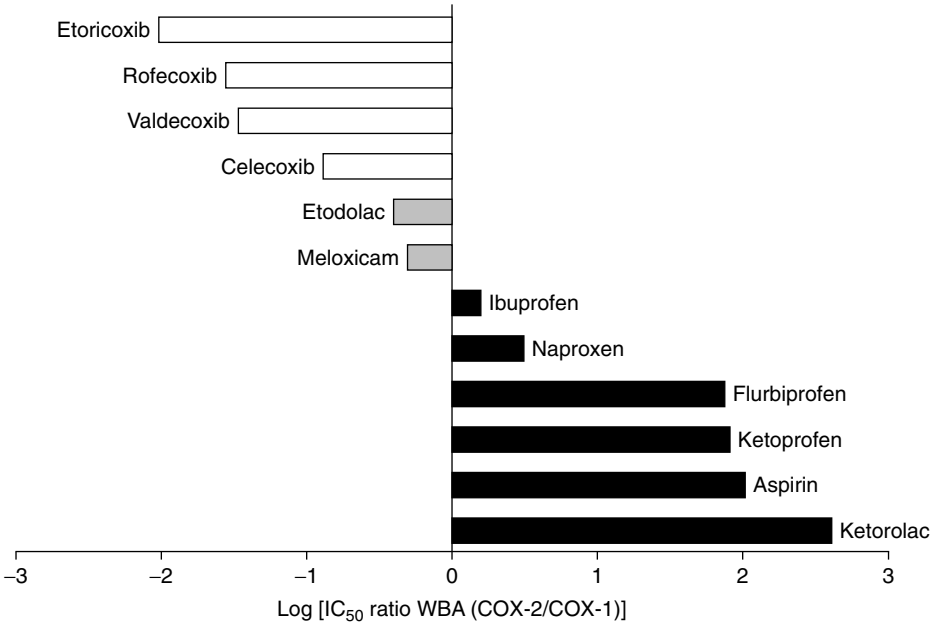

FIGURE **21-6** The ratio of the log of inhibitory concentrations (*IC*) of various nonsteroidal anti-inflammatory drugs needed to block 50% of COX-2 activity versus 50% of COX-1 activity in the whole blood assay (*WBA*). The zero line indicates equipotency. Bars on the right represent drugs with greater selectivity for COX-1, whereas bars on the left represent drugs with greater selectivity for COX-2. (Adapted from Riendau D, Percival MD, Brideau C, et al: Etoricoxib [MK-0663]: preclinical profile and comparison with other agents that selectively inhibit cyclooxygenase-2, *J Pharmacol Exp Ther* 296:558-566, 2001; Warner TD, Guiliano F, Vojnovic I, et al: Nonsteroid drug selectivities for cyclo-oxygenase-1 rather than cyclo-oxygenase-2 are associated with human gastrointestinal toxicity: a full in vitro analysis, *Proc Natl Acad Sci U S A* 96:7563-7568, 1999.)

PG production during inflammation, but also enables COX-2 to produce 15-hydroxyeicosatetraenoic acid.[98,123] This metabolite may be associated with certain adverse effects. Other salicylates and NSAIDs do not acetylate COX but are reversible competitive inhibitors of the enzyme. Because PGs are not stored, but rather are synthesized immediately before release, the reduction of PG concentrations by NSAIDs can be observed quickly.

The potency of the salicylates as inhibitors of PG synthesis in vitro correlates well with their ability to alleviate carrageenin-induced inflammation in animals (Table 21-2). In humans, anti-inflammatory doses of aspirin (3 g daily), sodium salicylate (3 g daily), or indomethacin (100 mg daily) reduce the output of PG metabolites in the urine by more than 75%, indicating a close correlation of the inhibition of COX with anti-inflammatory effects.[71] Although inhibition by COX is the major mechanism of action of the NSAIDs, participation in other anti-inflammatory mechanisms may occur and account for some of the variation in clinical response seen with these drugs. Salicylates may inhibit cell migration and some functions of neutrophils. A reduced production of rheumatoid factor may also occur by stimulation of suppressor T-cell activity. Other mechanisms contributing to anti-inflammatory effects include reduced capillary permeability, reduced antibody production, and alterations in connective tissue synthesis. The relative potencies against COX-1 and COX-2 also account for important differences among various NSAIDs.

Inhibition of PG synthesis at the site of injury or inflammation can explain at least some of the analgesic effect of

TABLE **21-2**

aspirin. Although PGs themselves do not seem to cause pain when injected locally, PGE_2 and $PGF_{2\alpha}$ do sensitize pain receptors to other mediators such as histamine and bradykinin. In this connection, aspirin and related drugs can prevent the writhing response elicited by bradykinin but not that produced by PGs. This finding is explained by the fact that the salicylates and all other NSAIDs inhibit the synthesis of PGs induced by bradykinin but not the binding of PGs to their receptors. Animal experiments have revealed that NSAIDs also have central analgesic actions, which may involve the inhibition of COX or other unknown mechanisms at the level of the spinal dorsal horn or at higher levels of the CNS.[106,110] The antipyretic effect of aspirin and similar drugs is also mediated by the reduction of PGE_2 synthesis as a result of inhibition of COX.

General therapeutic effects

Aspirin has clinically useful analgesic, antipyretic, anti-inflammatory, and antiplatelet effects. The analgesic effect sought and attained with aspirin is probably caused in many cases by its anti-inflammatory actions, a fact not usually appreciated by its users. In addition to their widespread use for the symptomatic relief of acute pain and fever, salicylates (most commonly aspirin) are important drugs in the treatment of numerous chronic inflammatory diseases. Some of the major therapeutic uses of aspirin are considered next.

Acute pain. It is difficult to separate the analgesic and anti-inflammatory effects of NSAIDs because most painful conditions have an inflammatory component. There is little doubt that the cascade of reactions leading to the formation of PGs is integrally involved with the inflammatory response and that aspirin's efficacy in treating inflammation and pain is closely related to its inhibition of PG synthesis. By using microdialysis techniques, it has been shown that after dental surgery the analgesic effects of NSAIDs correlate with a local reduction in PG synthesis.[121,129] Nevertheless, several observations suggest that the analgesic and anti-inflammatory effects of NSAIDs may occur by different mechanisms. First, there is a different time course for the onset of analgesic and anti-inflammatory effects. Clinically significant analgesia usually occurs within 1 hour of drug administration, whereas anti-inflammatory effects sometimes take several days or weeks to reach maximum levels because chronic inflammatory processes may be occurring that cannot be quickly reversed by inhibiting PG production. Also, the maximal human analgesic effect usually occurs at lower doses than the antirheumatic and other anti-inflammatory effects.

Aspirin is an effective analgesic for almost any type of acute dental pain. Double-blind, controlled studies of the relief of pain after the surgical extraction of third molars have shown that 650 mg of aspirin is substantially more effective than 60 mg of codeine in relieving postoperative pain (Figure 21-7).[31] Most controlled clinical studies have established that, regardless of the cause of the pain, aspirin (650 mg) provides equal or greater pain relief than codeine in standard doses (60 mg).[12] Aspirin and other NSAIDs and acetaminophen have what is known as a ceiling or plateau effect in the treatment of acute pain. In other words, there is a dose-response for pain relief up to 650 to 1000 mg of aspirin, but increasing the dose beyond these amounts does not enhance the analgesic effect further and does increase the likelihood for toxic effects.

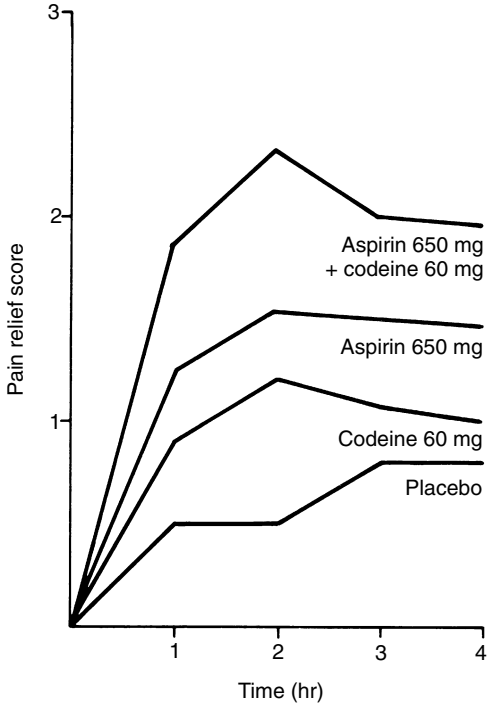

FIGURE **21-7** Time-effect curves for placebo, aspirin, codeine, and an aspirin-codeine combination. The mean pain relief scores are plotted against time in hours. (Adapted from Cooper SA, Engel L, Ladov M, et al: Analgesic efficacy of an ibuprofen-codeine combination, *Pharmacotherapy* 2:162-167, 1982.)

Rheumatic fever. One of the early uses of salicylates was in the treatment of rheumatic fever. Aspirin markedly reduces the acute inflammatory components of the disease, such as fever, joint pain, swelling, and immobility. Salicylates do not affect other aspects of the disease, however, such as the proliferative reaction in the myocardium leading to scarring, and they do not alter the progression of the disease.

Although anti-inflammatory drugs, including corticosteroids (see Chapter 35), may be used to reduce inflammation, antibiotic therapy is the major therapeutic strategy.

Rheumatoid arthritis. Rheumatoid arthritis is a chronic systemic disease of unknown origin. Several tissues and organs may be involved, but in most patients the chief clinical and pathologic features result from chronic inflammation of synovial membranes. Irreversible joint injury (subluxation, loss of motion, or ankylosis) results from formation of chronic granulation tissue that causes erosions of articular cartilage, subchondral bone, ligaments, and tendons. Extra-articular manifestations, such as subcutaneous or subperiosteal nodules of granulation tissue, peripheral neuropathy, and chronic skin ulcers, occur to a variable extent and seem to result from generalized focal vasculitis. Patients with rheumatoid arthritis are at increased risk of developing cardiovascular disease, including myocardial infarction (MI).[168]

The cause of the inflammatory response in rheumatoid arthritis is obscure, but the inflammatory events result largely from an autoimmune reaction. Rheumatoid arthritis is considered an autoimmune disease with many contributing factors. Lymphocytes that have become activated produce TNF-α and IL-1. These cytokines lead to the release of other inflammatory mediators, such as the PGs. Anti-immunoglobulins, referred to as the *rheumatoid factor* and found in rheumatoid synovial fluid, can form complexes with IgG. These complexes may activate complement, which triggers a number of inflammatory phenomena in the joint tissues, including histamine release, production of factors chemotactic for neutrophils and mononuclear cells, cell membrane damage, and PG synthesis. The antigen-antibody complexes also activate antigen-presenting cells, which stimulate T cells, leading to the further release of cytokines. Neutrophils and macrophages accumulate in the synovial fluid and are found to contain aggregated IgG, rheumatoid factor, complement fragments, and fibrin; these substances are apparently acquired by phagocytosis. Lysosomal materials are released that amplify the inflammatory reaction and may directly damage tissues. Cytokines produced by the lymphocytic cell infiltrate may also help propagate the reaction and participate in tissue destruction.

Salicylates (usually as aspirin) are still widely used in the clinical management of rheumatoid arthritis. The pain and inflammation of rheumatoid arthritis can often be controlled with salicylates alone (or with another NSAID).[152] Salicylates produce a measurable reduction of inflammation in the joints and associated tissues, a lessening of symptoms, and improved mobility. Salicylates may also reduce neutrophil activity in addition to inhibiting PG synthesis. Clinical observation suggests that salicylate therapy can diminish or delay the development of crippling associated with the disease. This benefit is not a direct effect of the drug on the progression of the disease, but relates more to reduction of pain and subsequent facilitation of mobility. In addition to salicylates, the basic therapeutic regimen in rheumatoid arthritis includes rest, physical measures (primarily heat), and exercise.

When salicylate therapy is ineffective or is not well tolerated, other drugs, such as the NSAIDs ibuprofen and naproxen, or corticosteroids, can be used. Salicylates and related NSAIDs do not slow or arrest the joint destruction and extra-articular manifestations characteristic of the disease. For disease progression to be affected, DMARDs, which include gold compounds, sulfasalazine, penicillamine, antimalarials, methotrexate, azathioprine, cyclosporine, leflunomide, and TNF-α inhibitors, must be used.

In rheumatoid arthritis, salicylates are given in doses sufficient to control the symptoms, often 3 to 6 g/day. The degree of suppression of inflammation increases with the plasma salicylate concentration even beyond the point of toxicity. Patients with severe arthritis tolerate tinnitus and other mild toxic manifestations to obtain the anti-inflammatory effects gained by high plasma titers of salicylate. A regular dose interval to maintain constant effective blood concentrations is important. Evaluation of drug therapy in rheumatoid patients may be complicated by the spontaneous remissions and exacerbations characteristic of this disease.

Other inflammatory diseases. Aspirin is a commonly used anti-inflammatory agent in other inflammatory diseases, including juvenile rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, Reiter's syndrome, and degenerative joint disease (osteoarthritis). The arthralgia and fever of mild lupus erythematosus may be alleviated by aspirin. Acute episodes of inflammation in isolated joints, tendons, or bursae caused by trauma are also best treated with aspirin given in full doses immediately after the injury.

Fever. Fever is typically a symptom of a disease process, usually a viral or bacterial infection brought about by exogenous (microbial products) and endogenous pyrogens.[40,156] It is believed that exogenous pyrogens stimulate host cells to produce endogenous pyrogens, of which IL-1 has been the best characterized.[51,156] IL-1 is thought to act on the anterior hypothalamus, generating the local release of PGs.[51,155] Injection of PGs into the brain of various animal species is known to increase body temperature.[53] The PGs and possibly other non-PG endogenous pyrogens elevate the thermal set-point of the body so that it retains the ability to regulate closely its temperature, but at a higher temperature than normal.[40,156]

By inhibiting the synthesis of PGs in the hypothalamus, aspirin, other NSAIDs, and acetaminophen are thought to reduce the thermal set-point toward normal. The decrease in body temperature also involves the ability of aspirin and other antipyretics to induce a vasodilation of superficial blood vessels. Because of its association with Reye's syndrome, aspirin is no longer recommended to treat most febrile episodes in children.

Prophylaxis against platelet aggregation. The correlation between the ability of aspirin-like compounds to inhibit simultaneously platelet aggregation and the production of PGs has been known for almost 40 years.[148] Aspirin inhibits the synthesis of TXA_2 by irreversible acetylation of the COX enzyme in platelets.[73,130] Lacking a nucleus, platelets cannot generate new enzyme, and the ability of affected platelets to produce TXA_2 is permanently blunted during their 10-day lifetimes. Most platelet COX acetylation may occur presystemically as platelets pass through gut capillaries before the hydrolysis of aspirin to salicylate (a weak and reversible inhibitor of COX) in the gut and the liver.[125] This possibility may partially explain the relative lack of effect of low-dose aspirin on the antiaggregatory PGI_2 molecule produced by the systemic vascular endothelium.

The fact that endothelial cells, by possessing a nucleus, can generate new COX enzyme after aspirin administration may also contribute to the relatively selective and complete block of TXA_2 synthesis over PGI_2. This selective block of TXA_2 synthesis in platelets provides the rationale for using long-term low-dose aspirin therapy to prevent MI and occlusive stroke in at-risk patients. Other salicylates and NSAIDs are either much weaker or only reversibly inhibit COX in platelets and have limited therapeutically beneficial antiplatelet effects.

In 1998, the FDA published a set of indications for aspirin prophylaxis that include definitive dosing guidelines for each condition (Table 21-3).[44] Vascular indications include the reduction of death or nonfatal stroke in patients who have had ischemic strokes or transient ischemic attacks, reduction of vascular mortality in patients with acute MI, reduction of

TABLE **21-3**

Antiplatelet Indications and Dosing Guidelines for Aspirin

INDICATIONS	RECOMMENDED DAILY DOSE	DURATION OF THERAPY
Vascular Indications		
Ischemic stroke and TIA	50-325 mg	Indefinitely
Suspected acute MI	160-162.5 mg taken as soon as MI is suspected, then once daily	For 30 days after MI (after 30 days, consider further treatment if previous MI)
Prevention of recurrent MI	75-325 mg	Indefinitely
Unstable angina pectoris	75-325 mg	Indefinitely
Chronic stable angina pectoris	75-325 mg	Indefinitely
Revascularization Procedures in Selected Patients		
CABG surgery	325 mg starting 6 hr after procedure	1 yr
PTCA	325 mg 2 hr before surgery; maintenance therapy 160-325 mg	Indefinitely
Carotid endarterectomy	80-650 mg twice daily started before surgery	Indefinitely

CABG, Coronary artery bypass graft; *MI,* myocardial infarction; *PTCA,* percutaneous transluminal coronary angioplasty; *TIA,* transient ischemic attack.

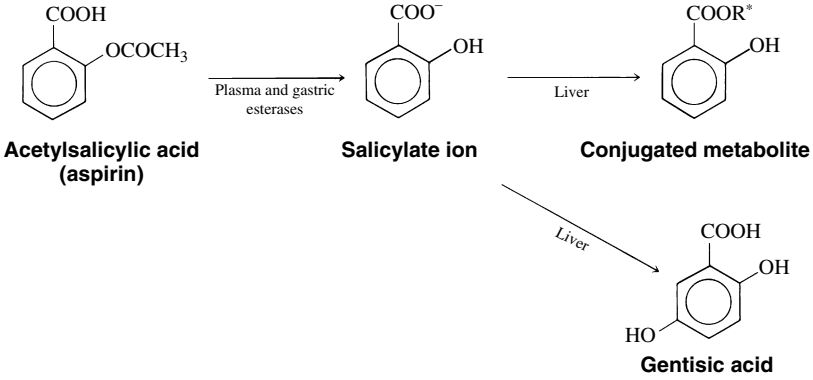

FIGURE **21-8** Metabolic fate of aspirin. *R**, Glycine or glucuronate. (The phenolic glucuronide metabolite is not shown.) The glycine conjugate is called *salicyluric acid*.

combined risk of death and nonfatal MI in patients with previous MI or unstable angina, and reduction of the combined risk of MI and sudden death in patients with chronic stable angina. The recommended daily dose for all these indications is low (≤325 mg/day) compared with the analgesic and anti-inflammatory uses of the drug. Aspirin also is indicated for patients who have undergone revascularization procedures, including CABG surgery, percutaneous transluminal coronary angioplasty, and carotid endarterectomy, when there are pre-existing conditions for which aspirin is already indicated.

Absorption, fate, and excretion

When aspirin is taken orally, it is rapidly absorbed from the stomach and small intestine. Aspirin is a weak acid, with a pK_a of approximately 3.5, which favors its absorption in the stomach. Most absorption occurs in the small intestine, however, because of its much larger surface area. The rate-limiting steps in the absorption of aspirin are the disintegration and dissolution of the tablet. These two steps can be greatly influenced by the manufacturing process, which determines factors such as particle size and compression of the tablet. Buffering the tablet increases the rate of dissolution, but the fastest absorption is obtained when aspirin is dissolved in hot water before ingestion. Other factors, such as gastric emptying time, gastric contents, and level of autonomic activity of the patient, may also influence the rate of absorption.[100,102]

Aspirin has a 15-minute half-life.[124] Because its acetylation of COX in the platelet is irreversible, however, the full extent of its antiplatelet action depends on the life span of the platelet (8 days) and not on the short half-life of aspirin.[4,124] It is quickly metabolized by gastric and plasma esterases to salicylate ion (Figure 21-8). Although some aspirin becomes bound to plasma proteins, 80% to 90% of the salicylate ion is bound for a short time, principally to albumin. Salicylate is distributed throughout most body fluids and tissues. It can be isolated from spinal, peritoneal, and synovial fluids; saliva; breast milk; and sweat. Salicylate freely crosses the placenta from mother to fetus.

The elimination half-life of sodium salicylate is 2 to 3 hours after a single analgesic dose. The liver is the main site of biotransformation, and conjugation is the primary route. Because the metabolism of salicylate is capacity limited, large repeated doses or single toxic ingestions result in plasma half-lives of 5 to 30 hours. When describing the duration of analgesic and anti-inflammatory action of aspirin, its ultimate dosing interval reflects the summed half-lives of the parent molecule and the active metabolite, salicylate. Salicylate, in contrast to the parent aspirin molecule, is only a reversible inhibitor of COX (most notably in the platelet), however. The three primary products of salicylate conjugation are salicyluric acid (the glycine conjugate), the ether or phenolic glucuronide, and the acyl or ester glucuronide. A small portion (<1%) is oxidized to gentisic acid (see Figure 21-8). Free salicylate and the salicylate metabolites are excreted by glomerular filtration and by active proximal tubular secretion in the kidney. In normal humans, approximately 10% of ingested salicylate appears unchanged in the urine; however, this fraction may decrease to 2% or increase to 30% with urinary acidosis or alkalosis. A higher percentage of free salicylate is excreted at

higher doses because the liver is unable to maintain the same percentage of metabolism at higher doses of salicylates.

Adverse effects

The severity of side effects that can accompany aspirin ingestion depends on the overall health of the patient, the length of dosing, and the total daily intake of drug. When used under OTC package insert guidelines (for ≤10 days and ≤4 g/day), most reported side effects are more annoying than serious, with dyspepsia and nausea occurring in 10% of patients. In addition, occult bleeding (hidden amounts of blood in the stool), which is usually less than 10 mL/day, develops in more than 70% of patients ingesting the drug. The bleeding is thought to originate from direct capillary and mucosal damage as aspirin disintegrates in contact with gastric tissues and from the ability of aspirin to inhibit COX-1, which interferes with cytoprotective mechanisms and platelet aggregation. Although this occult bleeding is usually of little clinical significance, aspirin and all related NSAIDs are contraindicated in patients with active GI ulcers because their ingestion may lead to sudden, potentially fatal GI hemorrhage.

With more long-term, high-dose regimens of aspirin and other nonselective NSAIDs used in the treatment of various inflammatory disorders, the inhibition of COX-1 leads to several common and predictable effects, the occurrence of which varies with each drug. The inhibition of PGI_2 and PGE_2 synthesis and the resulting loss of their protective effects on the gastric mucosa lead to a significant increase in GI problems, the most serious of which include significant gastric bleeding, symptomatic peptic ulcers, and GI perforations and obstructions. The incidence of these more serious events ranges from 1% to 5% of patients per year. Even long-term low-dose (81 mg/day) aspirin therapy is associated with an increased risk of serious GI events, at a rate of 0.1% to 0.2% of patients per year.[124] This increase in GI complications has led experts to question the widespread use of low-dose aspirin therapy in patients without significant cardiovascular or cerebrovascular risks. Nonaspirin salicylates generally elicit fewer adverse effects in the GI tract but cannot be used for platelet antiaggregatory therapy. Most of the other NSAIDs have some antiplatelet effect based on inhibition of the production of TXA_2, but the effects are not as pronounced as with aspirin because aspirin is an irreversible inhibitor of COX.

The antiplatelet effects of aspirin can lead to pronounced increases in bleeding time. As previously discussed, this effect is long lasting compared with other NSAIDs because aspirin irreversibly acetylates COX-1 in the non-nucleated platelet. Even a single dose of aspirin can increase the bleeding time for several days. A theoretic concern is the fact that this prolongation of bleeding time can promote intraoperative and postoperative hemorrhage in dental surgical patients. Limited data suggest extractions and periodontal surgery may be performed without special risk in patients kept on aspirin therapy. Although the risk/benefit ratio of discontinuing long-term cardioprotective low-dose aspirin therapy before dental surgery remains controversial, from a medicolegal standpoint it should not be done without the approval of the patient's physician. The remote but real chance of a patient having MI or occlusive stroke shortly after a dental practitioner interrupts low-dose aspirin therapy dictates medical consultation. In addition, aspirin therapy may be reinstituted when a clot is established.

The adverse effects of aspirin and other NSAIDs on the kidney are well known. Normal renal function is partly dependent on PG synthesis. It is believed that COX-1 and COX-2 are important in producing PGs involved in reducing water and Na^+ reabsorption at the ascending loop of Henle and maintaining proper dilation of the renal vasculature (see Figure 21-3).[17] With NSAID therapy, dose-dependent water and Na^+ retention manifested by peripheral edema, elevation in blood pressure, and rarely congestive heart failure is thought to follow the inhibition of PGE_2 synthesis. Renal artery vasoconstriction, possibly causing acute renal ischemia and kidney failure, is ascribed to an inhibition of PGI_2 synthesis. Acute renal failure is more likely to develop in patients with preexisting renal insufficiency, congestive heart failure, or dehydration because the renal arterioles are more dependent on PGs to maintain normal perfusion of the glomeruli.[117] Acute renal failure is also more likely when NSAIDs are given concurrently with an angiotensin-converting enzyme (ACE) inhibitor because the lack of angiotensin II weakens reactive constriction of the efferent arteriole, a normal protective response for maintaining glomerular filtration in patients with reduced renal blood flow.

NSAIDs are likewise responsible for chronic renal toxicity, commonly known as *analgesic-associated nephropathy*. This disorder sometimes occurs with long-term use of high doses of NSAIDs and is characterized by papillary necrosis and chronic interstitial nephritis. The mechanism may be related to the acute ischemic response described earlier, but the cause has not been definitely established. It is estimated that serious renal problems requiring hospitalization occur in 0.5% to 1% of long-term NSAID users.

The use of aspirin in children with viral infections has been associated with Reye's syndrome.[84] First described in 1963, Reye's syndrome is an acute childhood illness that produces metabolic encephalopathy and liver disease.[126] Typically, a child is recovering from influenza or varicella when the acute encephalopathic symptoms of lethargy, agitation, delirium, and seizures appear. Without aggressive supportive treatment, the disease progresses to deep coma, brainstem dysfunction, and death in 80% to 90% of cases.[84] Even with heroic treatment, the mortality rate can exceed 30%, and survivors can be left with permanent brain damage. Clinical reviews and case-controlled studies performed in the 1970s and 1980s reported a strong association between the development of Reye's syndrome and the ingestion of aspirin in children and teenagers with viral infections.[85,104,171] Aspirin and related salicylates are contraindicated for the treatment of flulike symptoms, chickenpox, gastroenteritis, and, in the opinion of most pediatricians, any febrile respiratory condition in children or teenagers. Acetaminophen and ibuprofen have not been associated with the development of Reye's syndrome.[81]

Toxicity caused by aspirin overdose is common. The symptoms and severity depend on the dose. Chronic toxicity caused by salicylates results in a syndrome termed *salicylism*, which is characterized by tinnitus, nausea, vomiting, headache, hyperventilation, and mental confusion. Aspirin is one of the more frequently used drugs for attempted suicide. The drug is commonly involved in accidental poisoning, especially in children, because it is found in almost every household and proper precautions for its storage are often neglected. Serious clinical manifestations of acute aspirin overdose typically occur at doses greater than 6 to 10 g in adults or when intake exceeds 150 to 200 mg/kg of body weight.

The cardinal signs and symptoms of acute aspirin overdose include nausea, vomiting, tinnitus, hyperthermia, and hyperventilation. Hyperventilation arises in part from a direct stimulation of respiratory centers in the brain and from a compensatory increase in respiration in response to excessive carbon dioxide produced by large doses of aspirin partially uncoupling oxidative phosphorylation. This uncoupling also accounts for the paradoxic (because therapeutic doses of aspirin are used for antipyresis) increase in body temperature.[18] The hyperventilation eventually can lead to respiratory alkalosis, which may be followed by a combined respiratory and metabolic acidosis accompanied by dehydration. Acidosis is more prominent as the level of overdose increases. Acidosis is also more likely to occur in children and infants. Impaired

vision, hallucinations, delirium, and other CNS effects may be evident, and the situation is considered life-threatening.
